V. CONCLUSION

Investigating community recognition in social networks is an important issue in many fields and disciplines, such as marketing and information technology. Community detection in social networks can be considered a graph clustering problem, where each set corresponds to a cluster in the graph. The goal of conventional community detection methods is to partition a graph so that each node belongs to exactly one cluster. A community can be defined as a group of individuals close to each other compared to other entities in the dataset.

The proposed algorithm is checked and compared with the evaluated algorithms. This comparison is done according to the introduced criteria. To provide more accurate and complete results, five data sets have been used. Examining the results shows that the proposed method has led to better results. The performance of the algorithm has been tested on large datasets, for which scaling optimization is increasingly difficult and has shown satisfactory improvement. Among the advantages of NMI compared to other related methods, we can mention the competition with the latest technologies in the accuracy and

scale of data, the ability to execute and implement the system in the real world, and the ability to perform all the steps of the proposed system online. The results show that the proposed algorithm has improved by 23.6% compared to previous similar work. In order to improve the quality of detecting effective nodes in future works, it is possible to mention the discovery of the semantic relationship between nodes and the virtual networks between them. Hidden connections between nodes are introduced as virtual associations. Discovering virtual associations between nodes can help algorithms based on participation in the detection process. Also, tagging the content of messages sent between nodes can help to discover nodes.

Abstract—The synchronization of neural activity in the human brain has great significance for coordinating its various cognitive functions. It changes throughout time and in response to frequency. The activity is measured in terms of brain signals, like an electroencephalogram (EEG). The time-frequency (TF) synchronization among several EEG channels is measured in this research using an efficient approach. Most frequently, the windowed Fourier transforms-short-time Fourier transform (STFT), as well as wavelet transform (WT), and are used to measure the TF coherence. The information provided by these model-based methods in the TF domain is insufficient. The proposed synchro squeezing transform (SST)-based TF representation is a data-adaptive approach for resolving the problem of the traditional one. It enables more perfect estimation and better tracking of TF components. The SST generates a clearly defined TF depiction because of its data flexibility and frequency reassessment capabilities. Furthermore, a non-identical smoothing operator is used to smooth the TF coherence, which enhances the statistical consistency of neural synchronization. The experiment is run using both simulated and actual EEG data. The outcomes show that the suggested SST-dependent system performs significantly better than the previously mentioned traditional approaches. As a result, the coherences dependent on the suggested approach clearly distinguish between various forms of motor imagery movement. The TF coherence can be used to measure the interdependencies of neural activities.

Keywords—Brain-Computer Interface (BCI); Electroencephalogram (EEG); Short-time Fourier Transform (STFT); Synchrosqueezing Transform (SST); time-frequency coherence

I. INTRODUCTION

Brain signals (EEG) can be used to build the Brain Computer Interface (BCI), which is a more convenient and affordable method. EEG signals are captured by spatially scattered scalp sensors. The connections between the various areas of the brain, which is the primary organ of the nervous system, are becoming important in BCI research. The various sensors record the EEG signals, and coherence analysis is used to determine how coherent the signals are [1, 2, 3]. Coherence is typically estimated using spectral methods such as a Fourier or wavelet [4] transform. Coherence analysis is challenging to implement because cerebral activity signals are inherently non-stationary. Although the time-dependent Fourier transform (STFT) is one approach to solving the issue, it has not been completely effective for the aforementioned reasons: one cannot guarantee the stationarity of brain signals during each brief time interval and two the Heisenberg uncertainty

principle limits the resolution of time-frequency representation. Despite being a data-adaptive signal analysis technique, the mother wavelet basis function is used in the wavelet transform to decompose signals. The approach also has difficulty with time-frequency resolution, where the resolution of the frequency is greater at low frequencies and less so at high frequencies. Also, this method is founded on choosing a mother wavelet. Because the mother wavelet was arbitrarily chosen without being matched to the analyzing signal, that led to an inaccurate and irreversible breakdown.

When combined with the continuous wavelet transform (CWT), the technique, known as synchrosqueezing transform (SST) [5], produced astoundingly precise time-frequency depictions of nonstationary as well as nonlinear data. This aspect of SST addresses the drawbacks of linear perception time-frequency techniques, such as windowed Fourier transforms (STFT) as well as continuous wavelet transforms. The synchrosqueezing transformation focuses the coefficient values around the frequency response graph of the tuned oscillations by dispersing the STFT and CWT strengths [6]. The frequency redistribution approach used in time-frequency representation [7] improves the proper location of instantaneous amplitude in the time and frequency domains.

Since neural synchronization is characterized by several frequency bands but is anticipated to change over time, TF coherence is typically employed for measuring it. Smoothing the cross as well as auto-spectra between the signals is essential since noise has a significant impact on coherence. One of the following techniques is used to execute the smoothing operation: periodogram smoothing can be accomplished in one of three ways: (i) Periodogram smoothing through ensemble averaging using the WOSA (Welch's overlapped segment averaging) technique; (ii) the temporal or frequency domains may be smoothed separately or together [8, 9]; and (iii) By averaging a collection of spectra generated using various orthogonal taper functions, cross and auto spectra are smoothed. The cross and auto spectra are typically smoothed with the same smoothing agents in all of the approaches mentioned above to estimate TF consistency. The employment of the same smoothing operator constrained the coherence to the range [0, 1] since the TF coherence satisfies the Cauchy-Schwarz inequality. Furthermore, the estimator using the same operation fails when the smoothing coefficient rises to one. Selected auto spectra smoothing can be used to get the improved temporal resolution. However, since the cross spectra are therefore not flattened when non-identical smoothing operators are used, the bias of the

estimator cannot reach one [8]. As a result, the estimator has better time resolution. In order to properly depict TF consistency and uncover weak correlations among signals, non-identical smoothing agents may be used. Bispectrum-based channel selection (BCS) was employed in this study [10] for MI-based BCIs. In this paper [11], the performance of the BCI model may be considerably impacted by using different time segments for training the data. They recommend against using any other temporal data as training data besides that utilized for motor imaging. For BCI Competition IV 2a and 2b, models using machine learning and deep learning suggested a potential improvement in visual display time, categorization efficiency. It was argued that models might be picking up more visual information. In fact, during the visual presentation, spatial topography revealed activation of the visual cortex. In the research [12], MI classification using EEG signals is accomplished using a supervised feature selection method. Another work [25] suggests a technique for producing a spatio spectral feature representation that can maintain the multivariate information of EEG data. In particular, subject-optimized and subject-independent spectrum filters were combined, and the filtered data were then stacked into tensors to create 3-D feature maps. In order to automatically choose the best frequency bands based on MIF [13], the MIFCSP method combines multivariate iterative filtering (MIF) and CSP. This method may then be used to extract discriminant features.

The SST approach is employed in the present study to calculate the TF coherence of brain signals, as well as the coherence is therefore subjected to a non-identical smoothing procedure. Moreover, the same analysis is carried out using the short-time Fourier transform rather than the SST. With synthetic and actual EEG signals, both findings are validated. The SST-dependent TF consistency outperforms the STFT-dependent technique, according to the observation in both synthetic and real data. The following is how the paper is set up: The time-frequency representation techniques, such as STFT and SST, are covered in Section II, along with the consistency in the TF domain in Section II, the synchronized transformation research findings in Section III, and discussion and some closing thoughts in Sections IV and V, respectively.

II. METHODS

The neuronal synchronization changes both over time and with frequency. Any signal's energy is described as a function of both times as well as frequency by the time-frequency representation (TFR). It converts a single-dimensional time-series signal through a double-dimensional function integrating frequency and period. The TFR space value gives a sense of which spectral components are present. Non-stationary or time-varying signals can be analyzed and created using the TFR.

A. Windowed Fourier Transform

An approach that works well for the TF characterization of non-stationary EEG signals is the short-time Fourier transform (STFT). A kind of trade-off between a signal's time and frequency is made by the STFT, which contains all the data on

frequency variations with the period. A signal event's timing and frequency are also disclosed through this information. The signal is broken up into manageable chunks for the duration of the STFT, and it may be expected that each of these chunks will remain stationary. A window function (w) is selected in order to achieve this. This window must have the same width as the area of the signal when the normality of the data is guaranteed. The definition of the STFT for a non-stationary signal $s(t)$ is

$$\Psi(t, f) = \int_{-\infty}^{\infty} [s(t) \cdot w^*(t-t')] \cdot e^{-2\pi f t} dt \quad (1)$$

where even the window function $w(t)$ and the complex conjugate $*$ are both present. The signal's STFT is the signal's Fourier transform times a tapering function [27].

In the interests of demonstrating the time-frequency depiction, a noise-free artificial signal is created that is called $\delta(t)$ by chaining three sinusoids $s1(t)$, $s2(t)$, and $s3(t)$ with frequencies of 10Hz, 5Hz, and 20Hz, respectively, with the formula as $\delta(t) = [s1(t) s2(t) s3(t)]$. For sampling, 500 hertz (Hz) is employed. The STFT-based synthetic signal and TFR are shown in Fig. 1(a) and 1(b), respectively. A Hamming window with a 50% overlap and a length of 256 is employed in the STFT. Although with poor resolution, the STFT can distinguish between the three factors.

B. Synchronized Transformation

A useful method for the Continuous Wavelet Transform (CWT) is the Synchrosqueezing Transform (SST). This method is employed to concentrate the frequency elements of non-stationary signals in the TF space. The CWT successfully creates a high-resolution TF representation. In Fig.1, the SST-dependent TF visualization derived from the artificial signal $\delta(t)$ is displayed. The right CWT scales are used for discretization, and a bump mother wavelet is used to achieve SST. It has been highlighted that STFT-based TF space suffers from extremely poor frequency resolution and reduced temporal resolution owing to the employment of the window function. Using a set of wavelets, which are time-frequency filters, the CWT method detects oscillatory elements in a signal. The CWT is used to create wavelets from a successive time function. In the following form, a signal $s(t)$ is convolved with a mother wavelet $\Phi(t)$, which is a finite oscillatory consequence.

$$Z(p, q) = \frac{1}{|p|^{1/2}} \int_{-\infty}^{\infty} \Phi\left(\frac{t-q}{p}\right) s(t) dt \quad (2)$$

If each scale-time duet's (p, q) wavelet coefficients are represented by $Z(p, q)$, then it is possible to determine the instantaneous frequency $\omega_s(p, q)$ by using the formula

$$\omega_s(p, q) = -iZ(p, q)^{-1} \frac{\partial Z(p, q)}{\partial q} \quad (3)$$

Fig. 1. A synthetic signal $\delta(t)$ with three sinusoids is represented by TF utilizing (a) the simulated signal $\delta(t)$ and (b) STFT as well as (c) SST.

With TF representation, the information from the time-scale frame is translated to the time-frequency frame. During the synchrosqueezing procedure, each value is changed to $(q, \omega_s(p, q))$ [5]. It is able to have a scaling step because p and q are distinct numbers; for each, p_k , where $\omega_s(p, q)$ is calculated. When projecting from the time-scale frame to the time-frequency frame $(q, p) \rightarrow (q, \omega_{inst}(p, q))$, the SST $\Gamma(\omega_l, q)$ is only calculated [11] in the centres ω_l located in the spectral region $[\omega_l - \Delta\omega/2, \omega_l + \Delta\omega/2]$ with $\Delta\omega = \omega_l - \omega_{l-1}$.

$$\Gamma(\omega_l, q) = \sum_{p_k: |\omega_s(p_k, q) - \omega_l| \leq \Delta\omega/2} Z(p_k, q) p^{-3/2} \Delta p_k \quad (4)$$

Eq. (4) demonstrates that only the frequency (or scale) axis is synchrosqueezed in the TF representation of the signal [14, 28]. To obtain a focused image over the time-frequency plane for the SST, the CWT coefficients are reallocated [15]. The instantaneous frequencies are then taken from this image.

C. Coherence Evaluation

Effective communication between two parties can be achieved through coherence. Cohesiveness in neuroscience describes the systematic constancy among two neuronal cells. The establishment of more or less uniformity between oscillating modulations in different neurons' brain activity is known as neuronal coordination. Synchronization has a substantial impact on how the different neuronal regions synchronize their stimulatory behavior [16, 17, 18].

D. Frequency Coherence

A common technique for assessing consistency within brain waves is frequency consistency. Frequency coherence's major benefits include being highly implicit, hard, and noise-resistant while allowing for a quick overview of pertinent consistent frequencies in the sample [19]. The frequency coherence is a measure of how well multiple signals' cross-spectral levels hold up when normalized with respective auto-spectral levels. As functions of frequency, consider x and y , two stationary random processes. According to [26], the familiar consistency function of x , as well as y , is as follows:

$$|C_{x,y}(f)| = \frac{|J_{x,y}(f)|}{\sqrt{J_{x,x}(f)J_{y,y}(f)}} \quad (5)$$

wherever $J_{x,y}(f)$ is the cross-spectral density among the two processes. $J_{x,x}(f)$ and $J_{y,y}(f)$ are the auto spectral density functions of x as well as y , respectively, at frequency, f . The EEG is a non-stationary signal; hence the conventional coherence function is insufficient.

E. Coherence of Time and Frequency

Typically, coherence analysis only works with stationary signals since it calculates the relationship between two signals throughout the frequency region. Consequently, much like with non-stationary signals, traditional coherence analysis is unable to reveal the temporal features of EEG [20]. The sequential relationship among both processes in the time-frequency dimension is measured using an advanced ruling technique. The TF consistency has been employed to gauge the synchronization of cortical activity in the brain-computer interaction motor imagery experiment. The coherence characteristic of the TF is described as

$$|C_{x,y}(t, f)| = \frac{|J_{x,y}(t, f)|}{\sqrt{J_{x,x}(t, f)J_{y,y}(t, f)}} \quad (6)$$

At this point, $t = 1, 2, \dots, T$; $f = 1, 2, \dots$, is the distinct frequency and the signal is divided into T segments. The measurements of the sectional as well as auto-spectral concentrations are

$$J_{x,y}(t, f) = X(t, f)Y^*(t, f)$$

$$J_{x,x}(t, f) = |X^2(t, f)|, \quad J_{y,y}(t, f) = |Y^2(t, f)| \quad (7)$$

where $X(t, f)$ and $Y(t, f)$ are the respective x also y of TF transforms coefficients, besides $Y^*(t, f)$ is the complex quantity of $Y(t, f)$.

The TF consistency definitions are simple and also use a method akin to the Fourier analysis. Based on the spectrogram approach, which involves averaging the signal segments to arrive at the estimates, the spectra and the frequency coherence in the Fourier analysis can be calculated. As both time and frequency have two dimensions, the time-frequency consistency encounters challenges throughout averaging. SST, which performs better than STFT, is used throughout this study to compute the TF translation parameters accompanied by TF consistency

F. Smoothing Impacts on TF Coherence

To get rid of noise, utilize the smoothing operator, and a convolution operator. The operators for smoothing cross- and auto-spectral densities can be the same or different. The employment of non-identical operators, as opposed to identical operators, produces time-frequency consistency that is unrestricted to $[0, 1]$ and, as a result, improves temporal resolution [8]. Smoothing both time and frequency is necessary to increase the TF coherence’s constancy. Averaging a number of orthogonal-based spectrum estimations, such as those obtained using multi-taper methods, can serve as the smoothing operator. They are typically employed for amplitude- and auto-spectral densities. The non-identical smoothing agents are two-dimensional in both time and frequency [21] or a single-dimensional function of time. Thus, the standard magnitude squared TF coherence is calculated as [8]

$$|C_{x,y}(t, f)|^2 = \frac{|J_{x,y}(t, f) \otimes w[\phi]|^2}{\{J_{x,x}(t, f) \otimes w[\phi]\} \{J_{y,y}(t, f) \otimes w[\phi]\}} \quad (8)$$

Here, $w[\phi]$ also $w[\varphi]$ remain two different ($w[\phi] \neq w[\varphi]$) leveling windows of cross-spectral concentration and auto

spectral concentration, accordingly, and \otimes denote the convolution operator. The impacts of smoothing in TF consistency are demonstrated in Fig. 2, where two artificial signals $x_1 = [\sin(2\pi f_1 t) \sin(2\pi f_2 t)]$, $x_2 = [\sin(2\pi f_1 t) \sin(2\pi f_2 t)]$ with $f_1 = 5\text{Hz}$ also $f_2 = 10\text{Hz}$ and their TF consistency remain accessible. According to Fig. 2(a) and 2(d), respectively, the individual sinusoids that make up x_1 and x_2 have various temporal lengths.

As shown in Fig. 2(e), and 2(f), smoothing operations are shown to increase the TF coherence’s representativeness and clarity for both STFT and SST-based methods. On the other hand, as seen in Fig. 2(b) and 2(c), when the smoothing procedure is not carried out, a significant amount of irrelevant coherence is introduced. Hence, the measurement of time-frequency coherence is enhanced by utilizing diverse smoothing agents. Several 2-D Gaussian smoothing windows with various lengths are employed in this research. The kernel’s height in hertz and width in seconds are denoted by h and d , respectively, to reflect the window length $w = [h \ d]$.

G. Proposed Algorithm for TF Coherence

The steps that make up the suggested technique for calculating the time-frequency coherence amongst two signals dependent on SST are as follows:

- 1) Choose two EEG channels or two brain signals at random.
- 2) The time-frequency coefficients can be obtained by applying the SST to each individual signal.
- 3) The cross and auto spectral distributions should be calculated using the SST coefficients.
- 4) Using two acceptable non-identical (various window lengths) smoothing processes, amplify the cross and auto spectral densities.
- 5) Lastly, use Eq. (8) to get the time-frequency coherence by using smoothed auto and cross-spectral densities.

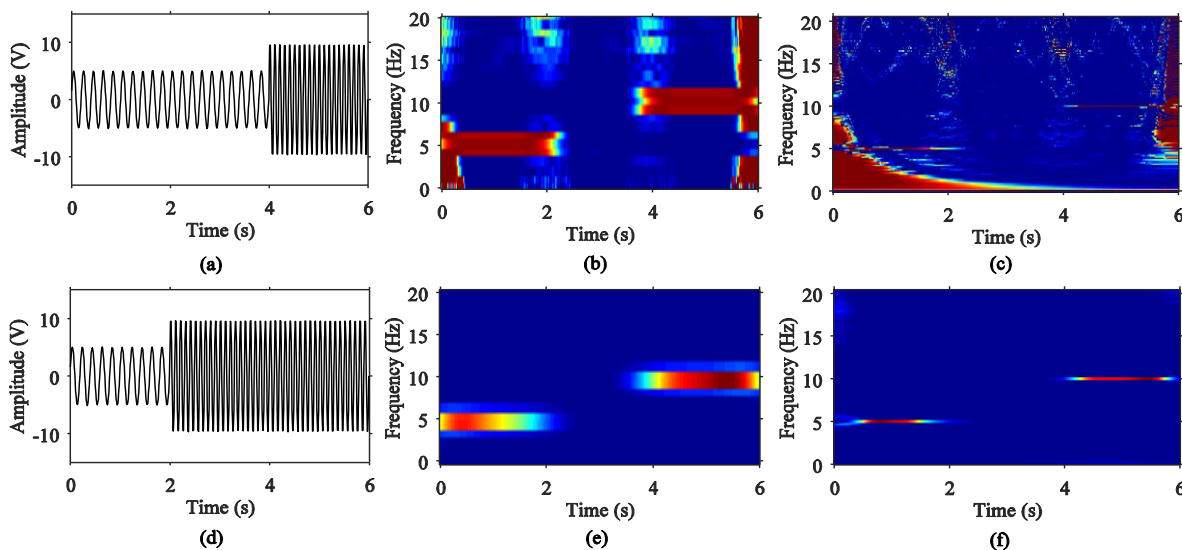

Fig. 2. The impact of smoothing operations on the TF consistency among the artificial signals x_1 (a) as well as x_2 (d). (b) STFT and (c) SST dependent TF lacking levelling, STFT and I STFT and (f) SST-dependent TF consistency through smoothing.

III. RESULTS

Both real EEG data and synthetic signals are utilized to evaluate the performance of the proposed SST-based time-frequency consistency. The outcomes are contrasted with time-frequency consistency dependent on STFT. With regard to STFT, a hamming window of length 100 is employed. Then, using non-identical smoothing windows, the spectral coefficients are smoothed for the calculation of TF coherence. The cross- and auto-spectral concentrations are levelled with Gaussian smoothing windows with lengths of w [2 1] and w [10 1], respectively. To execute the SST, a mother wavelet with bumps is utilized, and then the CWT scales' discretization is set at 32. The cross-spectral density is smoothed over in the SST because the Gaussian smoothing windows are w [3 1] and w [50 1] long. The Gaussian smoothing windows in the SST have lengths of w [3 1] and w [50 1], meaning that the cross and auto spectral densities are flattened across TF areas of 3 Hz and 1 s, respectively.

1) *Synthetic data:* Three sinusoids with frequencies of 5 Hz, 6 Hz, and 10 Hz are added together with a sampling frequency of 100 Hz to produce the trio of non-generated

signals X, Y, and Z. As shown in Fig. 3, each of the simulated signals are made up of such three signals with various temporal alignments. The distinct synthetic waveforms X, Y, and Z are then each polluted with 5 dB, 0 dB, and -5 dB of Gaussian noise, accordingly. Fig. 4 and 5 show the time-frequency consistencies within each couple of artificial signals produced by STFT and SST, separately. The consistency among the signals Y and Z (5Hz and 6Hz frequency) is displayed in Fig. 4. while Fig. 5 shows the cohesiveness between the exact same pair of signals is separated in a more pronounced manner, they overlapped each other. Fig. 6, which shows the marginal frequency coherences of two approaches, exemplifies the phenomena clearly (STFT and SST). If $f=1,2,\dots,F$, the definition of the marginal frequency coherence is $\tilde{C}_{x,y}(f) = \sum_{t=1}^T |C_{x,y}(t,f)|^2$. In STFT, values for closer frequency coherence values overlap, whereas, with SST, the coherence of each individual frequency component is strongly represented. It is believed that the SST-based technique has better resolution than the STFT-based time-frequency coherence technique.

Fig. 3. Development of a multiple non-stationary [X, Y, Z] signal. Three separate frequencies sinusoids are present within the initial three rows (S1, S2, as well as S3). The three sinusoids in S1, S2, and S3 have, correspondingly, 10 Hz, 6 Hz, and 5 Hz frequency properties. To produce the artificial signals X, Y, and Z, alternative time alignments of the sinusoids are used. 5dB, 0dB and -5dB noises are inserted to sinusoids (a) to (c), (d) to (f) and (g) to (i) correspondingly. The synthesized signal in the fourth row is made up of the three sinusoids; $X=(a)+(b)+(c)$, $Y=(d)+(f)$ and $Z=(g)+(h)+(i)$.

Fig. 4. Artificial signal STFT-dependent TF consistency among (a) X and Y, (b) X and Z, and (c) Y and Z.

Fig. 5. Artificial signal coherence (a) between X as well as Y, (b) between X and Z, and (c) between Y and Z using SST-dependent TF.

Fig. 6. Marginal frequency consistencies of STFT-depended coherence (black line) with SST-depended coherence (red line) between the artificial signals Y and Z.

2) *Real data:* The actual EEG data was gathered from the calib_ds1a. (IV dataset) generated from the 4th Brain-Computer Interface (BCI) Competition, which is openly accessible. The information is used to determine how well the suggested strategy performs. It is noted in subjects who are in good health. Motor imagery is accomplished during the entire session without any input. Two kinds of motor images are chosen from left hand, right hand, and foot movement for each

subject. Movement signals of the left hand and foot are present continuously in the calibration dataset calib_ds1a. 59 EEG channels comprising 200 trials lasting four seconds each make up the data. The data are sampled at a rate of 100 Hz. The data offset from the EEG signals has been eliminated during pre-processing. In order to get the alpha frequency band, which has intricate patterns of intermittent synchronization, The brain wave then goes across a 4th-order

Butterworth band transfer filter with a frequency range of 8 Hz to 12 Hz. [8]. The inter-channel coherence is measured in this experiment using the two channels T7 and T8. Fig. 7 shows the unprocessed EEG signal, the purified alpha ingredient, as well as the spectrum of alpha for the left-hand movement channels T7 and T8. The foot movement data from channels T7 and T8 are similarly depicted in Fig. 8. The STFT-based time-frequency coherence for left hand and foot movement motor images are shown in Fig. 9(a) and 9(c) for channels T7 and T8. The time-frequency coherence between channels T7 and T8 of left hand and foot movement, based on SST, are shown in Fig. 9(b) as well as 9(d), correspondingly. Fig. 9 shows how SST-based TF coherence, in contrast to STFT, exhibits remarkable localization of extremely small band frequency components.

3) *BCI interpretation:* In this investigation, the time-frequency coherence across channels in the left and right hemispheres of the human brain, is investigated. Moreover, the distinction involving left hand and left foot action in motor imagery is seen. Sensorimotor rhythms can be managed with the help of motor imagery [22], and the patterns are more active in the central region of the brain [23]. The 59 EEG channels are therefore divided into three channels from each hemisphere (T7, FC5, and CP5) and three channels from each hemisphere (T8, FC6, and CP6) for coherence assessment. Fig. 11 depicts the spatial distribution of the scalp's channels in the 10/20 EEG system. To evaluate time-frequency coherences, there are eight-channel clusters used: FC5FC6, FC5T8,

FC5CP6, T7FC6, T7T8, T7CP6, CP5FC6, CP5T8, as well as CP5CP6. On every one of the chosen channel pairings, time-frequency coherences based on STFT and SST are assessed. Eq. (9) determines how to weight the time-frequency coherences

$$\left|C_{x,y}(t, f)\right|_{weighted}^2 = \left|C_{x,y}(t, f)\right|^2 \bullet \tilde{C}_{x,y}(f) \quad (9)$$

Here, the weight matrix is the marginal frequency coherence and the notation \bullet is a binary singleton multiplication function. Using the weighted time-frequency coherence, the marginal time coherence is computed. It is said that minimal time coherence is

$$\tilde{C}_{x,y}(t) = \arg \max_f \left(\left|C_{x,y}(t, f)\right|_{weighted}^2 \right); t = 1, 2, 3, \dots, T \quad (10)$$

The minimal time consistency in this study is determined by averaging the marginal time coherence throughout 100 trials. The normalized readings during the time for several connection pairs of left-hand and foot swing data are displayed in Fig. 12. Data on left-hand movement is represented by solid lines, and information on foot movement is represented by dashed lines. Fig. 12's left panel displays SST-based marginal temporal coherences, while the right panel displays STFT-dependent marginal time consistencies. For both the left hand as well as foot activities sensory motor imaging information are distinguishable using the SST-based marginal time coherence.

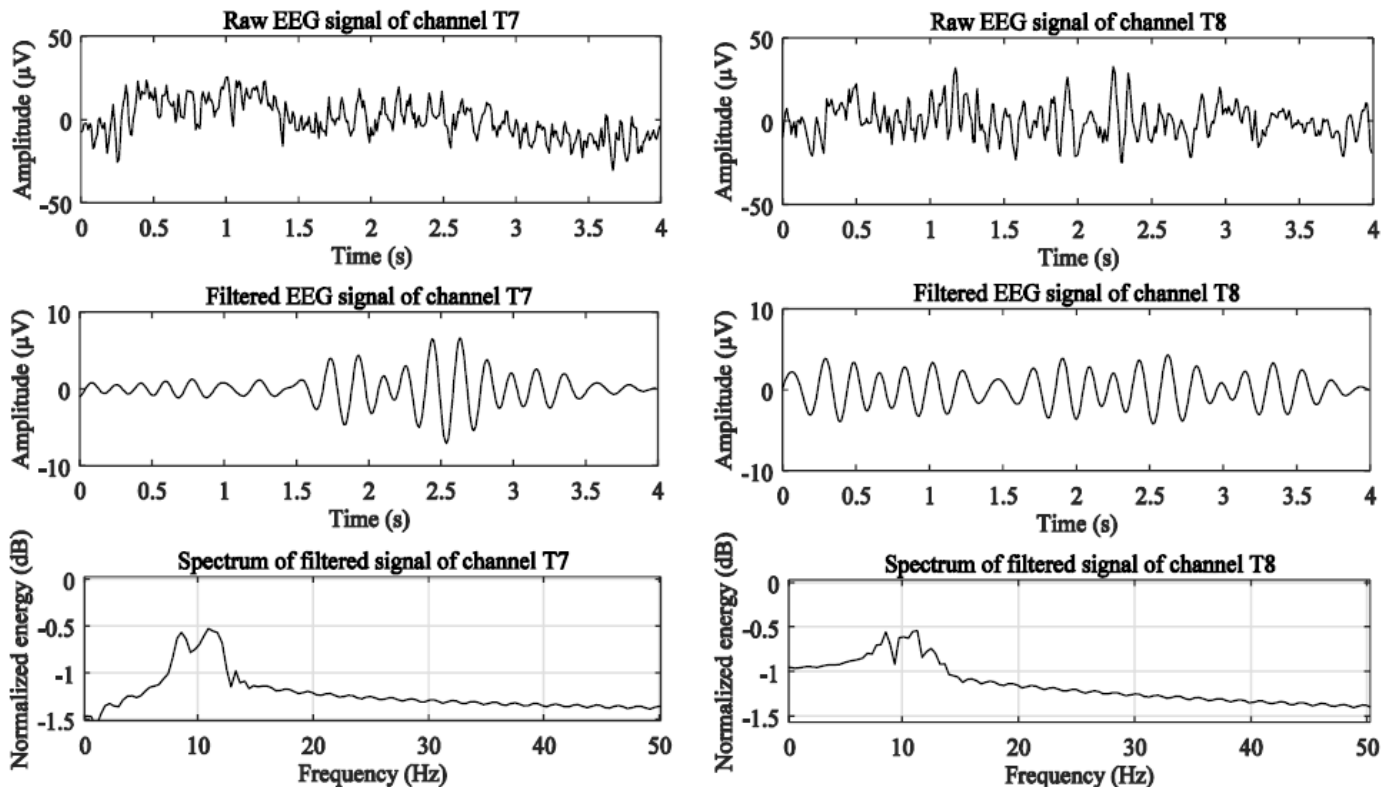

Fig. 7. Left hand movement data: first row is the raw EEG signals, second and third row are the filtered EEG signals and spectrums of the filtered component respectively.

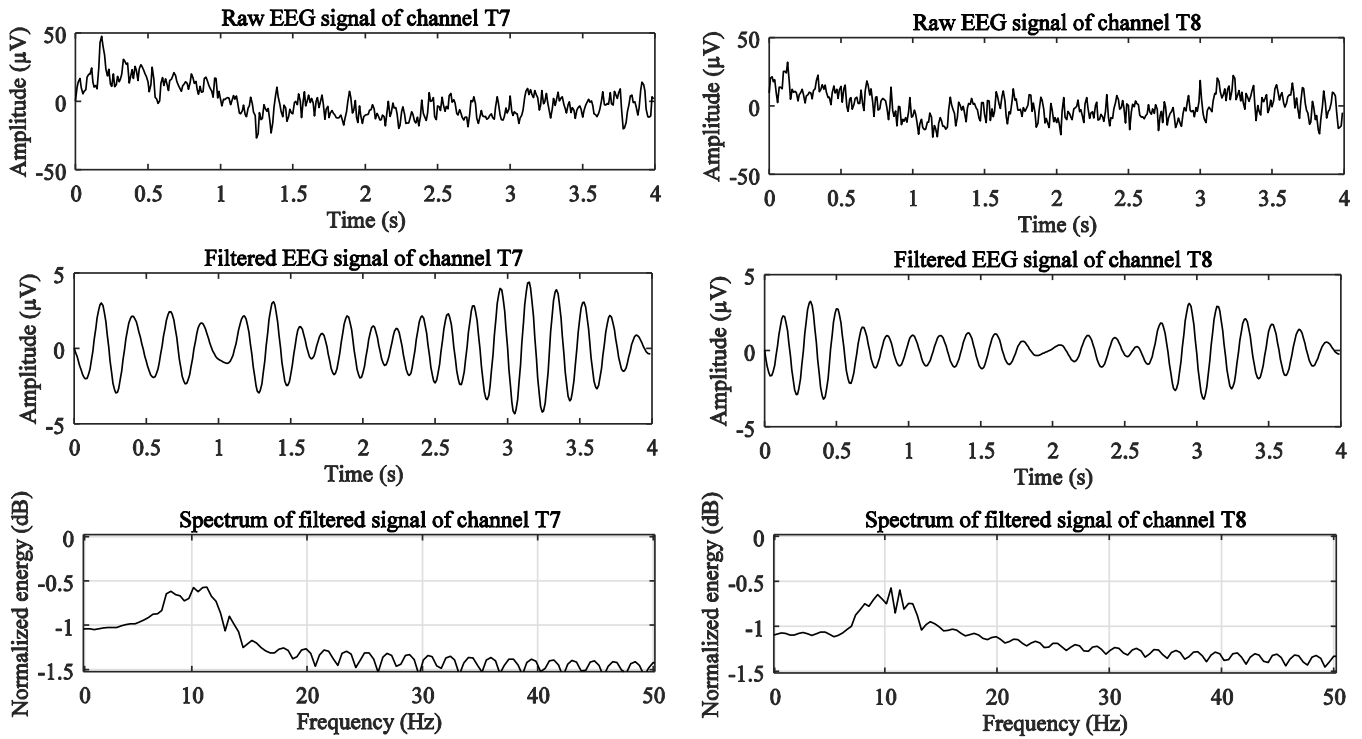

Fig. 8. Foot movement data: first row is the raw EEG signals, second and third row are the filtered EEG signals and spectrums of the filtered component respectively.

Fig. 9. TF coherence between channels T7 and T8 based on (a) STFT and (b) SST of left hand movement data, (c) STFT and (d) SST of foot movement data.

Fig. 10. Left hand action (a) as well as foot action (b) of channels T7 and T8 with marginal frequency consistencies.

Fig. 11. The American EEG Society has standardized the electrode map of something like the 10/20 EEG system. For the dataset utilized in this experiment, the marked conductors T7, FC5, as well as CP5 beginning the left cerebral hemisphere and T8, FC6, as well as CP6 as of the right side of the brain were chosen.

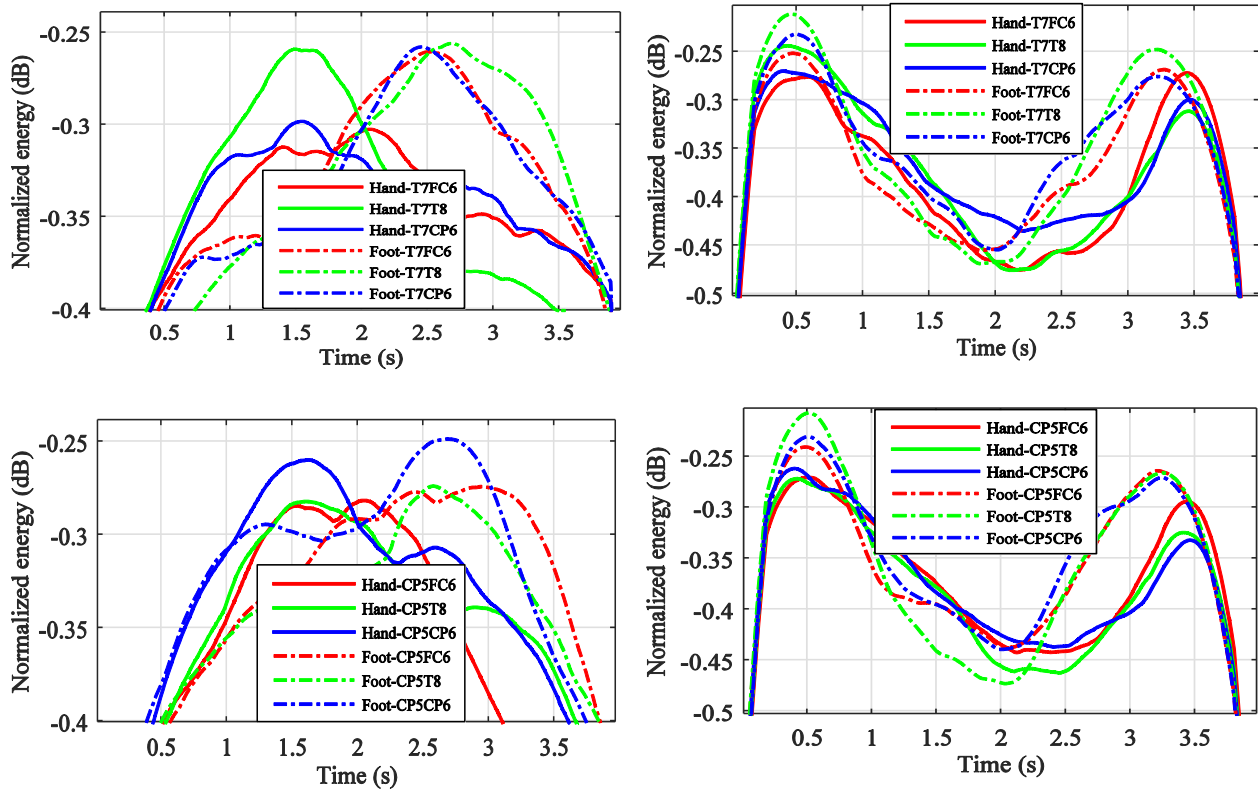

Fig. 12. Movement information for the left hand and foot for STFT-dependent (right panel) and SST-based models (left panel) approaches exhibit a small amount of time coherence between distinct channel pairings.

IV. DISCUSSION

EEG outputs are used in the research to examine how well SST performs in time-frequency illustration. Fig. 9 displays the TFR derived from left hand and foot movement data utilizing STFT and SST motor images. Fig. 10 shows, for left hand and left foot movement data, the energy related to the marginal frequency consistency. Although the SST-based technique shows acute localization of each frequency element within a relatively small band of frequencies, the marginal frequency coherence depended on STFT displays weak localization of frequency agents. The frequencies of 9 Hz and 11 Hz in Fig. 10(b) can be clearly distinguished using SST-based marginal frequency coherence, whereas they cannot be achieved using an STFT-dependent method. From now, SST-dependent time-frequency consistency is better than STFT-based time-frequency coherence. The fundamental cause is that the employment of something like a window function for covering in STFT results in the introduction of cross-spectral energy, which causes the energy to spread over a broad range of frequencies. The TFR performance of the SST has been evaluated in our previous work [24]. This paper is a development of our earlier paper [24]. Our prior work is expanded upon in this one. In addition, the smoothing operations on the TFR, as well as BCI interpretation, are introduced in this paper. BCI can use marginal frequency coherence followed by marginal time coherence based on SST. The coherence value for left-hand movement data in the left panel of Fig. 12 is at its highest in the time range of 1-2 seconds, whereas the coherence value for foot movement data

across all channel pairs is at its highest in the time range of two to three seconds. In the SST-based marginal temporal coherence, left-hand and foot measurement data are explicitly distinguished from one another. The marginal temporal coherence model based on STFT, however, does not exhibit this kind of selectivity (in the right panel). The main cause is the fact that the STFT has a fixed time-frequency window while the SST has a changeable one, making it difficult to accurately evaluate signals with broad bandwidths that fluctuate rapidly over time. Moreover, the STFT demands that the brain wave be stationary for a given time period, yet EEG signals exhibit non-stationary characteristics.

V. CONCLUSIONS

The analysis of the time-frequency (TF) consistency among two signals is offered in this work using an innovative approach. For each of the provided signals, the time-frequency densities of the crossed and auto spectrums are calculated. Then, using quasi smoothing agents, the spectral densities are smoothed. The TF coherence is calculated using smooth spectral densities for artificial signals with time-frequency representations based on STFT and SST. A genuine EEG signal with various motor images is used to test the suggested SST-based coherence estimate method. Comparing the two strategies' performances reveals that the SST-based approach is more effective than STFT at locating frequency contents with greater spatial precision. Then, using both SST and STFT-based coherences, marginal time coherences are computed. It is clearly shown that the STFT-dependent

marginal time consistencies are incapable to distinguish among left hand and foot activity data, in contrast to the SST-dependent marginal time coherences, which can. This implies that these marginal time coherences can enhance BCI design. In order to get greater performance, it is advised BCI designers to take these coherences as supplementary features when designing a BCI system.

Future study might explore brand-new combinations of features and feature selection, as well as the use of these features for BCI tasks other than motor imagery. Additionally, there is a need for work in the design of novel algorithms, including physiologically realistic error functions for EEG signal predictions for the complexity feature.

Abstract—Phonocardiography, the recording and analysis of heart sounds, has become an essential tool in diagnosing cardiovascular diseases (CVDs). In recent years, machine learning and deep learning techniques have dramatically improved the automation of phonocardiogram classification, making it possible to delve deeper into intricate patterns that were previously difficult to discern. Deep learning, in particular, leverages layered neural networks to process data in complex ways, mimicking how the human brain works. This has contributed to more accurate and efficient diagnoses. This systematic review aims to examine the existing literature on phonocardiography classification based on machine learning, focusing on algorithms, datasets, feature extraction methods, and classification models utilized. The materials and methods used in the study involve a comprehensive search of relevant literature and a critical evaluation of the selected studies. The review also discusses the challenges encountered in this field, especially when incorporating deep learning techniques, and suggests future research directions. Key findings indicate the potential of machine and deep learning in enhancing the accuracy of phonocardiography classification, thereby improving cardiovascular disease diagnosis and patient care. The study concludes by summarizing the overall implications and recommendations for further advancements in this area.

Keywords—Heart sounds classification; Phonocardiogram (PCG); CVDs; deep learning

I. INTRODUCTION

Phonocardiography (PCG) is one of the basic techniques used to understand the heart's state and assess whether the heart is in a natural state or has some abnormal pattern. PCG is a diagnostic procedure that allows a visual record of the sounds and murmur created by the contracting heart, including its valves and connected large vessels. In the absence of diagnosis equipment, the stethoscope is only the tool available to general physicians to examine a patient's heart sounds [1]. Cardio-specialist can understand the heartbeat as a specialist and recommend further medical procedures to the patients according to their heart condition but usually, in the unavailability of a cardio-specialist, the general physicians cannot detect, if the heart is functioning properly or if there is any type of exception due to the closure of heart walls. Environmental interferences, such as those caused by friction between the device and a human's skin, Electromagnetic

Interference (EI), and unrelated noises like breath, lung, and ambient sounds, can readily interfere with the process of PCG because signals in the form of sound generated by the human heart are frequently paired with EI, out-of-band noise must be removed [2], [3].

To cope with the limitations in traditional phonocardiography techniques, machine learning (ML) based methods can be a good solution for phonocardiography for several reasons [4]. ML models can automate the process of analyzing PCG recordings, which can be time-consuming and subject to human error when done manually. ML models can be trained on large datasets of labeled PCG recordings, which can improve their accuracy in detecting and diagnosing heart conditions. ML-based methods can handle large amounts of data, which is important in PCG as it requires analyzing audio signals over time and adapting to new data, and improving their performance over time, which can be useful in handling diverse populations and detecting new conditions [5].

Using ML-based approaches to achieve real-time heart disease detection from audio signals is challenging because heart sounds can vary significantly depending on factors such as the person's age, sex, and underlying medical conditions [6]. This makes it difficult to develop an ML model that can accurately detect and classify heart sounds in a wide range of individuals. Heart sounds can be difficult to distinguish from other sounds in the body, such as breathing and blood flow [7]. Additionally, external noise such as background noise or equipment noise can also interfere with the recording and analysis of heart sounds [5]. Collecting a large and diverse dataset of heart sounds for training machine learning models can be difficult and time-consuming.

Heart sounds are complex and have a lot of variations, which can make it difficult for machine learning algorithms to accurately classify them. Overfitting is a common problem when building machine learning models, and can occur when a model is trained on a limited dataset and then performs poorly on new, unseen data [8]. The interpretation of phonocardiography signals requires expertise and knowledge of human anatomy and physiology, this is a challenge when using machine learning algorithms to interpret the signals. Designing a phonocardiography system using machine learning is a big challenge because it requires overcoming several

technical and logistical hurdles in accurately and reliably detecting a classifying heart sound [9]. The core phases involved in the phonocardiography process i.e., segmentation, feature extraction, and final classification results, are all considerably impacted by denoising. Preprocessing is required in phonocardiography systems to clean and enhance the quality of the raw phonocardiography signal before it is further analyzed.

It is necessary to create these components, incorporating the applicable criteria that follow.

II. AN OVERVIEW OF PHONOCARDIOGRAPHY

Machine Learning based phonocardiography systems models used in real-time to analyze Phonocardiography (PCG) recordings and provide diagnostic information, which can be useful in critical care settings. Overall, the combination of machine learning and PCG data can provide more accurate and objective results and helps to improve the diagnosis and monitoring of heart conditions [10]. The generic ML-based phonocardiography systems are depicted in Fig. 1.

Fig. 1. ML-based phonocardiography general framework.

A. Heart Sound Signal

Heart sound signals, also known as phonocardiograms or PCG signals, are acoustic signals generated by the mechanical activities of the heart. These signals provide important information about the structure, function, and abnormalities of the cardiovascular system. Heart sound signals typically consist of two prominent components: the first heart sound (S1) and the second heart sound (S2). S1 is produced by the closure of the mitral and tricuspid valves during the systolic phase of the cardiac cycle, while S2 is generated by the closure of the aortic and pulmonary valves during the diastolic phase. These components are accompanied by additional sounds such as the third heart sound (S3) and fourth heart sound (S4), which can indicate specific cardiac conditions.

Heart sound signals are characterized by their duration, intensity, frequency content, and temporal relationships between different components. They contain valuable information about heart rate, heart rhythm, valve function, and the presence of murmurs, stenosis, or other cardiovascular abnormalities. Traditionally, heart sound signals were recorded using specialized electronic stethoscopes or phonocardiography equipment. However, with advancements in technology, heart sound signals can now be captured using digital stethoscopes, wearable devices, or even smartphone applications equipped with appropriate sensors.

Heart sounds (signals) are produced from a specific cardiac event such as the closure of a valve or tensing of a chordae tendineae. Most normal heart sound (Lub, Dub) signal rates at rest are between about 60 and 100 beats per minute. Sound is the pressure of air propagating to our ears. The digital audio

file is gotten from a sound sensor that can detect sound waves and convert them to electrical signals.

B. Normal Heart Sound Signal

Normal heart sounds, also known as physiological heart sounds, are the characteristic sounds produced by a healthy heart during its regular functioning. These sounds are a result of the synchronized mechanical activities of the heart's valves and chambers. The normal heart sound consists of two primary components: the first heart sound (S1) and the second heart sound (S2). S1 is a low-frequency sound that occurs at the beginning of each cardiac cycle and is caused by the closure of the mitral and tricuspid valves. S2 is a higher-pitched sound that occurs at the end of the cardiac cycle and is produced by the closure of the aortic and pulmonary valves. These two sounds create the familiar "lub-dub" rhythm associated with a normal heartbeat. The normal heart sound signifies the proper functioning of the heart's valves and chambers, reflecting a healthy cardiovascular system. Understanding the characteristics and timing of normal heart sounds is crucial in differentiating them from abnormal sounds and diagnosing various cardiac conditions [11].

C. Artifact Heart Sound Signal

Artifact heart sounds refer to extraneous or spurious sounds that may be inadvertently recorded or introduced during the process of capturing heart sound signals. These sounds are not of physiological origin and do not reflect the actual functioning of the heart. Artifact heart sounds can arise from various sources, such as environmental noise, patient movement, electrical interference, or improper placement of the recording device. They can manifest as random noise, clicking sounds, buzzing, or other irregular patterns that may obscure or distort the true heart sounds. Artifact heart sounds pose a challenge in the accurate analysis and interpretation of heart sound signals, as they can interfere with the detection of abnormal cardiac conditions or mask important diagnostic information. Efforts are made to minimize artifacts during data collection by ensuring proper recording techniques, reducing environmental noise and employing noise cancellation methods. Additionally, careful signal processing and expert interpretation are essential to distinguish artifact heart sounds from genuine physiological sounds and ensure the reliability and accuracy of heart sound analysis in clinical practice and research [12].

D. Extrastole Heart Sound Signal

Extrastole, also known as an extra heart sound or premature beat, refers to an abnormal additional sound that occurs in the cardiac cycle, occurring either before or after the normal heart sounds. It is typically characterized by a distinctive "gallop" or "clicking" sound. Extrastole is caused by premature contractions of the heart's ventricles, atria, or both. These premature contractions disrupt the normal rhythm and timing of the cardiac cycle. Common types of Extrastole include atrial premature complexes (APCs) and ventricular premature complexes (VPCs). Extrastole can be indicative of underlying heart conditions such as arrhythmias, valvular disorders, or heart muscle abnormalities. Detecting and analyzing Extrastole in heart sound signals is crucial for diagnosing and monitoring cardiac abnormalities. Advanced signal processing techniques and machine learning algorithms are employed to identify and

classify Extrastole patterns accurately. Understanding the presence and characteristics of Extrastole heart sounds aids in the comprehensive evaluation and management of cardiovascular health [13].

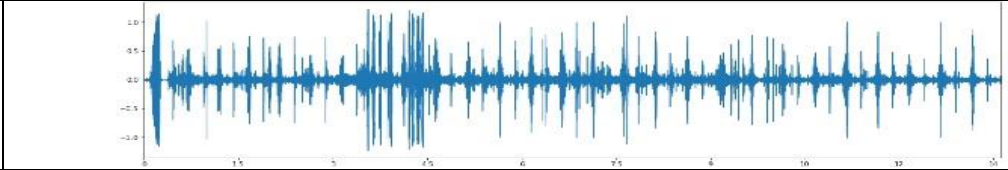

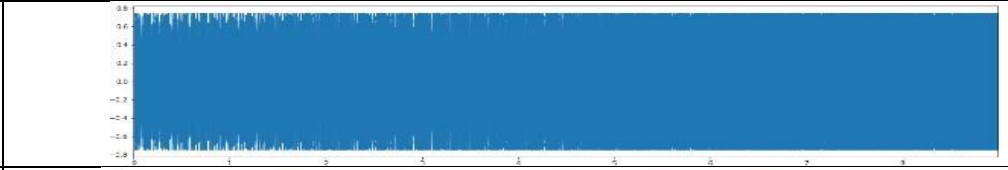

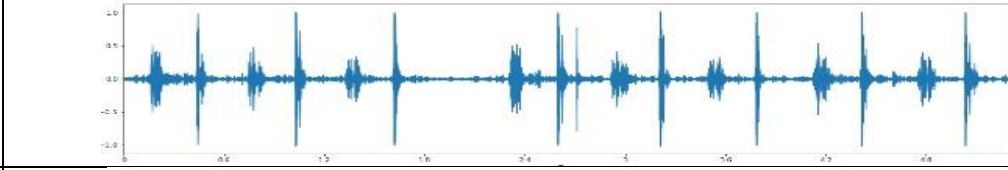

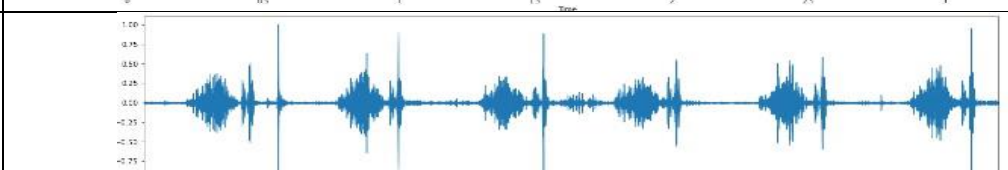

E. Extrahls Heart Sound Signal

Extrahls, also known as extraneous heart sounds or adventitious heart sounds, refer to abnormal sounds that are superimposed on normal heart sound signals. These sounds are not typically associated with the regular functioning of the heart and can arise from various pathological conditions or abnormalities within the cardiovascular system. Extrahls can manifest as additional clicks, murmurs, or abnormal sounds that occur in addition to the first and second heart sounds. They can be indicative of structural heart defects, valve abnormalities, turbulent blood flow, or other cardiac disorders. Analyzing Extrahls in heart sound signals is crucial for diagnosing and monitoring cardiovascular conditions, as they can provide valuable insights into the presence and severity of cardiac abnormalities. Advanced signal processing techniques, such as spectrogram analysis, wavelet analysis, or machine learning algorithms, are employed to identify and characterize Extrahls accurately. By detecting and analyzing Extrahls in heart sound signals, clinicians and researchers can improve their understanding of cardiac pathologies and make informed decisions regarding patient care and treatment strategies [14].

F. Murmur Heart Sound Signal

Murmur heart sound signals refer to abnormal or atypical sounds that are heard during auscultation of the heart. Murmurs are characterized by a prolonged, swishing, or whooshing sound that occurs between the normal heart sounds (S1 and S2). These sounds are caused by turbulent blood flow within the heart or blood vessels, typically due to structural abnormalities such as valve defects, stenosis, regurgitation, or abnormal blood flow patterns. Murmurs can be classified based on their timing, intensity, pitch, and location within the cardiac cycle. They are often graded on a scale from 1 to 6, with higher grades indicating more pronounced murmurs. Accurate identification and characterization of murmurs in heart sound signals are crucial for diagnosing and managing various cardiovascular conditions. Advanced signal processing techniques, such as spectral analysis, time-frequency analysis, or machine learning algorithms, can aid in the automated detection and classification of murmur patterns. By analyzing murmurs in heart sound signals, healthcare professionals can assess the severity of underlying cardiac abnormalities, determine appropriate treatment strategies, and monitor the effectiveness of interventions for improved patient care [12]. Table I depicts a human’s heart-generated sound Wave-form signal.

TABLE I. HEART SOUND WAVE-FORM SIGNAL, X-AXIS REPRESENTS TIME AND Y-AXIS MEASURES AMPLITUDE (GENERATED BY USING PYTHON LIBRARY: MATPLOTLIB)

4.	Extrahls	
5.	Murmur	

G. Signal Denoising

Signal denoising refers to the process of removing unwanted noise or interference from a signal while preserving the underlying information of interest. It is a fundamental technique in signal processing used to improve the quality and reliability of signals in various domains, such as audio, image, and biomedical signals. The presence of noise in a signal can distort or mask important features, making it challenging to extract meaningful information or make accurate measurements. Signal denoising methods aim to reduce or eliminate this noise, enhancing the signal's clarity and fidelity. These methods employ various techniques, such as filtering, statistical analysis, wavelet transforms, or machine learning algorithms, to suppress or attenuate the noise components while preserving the desired signal components. Signal denoising is widely used in applications where the accuracy and reliability of signal analysis, interpretation, or decision-making are critical, allowing researchers, engineers, and practitioners to obtain cleaner and more accurate signals for further analysis or processing.

Signal denoising is highly important in various applications due to its ability to enhance signal quality, improve data analysis accuracy, facilitate signal interpretation, increase measurement precision, optimize signal processing techniques, enable better signal visualization, and enhance communication and signal transmission reliability. By removing unwanted noise and interference from signals, signal denoising improves the accuracy, clarity, and reliability of the underlying information, leading to more meaningful analysis, interpretation, and decision-making. It is a crucial step in fields such as biomedical signal processing, image and audio processing, communication systems, and scientific research, where accurate and reliable signal analysis is essential for successful outcomes.

Environmental interferences, such as those caused by friction between the device and a human's skin, Electromagnetic Interference (EI), and unrelated noises like breath, lung, and ambient sounds, can readily interfere with the process of recording heart sounds [15]. Because signals in the form of sound generated by the human heart are frequently paired with EI, out-of-band noise must be removed. The segmentation, feature extraction, and final classification results are all considerably impacted by denoising. Wavelet denoising, variational mode deconstruction denoising, and Digital Filter Denoising (DFD) are the three most often used denoising techniques [16]. A new line of study in the field of heart sound feature extraction is the creation of a wavelet function for the human heart's signals based on the past understanding of heart sound data [17].

A sound spectrum refers to the distribution of the different frequencies present in a sound signal. It represents the energy or intensity of each frequency component within the signal. The spectrum provides valuable information about the composition and characteristics of the sound, allowing for the identification and analysis of specific frequency components. In the context of heart sound signals, a sound spectrum can reveal the presence and intensity of different sound frequencies

associated with normal or abnormal heart sounds. By analyzing the spectrum, healthcare professionals and researchers can gain insights into the underlying physiological conditions and abnormalities of the heart.

Spectral analysis techniques, such as Fourier transform or wavelet transform, are commonly employed to compute the sound spectrum and visualize the frequency content of the signal. This information can assist in the diagnosis, monitoring, and treatment of various cardiovascular disorders, providing valuable insights into the acoustic properties of the heart. Table II depicts different Heart Sound spectrums after denoising of heart's sound wave signal.

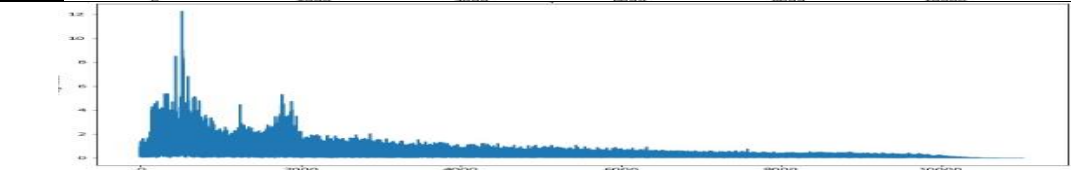

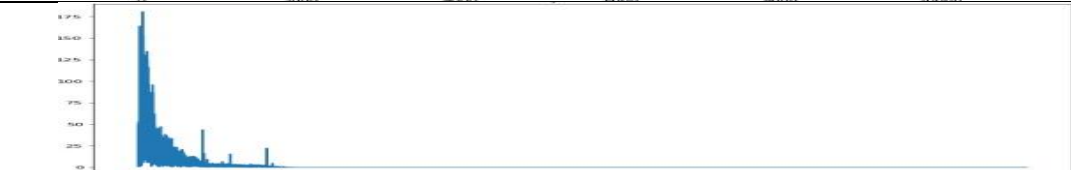

H. Signal Segmentation

Signal segmentation is a fundamental process in signal processing that involves dividing a continuous signal into shorter segments or intervals. This technique is essential for isolating specific regions of interest within a signal, allowing for targeted analysis and processing. Signal segmentation is commonly used in various fields, such as speech recognition, audio processing, image analysis, and biomedical signal analysis. By segmenting a signal, researchers can focus on specific time intervals or frequency components for further analysis, enabling the extraction of meaningful features and patterns. This approach facilitates tasks such as event detection, signal classification, anomaly detection, and time-frequency analysis. Additionally, signal segmentation helps in dealing with non-stationary signals by breaking them down into smaller, more manageable segments. Overall, signal segmentation plays a vital role in signal processing applications, allowing researchers and practitioners to effectively analyze and understand complex signals by examining their constituent segments individually.

As part of the segmentation process, the heart sounds of the first human (S1), the second human (S2), and the diastole are split into four parts or segments. Each section has useful components that help distinguish between the different types of heart sounds. However, individual differences in the length of the human heartbeat cycle, the number of human heart sounds, and the kinds of heart murmurs result in erroneous PCG signal segmentation. Thus, segmenting the FHS is a crucial step in the automated PCG analysis process.

In recent years, envelope-based techniques have been among the most frequently utilized techniques for segmenting heart sounds [18], [19]. Electrocardiogram (ECG) [20], feature-based methods [21], time-frequency analysis methods [22], and probabilistic model methods [23], [24], [25], [26] are some important segmentation methods. The underlying premise of the employed algorithms is that the diastolic interval is more prolonged than the systolic time. In actuality, especially in newborns and cardiac patients, this supposition is not always accurate for an aberrant heart sound [27]. Based on the similarity between the ECG and the human heart signals, it has been discovered that algorithms that combine the cardiac cycle with an ECG signal perform better at segmenting data. They do have higher hardware and software requirements, though.

TABLE II. HEART SOUND SPECTRUM, X-AXIS REPRESENTS FREQUENCY AND Y-AXIS REPRESENTS MAGNITUDE (GENERATED BY USING PYTHON LIBRARY: MATPLOTLIB)

S.No	Heart State	Human's Heart Sound Signal Spectrum
1.	Normal	
2.	Artifact	
3.	Extrastole	
4.	Extrahls	
5.	Murmur	

Humans can hear sound not only at a particular time by its intensity but also by its pitch. The pitch is the frequency of the sound, a higher pitch corresponds to a higher frequency, and vice versa. So, to have a representation that is closer to the human brain, another dimension which is frequency is added to the representation, which is the spectrogram.

III. REVIEW

This review will provides a compendious review of Phonocardiography, Machine Learning (ML) literature including experimental, empirical, and theoretical studies. The modern advancements and contributions from recent studies related to major and compelling administration depict this research.

Previously proposed phonocardiography, Machine learning techniques such as Deep Learning (DL), Extreme Learning Machines (ELMs), Deep Extreme Learning Machines (DELMS), and previous technologies and techniques are comprehensively reviewed. The literature mentioned is either the most benchmark research contributions, most relevant, highly cited, or published in well-reputed research journals.

A. Phonocardiography

Phonocardiography is a non-invasive diagnostic technique used to capture and analyze the sounds produced by the heart during its normal functioning. It involves recording the sounds made by the heart using a sensitive microphone or electronic sensor and then analyzing the recordings to identify any abnormal sounds or patterns that may indicate the presence of heart disease. Fig. 2 shows the Phonocardiography Signals of Normal Heart. In the phonocardiograph, the process of determining the state of the heart is done using the waves that come from the heart, and the process of classification of the heartbeats is done as normal and abnormal [28].

Fig. 2. Phonocardiography signals of normal heart.

The normal is defined as the state that an adult's blood pressure at rest varied from 60 to 100 beats per minute. In general, improved cardiac function and improved cardiovascular health are demonstrated by a lower resting heart rate. As for the abnormal state, the heart is in a state of disorder, unstable, and known any erratic heartbeat is known to be an abnormal heart rate or an increased heart rate. An irregular heart rhythm (rapid heartbeat, called tachyarrhythmia, or slow pulse, called slow arrhythmia-bradyarrhythmia) can accompany arrhythmia [29]. Fig. 3 shows the Phonocardiography Wave Signals of Arrhythmia-Bradyarrhythmia.

One of the most prominent application features of phonocardiography is the detection and monitoring of the evaluate the effectiveness of treatment of the key heart abnormalities symptoms like ventricular dysfunction, aortic regurgitation, mitral regurgitation, aortic stenosis, heart failure, hypertrophic cardiomyopathy, tricuspid regurgitation, coronary artery disease, pulmonic stenosis, atrial fibrillation, ventricular tachycardia, heart murmurs, aortic aneurysms, systolic heart murmurs, ventricular hypertrophy, ventricular septal defects and ductus arteriosus [30].

Left ventricular dysfunction refers to a condition where the heart's left ventricle, which is responsible for pumping oxygenated blood to the rest of the body, is not functioning properly. This can occur due to a variety of reasons, including damage to the heart muscle, high blood pressure, heart valve problems, or coronary artery disease. Left ventricular dysfunction can lead to a range of symptoms, including shortness of breath, fatigue, swelling in the legs and feet, and chest pain. It can also increase the risk of heart failure, heart attack, and other cardiovascular complications.

Phonocardiography-based detection of left ventricular dysfunction was reviewed in detail by Jagannath [31].

Some notable contributions along with the feature extraction techniques, datasets, modeling techniques, and results are depicted in Table III.

From Table III, it can be noted that most of the research work has been done using different feature extraction techniques including MFCC. Also, different researchers used different machine learning techniques like KNN, ANN, and SVM.

All the results have differences due to the use of different datasets, feature extraction techniques, and machine learning techniques. Most of the datasets used were private and the researchers did not share their data set on the web, or in other words, we can say that those data sets are not publicly available. We have found that Ziaee Hospital recorded Ardakan dataset. The dataset contains 148 PCG signals from 22 subjects (8 males, 14 females; between 3 and 85 years old), unfortunately, the data is not publicly available from the literature.

Fig. 3. Phonocardiography wave signals of arrhythmia-bradyarrhythmia.

TABLE III. DETAILS OF FEATURE EXTRACTION AND ACCURACY

Article	Feature Extraction Technique	Machine Learning Techniques	Dataset	Results Accuracy in %
[32]	MFCC	CNN	PASCAL	87.65
[33]	SEE, HT, MFCC, WT	SVM, KNN	hospital in Ardakan	98.78
[34]	WPT, SVD	CNN, RNN, LSTM	PhysioNet	79.8
[35]	MFCC, Time & Freq	HMM, SVM, CNN	PhysioNet	89.22
[36]	MFCC	DFT, CNN	PhysioNet	86.02
[37]	MFCC	CNN, Springer's algorithm	PASCAL	90.4
[38]	DL	RNN, LSTM, GRU	PASCAL	76.9
[15]	DWT, CWT, STFT, MFCC	SVM, ANN, KNN	PhysioNet	99.7
[39]	MFCC	SVM, RF, MLP	PhysioNet	84.88
[40]	FT, WT, FLP	LVQ, PNN, LS-SVM	PhysioNet	98
[41]	MN, SD, RPAB, SC	SVM	Not available	71.13
[70]	LDA	K-mean	Peter Bentley heart sound	84.39

Another dataset that some researchers have used is GitHub. GitHub dataset they have obtained the PCG signals from a public database but the best result was from GitHub. There are 1,000 PCG recordings present in the database for different subjects. Out of these 1,000 recordings each class contains 200 recordings. There are five classes of PCG signals given in the database namely the healthy control (HC), AS, MS, MR, and mitral valve collapse (MVP). Most of this dataset it's not clear and even the data set is not labeled.

Considered the most popular among the research and the most used in the experiment, the dataset (PASCAL challenge dataset) consists of 312 auscultations collected in the Real Hospital Português (RHP) Maternal and Fetal Cardiology Unit in Recife, Brazil, using the DigiScope. Each inspection is reported for six to ten seconds. The normal count is 200. And the abnormal count of 112. In reference [37] the collected dataset is divided into two parts: Dataset A contains 31 normal heart sounds and 34 abnormal heart sounds. For the training set, 15 normal and 17 abnormal sounds are selected, and the rest is for the test. Dataset B contains 200 normal and 66 murmurs, 100 normal and 33 abnormal for the training, and the rest is left for the test.

After we collected a large number of databases and searched for them, we found that what is publicly available is PASCAL and PhiysoNet. Thus our research based on them in addition to the availability of a new database called (heartbeat sound) through the site "Kaggle" which is the largest site for contests and review of databases.

B. Mel-Frequency Cepstral Coefficients

Mel Frequency Cepstral Coefficients (MFCC) is a feature extraction technique used in speech processing and audio signal analysis. The MFCC algorithm was first proposed by Davis and Mermelstein in 1980 [42]. It has since become one of the most widely used techniques in speech and audio signal processing. The basic intuition behind MFCC is to extract a compact representation of the spectral envelope of an audio signal, which can then be used for further analysis. The spectral envelope is essentially a smoothed version of the power spectrum of the signal, and it contains information about the distribution of energy across different frequency bands [43]. Fig. 4 shows the signal in the Time Domain.

Fig. 4. Signal in the time domain.

To extract the spectral envelope, the MFCC algorithm first divides the signal into short overlapping frames, typically 20-40 MS in duration. Each frame is then transformed into the frequency domain using a Fourier Transform. The resulting frequency spectrum is then passed through a bank of Mel-scale filter banks, which are spaced uniformly on the Mel-scale, a perceptual scale that is more closely related to the way humans perceive pitch than the linear frequency scale [44]. The output of each filter bank is then logarithmically scaled, and the

resulting values are transformed using the Discrete Cosine Transform (DCT) to obtain the MFCCs.

The DCT is used to decorrelate the filter bank outputs and to obtain a set of décor-related coefficients that are more suitable for further analysis [45]. The number of MFCCs extracted depends on the specific application, but typically, 12-13 coefficients are used for speech recognition tasks. The resulting MFCCs can be used as features for machine learning algorithms such as Hidden Markov Models (HMMs), which are commonly used in speech recognition [2].

A Comparative Study on MFCC and MEL spectrogram features for automatic speech recognition presented by J.M. Azevedo, et al. [46]. This study compared the performance of MFCC and Mel spectrogram features for automatic speech recognition using deep learning models. The results showed that Mel spectrogram features outperformed MFCCs in terms of recognition accuracy [46].

Exploring the impact of MFCC and its derivatives on EEG-based emotion recognition was proposed by S. Almogbel, et al. [47]. In this study, the authors investigated the use of MFCC and its derivatives for EEG-based emotion recognition. The results showed that incorporating MFCC and its derivatives improved the accuracy of emotion recognition compared to using raw EEG signals alone [47].

MFCC-based speech enhancement using Deep Neural Networks (DNN) was investigated by Mohamed, et al. [48]. This study proposed a deep neural network-based approach for speech enhancement using MFCC features. The results showed that the proposed approach improved speech quality and intelligibility compared to traditional MFCC-based speech enhancement methods [48]. MFCC and its derivatives-based features extraction for automated speech recognition of spontaneous Tamil language was put forward by S. Sivaprakasam, et al. [49]. This study investigated the use of MFCC and its derivatives for automated speech recognition of the spontaneous Tamil language. The results showed that using higher-order derivatives of MFCCs improved the recognition accuracy compared to using only MFCCs [49].

Comparison of MFCC and Gamma tone filter bank features for speech emotion recognition presented by S. Mohapatra and S. Lenka [50]. This study compared the performance of MFCC and gamma tone filter bank features for speech emotion recognition using machine learning models. The results showed that both features performed similarly in terms of recognition accuracy [50]. An Improved MFCC algorithm for speech recognition lodge by J. Wu, et al. [51]. This study proposed an improved MFCC algorithm for speech recognition by adding a Gaussian filter to the Mel filter bank. The results showed that the proposed algorithm outperformed traditional MFCCs in terms of recognition accuracy [51].

A Comparative Study of MFCC and Gammatone Filter Bank features for phoneme recognition advanced by Y. Sun, et al. [52]. This study compared the performance of MFCC and Gamma tone filter bank features for phoneme recognition using deep learning models. The results showed that Gammatone filter bank features outperformed MFCCs in terms of recognition accuracy [52].

Speaker recognition based on MFCC and XGBoost initiated by Z. Yang, et al. [53]. This study proposed a speaker recognition system based on MFCC features and XGBoost, a gradient-boosting algorithm. The results showed that the proposed system achieved high accuracy in speaker recognition tasks [53]. A Comparative Study of MFCC and DL features for speech emotion recognition argued by X. Liu, et al. [54]. This study compared the performance of MFCC and deep learning features for speech emotion recognition. The results showed that deep learning features outperformed MFCCs in terms of recognition accuracy [54].

MFCC-based speech separation using Convolutional Recurrent Neural Networks tender by M. Hossain, et al. [55]. This study proposed a convolutional recurrent neural network-based approach for speech separation using MFCC features. The results showed that the proposed approach outperformed traditional MFCC-based speech separation methods [55].

C. Machine Learning and Medical Diagnosis

Machine Learning (ML) continues to hold immense significance in medical diagnosis, especially in this digital and AI age. One of its key contributions lies in the increased accuracy it offers. ML algorithms possess the capability to analyze vast amounts of medical data, encompassing patient records, medical images, and genomic information. By identifying complex patterns and relationships within this data, ML models can provide more accurate and reliable diagnoses, often surpassing human capabilities. ML algorithms excel at the early detection and prevention of diseases by analyzing patient data over time, these models can identify subtle indicators and early signs of conditions such as cancer, heart disease, or neurological disorders. Early detection enables healthcare professionals to intervene sooner, improving patient outcomes and potentially saving lives. ML also enables personalized medicine, as it allows for the development of tailored treatment plans based on an individual's unique characteristics, such as genetics, lifestyle, and medical history. By considering these factors, ML algorithms can predict the effectiveness of different treatment options, helping physicians make informed decisions that are specifically catered to each patient's needs [56].

In the field of medical imaging, and medicine phonography ML algorithms have made significant strides. They can

automatically analyze and interpret medical images like X-rays, MRIs, and CT scans, detecting patterns and anomalies that may be challenging for human observers to identify from the image, and sound data. This capability enhances radiologists' efficiency and accuracy, leading to more precise diagnoses and reducing the chances of misinterpretation. ML's integration into electronic health records (EHRs) enables the analysis of large-scale patient data, allowing for data integration and decision support. ML algorithms can uncover hidden correlations between symptoms, risk factors, and treatment outcomes, providing healthcare professionals with valuable insights to make informed decisions. ML-powered decision support systems can suggest diagnoses, treatment plans, and medication recommendations, ultimately improving the overall quality of patient care [57].

Furthermore, ML contributes to increased efficiency and cost savings in healthcare. By automating time-consuming tasks like data entry, documentation, and administrative processes, ML frees healthcare providers to focus more on direct patient care, reducing the burden of paperwork and enhancing operational efficiency. Additionally, ML helps optimize resource allocation and treatment pathways, potentially reducing healthcare costs.

ML process passes through many phases like pre-processing, learning, and evaluation. Data is mostly in the form of unstructured, inconsistent, incomplete, redundant, heterogeneous, as well as noisy. Using techniques like data cleaning, extraction, fusion, transformation, etc. data pre-processing helps prepare raw data usable and consistent for the subsequent phases. The learning phase selects algorithms of learning and refines the parameters of the model to get the required results through the usage of the pre-processed input data. The evaluation phase follows to ensure the attained performance of the learning model, i.e. performance evaluation of the learning algorithm included the selection of dataset, error estimation, measuring performance, and the different tests of statistics. The results of the evaluation phase may lead to the parameters of adjusting for the selected learning algorithm or selecting various algorithms and classifiers. Through the multiple facets like nature of learning, learning target, type of input data, data availability timing, users (stakeholders), and domain factors. Fig. 5, illustrates the Machine Learning framework.

Fig. 5. Machine learning framework (Rizvi, 2019).

D. Supervised Learning

There are three major administrations of conventional machine learning which are supervised, unsupervised, and semi-supervised learning. Supervised learning (SL) is claimed as the uttermost decisive and intrusive annex of machine learning (ML) and pattern recognition. In supervised learning, the learning system is commenced with examples of input and output braces and the prime objective is to learn a function that decorously maps inputs and outputs [58].

Supervised machine learning which is also known as a classification learning advent is employed for analyzing training or labeled data to draft concealed and unseen instances of data for future and imminent classification. To train a classifier that learns to differentiate between different pattern classes, extracted features from recognition units are used [59]. The supervised learning approach carves an acceptable amount of training data or labeled data for the classification of unseen test data [1].

SL, which is also called sometimes a classification learning advent, is implemented for data labeling or training analysis for drafting unseen and concealed data instances for both the imminent and future classification. In training, a classifier for learning to differentiate between the distinct pattern's classes and extracted features from the units of recognition are utilized. The SL approach carves an acceptable amount of training data or labeled data for the classification of unseen test data [59]. The SL model is shown in Fig. 6.

Fig. 6. Supervised machine learning model [59].

E. Artificial Neural Network

Being an SL-based information processing discipline, Artificial Neural Network (ANN) is used for solving circuitous problems. Besides, ANN facilitates understanding the conduct of complex systems through the usage of computer simulations. The final objective of the ANN paradigm is to solve computational problems in the way, the human brain would do. A very simple ANN comprises abounding elementary nodes/processors, often dubbed neurons. These neurons cause a catenation of real-valued activation. Apart from that, sensory input is evoked by the input neurons through the perception of the environment. In the same way, other neurons receive the input of activation from weighted connections of the past antecedent neurons. In this way, only a few neurons, output neurons, for instance, may affect the environment through various prompting actions [60].

The discipline of ANN can be thought of as a set of massively parallel computing systems comprising many interconnected processors. ANN models try to utilize organizational principles like generalization, learning, and computation in a network of weighted graphs. The nodes being used in this network are artificial neurons. Further, the edges

with the weights are joined with the input and the output neurons. In ANN, the process of learning is the determination of weights that force the ANN to show the expected behavior or output. Comprehending the conduct of neurons may entail an array of computational stages and phases in a non-linear manner. Further, each stage converts the network's accumulated activation. Specifically, the techniques of ANN deputize the credit beyond many such stages. Besides, this paradigm is normally adopted due to its vibrant adequacy of the mapping for nonlinear systems [61].

F. Extreme Learning Machines

Both the DL and the classical ML techniques proved a springboard for yet another efficient approach to learning which was introduced during the last decade. This new approach to learning is termed Extreme Learning Machines (ELM). ELM based on the SL approach has been introduced by Huang et al. [62]. Both the bias of ELM and the spawning of input weights in a random fashion are the source of major anomalies between classical DL and ELMs, which are prone to fast learning speed [63]. On the other hand, ELM is a very straightforward, naive, and efficient algorithm, which stands on the principle of Single Layer Feed-Forward Neural Networks (SLF-FNN).

ELM is a special architecture of a Multi-Layer Neural Network, consisting of a Single-Layer Feed-Forward Neural Network (SLFFNN) equipped with hidden neurons, and designated input weights. Further, it has random bias values in the hidden layer, whereas the output is computed by utilizing single multiplication of the weights of the vector matrix. ELM utilizes SLFFNN due to its sufficiency to advance any continuous function and to assert any discontinuous area. If we compare the efficiency of ELM and traditional Back Propagation Neural Networks (BP-NN), the ELM has far better learning time for N sample data. In ELM settings, parameters being used in the hidden layers are absolute i.e., independent of the data. Further, hidden level parameters for the function of activation are haphazardly generated before the perception of training data [64], [65].

G. Deep Extreme Learning Machines

DELM is normally employed for regression and classification purposes in diverse settings since its rate of learning is very rapid. Further, it is very effective as far as the rate of computational convolution is concerned. Classical ANN algorithms require sophisticated measurements and the learning times should be very slow. Further, they can override the learning model given by Khan [66]. Deep Extreme Learning Machines (DELMS) take advantage and benefit from both ELMs and DL techniques. In the phenomenon of DELMs, hidden layers get enhanced in the network structure of ELM and the random initialization process for the weights of input-layer and initial hidden-layer weights along with the initial hidden layer's bias.

Besides, DELMs utilize a new way to calculate the parameters to be used in all the hidden layers except the first using the Least Square Method (LSM) for calculating the output network weight [67]. DELM consists of the architecture with the multi-layer network which has been distributed in two halves. The first half of these two halves learns the original

data in depth to get the most representative novel data through the usage of ELM-AE. As far as the second half is concerned, it calculates the parameters of the network by utilizing the kernel ELM algorithm [68].

There are two main steps of the Deep Extreme Learning Machines DELMs based classification of image-set. In the first step, the global domain-specific DELM model is found by utilizing training images. In the second step, an initialization building of class-specific DELM is carried out through the usage of global representation. It is to be noted that the encoding of both domain-level, as well as class-specific properties of data, is essential in the performance of both steps [69].

IV. DISCUSSION AND CONCLUSIONS

This review paper explored various studies, research papers, and scholarly works related to the integration of phonocardiography and machine learning. This paper provides a detailed introduction that highlights the importance of phonocardiography and machine learning in the field of healthcare, providing background information on phonocardiography by discussing the components of the phonocardiogram and the challenges associated with signal acquisition and processing. Transitioning to machine learning, the algorithms used in analyzing phonocardiograms and the steps involved in developing a machine learning model.

In the view of the research that we have collected that most of the researchers use Mel-frequency cepstral coefficients (MFCC), which is one of the conventional feature extraction techniques. Looking at the machine learning techniques that researchers have tried, we found that two techniques are the most used and the highest performing, which are support vector machine and Artificial neural network (SVM, ANN).

Review outcomes provide a roadmap for future research by pinpointing underexplored areas, automated detection and classification of heart sounds for the early detection of cardiac abnormalities. Studies in arrhythmia detection, heart sound segmentation, and abnormality classification. The paper concludes with a discussion on the limitations and future directions of phonocardiography and machine learning, addressing challenges and suggesting future research possibilities including deep learning models. The presented literature review provides a comprehensive overview of phonocardiography and machine learning, covering fundamental concepts, applications, and potential advancements in the field.

ACKNOWLEDGMENT

I want to express my profound appreciation and gratitude to the supervisor for their unwavering support and encouragement throughout the development of this paper. Their active participation and valuable insights have played a pivotal role in shaping the direction and content of our research. Additionally, I extend heartfelt thanks to the reviewers for their diligent assessment and constructive feedback, which has significantly enhanced the quality and credibility of this work. This paper would not have been possible without the valuable contributions of both the supervisor and the reviewers, and I

am immensely thankful for their involvement in this research journey.

A Hybrid Classification Approach of Network Attacks using Supervised and Unsupervised Learning

Rahaf Hamoud R. Al-Ruwaili, Osama M. Ouda

Department of Computer Science-College of Computer and Information Sciences,
Jouf University, Al-Jouf, Saudi Arabia

Abstract—The increasing scale and sophistication of network attacks have become a major concern for organizations around the world. As a result, there is an increasing demand for effective and accurate classification of network attacks to enhance cyber security measures. Most existing schemes assume that the available training data is labeled; that is, classification is based on supervised learning. However, this is not always the case since the available real data is expected to be unlabeled. In this paper, this issue is tackled by proposing a hybrid classification approach that combines both supervised and unsupervised learning to build a predictive classification model for classifying network attacks. First, unsupervised learning is used to label the data available in the dataset. Then, different supervised machine learning algorithms are utilized to classify data with the labels obtained from the first step and compare the results with the ground truth labels. Moreover, the issue of the unbalanced dataset is addressed using both over-sampling and under-sampling techniques. Several experiments have been conducted, using the NSL-KDD dataset, to evaluate the efficiency of the proposed hybrid model and the obtained results demonstrate that the accuracy of our proposed model is comparable to supervised classification methods that assume that all data is labeled.

Keywords—Network attacks; supervised learning; unsupervised learning; machine learning

I. INTRODUCTION

The extensive use of the Internet and its continuous development benefit many network users in many aspects. However, in recent years, cyber-attacks have become a growing concern due to their increasing complexity and diversity posing a major threat to governments, businesses, and networks[1]. As a result, network security becomes more important with the widespread use of the network. The purpose of network security is to provide protection and defense against misuse such as modification and unauthorized access.

The task of detecting anomalies in network traffic is experiencing growing demand due to the expanding internet accessibility among individuals[2]. The potential consequences of an intrusion on a computer network encompass a wide range of concerns, including but not limited to the compromise of confidentiality, integrity, and accessibility. These issues can manifest in various ways, such as breaches of privacy or compromise of systems. The primary classifications of intrusion detection systems encompass signature-based detection systems and anomaly-based detection systems[3]. Signature-based systems predominantly depend on established attack signatures to identify and detect unauthorized activities.

In contrast, when encountering unfamiliar attack signatures, the identification of abnormal network activity is mostly conducted through the utilization of anomaly-based technologies.

There are many mechanisms trying to protect the network from outsiders, but these mechanisms can be hacked because the attacker spends enough time and resources to penetrate this perimeter, which may be mostly successful. Despite the multitude of mechanisms implemented to safeguard networks from external threats, determined attackers often invest significant time and resources to breach these defensive perimeters, leading to a high success rate. While firewalls are renowned as one of the most widely used network defense systems, they alone are insufficient in providing comprehensive protection against cyber-attacks. While access control policies play a crucial role in ensuring network security, they can be circumvented through passive authentication methods, thereby undermining their effectiveness. Passive authentication attacks pose a significant challenge to network security because they exploit the trust established within the network. By leveraging legitimate user credentials or session information, attackers can effectively bypass the access control policies implemented by firewalls.

This highlights the need for additional security measures beyond traditional firewall systems. To mitigate the risks associated with passive authentication attacks, organizations should consider implementing supplementary security measures such as strong user authentication protocols, encryption mechanisms, and intrusion detection systems. These layers of defense can help detect and prevent unauthorized access attempts, even if attackers manage to bypass the firewall's access control policies. By adopting a multi-faceted approach to network security, organizations can enhance their resilience against evolving cyber threats and minimize the potential impact of successful attacks[4]. On the other hand, encrypting stored data is a way to achieve data-centric security. However, encrypting stored data is not appropriate for all environments and contexts. Despite the many ways of protection, the attackers always find an entrance to fulfill their desires[5]. Thus, there is a need to identify methods for extracting security information from network data.

Most of the existing methods for classifying network attacks assume that the available datasets are labeled. Hence, they utilize supervised learning techniques to classify network packets. However, in real scenarios, network data are not labeled, and hence supervised learning-based classification methods might not be practically useful. Another issue with existing datasets is that most of the available datasets are

highly unbalanced in the sense that the training samples for some classes are much smaller than the samples available for other types. Ignoring this class imbalance increases the chances that the developed model will learn more about classes with large samples in the data set than about classes with fewer samples. This paper aims to address the class balance problem and use machine learning techniques to identify and extract useful security information from network data to classify different types of network attacks. Network attack classification plays a vital role in detecting and mitigating potential threats to network security. Traditional signature-based methods have limitations in identifying new and sophisticated attacks. Thus, the need for predictive models that can effectively identify attack patterns and classify them with a high degree of accuracy emerges [4] which affects the protection of the network.

Machine learning plays a pivotal role in the development and advancement of several domains within the field of IDS. Statistical methodologies and methods are utilized in order to train the model using a set of training data. When faced with unfamiliar data, the system extracts distinctive and hidden patterns from the dataset in order to provide predictions or classifications, thereby forecasting future trends based on the available data[6]. There are two primary categories of machine learning algorithms: unsupervised learning and supervised learning. In the training phase of Supervised Learning, the model is trained using data that includes both the dependent variable and its corresponding outcome. Conversely, in Unsupervised Learning, the model is trained on unlabeled data, which consists of input data without any associated output information[7].

In this study, an unsupervised pooling technique has been devised, utilizing the K-means method for the purpose of detecting and grouping network intrusion. Next, a supervised learning technique was employed using three distinct algorithms: Random Forest (RF), K-Nearest Neighbor (KNN), and Support Vector Machines (SVM), in order to classify attacks. The NSL-KDD dataset was utilized in this study, employing two distinct methodologies, namely oversampling and under sampling, to ensure the maintenance of data balance.

The main contributions of this work are outlined as follows:

- A data preprocessing strategy is provided as well as data sampling techniques that aim at achieving a more accurate representation of the dataset's features, with the ultimate goal of reducing model bias.
- Introduce and compare the utilization of three models, namely Random Forest (RF), K-Nearest Neighbors (KNN), and Support Vector Machine (SVM), in the context of classifying network intrusion attempts. The classification task is performed using unsupervised learning through the application of the K-means algorithm.
- Presenting a complete review of network intrusion attacks, focusing on the datasets used in previous research. The analysis evaluates the accuracy of four different models, identifying the most realistic model among them.

The subsequent sections of the paper are structured in the following manner: The literature review is presented in Section II. The suggested method is explicated in Section III. Section IV discusses the evaluation metrics while the discussion of the outcomes is presented in Section V. The final Section VI contains future work and the conclusion.

II. RELATED WORKS

In [1], machine learning was used to detect the occurrence of malicious attacks and introduce a feature-based transfer learning framework and transfer learning approach. They also introduced the feature-based learning approach using a linear transformation, called HeTL. A cluster-enhanced transfer learning approach, called CeHTL, has been proposed to make it more potent to detect unknown attacks and evaluation of learning transfer approaches on shared workbooks. The results show that transfer learning methods improve the detection performance of unknown network attacks compared to baselines.

In [5], the authors cover most of the papers that have been released on the attack and defense of membership inference on ML models. They familiarize MIAs with ML models and present current attack methods. They also rated all MIAs papers next to discuss why MIAs work on ML models and summarize the most current evaluation metrics, datasets, and open-source applications of common approaches.

In [4], the researchers proposed a machine learning approach to classify and predict types of DDoS attacks. The authors also used Random Forest and XGBoost classification algorithms. The UNWS-np-15 dataset was extracted from the GitHub repository and Python was used as a simulation. After applying the machine learning models, they generated a confusion matrix to determine the performance of the model. For the Random Forest algorithm, the results show that both Precision (PR) and Recall (RE) are ~89%. For the XGBoost algorithm, the results show that both Precision (PR) and Recall (RE) are about 90%.

The researchers in [8] proposed an efficient framework that learns minimal temporal preferential attack targeting the LSTM model with electronic medical record inputs, they also proposed an efficient and effective framework that identifies sensitive locations in medical records using adversarial attacks on deep predictive models. The results showed weakness in the deep models, as it was more than half of patients can be successfully attacked by changing only 3% of the recording sites with maximum perturbation less than 0.15 and mean perturbation less than 0.02.

In [9], the researchers suggested a stack-based ensemble approach to obtain reliable predictions by combining different algorithms. A powerful processing model called Graphlab Create (GC) was used to perform experiments involving many cases. Recent datasets consisting of attack types were compiled from the UNSW NB-15 and UGR'16 datasets.

In [10], SVM models detect malicious behavior within low-power, low-speed, and short-range networks. They evaluated two SVM approaches, namely C-SVM and OC-SVM. Actual network traffic was used along with the specific network layer attacks that they have implemented to generate and evaluate

VPM detection models. They show that C-SVM achieves a classification accuracy of 100% when evaluated with unknown data taken from the same network topology in which it was trained and an accuracy of 81% when running in unknown topologies.

In [11] the authors proposed the first survey of its kind on adversarial attacks on machine learning in network security. They discussed aggressive attacks against deep learning in computer vision only. They introduced a new classification of adversarial attacks based on machine learning applications in network security and developed a matrix to correlate different types of adversary attacks with a classification-based classification to determine their effectiveness in causing misclassification. A new idea of the adversarial risk network map concept was presented for machine learning in network security.

In [12] they compared different classifiers in the NSL-KDD dataset for binary and multiclass classification. SVM, random forest, and LSTM-RNN model were considered. They show that the proposed model produced the highest accuracy rate of 96.51% and 99.91% for binary classification using 122 features and an optimal set of 99 features, respectively. LSTM-RNN obtained higher accuracy than SVM in binary classification.

In [13], the researchers presented an exploration of how adversarial learning can be used to target supervised models by generating adversarial samples using the Jacobian-based Saliency Map attack and an exploration of classification behaviors. An authentic power system dataset was used to support the experiments presented. The classification performance of two widely used classifiers, Random Forest and J48, decreased by 6 and 11 percentage points when hostile samples were present.

In [14], the authors aimed to detect distributed denial-of-service (DDoS) attacks on financial institutions by using banking datasets. They used multiple classification models to

predict DDOS attacks. Some complexity has been added to the architecture of the generic models to enable them to perform well and application of support vector machine (SVM), k-nearest neighbors (KNN), and random forest (RF) algorithms. SVM showed an accuracy of 99.5%, while KNN and RF recorded an accuracy of 97.5% and 98.74%, respectively, for detecting DDoS attacks. When compared, it is concluded that SVM is more powerful compared to KNN, RF, and existing machine learning (ML) and deep learning (DL) approaches.

In [15], the authors applied the MeanShift algorithm to detect an attack in a network traffic dataset and evaluated the performance of the MeanShift algorithm by two metrics. These metrics are detection rate and detection accuracy. The results of this study showed that the detection rate of the MeanShift algorithm was 79.1 percent, and the detection accuracy of the MeanShift algorithm was 81.2 percent.

In [16], the authors proposed a method for infiltration detection based on deep neural networks. They trained the encoder block based on self-supervised variance learning using unclassified training patterns. Then they inserted the resulting representation into the classification header which was trained using a labeled data set.

In [17] they implemented the machine learning-based detection, classification, and investigation of flood DDoS attacks. They used four supervised learning methods (CART, K-NN, QDA, GNB) and implemented them well, but CART outperforms others based on the investigations that have been conducted.

In [18] they performed a comparative study to analyze the performance of ML algorithms for intrusion detection on the NAL-KDD dataset. They selected only the relevant features. They concluded a reliable identity detection system capable of real-time intrusion detection using different. Table I summarize some related works and provide a comparison between different approaches.

III. PROPOSED METHOD

For developing a hybrid classification model for classifying network attacks, a standard approach was followed, relying on the NSL-KDD dataset. Fig. 1 illustrates the workflow that is followed to achieve the goal of detecting intrusions. Initially, the NSL-KDD dataset is acquired, after which data pre-processing takes place. The pre-processing procedure involves many steps that are required to render the data suitable for the algorithms that will be used later. For instance, in this study, data pre-processing includes removing null and duplicated values, in addition to data normalization and fixing the oversampling and under-sampling issues. After that, the data is fed to unsupervised machine learning model, where a K-means algorithm is used, followed by a supervised learning model where three different algorithms are implemented: Random Forest, Support Vector Machine, and K-Nearest Neighbor. Finally, the performance of each of these algorithms is evaluated according to F1 score, involving recall and precision.

A. Dataset

NSL-KDD dataset has been significantly popular in the field of intrusion detection due to its qualities, among many other datasets that are frequently used, whether they are

private, public, or simulated network traffic datasets. Initially, Tavallaee et al. [19] proposed the NSL-KDD dataset as an enhancement of the KDD-99 cup dataset, overcoming its numerous issues, such that the enhanced dataset only contains the selected records from the complete KDD dataset. Despite the enhancement process, the NSL-KDD dataset still suffers from minor issues such as its lack of representation of the low-footprint attacks [20].

The choice fell upon the NSL-KDD dataset since it has less data points than KDD-99, the number of selected records from each difficult level group is inversely proportional to the percentage of records in the original KDD dataset, and it includes no duplicate records in the test set, ultimately leading to better reduction rates. Furthermore, the selected dataset provides less computational expenses for training ML models. Overall, the NSL-KDD dataset contains 41 attributes and one class attribute [21]. The class attribute indicates the type of network traffic, which can be one of five classes: normal, DoS, Probe, R2L, and U2R. The label counts for the NSL-KDD dataset are as follows: normal: 76967, DoS: 52985, Probe: 13954, R2L: 3749, U2R: 252 The dataset has a total of 147,907 rows and 42 columns, with the additional column being the class attribute.

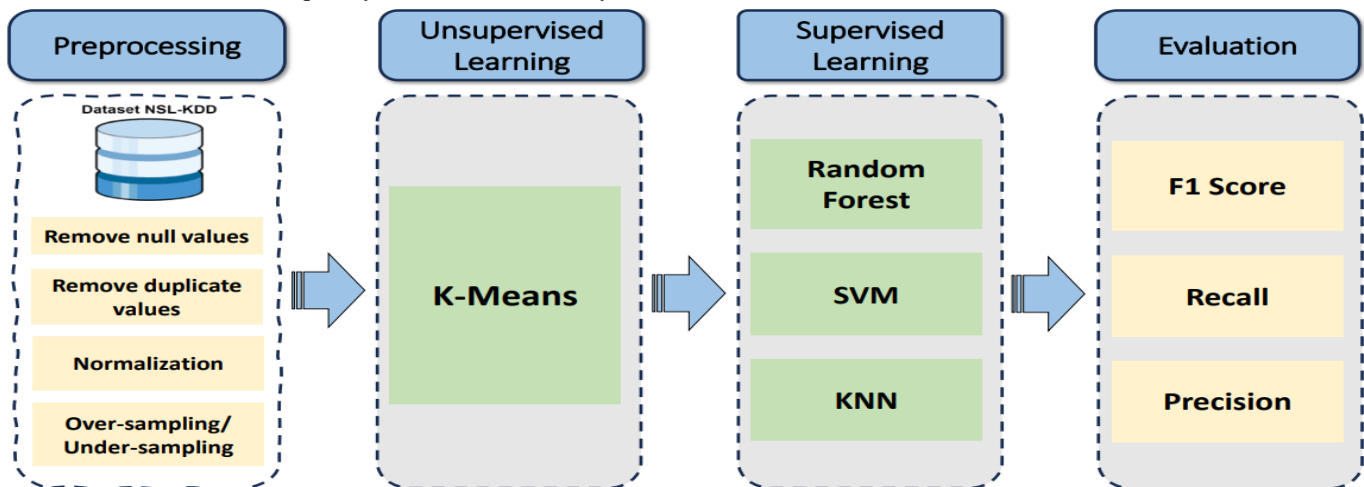

Fig. 1. Proposed framework for the hybrid classification model.

B. Exploratory Data Analysis

Exploratory data analysis EDA is one of the essential steps on any given dataset, as it allows the understanding of the data through observing and analyzing its characteristics, usually by charts. EDA also helps in identifying patterns, possible anomalies, and possible outliers in the data.

The total number of labels within the dataset is 147907 distributed over the following labels: normal, DoS, Probe, R2L, and U2R. The distribution of these labels is presented in Fig. 2 such that the percentage of each label among the whole data is given respectively. Upon observation, the normal label takes up 52% of the total labels which is the highest percentage, followed by 35.8% taken by the DoS label (from the attack labels). Additionally, the Probe labels take up 9.4% of the total labels, while R2L and U2R labels have the lowest percentages.

Fig. 2. Labels distribution in the NSL-KDD dataset.

In addition, there are three protocol types within the dataset, namely tcp, udp, and icmp. The percentage of each of these protocol types is shown in Fig. 3. The majority of the protocols are represented by the tcp protocol (82.1%) followed by the udp protocol (11.9%) and the icmp protocol (6.1%).

Fig. 3. Protocol type distribution in the NSL-KDD dataset.

It is also possible to know the distribution of the different labels within the dataset over the protocol types that are present. This data is given in Fig. 4. Fig. 4 shows the relationship between the labels and the protocols, where the count plot shows that most of the attacks are carried out using the TCP protocol, with DoS attacks being the most prevalent in this protocol category. It can also be seen that DoS attacks are most prevalent in the UDP protocol, even though UDP doesn't present that many attacks compared to the TCP protocol. Finally, the probe attacks are the most prevalent label within the icmp protocol.

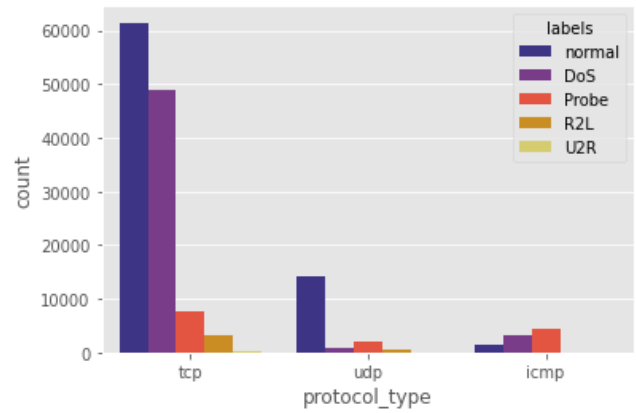

Fig. 4. Label-Protocol distribution count plot.

The relationship between flags and labels can also be acquired from EDA, as presented in Fig. 5. There are numerous flags, namely normal REJ, SF, S0, RSTO, RSTR, RSTOS0, S1, S3, S2, SH, and OTH. It appears that most of the attacks were carried out through the SF flag, where the other dominant flags are REJ flag and S0 flag. The SF flag shows a high count of normal label, whereas the S0 flag shows the highest count of attacks, namely the DoS attacks. It's noteworthy that the DoS attack dominates the REJ flag as well, but in a less prominent way.

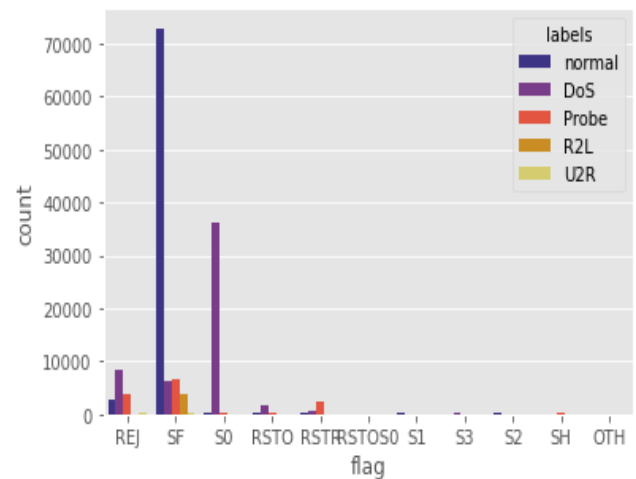

Fig. 5. Label-Flag distribution count plot.

C. Data Pre-processing

Data pre-processing is yet another essential step to prepare the data for use on different machine learning algorithms. The purpose of applying data pre-processing techniques is to improve the quality of data by removing noise and dealing with missing values, for example. It also enhances the efficiency of data analysis and interpretation, while also improving the overall performance of the model. In this study, three main steps were followed as data pre-processing procedures.

1) *Missing values*: The NSL-KDD dataset was checked for missing values or duplicate values. After inspection, it was clear that the dataset does not contain any missing values or duplicate values, which renders it of high quality.

2) *Normalization*: Data normalization works on transforming the data into the same scale without interfering with the relationship between variables or their distribution. This step helps in improving the efficiency and accuracy of the ML model. In this study, the MinMaxScaler function was used to normalize the data, scaling them to a range between 0 and 1.

3) *Class imbalance*: In cases of class imbalance, such as the case of the NSL-KDD dataset, the end results of the ML can be biased. For this reason, the NSL-KDD dataset was subjected to over-sampling and under-sampling to fix the class imbalance issue. Under-sampling is a method used to decrease the number of samples in classes that are overrepresented in a dataset. This can be achieved by randomly selecting a portion of the samples or eliminating samples that have a high degree of similarity to other samples in the dataset. Conversely, oversampling is a technique that aims to increase the number of samples in minority classes by creating synthetic data points.

TABLE II. COUNTS OF EACH CLASS BEFORE AND AFTER SAMPLING METHODS

Sampling Method	Class	Count Before	Count After
Over-sampling	normal	76967	76967
	DoS	52985	76967
	Probe	13954	76967
	R2L	3749	76967
	U2R	252	76967
Under-sampling	normal	76967	252
	DoS	52985	252
	Probe	13954	252
	R2L	3749	252
	U2R	252	252

Table II shows the count of each of the five classes before and after the class imbalance procedures, which are over-sampling and under-sampling. For instance, the normal class contained 76967 instances before under-sampling, and that number became 252 after the procedure was done. Another example is the R2L class which contained 3749 instances before over-sampling, and after the procedure the count became 76967.

The shape of the data before and after the two sampling methods (over- and under-sampling) can be visualized in Table III.

TABLE III. SHAPE OF DATA BEFORE AND AFTER SAMPLING METHODS

Sampling Method	Shape Before	Shape After
Over-sampling	(147907, 122)	(384835, 122)
Under-sampling	(147907, 122)	(1260, 122)

D. Classification Methods

Since there are five different classes or labels within the dataset, this means that the classification problem is a five-class classification problem, where the classes are: benign (or normal), u2r, r2l, dos, and probe. In addition, multiple algorithms exist such that they support this kind of multi-class classification task. Yet, selecting the suitable ML algorithm is the obvious challenge in this case. In this study, initially the cases where labeled data can be used will be considered, which means that supervised machine learning techniques will be used. After that, semi- and un-supervised machine learning techniques will be considered as well.

1) *Supervised classification*: For classifying attacks through supervised classification, three supervised machine learning algorithms were chosen, namely: Random Forest RF, K-Nearest Neighbor KNN, and Support Vector Machine SVM. The dataset is divided by a 80:20 ration for training and testing respectively, upon which these three ML algorithms will be trained and evaluated.

a) *Random forest*: RF is one of the supervised machine learning algorithms, and its concept is randomly creating a forest of decision trees such that the number of the trees directly correlates with the accuracy of performance. Yet, it is noteworthy to consider that creating the forest is different from constructing a decision tree using the information gain or gain index approach. The main difference between Random Forest and Decision Tree algorithms is that in Random Forest, the processes of finding the root node and splitting the feature nodes occur randomly [22]. Two stages are required for RF classification: the forest creation stage where decision trees are created, and the prediction stage where predictions take place.

The Random Forest algorithm creation method involves the following steps:

- (a) Randomly selecting "K" features from the total "m" features, where $k \ll m$.
- (b) Calculating the node "d" among the "K" features using the best split point.
- (c) Splitting the node into daughter nodes using the best split.
- (d) Repeating steps a to c until "l" number of nodes has been reached.
- (e) Building the forest by repeating steps a to d for "n" number of times to create "n" number of trees.

b) *K-Nearest Neighbor*: KNN is described as a non-parametric and lazy learning method. Non-parametric indicates that no assumptions are made about the underlying data distribution, whereas a lazy algorithm indicates the no need for any training data points to achieve model construction. K-nearest neighbors (K-NNs) classifier depends on Manhattan or Euclidean distances to evaluate similarities or differences between instances in the dataset. Often, the Euclidean distance is the metric of choice in KNN classifiers. In KNN, k represents the number of nearest neighbors used

for classification. The algorithm finds the data point with the minimum distance to the test point and assigns it to the same class [23].

Even though KNN is a simple algorithm to implement, it still has the disadvantage of slow prediction time because of calculating the distance between each data point.

The KNN algorithm is implemented by following these steps:

- Loading the data
- Initializing the value of k
- Iterating from 1 to the total number of training data points (*to obtain the predicted class*).
 - Calculating the distance between the test data and each row of training data using a distance metric such as Euclidean, Chebyshev or cosine.
 - Sorting the calculated distances in ascending order based on distance values.
 - Retrieving the top k rows from the sorted array.
 - Determining the most frequent class of these rows
 - Returning to the predicted class.

c) *Support Vector Machine*: SVM is a supervised type of machine learning algorithm in which, given a set of training examples, each marked as belonging to one of the many categories, an SVM training algorithm builds a model that predicts the category of the new example. SVM has the greater ability to generalize the problem, which is the goal in statistical learning. The statistical learning theory provides an outline for studying the problem of gaining knowledge, making predictions, and making decisions from a set of data. SVM is a type of linear and non-linear classifier, which is a mathematical function that can distinguish between two different classes of objects [24]. SVM has the benefit of being capable of managing high-dimensional data and data with non-linear decision boundaries. Nevertheless, its drawback is that it can be computationally demanding and necessitates careful adjustment of the hyperparameters, such as C and the kernel function, to achieve the best possible performance.

Training an SVM algorithm can be achieved with the following pseudocode:

Require: X and y containing the labeled training data, $\alpha \leq 0$ or $\alpha \leq$ partially trained SVM

- $C \leq$ some value (10 for example)
- repeat
- for all $\{x_i, y_i\}, \{x_j, y_j\}$ do
- Optimize α_i and α_j
- end for
- until no changes in α or other resource constraint criteria met

Ensure: Retain only the support vectors ($\alpha_i > 0$)

In SVM, the C value is a regularization parameter that manages the balance between maximizing the margin and minimizing the classification error. The algorithm progressively improves the values of α_i and α_j to locate the support vectors, which are the data points nearest to the decision boundary. After the algorithm concludes, only the support vectors with $\alpha_i > 0$ are maintained.

2) *Unsupervised classification*: The NSL-KDD dataset was also clustered using an unsupervised ML algorithm. K-Means clustering is employed to group similar instances together and new labels are predicted for the instances. The predicted labels will then be used as the target variable, and the instances will be classified using the same supervised ML algorithms (KNN, SVM, and RF). The performance of each algorithm will be evaluated using the same performance metrics utilized in the supervised classification.

a) *K-Means*: K-Means is an unsupervised clustering technique that is frequently employed for partitioning data into k-clusters. The algorithm is iterative and aims to obtain the optimal value for each iteration. Initially, a preferred number of clusters is chosen, and the data points are distributed into k clusters. A greater k produces smaller groups with finer detail, while a lower k results in larger groups with less detail.

The K-Means algorithm can be summarized in two steps that are repeated until the clusters and their means are stable:

- i. Assign each data item to the nearest cluster center. The nearest distance can be calculated using distance algorithms.
- ii. Calculate the mean of the cluster with all data items [23].

IV. EVALUATION METRICS

The performance of the proposed algorithms is evaluated based on their results in the testing dataset. There are several metrics that can be used to evaluate the performance of the models such as precision, recall, and f1 score. Recall is another term used for sensitivity, which resembles the true positive value, which is also the portion of the correctly classified inputs as positive among the entire inputs that should have been classified as positive. Precision is the portion of the true positive classifications over the entirety of the positive results. F-measure is the harmonic mean of the precision and recall and sums up the predictive performance of a model.

$$Recall = \frac{TP}{TP + FN}$$

$$Precision = \frac{TP}{TP + FP}$$

$$F - Measure = \frac{2 (Precision \times Recall)}{Precision + Recall}$$

True positive is designated by TP. True negative is designated by TN. False positive is designated by FP. False negative is designated by FN.

V. RESULTS

In computer security, intrusion detection encompasses monitoring computer systems and network to look out for any potential threats embodied by malicious activities, security breaches, or unauthorized access. For intrusion detection models, usually NSL-KDD dataset is used since it comprises many network connections that can be classified as normal traffic or attacks of different types. In this study, two different approaches are implemented to detect intrusion, namely the supervised learning approach (through RF, KNN, and SVM), and the unsupervised clustering followed by supervised learning approach. Both approaches are compared according to their performance in terms of accuracy, precision, recall, f1 score, and confusion matrix. By examining the results of these approaches, the strength, and limitations of each one of them becomes clearer, and it can be considered as an insight into building effective intrusion detection systems and identifying areas for future research.

A. Supervised Learning Approach

1) *Random Forest algorithm after over-sampling:* After applying oversampling techniques, the random forest algorithm was able to score a perfect accuracy rate of 100% on the NSL-KDD dataset. Among the five different classes within the dataset (DoS, Probe, R2L, U2R, and normal), the RF model also scored high precision, recall, and f1 score values as can be seen in Table IV. In fact, RF achieves perfect performance when taking into consideration all the evaluation metrics. These results prove that this model accurately detects intrusions and normal connections.

TABLE IV. RANDOM FOREST CLASSIFICATION REPORT / OVER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	100%	1.00	1.00	1.00

Aside from the perfect recall, precision, and f1 score, the RF algorithm also correctly predicted most of the instances except for a few misclassifications that can be seen in the confusion matrix in Table V. The instances in the attacks category (DoS, Probe, R2L, and U2R attacks) were all perfectly classified, yet the misclassifications fall in the normal category. More specifically, 10 normal connections were classified as DoS attacks, 14 as Probe attacks, and 40 as R2L attacks. These misclassifications may be due to the similarities in network traffic patterns between normal connections and certain types of attacks.

TABLE V. RANDOM FOREST CONFUSION MATRIX / OVER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	15602	1	0	0	2
Probe	0	15447	0	0	0
R2L	0	0	15286	0	0
U2R	0	0	0	15400	0
normal	10	14	40	0	15165

2) *K-Nearest Neighbor algorithm after over-sampling:* After over-sampling on the NSL-KDD dataset, the KNN algorithm was able to score a perfect 100% accuracy in classifying intrusions. Similarly, the precision, recall, and F1 score values were very high as can be seen in Table VI. These

results indicate that the KNN algorithm can identify attack classes with ease, while finding some difficulties in correctly identifying all of the normal connections.

TABLE VI. KNN CLASSIFICATION REPORT / OVER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	100%	1.00	1.00	1.00

As for the confusion matrix depicted in Table VII, the results show that the KNN algorithm can correctly identify most of the instances as attacks and normal connections, with a few errors in the normal class. For instance, 21 normal connections were identified as DoS attacks, 46 as Probe attacks, 150 as R2L, and 15 as U2R attacks. This reflects the poor ability of KNN to classify normal connections. On the other hand, KNN was able to correctly identify all of the instances within the DoS, Probe, R2L, and U2R classes.

TABLE VII. KNN CONFUSION MATRIX / OVER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	15596	3	0	0	6
Probe	9	15425	1	0	12
R2L	0	0	15286	0	0
U2R	0	0	0	15400	0
normal	21	46	150	15	14997

3) *Support Vector Machine algorithm after over-sampling:* The achieved accuracy level by the SVM algorithm after over-sampling of the NSL_KDD dataset was 96%. Similarly, all the other metrics reached high values as shown in Table VIII. for all of the attack classes as well as the normal classes. Even in terms of precision, the SVM model achieved lower values scoring 0.97, with 0.96 recall and 0.96 F1-score.

TABLE VIII. SVM CLASSIFICATION REPORT / OVER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	96%	0.97	0.96	0.96

Table IX describing the confusion matrix of SVM algorithm shows that the model achieves acceptable results in the attack classes, where only a few misclassifications took place. on the other hand, it was demonstrated that the model performs poorly in identifying the normal classes, where a lot of misclassifications can be seen. 76 normal connections were mistakenly identified as DoS, 159 were mistakenly identified as Probe, 122 were mistakenly identified as U2R, and 713 were mistakenly identified as R2L. Another class that shows a rather poor performance of SVM is the U2R class, were 1031 instances were mistakenly identified as R2L attacks. The SVM model rather shows a better performance in the other classes.

TABLE IX. SVM CONFUSION MATRIX / OVER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	15511	8	0	0	86
Probe	26	15315	4	17	85
R2L	0	17	14859	149	261
U2R	0	0	1031	14369	0
normal	76	159	713	122	14159

4) *Random forest algorithm after under-sampling*: When under-sampling techniques were followed, the RF model scored 98% accuracy on the NSL-KDD dataset.

Table X illustrates the high values of accuracy, precision (0.98), recall (0.97), and F1 score (0.98) achieved on all the attack classes as well as the normal class. The achieved results, however, were lower than those scored by RF in over-sampling.

TABLE X. RANDOM FOREST CLASSIFICATION REPORT / UNDER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	98%	0.98	0.97	0.98

Interestingly, the confusion matrix of RF after under-sampling, shown in Table XI demonstrates nearly perfect classifications in all classes, including the normal class. There is 1 misclassification only in the DoS class (classified as Probe), and 1 misclassification only in the Probe class, identified as R2L attack. Other than that, the RF forest after under-sampling is so far the only algorithm that perfectly classified all of the normal connections.

TABLE XI. RANDOM FOREST CONFUSION MATRIX / UNDER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	29	1	0	0	0
Probe	0	26	1	0	0
R2L	0	0	17	0	0
U2R	0	0	0	28	0
normal	0	0	0	0	24

5) *K-Nearest Neighbor algorithm after under-sampling*: After performing under-sampling on the dataset, KNN was able to achieve an overall of 96% accuracy in predicting the classes. Tabel XII shows that KNN achieved a good precision (0.97), good recall (0.96) and goof F1-score (0.96).

TABLE XII. KNN CLASSIFICATION REPORT / UNDER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	96%	0.97	0.96	0.96

Furthermore, the confusion matrix for KNN after under-sampling in Table XIII shows that KNN perfectly classified U2R and Normal classes, while it misclassified DoS in 1 occasion (as Probe) only. Probe class was also misclassified only once by KNN as R2L. The most misclassifications achieved by KNN were in the R2L class, where it misclassified 2 of them as DoS.

TABLE XIII. KNN CONFUSION MATRIX / UNDER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	29	1	0	0	0
Probe	0	26	1	0	0
R2L	2	0	15	0	0
U2R	0	0	0	28	0
normal	0	0	0	0	24

6) *Support Vector Machine Algorithm after under-sampling*: After under-sampling, SVM was able to achieve a total of 96% accuracy on the NSL-KDD dataset. Table XIV shows that SVM has good precision (0.97), recall (0.96), and F1 score (0.96).

TABLE XIV. SVM CLASSIFICATION REPORT / UNDER-SAMPLING

Algorithm	Accuracy	Precision	Recall	F1-Score
	96%	0.97	0.96	0.96

In addition, the confusion matrix for SVM shows in (Table XV) that it can perfectly classify normal and U2R labels without any misclassifications. On the other hand, SVM misclassifies DoS in 1 instance as probe, it also misclassifies Probe in 1 instance as R2L. SVM has 2 misclassifications in the R2L label, where 2 instances are falsely classified as DoS.

TABLE XV. SVM CONFUSION MATRIX / UNDER-SAMPLING

	DoS	Probe	R2L	U2R	normal
DoS	29	1	0	0	0
Probe	0	26	1	0	0
R2L	2	0	15	0	0
U2R	0	0	0	28	0
normal	0	0	0	0	24

B. Overall Performance in Supervised Classification

The scores achieved by all of the supervised algorithms “RF, KNN, and SVM” are shown in Fig. 6. The performances are shown in terms of accuracy, Precision, Recall, and F1-score in both cases of over-sampling and under-sampling.

Fig. 6. Performance of supervised ML algorithms in over- and under-sampling.

The results of the three algorithms in terms of accuracy through over-sampling and under-sampling of the NSL-KDD dataset are shown in Table XVI.

TABLE XVI. ACCURACY RESULTS FOR SUPERVISED LEARNING ALGORITHMS IN OVER-SAMPLING AND UNDER-SAMPLING

	KNN	SVM	Random Forest
Over Sampling Accuracy	100%	96%	100%
Under Sampling Accuracy	96%	96%	98%

C. Overall Performance in Unsupervised Classification

The outcomes of the unsupervised categorization employing K-Means indicated that the precision of the supervised algorithms fluctuated based on the sampling method utilized. Following oversampling, the SVM and Random Forest algorithms attained an accuracy of 0.94, whereas KNN attained an accuracy of 0.92. In contrast, following under-sampling, KNN achieved an accuracy of 0.92, while SVM and Random Forest attained an accuracy of 0.94. These results are presented in

XVII.

TABLE XVII. PERFORMANCE OF ALGORITHMS AFTER K-MEANS CLUSTERING AS UNSUPERVISED CLASSIFICATION

	KNN	SVM	Random Forest
Over Sampling	92%	94%	94%
Under Sampling	92%	94%	93%

In addition, the same results can be visualized in Fig. 7 which shows the accuracy, Precision, Recall, and F1-score values for SVM, KNN, and RF after K-means clustering, in both over- and under-sampling techniques on the NSL-KDD dataset.

Fig. 7. Performance of unsupervised classification in over- and under-sampling.

VI. CONCLUSION AND FUTURE SCOPE

Intrusion detection is an essential component of cybersecurity and organizations of all sizes to protect their networks and systems from attacks. Effective intrusion detection requires a combination of technical tools and expertise and a thorough understanding of the organization's potential threats and vulnerabilities. This paper proposed a hybrid intrusion detection method that employs both unsupervised and supervised learning to address those issues of unlabeled and unbalanced datasets. Several supervised learning

techniques including Random Forest, K-Nearest Neighbor, and Support Vector Machine were tested along with the K-means unsupervised classification technique. The main task was to perform intrusion detection by classifying traffic data as Normal, DoS, Probe, R2L, and U2R after training the ML algorithms on the NSL-KDD dataset. The obtained results showed that all algorithms can achieve high accuracy, recall, and F1 score. In the future, the integration of ensemble models for classification [25] can be explored. Moreover, the utilization of federated learning to maintain data integrity and privacy [26], and the adoption of transformer ViT models[27] to enhance network attack defense across many datasets can be considered.

Abstract—The use of surveillance cameras has made it possible to analyze a huge amount of data for automated surveillance. The use of security systems in schools, hotels, hospitals, and other security areas is required to identify the violent activities that can cause social, economic, and environmental damage. Detecting the mobile objects on each frame is a fundamental phase in the analysis of the video trail and the violence recognition. Therefore, a three-step approach is presented in this article. In our method, the separation of the frames containing the motion information and the detection of the violent behavior are applied at two levels of the network. First, the people in the video frames are identified by using a convolutional neural network. In the second step, a sequence of 16 frames containing the identified people is injected into the 3D CNN. Furthermore, we optimize the 3D CNN by using the visual inference and then a neural network optimization tool that transforms the pre-trained model into an average representation. Finally, this method uses the toolbox of OPENVINO to perform the optimization operations to increase the performance. To evaluate the accuracy of our algorithm, two datasets have been analyzed, which are: Violence in Movies and Hockey Fight. The results show that the final accuracy of this analysis is equal to 99.9% and 96% from each dataset.

Keywords—Violence detection; surveillance cameras; 3D Convolutional Neural Network (3D CNN); Spatio-temporal convolution; deep learning; abnormal behavior

I. INTRODUCTION

The perception of human behavior and the analysis of its activities has been faced with many challenges so far [1]; therefore, the processing of movies and also the perception of the movies' content with the proper accuracy and on a large scale has particular importance [2]. In this regard, due to the use of cameras in the city, we are faced with a very large amount of video and its content. It is impossible to analyze this amount of information by humans [3]. By analyzing the recorded frames from the surveillance videos, it is possible to recognize the abnormal behavior and the violent activity that has occurred, and it is possible to make effective decisions at the appropriate time and conditions [4]. In the prior years, with the development in the area of computer vision, a large number of new methods have emerged and have attracted much attention from researchers because of their wide-ranging security applications. In 2017, for example, 954,261 CCTV cameras were fixed at the generic level in South Korea, with an increase equal to 12.9% from the prior year [5]. The target of the installation of the cameras is to provide security in generic

locations. To this end, we concentrate on violence detection with the use of cameras. Violence is an unusual activity that includes the bodily power to harm something or to murder or injure a person or a brute. These operations can be detected by an intelligent monitoring model that can be applied to ban these incidents before they become more deadly. The main application of the security systems, which are fixed in various locations such as schools, hotels, streets, and so on, is to comfort the availability of security guards by alarming them to violent activities. However, the human performance monitor on the surveillance film is too slow, which causes life loss and property. Therefore, there is a request for an automatic violence recognition model [6]. Hence, this area of study is constantly expanding, and different techniques have emerged in this field.

Violence detection has shown its application in the modern systems used by humans due to its wide and significant applications in the field of human security and comfort. By reviewing the existing articles in the field of violence detection, we can refer to the presented method in [7]. This method extracts the proper features by combining the spatiotemporal features and also acceleration features, each of which is obtained by using a two-dimensional convolutional network and then a recursive LSTM network. The acceleration changes are the important components in the detection of person-to-person violence. In this article, this acceleration has been calculated and has been modeled by using the severity of the ocular stream changes in three consecutive frames. To calculate spatial features, this article uses the VGG19 network [8] trained on Imagenet and then selects the features from the penultimate layer as the feature vectors. Another network that considers the changes in the optical flow as a feature is a Tdd network [9] which was trained and created by using the UCF101 dataset.

In another research presented in [10], the idea of TSN, that is, the temporal division network, was introduced. This method was actually a new framework for the detection of movie-based performance, and it was based on the concept of long-range domain structure modeling. Their method was the extraction of the sparse temporal feature, which involves surface video monitoring to enable effective learning by using violent and action-packed videos that sparsely sample the input frames. It can be said that this architecture is segmental. In research [11], the authors used 3D ConvNet and the key-frame to extract the features from clips that contain violent scenes. They have used 3D ConvNet for the short clips, and also, they have used the

key-frame for the longer clips. The key-frame method divides the movie based on the extracted key-frames, and then it examines the similarity between adjacent frames by changing the position of the gray center.

In research [12], the authors present a method for detecting violent robberies from CCTV footage by using a deep end-to-end sequence model. They have used VGG-16 and a pre-trained CNN by the input video frames (which extract features). They process the features trail with two long-term and short-term memories (convLSTM) using LSTM convolutional, which receives the trail of the obtained features. After these steps, in the end, they used several fully-connected layers for the prediction and classification. In this method, the types of firearms and cold weapons in the image are recognized; in this way, the robberies that show different levels of aggression can be classified.

According to the different detection methods that were examined, it was found that there is a gap in the correct extraction of the features; thus, each of the methods has a high computational complexity and a high cost, as well as they have network overhead and the loss of the movement's features. So, to dissolve the moot point of violence detection, the scene information of both levels is needed (namely, the structure of the scene and the movement made by the people present in the scene). Therefore, by examining different methods, a network has been designed, which is fully explained in the following sections. Our contributions include:

- By taking into account the limitations of the presented methods in this field which are presented in the next section, we present a 3D CNN model for learning the complex sequential patterns to accurately predict the violence from video frames.
- A major limitation in the existed methods is the processing of the un-important frames, which leads to the use of the more memory and the very time-consuming. By considering this limitation, we first identified the people in the video stream by using a pre-trained MobileNet CNN model. Only a trail of 16 frames containing the individuals was transferred to the 3D CNN model for the final prediction, which has helped to achieve the efficient processing.
- Next, inspired by the concept of the transfer learning, 3D-CNN was set up by using the standard datasets to detect the violence in the internal and external surveillance.
- After obtaining the trained deep learning model, it was optimized by using the toolbox of OPENVINO to speed up and improve its performance in the phase of the model deployment. By using this strategy, the trained model was transformed into an average representation based on the trained weights and topology.

The research rest is as follows: Section II discovers our method. The empirical evaluation is considered in Section III. The conclusions and suggestions are presented in Section IV.

II. PROPOSED METHOD

In this part, we explain our method. In this method, violent behavior is recognized with the use of the end-to-end deep learning scheme. The general procedure is as follows: The camera records the film sequence. These film frames are sent directly to a trained MobileNet CNN model. This work is done to identify the persons in the film frame. When a person is detected in the film, a sequence of 16 frames is formed, and then it is sent to a 3D CNN to exploit the spatiotemporal features. These extracted spatiotemporal characteristics are fed to the Softmax classifier to examine the extracted characteristic associated with an activity, and then it provides the predictions. When violence is detected in the video frame, an alarm is sent to the nearest police stand. The suggested method is displayed in Fig. 1. In each of the following subsections we illustrate one step of our method.

A. Pre-Processing

To detect the violent behavior, the first step is the step of recognition of the persons in the video frame. Therefore, the first phase in the pre-processing stage is to use the methods to identify the persons. We only process the parts of the video that contain the persons, avoiding the irrelevant frames, instead of processing the total film. The input video is injected into the MobileNet-SSD CNN system [13], and the persons in the video are identified. The presented model uses CNN to identify the persons because it limits the delay and the size. The MobileNet model processes the separable deep convolutions for object recognition. If the deep and point convolutions are numbered separately, then there will be 28 layers, and each layer will have a non-linear Batch of the ReLu type. Of course, the fully-connected layer will not have this feature. The first convolution layer will consist of 2-strides with a filter form equal to $3 \times 3 \times 3 \times 32$ and the size of input equal to $224 \times 224 \times 3$. The subsequent deep convolution has one stride, its filter form is equal to $3 \times 3 \times 32$, and its input size is equal to $112 \times 112 \times 32$. Mainly, the MobileNet model is applied for the classification tasks. Meanwhile, its SSD is applied to put the multi-box recognizer, and it performs a combination of object recognition. This version, for this purpose, is added at the terminal of the network that performs the feed-forward convolution. Also, it generates a constant-size team of marginal boxes to certify the object detection in the video by extracting its feature maps. The boundary box convolution filters are formed using a predicted category and a certain probability for each category. The category which has the highest probability represents the existing object. An example of the detection of the persons existing in a video frame by using the described model is presented in Fig. 2.

Fig. 1. The presented method for recognition of violent behavior in video frames.

Fig. 2. An instance of the detection of the persons existing in a video frame by using the MobileNet-SSD model.

B. Creation of The 3D CNN Model and Learning Phase

A 3D convolution model is implemented correctly to extract the appropriate spatiotemporal features, and it preserves better temporal information than the Pooling and the 3D convolution operations. There is only spatial information in 2D CNNs, while a 3D CNN can have total temporal information about the input video trail. Some existing methods use the two-dimensional ConvNets. This method is used to exploit the spatial relevance in the film (which simultaneously has temporal relevance). For example, in [14, 15], the 2D CNN model processes several frames. Also, it provides the relevance of total temporal features cumulatively. The 3D convolution model works by convolving a 3D mask in a designed cube (by using assembling the connected frames). In order to capture the motion information, the convolutionally produced feature maps are linked to multiple connected frames on the previous layer. Therefore, the obtained value at the $x.y.z$ location in the map of the feature q on the layer p , which has a bias equal to t_{pq} , is defined by the following relationship:

$$\tanh(t_{pq} + \sum_k \sum_{a=0}^{A_p-1} \sum_{b=0}^{B_p-1} \sum_{c=0}^{C_p-1} \omega_{pqk}^{abc} N_{(p-1)k}^{xyz} = \tag{1}$$

Where C_p is the size of the three-dimensional mask with a time dimension and ω_{pqk}^{abc} is equal to $(a.b.c)$ th value of mask value connected to k th feature mapping on the previous layer. Only the 3D convolutional mask can extract one type of feature because the kernel weights are repeated throughout the cube. Fig. 3 shows the 3D CNN feature maps, which consist of two layers, $conv3a$, and $conv5a$. The presented sample input in Fig. 3 is obtained from the violence class in the dataset.

The average volume of the training data and test data is calculated before starting the training. The proposed network model is well-tuned to take these trails as input. In the Softmax layer, the final divination is calculated as it belongs to the violent category or the non-violent category.

Fig. 3. The 3D CNN feature maps for two layers *conv3a* and *conv5a*.

C. Preparation of Data

To detect the violence, we use a violence dataset that includes a certain number of the stunted film with various times. Each film dataset includes two categories: the violent category and the non-violent category. The entire dataset is separated into a trail of 16 frames with 8-frames overlay among every two consecutive films before starting the training. Then, after obtaining the frames, the total available data is divided into the training set and the test set. A considered ratio for the training set and the test set is equal to 80% and 20%, respectively. When the training set and the test set are taken, a list of files containing paths of the training $L_{tr} = \{S_1, S_{17} \dots S_N\}$ and the test $L_{te} = \{S_1, S_{17} \dots S_N\}$ is generated.

D. Architecture of Proposed Three-Dimensional Convolution

By using the presented 3D CNN model in [16-19], we present our 3D CNN model. The proposed network consists of eight convolutions: five pooling layers, two fully-connected layers, and one Softmax layer. Each convolution layer has a $3 \times 3 \times 3$ kernel by one stride, as well as all pooling layers have a maximum kernel size of $2 \times 2 \times 2$. Of course, the first pooling layer has a kernel size of $2 \times 2 \times 1$ with 2-strides. This exception is to preserve temporal-based data. In the first layer, the number of the considered filters for each convolution, second layer, and third layer, respectively, is 64, 128, and 256. Two fully-connected layers (*fc6*, *fc7*) contain 4096 neurons; also Softmax layer contains N outputs which depend on the number of classes on a dataset. In this paper and in the used dataset, the number of the outputs is equal to two owing to which we have

two categories: the violent scenes and the non-violent. Detailed architecture is shown in Fig. 4.

The proposed architecture catches a trail of 16 frames for input. The input dimensions are equal to 128×171 , but we have used the random cuts with a size equal to $3 \times 16 \times 112 \times 112$ to avoid the problem of overtraining and the problem of not achieving efficient learning. Then, the frames trail is followed by the convolution operations and the 3D pooling operations. The network works as a public feature extractor when the training is done. The various features are trained on the various layer of this network hierarchy. Finally, the exit class is doped as violent or non-violent.

E. Optimization of Proposed Model

The optimization of this model is a process that is applied to produce an optimal design model based on the prioritized limitations. Meanwhile, the power, efficiency, and reliability of this model are maximized. With these methods, we have used the open-source tool of OPENVINO which was created by Intel. This tool develops the workflow through hardware with the maximization of the hardware performance. It runs on the hardware of Intel, and also it takes the prior-trained modules like ONNX, Caffe, TensorFlow, and MXNet as the input, then it transforms them to IR with the use of the model optimizer. Simultaneously and accurately, the model optimizer is applied to make possible a transmission among the training and deployment layers to tune the defined model for optimal implementation in the final model. The stream and the trend of the platform optimization are brief: the model training, the model optimizer, the output (IR), as well as the final platform.

Fig. 4. The structure of the proposed three-dimensional convolution network.

III. TESTS AND REVIEW OF RESULTS

In this part of the article, we present the implementation details of the proposed algorithm, and also we show the performed tests on the dataset and the obtained results. The Python programming language has been used for the implementation of these tests. The presented method is implemented on a computer with a 3.0 GHz Intel(R) Core(TM) i7 CPU and 8G RAM. The convolutional neural network is implemented in GPU, and the graphics card used in this method is NVIDIA GEFORCE 840M.

A. Used Dataset

In this part, the dataset used for the evaluation of our method is explained. In the field of detection of violent behavior, there are different datasets, but in this article, we use two datasets of, Violence in Movies [5] and Hockey Fight [5], which are used in most of the articles in this field.

The dataset of Violence in Movies was nominated by Nievas et al. [5]. This dataset contains 200 videos which include person-to-person combat videos. These scenes are taken from the action movies. Also, in this dataset, the non-combat films are exploited from the datasets of the available act recognition. This dataset discovers the various locations with a mean resolution equal to 360×250 pixels, and each film is restricted to 50 frames. The first person in this dataset, which in the sequence is placed, has little or no camera movement. Similar to the previous dataset, the dataset of Hockey Fight

was nominated by Nievas et al. [5] and consisted of 1000 stunted films obtained from the National Hockey League (NHL). Five hundred clips in this dataset are tagged as violent, as well as 500 clips are tagged as non-violent. Each film contains 50 frames which have a resolution equal to 360×288 pixels. The examples of the frames in these two datasets are mentioned in Fig. 5. The first row is related to the dataset of Violence in Movies, and the second row is related to the dataset of Hockey Fight.

B. Evaluation Results of Proposed Method

In this part, details of the obtained results from the performed experiments on the introduced datasets are presented. Table I displays the results of the performed tests in the dataset of Violence in Movies. As it is known, the highest obtained accuracy is equal to 99.9%, which has a loss equal to 1.67×10^{-7} . This result is obtained at the maximum iterations equal to 5000 with a base learning rate equal to 1×10^{-5} . The important point is that violence detection is easier in the dataset of Violence in Movies than violence detection in the dataset of Hockey Fight. The reason is that there are more people in the clips.

Also, Table II displays the results details of the performed tests on the dataset of Hockey Fight where the highest obtained accuracy is equal to 96% with a loss equal to 5.77×10^{-4} . This result is obtained at the maximum iterations of 5000 as well as the learning rate equal to 0.0001.

Fig. 5. Examples of frames in a used dataset.

TABLE I. THE RESULTS OF OUR METHOD ON THE DATASET OF VIOLENCE IN MOVIES

Learning Rate	Number of Iterations	Loss	Accuracy
0.001	1000	0	99.4%
	3000	0	
	5000	1.21×10^{-2}	
1×10^{-5}	1000	1.99×10^{-3}	99.9%
	3000	5.4×10^{-4}	
	5000	1.67×10^{-7}	

TABLE II. RESULTS OF THE PROPOSED METHOD ON THE DATASET OF HOCKEY FIGHT

Learning Rate	Number of Iterations	Loss	Accuracy
0.001	1000	1.49×10^{-2}	94.9%
	3000	0	
	5000	1.85×10^{-2}	
0.0001	1000	1.79×10^{-3}	96%
	3000	2.27×10^{-3}	
	5000	5.77×10^{-4}	

Fig. 6. The trend of the obtained loss value in the dataset of Hockey Fight.

In the experiments, it was found that a learning rate has a significant trace in the amount of the loss. In Fig. 6, the process of changing the loss value is specified. This trend is demonstrated with the change in several learning rates and the iterations equal to 0.001 in the dataset of Hockey Fight. In the 500th iteration of this process, the gained loss value is equal to 1.97×10^{-2} . This value reduces at the same time as the number of iterations. In maximum iteration equal to 5000, this value is equal to 2.32×10^{-7} while the test conditions have not changed, and only the learning rate has changed to 0.0001.

The value of the loss in the dataset of Violence in Movies is very high in the early stages. Then, with increasing in the iteration, the value of the loss is decreased. In this way, the value of the obtained loss in the iteration of 5000 is equal to 5.4×10^{-4} . The trend of the loss reduction in the dataset of Violence in Movies is shown in Fig. 7.

Also, we have appraised the performance of our method by checking the precision, recall, and comparison between datasets with the presentation of AUC in Table III. This table shows the performance of our platform for two datasets. The relationship between the precision and recall is as follows:

$$\text{Precision} = \frac{\text{True Positive (TP)}}{\text{True Positive (TP)} + \text{False Positive (FP)}} \quad (2)$$

$$\text{Recall} = \frac{\text{True Positive (TP)}}{\text{True Positive (TP)} + \text{False Negative (FN)}} \quad (3)$$

Moreover, the taken confusion matrix is displayed in Table IV. The values of recall as well as precision values for two datasets, respectively, are between $Xmin$, $Ymin$ and $Xmax$, $Ymax$ where X displays precision and Y displays recall for two datasets.

C. Comparison of Presented Method with Similar Methods

One of the important parts of the presentation of a new network is the provision of a complete report of the efficiency of the designed network and the correctness and accuracy of the network performance in different conditions. For this purpose, to demonstrate the better performance and accuracy of the designed network in comparison to similarly designed networks that have been presented and implemented by other researchers, the obtained results from the performance of this network have been compared with other networks. The similarity of the test conditions is related to the same dataset and the same quality evaluation parameters. Therefore, in this part, we contrast the results of two datasets with existing methods. A comparative evaluation with the existing platforms is displayed in Table V. We present the results of the presented method in [20] in the first row. It uses Oriented Violent Flows for motion enlargement. Also, it uses AdaBoost as a feature. Another comparison method that uses Hough forests with two-dimensional CNN for violence detection is presented in [21], and its results are listed in the second row. In addition, we have contrasted the results of our method with the proposed method in [22] that uses motion bubbles and random forests for rapid violence detection. Its results are presented in the third row. Also, in [23], two descriptors are applied in order to identify unusual activities. They applied a simple histogram of the directional tracks together with a dense optical stream in order to detect the abnormal behavior in the terminal result. The fourth row shows the results related to this method. In [24], the writers applied a sliding window method. Also, they use the method of the improved Fisher's vector for violence detection. The results of this method are also displayed in the fifth row.

Fig. 7. The trend of the obtained loss value in the dataset of Violence in Movies.

TABLE III. PRECISION, RECALL AND AUC FOR OUR METHOD IN TWO DATASETS

Dataset	Values				Precision	Recall	AUC
	TP	TN	FP	FN			
Hockey Fight	262	230	11	9	0.9957	0.9667	0.97
Violence in Movies	50	57	0	0	1.0	1.0	0.997

TABLE IV. CONFUSION MATRIX

The classes in the dataset	1Hockey Fight		1Violence in Movies	
	Violent	Non-Violent	Violent	Non-Violent
Violent	262.0	11.0	50.0	0
Non-Violent	9.0	230.0	0.0	57

TABLE V. RESULTS OF COMPARISON OF OUR METHOD WITH THE SIMILAR METHODS

Methods	Achieved Accuracies (%)	
	Violence in Movies	Hockey Fight
The method presented in [21]	-	87.5
The method presented in [22]	99	-
The method presented in [23]	96.9	-
The method presented in [24]	98.5	83.1
The method presented in [25]	99.5	93.7
Our proposed method	99.9	96

IV. CONCLUSIONS AND SUGGESTIONS

In this article, the main goal is to identify the violent behaviors in the video frames. Therefore, a three-step method for detecting the violence in the video frames is presented. In this method, first, the people in the video frames are identified. The identification of the people is done by using CNN, which makes the undesirable frames to be ignored and the overhead of the proposed system is reduced. In the second step, a sequence of the frames containing the detected individuals is injected into a trained 3D CNN model, which is performed on two standard datasets. In this dataset, the spatio-temporal features are used and sent to Softmax for the final predictions. Finally, this paper uses the toolbox of OPENVINO to perform the optimization operations to increase the performance. The results of conducted experiments on different datasets show the excellent performance of our proposed platform. These results show that our method is the best suited for detecting the violence in the video surveillance and has better accuracy than several other techniques. For future research, it is suggested that the researchers can ensure that our proposed system can be implemented on the resource-constrained devices. Also, the presented dataset is limited to few violent scenes that can be tried to complete this dataset. On the other hand, some violence is verbal and it is possible to prepare a dataset with this feature in the future works and evaluate the proposed method. In addition, the researchers can propose the edge intelligence to detect the violence in the Internet of Things by using the smart devices for the quick responses.

Construction of VR Video Quality Evaluation Model Based on 3D-CNN

Hongxia Zhao¹, Li Huang²

Information Engineering College, Jiangxi University of Technology, Nanchang, China

Abstract—Currently, virtual reality (VR) panoramic video content occupies a very important position in the content of virtual reality platforms. The level of video quality directly affects the experience of platform users, and there is increasing research on methods for evaluating VR video quality. Therefore, this study establishes a subjective evaluation library for VR video data and uses viewport slicing method to segment VR videos, expanding the sample size. Finally, a classification prediction network structure was constructed using a three-dimensional convolutional neural network (3D-CNN) to achieve objective evaluation of VR videos. However, during the research process, it was found that the increase in its convolutional dimension inevitably leads to a significant increase in the parameter count of the entire neural network, resulting in a surge in algorithm time complexity. In response to this defect, research and design dual 3D convolutional layers and improve 3D-CNN based on residual networks. Based on this research, a virtual reality video quality evaluation model based on improved 3D-CNN was constructed. Through experimental analysis, it can be concluded that the average overall accuracy value of the constructed model is 95.27%, the average accuracy value is 95.94%, and the average Kappa coefficient value is 96.18%. Being able to accurately and effectively evaluate the quality of virtual reality videos and promote the development of the virtual reality field.

Keywords—Virtual reality video; 3D convolutional neural network; residual network; quality evaluation

I. INTRODUCTION

VR panoramic video is a video shot at a full 360° angle with a panoramic camera or cameras. VR panoramic video technology is a real-scene virtual reality technology based on panoramic images, which effectively integrates computer graphics technology, computer simulation technology, sensor technology, display technology and other scientific technologies [1]. VR panoramic video technology covers a variety of content and various forms of video. Among them, the video forms favoured by modern youths, including movies and recorded short films, etc., can be completed by using VR panoramic video technology [2]. At first, VR panoramic video technology was only used for leisure and entertainment, and it was rarely used in other fields. With the continuous development of technology, VR panoramic video technology has entered the fields of education, medicine, tourism, etc. [3]. The video information in mainstream VR is spherical video information, and spherical video has higher requirements for clarity, presence, vertigo, and immersion due to user experience, so timely evaluate VR video quality and improve video design become particularly important [4]. The video quality evaluation can intuitively indicate the quality of the video. 3D convolutional neural network (3D-CNN) is based

on a two-dimensional convolutional neural network, adding a time dimension to the input of the neural network, extracting time and space features at the same time, performing deep learning for behaviour recognition, recognition processing and other operations method, which is widely used in video processing [5]. The research uses the viewport-cutting method to expand the number of videos. Finally, the data set is put into the training of the video quality evaluation model based on 3D-CNN. During the research process, it is found that the increase in the convolution dimension will lead to a sharp increase in the time complexity of the algorithm. In response to this defect, the study designs a double 3D convolutional layer and improves the 3D-CNN based on the shortcut of ResNet. Therefore, a VR video quality evaluation model based on improved 3D-CNN is constructed. Realize accurate and efficient objective evaluation of VR video.

This paper is divided into three parts. The first part is literature review, which analyzes the current research situation at home and abroad in the related research fields involved in the research, summarizes the existing research deficiencies, and points out the future research directions. The second part is the research method part, which expounds the VR video quality evaluation model constructed by the research institute and improves the technology used. The third part is the performance analysis part, which carries out a series of experiments to verify the performance of the model.

The importance and innovation of the research are as follows:

Traditional VR video quality evaluation methods are mainly divided into subjective and objective evaluation. The factors that affect users' perception of VR video quality are not only the perceived quality of the video, but also the subjective feelings such as presence, vertigo and accessibility. However, at present, there are few relevant subjective evaluation databases, and the traditional subjective evaluation is time-consuming and labor-intensive. However, the objective evaluation method needs to compound the subjective evaluation scores and has strong usability. The existing objective evaluation method is more complicated in calculation and its accuracy is not ideal. Therefore, a VR video quality evaluation method based on 3D-CNN was constructed. The research has two innovations, one is to establish a subjective evaluation database of VR video, which includes the quality of perception, the sense of presence, the sense of glare and the acceptability. Two: The existing VR video quality evaluation methods are full reference or partial reference. Firstly, the 3D convolutional channel network is used to evaluate the quality of VR video. Firstly, a visual

interface cutting method is proposed, and a non-reference VR visual frequency quality evaluation method is established by combining 3D convolutional channel network. This method does not need to participate in video, is driven by pure data, does not use human features extraction, and the obtained prediction results are in high consistency with the quality evaluation of V-R video, and the prediction results are good. Compared with the existing full-reference VR video quality evaluation methods, it has stronger competitiveness.

II. RELATED WORKS

With the gradual rise of VR videos, it is becoming more and more important to make accurate judgments on the quality of VR videos. Many scholars have conducted research on video quality evaluation. Tu et al. take user-generated content (UGG) videos as the research object, and comprehensively evaluate the leading no-reference/blind VQA (BVQA) features and models on a fixed evaluation framework. By employing a feature selection strategy on the BVQA model, a new fusion-based quality estimator for AIDeo (VIDEVAL) [6] was created. In order to compare the 8K high-resolution image quality of Versatile Video Coding (VVC) and High Efficiency Video Coding (HEVC) standards, Bonnineau et al. used PSNR, NS-SSIM and VMAF metrics for objective measurement, and obtained the comparative quality evaluation results of the two [7]. Zhang et al. aimed at the problem that many current predictive video quality of experience (QoE) models are too dependent on features specific to a specific feature set and lack generalization capabilities. Using word embedding and 3D convolutional neural networks to extract generalized features and learn them in neural networks, a new end-to-end framework (DeepQoE) was developed to perform classification and regression problems on different multimedia data [8]. Tian et al. used radial symmetric transformations on the luminance components of reference and distorted LF images to explore the depth features of geometric information in LF images. Symmetry and depth features are compared for similarity measurement to obtain video quality scores. It proposed a new full-reference image quality assessment (IQA) method [9]. Lee et al. extracted 3D shear transformation-based spatio-temporal features from overlapping video blocks and applied them to logistic regression, connected with conditional video-based deep residual neural networks to learn spatio-temporal correlations and predict quality scores. It proposed a new frequency-free reference quality assessment method [10]. Yang Aiming at the limitation of the traditional VQA method in capturing complex global time information in a panoramic video, combined spherical convolutional neural network (CNN) and non-local neural network, proposed an end-to-end neural network model for panoramic video and Stereo panoramic video for quality assessment [11].

3D-CNN is a deep learning method based on two-dimensional convolutional neural network, adding a time dimension to the input of neural network, extracting time and space features at the same time, and performing operations such as behaviour recognition and recognition processing. Mzoughi et al. proposed an efficient and fully automatic deep multi-scale three-dimensional convolutional neural network (3D-CNN) architecture based on 3D convolutional layers and deep networks to classify glioma brain tumors [12]. Ramzan et

al. proposed a one-line network for segmenting multiple brain regions based on 3D-CNN, using residual learning and dilated convolution operations to learn an end-to-end mapping from MRI volumes to voxel-level brain segments [13]. The 3D convolutional neural network designed by Liu et al. for the development of Deep-Fake detection has large parameters, resulting in serious memory and storage consumption problems. A lightweight 3D-CNN [14] for DeepFake detection is proposed by using the channel transformation module to extract parameters with fewer features and fusing the spatial features on the temporal dimension for the spatio-temporal module. Hassan-Harrirou et al. In order to reduce the time and cost of exploring the chemical search space in the development of new drugs, more quickly and accurately predict the binding affinity of the lead. An ensemble of 3D-CNNs (RosENet) was used to predict the absolute binding affinities of protein-ligand complexes [15]. Aldoj et al constructed a new semi-automatic prostate cancer classification model using 3D convolutional neural network and histological correlation analysis based on multiparameter magnetic resonance (MR) imaging [16]. Salama et al. took human emotion recognition as the research goal, used the 3D-CNN deep learning framework to extract spatiotemporal features from electroencephalogram (EEG) signals and face video data, and obtained fusion predictions using data enhancement and ensemble learning techniques. The study proposed a new framework for multimodal human emotion recognition [17].

According to the comprehensive literature, there are many video quality evaluation methods, among which 3D-CNN is widely used, but it is not used in 3D video quality evaluation. Therefore, the research builds a VR video quality evaluation model based on 3D-CNN. Evaluate video quality objectively and thoughtfully.

III. CONSTRUCTION OF VR VIDEO QUALITY EVALUATION MODEL BASED ON 3D-CNN

A. Evaluation Index Selection and Video Cutting

VR video is different from traditional video that only records image information from a specific angle per frame. Panoramic video captures image information from all directions at the same time. Through a professional VR head-mounted display, the video is mapped to a spherical surface for users to observe and obtain an immersive experience [18-19]. The VR video transmission framework is shown in Fig. 1.

Fig. 1. VR video transmission framework.

In order to analyze video information more efficiently, the research establishes a VR video quality evaluation model based on 3D-CNN based on the characteristics of the human visual system, gives quantitative indicators to analyze video information, and obtains corresponding scores to simulate the

results of subjective evaluation and scoring. Due to the spherical 360° video of VR video, the planar (peak signal-to-noise ratio) PSNR method is usually not accurate enough, so some objective evaluation methods for VR video quality are needed. The study uses Spearman's rank correlation coefficient (SRCC) and Pearson correlation coefficient (PCC) as the correlation evaluation index of subjective and objective evaluation of video quality. The calculation formula of SRCC is shown in the following (1):

$$r_s = 1 - \frac{6 \sum_{i=1}^n d_i^2}{n(n^2 - 1)} \quad (1)$$

In (1), d_i represents the first i difference, which n is the number of data. The PCC calculation formula is shown in the following (2).

$$\rho(x, y) = \frac{E(XY) - E(X)E(Y)}{\sqrt{E(X^2) - E^2(X)} \sqrt{E(Y^2) - E^2(Y)}} \quad (2)$$

In (2), $E(X)$ is X the mean value of the variable, and is the mean value $E(Y)$ of the Y variable. The planar video quality evaluation method is not comprehensive. In addition, the study uses spherical-based CP-PSNR and WS-PSNR to obtain more objective evaluation indicators. The weight calculation formula of ERP mapping is shown in the following (3).

$$W(i, j) = \frac{w(i, j)}{\sum_{i=0}^{W-1} \sum_{j=0}^{H-1} w(i, j)} \quad (3)$$

In (3), W and H are the length and width of the video resolution, respectively, and are the scaling factors $w(i, j)$ for pixels to (i, j) be mapped from a plane to a sphere using ERP mapping. The formula is as follows: (4).

$$w(i, j) = \cos\left(\left(j - \frac{H}{2} + \frac{1}{2}\right) \cdot \frac{\pi}{H}\right) \quad (4)$$

The calculation formula of WS-PSNR is shown in (5) below.

$$\left\{ \begin{aligned} WMSE &= \sum_{i=0}^{W-1} \sum_{j=0}^{H-1} (y(i, j) - y'(i, j))^2 \cdot W(i, j) \\ WS - PSNR &= 10 \log\left(\frac{MAX^2}{WMSE}\right) \end{aligned} \right. \quad (5)$$

In (5), $y(i, j)$ and $y'(i, j)$ are respectively the original pixel and the reconstructed pixel, which MAX is the maximum value of the color of the image point. The calculation formula of CP-PSNR is shown in the following (6).

$$\left\{ \begin{aligned} \bar{w}'(s, t) &= \frac{w'(s, t)}{\sum_{s, t} w'(s, t)} \\ CP - PSNR &= 10 \log \frac{I_{\max}^2}{\sum_{s, t} (I(s, t) - I'(s, t))^2 \cdot \bar{w}'(s, t)} \end{aligned} \right. \quad (6)$$

In (6), $I(s, t)$ and represent $I'(s, t)$ the intensity of I_{\max} the point in the reference video and the damaged video respectively, which (s, t) is the maximum value of the color of the image point. In addition to the above-mentioned quality evaluation standards used in general videos, the study establishes a subjective evaluation library for VR videos, and scores the sense of presence, vertigo, and acceptability. A total of 48 VR videos were established in the research database, including 12 source reference videos. Each reference video generated 36 damaged videos through three kinds of QP, and 40 subjects were selected to participate in the establishment of the subjective evaluation database. After the subjects are trained, they evaluate the corresponding VR videos with scores. The evaluation indicators include perceptual quality, sense of presence, vertigo and acceptability. The scores given by the subjects are collected for the evaluation obtained by establishing an objective evaluation model in the future. The score (MOS) is compared with the objective evaluation of the subjects, and a corresponding scoring table is established for subsequent training. Due to the large amount of data required for deep learning, it is necessary to expand the video database, research on cutting VR videos, and cut them into small pieces of video. VR video needs to convert between spherical model and planar model. Before VR video transmission, the spherical model is mapped to the planar model. When the user watches the VR video through the HMD, the planar model is re-projected into the spherical model, so the user actually sees these are the viewpoints of the VR video. After VR video is projected, oversampling will occur. Based on this difference, the study uses the unique viewport characteristics of VR videos to propose a viewport cutting method to cut VR videos. The viewport segmentation diagram is shown in Fig. 2.

Fig. 2. Schematic diagram of viewport cutting.

Assuming that the user's viewing direction is the negative axis of the X axis and set as the initial position of the head, set the rotation matrix representing the user's rotation relative to the initial position, R and transform the three-dimensional and two-dimensional homogeneous coordinates through intrinsic matrix modeling, such as (7) as shown.

$$K = \begin{bmatrix} f_x & 0 & C_x \\ 0 & f_y & C_y \\ 0 & 0 & 1 \end{bmatrix} \quad (7)$$

In (7), C_x and C_y represent the center point of the viewport texture coordinates, f_x and f_y is the focal length expressed in pixels. The projection relationship formula is shown in the following (8).

$$w \cdot e' = K \cdot R^T \cdot E \quad (8)$$

In (8), E is a point on the spherical surface in the current visible area, e' indicating the two-dimensional homogeneous coordinates of the point mapped on the viewport, and w is the scale factor. By projecting the VR video onto a spherical surface, a series of viewports of VR videos are extracted, and the extracted viewport videos are used as the input of the VR video quality evaluation network.

B. Evaluation Model Construction based on Improved 3D-CNN

After selecting the evaluation index and establishing the evaluation library, the study uses 3D-CNN to evaluate the quality of VR video. The computing modules of traditional convolutional neural networks are mainly divided into four types: convolution, pooling, full connection and classifier prediction. The spatial structure features are extracted through the convolutional layer, and the larger-scale feature learning results are formed through the pooling layer, and then the depth of the convolutional layer and the pooling layer is continuously deepened to extract the spatial features of the image [20-21]. Convolutional neural network (CNN) was originally designed for the feature extraction of two-dimensional data, which can directly establish the mapping relationship from low-level features to high-level semantic features, and has achieved remarkable results in the field of two-dimensional image classification. However, 2D-CNN only carries out sliding calculation on the two-dimensional plane and cannot carry out feature extraction on the spectral dimension of hyperspectral image, so the extracted information is insufficient. A large number of theories and experiments show that 3D-CNN can extract features from both spatial and spectral information dimensions of hyperspectral images to improve the classification

$$a = [M_{1,1,1}, M_{1,1,2}, \dots, M_{1,1,n}, \dots, M_{1,2,1}, M_{1,2,2}, \dots, M_{1,2,n}, \dots, M_{1,m,n}, M_{2,m,n}, \dots, M_{j,m,n}]^T \quad (11)$$

In (11), the original feature map is M_1, M_2, \dots, M_n . The study uses the Softmax regression model at the output layer to realize the multi-category prediction function, and uses the hypothesis function to estimate the probability value of a certain class in the data set. The formula is shown in the following (12).

$$P(y^i = j | x^i; \theta) = \frac{e^{\theta_j^i x^i}}{\sum_{t=1}^D e^{\theta_t^i x^i}} \quad (12)$$

performance of the network. 3D-CNN is a convolutional network with three dimensions, namely image width, image height and image channel. The convolution kernel can move in three directions, and it can be used to better capture the temporal and spatial feature information in the video. The convolution operation formula is shown in the following (9).

$$f(x, y) * w(x, y) = \sum_{s=-a}^a \sum_{t=-b}^b w(s, t) f(x-s, y-t) \quad (9)$$

In (9), it represents $f(x, y)$ the gray value of the point whose $w(x, y)$ coordinates are in the image, which (x, y) is the convolution kernel. Sliding on the image through the weight window, the weighted sum of the pixels on the image and the weight window is used to extract the advanced features of the image. The number of input and output feature maps of the pooling layer is the same, and the calculation matrix form of the pooling layer is expressed as (10).

$$vec(y) = S(x)vec(x) \quad (10)$$

In (10), $vec()$ represents the vectorization operation, and $S(x)$ the feature selector matrix of the input feature map for the pooling layer. In order to prevent the fitting phenomenon, reduce the number of parameters, and perform maximum pooling on the image, the process is shown in Fig. 3.

Fig. 3. Maximum pooling process.

After the pooling layer, since the output is a two-dimensional feature map, the fully connected layer vectorizes the map, and the obtained vector is as in (11).

In (12), θ is the model parameter, D is the number of categories, y is the label, and x is the test input. The cost function of Softmax is as follows (13).

$$J(\theta) = -\frac{1}{m} \left[\sum_{i=1}^m \sum_{k=1}^D 1\{y^i = k\} \log \left(\frac{e^{\theta_k^i x^i}}{\sum_{t=1}^D e^{\theta_t^i x^i}} \right) \right] + \frac{\lambda}{2} \sum_{i=1}^m \sum_{j=0}^n \theta_{ij}^2 \quad (13)$$

In (13), $1\{\}$ is the indicative function, where $1\{true\} = 1, 1\{false\} = 0$ is the coefficient of the penalty term.

λ The partial derivative of the cost function to the parameters is as follows (14).

$$\nabla_{\theta_j} J(\theta) = -\frac{1}{m} \sum_{i=1}^m [x^i 1\{y^i = j\} - P(y^i = j | x^i; \theta)] + \lambda \theta_j \quad (14)$$

The optimal solution for global convergence is obtained by minimizing the gradient descent algorithm. $J(\theta)$ Traditional convolutional neural networks can only extract spatial features in images, and are not suitable for video processing. 3D convolutional neural networks extract temporal features in videos based on traditional convolutional neural networks. And use the spatio-temporal features to classify and then predict. First of all, study the use of 3D-CNN to form a ten-category network structure. First, divide VR videos into ten categories through MOS points, of which 1-10 points are divided into one category, 10-20 points are divided into two categories, and so on, 90- 100 points are divided into 10 categories. 3D-CNN extracts temporal and spatial features based on 2D convolutional neural networks. The classification structure of 3D-CNN consists of eight 3D convolutional layers,

five 3D maximum pooling layers, two fully connected layers and a ten-category output layer. After the output layer is calculated by softmax, the classification result is obtained. The research uses the cross entropy function of Softmax as the loss function, and the formula is shown in the following (15).

$$L = -[y \log \hat{y} + (1 - y) \log (1 - \hat{y})] \quad (15)$$

In (15), y represents the subjective MOS score obtained in the evaluation database, and \hat{y} represents the predicted score. The training iterations are performed according to the loss function to obtain ten classes. After the classification is completed, use 3D-CNN to form a regression prediction model, use transfer learning, load the model parameters saved by classification as the pre-training model of the regression prediction model, and then train the regression model to give the predicted value of the video MOS score. The regression prediction structure of 3D-CNN is similar to the classification structure, the difference is that the fully connected layer of the network structure is followed by a regression prediction node. The schematic diagram of the structure is shown in Fig 4.

Fig. 4. Prediction structure diagram.

The parameters such as weight parameters and bias items obtained after loading the classification process through transfer learning are loaded to include all convolutional layer and pooling layer parameters, and the parameters of the two fully connected layers are discarded. The loss function uses the mean square error (MSE), and the calculation formula is as follows (16).

$$MSE = \frac{1}{N} \sum_{i=1}^N (y - \hat{y})^2 \quad (16)$$

In (16), N is the number of video clips, y represents the subjective MOS score obtained in the evaluation database, and \hat{y} represents the predicted score. Put the predicted value into the loss function to participate in the regression training, and finally get the most suitable prediction result. Although 3D-CNN can effectively extract features from VR video data, the increase in the convolution dimension will inevitably increase the parameters of the entire neural network, resulting in a sharp increase in the time complexity of the algorithm. The conventional network input is obtained through the calculation output of the upper layer, while the residual network (ResNet) will have a "short-circuit" structure, and the data processed by the multi-layer network and the data processed by the network layer are jointly input and transmitted to in the next layer of the network. The learning goal of ResNet is to solve the residual error, as shown in (17).

$$F(x) = H(x) - x \quad (17)$$

In (17), $H(x)$ is the expected mapping of learning. The difference is obtained through (17), so that the same part before and after the cell mapping highlights the slight changes, so that the deep network structure will not degenerate while ensuring the structural performance. ResNet can reduce the complexity of parameter calculation and reduce the error caused by network depth through the unique design of shortcut. Research on improving 3D-CNN based on ResNet's shortcut. In order to reduce the nonlinear conversion operation and improve the feature extraction ability, a double 3D convolutional layer is designed, and no pooling calculation is performed between the two convolutional layers. Batch regularization calculation is performed after each convolution, and the ReLu function is used as the activation function to reduce the risk of gradient disappearance and gradient explosion. The improved 3D residual convolution unit structure is shown in Fig. 5 below:

Fig. 5. Structure of 3D residual convolution unit.

Based on the above operations, the study selects video quality evaluation indicators, establishes a subjective evaluation database, uses improved 3D-CNN to classify and predict video data, obtains objective evaluation results, and uses the relationship between subjective evaluation and objective evaluation in the training process. The loss function continuously corrects and trains the model. Finally, a VR video quality evaluation model based on the improved 3D-CNN is obtained, which can accurately evaluate the VR video quality.

IV. ANALYSIS OF VR VIDEO QUALITY EVALUATION MODEL BASED ON 3D-CNN

An accurate and efficient video quality evaluation model is an indispensable tool to measure the pros and cons of video processing algorithms and to control video quality in real time [22]. Therefore, a VR video quality evaluation model based on improved 3D-CNN is constructed. In order to verify the performance of the constructed model, the study used three different data sets to carry out classification training on the research constructed model (model 1), the unimproved 3D-CNN model (model 2), and the BP neural network (model 3), and the convergence of the loss function as shown in Fig. 6 below:

Fig. 6. Comparison of model loss function training.

It can be seen from Fig. 6 that as the number of iterations increase, the value of the loss function of the model decreases, and gradually decreases to a certain extent. Among them, in data set 1, model 1 has the fastest decline rate and reaches the target loss value of 0.16 when the number of iterations reaches 62. However, model 2 reached the target loss value of 0.21 when iterated to 168 times, which was 0.05 higher than model 1. Model 3 reached the target loss value of 0.38 when iterated to 75 times, which was 0.21 higher than model 1; in dataset 2, model 1 reached the target loss value of 0.15 when iterated to 101 times. Model 2 reaches the target loss of 0.28 when iterating to 152 times, which is 0.13 higher than Model 1. Model 3 reaches the target loss of 0.29 after 197 iterations, which is 0.14 higher than that of model 1; in data set 3, model 1 reaches the target loss of 0.11 when iterated to 47 times, and model 2 reaches the target loss of 0.23 when iterated to 128 times. 0.12 higher than Model 1. Model 3 iterates to 149 times

to reach the target loss value of 0.22, which is 0.11 higher than Model 1. Comprehensive comparison and analysis of the content in the above figure, it can be concluded that model 1 has the best convergence effect and the fastest convergence speed.

In order to further verify the improvement effect of 3D-CNN, after the model training, the test set was tested using model 1 and model 2. The results of the linear regression analysis graph obtained from the test and the predicted value and subjective score change fitting graph are shown in Fig. 7 shown.

Comparing Fig. 7(a) (b), we can see that the left picture is a linear regression analysis chart, and we can see the correlation between the predicted score and the subjective score. Before the improvement, the Pearson correlation coefficient of the model was 0.9025, the Spearman coefficient

was 0.8963, and the RMSE value was 0.3258. The Pearson correlation coefficient of the improved model is 0.9437, which is 0.0412 higher than that before the improvement, the Spearman coefficient is 0.9359, which is 0.0396 higher than that before the improvement, and the RMSE value is 0.2051, which is 0.1207 lower; the right picture is the predicted value of the test sample. The degree of deviation from the subjective score. It can be seen that the predicted score curve obtained by the improved model has a high degree of coincidence with the subjective score. Based on the analysis of the content in the

above figure, it can be seen that the improvement of the model can effectively reduce the prediction error.

In order to compare the rationality of introducing viewport cutting into VR video clips of the model more specifically, the MOS score of each evaluation category in the subjective evaluation library before and after cutting is compared with the model prediction results, and the prediction accuracy, missed detection rate and false recognition rate are compared. The details are shown in Table I below.

Fig. 7. Model test results before and after improvement.

TABLE I. COMPARISON AND ANALYSIS OF MODEL PREDICTION SCORE AND SUBJECTIVE SCORE

Evaluation type	Before cutting			After cutting		
	Accuracy (%)	Undetected rate (%)	Error rate (%)	Accuracy (%)	Undetected rate (%)	Error rate (%)
Perceived quality	84.10	11.23	15.70	93.26	9.56	7.46
Presence _	83.46	10.96	16.32	94.58	9.32	5.68
Vertigo	86.59	12.36	13.46	93.91	8.99	6.12
Acceptability	87.46	11.02	12.39	95.21	9.12	5.34
Comprehensive _	88.21	11.47	11.04	95.43	8.97	4.69

Comparative analysis of the data in Table I shows that in the process of predicting various subjective evaluation scores, the average prediction accuracy rate of the model trained before the viewport cutting method is 85.97%, the average missed detection rate is 11.41%, and the average misrecognition rate is 85.97%. The average prediction accuracy rate of the model trained after viewport cutting is 94.48%, the average missed detection rate is 9.19%, and the average false recognition rate is 5.86%. Based on the data in the above table, it can be concluded that after viewport cutting,

the number of training samples is increased, and the model can evaluate video quality with higher accuracy.

In order to verify the prediction accuracy of the model and the change of running time under different sample sizes, in addition to the above three training models, the research will also commonly used classification prediction models: logistic regression (Logistics) (model 4), support vector machine (SVM) (model 5). As the number of VR video samples increases, the classification prediction accuracy of the model and the running time are shown in Fig. 8 below:

Fig. 8. Variation of prediction accuracy and running time with sample number.

It can be seen from Figure 8 that as the number of sample videos increases, the prediction accuracy of each model decreases and the running time increases. Among them, the accuracy curve of model 1 has the smallest decline. When the sample size is 500, the prediction accuracy of model 1 is 96.43%, and the running time is 0.236s. The prediction accuracy of model 2 is 90.37%, and the running time is 0.347s. The prediction accuracy of model 3 is 93.06%, and the running time is 0.343s. Model 4 has a prediction accuracy of 88.59% and a running time of 0.526s. The prediction accuracy of model 5 is 89.63%, and the running time is 0.623s; when the sample size is 4000, the prediction accuracy of model 1 is 92.64%, and the running time is 0.673s. Model 2 has a prediction accuracy of 76.85% and a running time of 0.921s.

Model 3 has a prediction accuracy of 79.78% and a running time of 1.032s. The prediction accuracy of model 4 is 77.43%, and the running time is 0.996s. The prediction accuracy of model 5 is 80.12%, and the running time is 0.963s. A comprehensive analysis of the content in the above figure shows that model 1 is less affected by the increase in the number of test samples, and the running time and prediction accuracy are in a relatively ideal state.

In order to further verify the classification prediction effect of the model, the study introduces overall accuracy (OA), average accuracy (AA) and Kappa coefficient as evaluation indicators, uses five models to predict three data sets, and compares and analyzes them, as shown in Table II below.

TABLE II. EVALUATION OF MODEL CLASSIFICATION PREDICTION EFFECT

Data No.	Evaluating indicator	model 1	model 2	model 3	model 4	Model 5
Dataset 1	OA (%)	95.86	91.05	89.21	88.01	85.46
	AA (%)	97.90	92.13	88.92	87.64	86.12
	Kappa×100	95.21	91.79	89.64	86.94	85.96
Dataset 2	OA (%)	95.46	90.99	88.54	87.46	86.01
	AA (%)	94.68	91.28	89.46	88.00	85.75
	Kappa×100	96.71	92.03	88.23	87.89	86.23
Dataset 3	OA (%)	94.95	91.78	88.07	87.65	85.69
	AA (%)	95.23	90.89	89.46	87.12	86.49
	Kappa×100	96.62	91.56	88.33	88.04	85.36

Analysis of the data in Table 2 shows that the average OA value of the three data sets in model 1 is 95.27%, the average AA value is 95.94%, and the average Kappa value is 96.18%; the average OA value of the three data sets in model 2 is 90.94%, and the average AA value The value is 91.43%, and the average Kappa value is 91.79%; the average OA value of the three data sets in model 3 is 88.61%, the average AA value is 89.28%, and the average Kappa value is %; the average OA value of the three data sets in model 4 is 87.71%, the average AA value is 87.59%, the average Kappa value is 87.62%; the average OA value of the three data sets of model 5 is 85.72%, the average AA value is 86.12%, and the average Kappa value is 85.85%. Based on the data in the table, the overall accuracy (OA), average accuracy (AA) and Kappa coefficient of model 1 are higher than those of the other four models.

V. RESULTS AND DISCUSSION

With the rapid development of virtual technology and the wide application of various fields, immersive experience with a sense of presence has been widely developed. In order to evaluate the quality of VR video, the improved 3D-CNN was used to construct a VR video quality evaluation model. Through a series of experiments, the following results are obtained. Model 1 has the fastest decline speed and reaches the target loss value of 0.16 when the number of iterations reaches 62, while model 2 and model 3 both need more than 100 iterations to converge. The results show that the proposed model has good convergence performance. After the improvement, the Pearson correlation coefficient increased by 0.0412, Spearman coefficient increased by 0.0396, RMSE value decreased by 0.1207, and the predicted score curve

obtained by the improved model had a high coincidence degree with the subjective score. The results show that the improvement of the model can effectively reduce the prediction error of the model. The average prediction accuracy of the model trained after viewport cutting is 94.48%, the average missing rate is 9.19%, and the average error rate is 5.86%. This shows that the viewport cutting algorithm is reasonable and can effectively improve the model performance. The average OA value of the constructed model was 95.27%, average AA value was 95.94%, and average Kappa value was 96.18%, which could effectively and accurately evaluate the video quality. The number of VR video databases used in this study is limited, and more diverse sample videos can be found for testing and training in subsequent studies to further improve the model.

VI. CONCLUSION

To achieve more precise and accurate VR video quality evaluation, a VR video quality evaluation model based on improved 3D-CNN was constructed. Through the experimental analysis, it is known that the average OA value of the model constructed in the study is 95.27%, the average AA value is 95.94%, and the average Kappa value is 96.18%. It has high heterogeneity with VR video subjective quality score, and the prediction effect is better. Compared with the existing VR video quality evaluation methods, it has a strong competitiveness. In future studies, more diverse sample videos can be found for testing and training to further improve the model.

Abstract—With the rapid development of big data technology, information technology and visualization technology, traditional national headdress design has gradually been combined with it. The strategies and applications related to national headdress design also fully reflect the beauty of modern science and technology, which is a model of the combination of national classics and modern technology. Based on this, this paper will deeply analyze the various links and processes of the design based on the data based on the specific information of Yao ethnic headwear. At the same time, based on the existing visual design, this paper will take spring, hibernate and other systems as the basic software architecture of the design system and deeply study the visualization principles and data information visualization methods of spring, hibernate and other software, and carry out data information visualization processing on the relevant design of national headwear, to build the corresponding digital material library with national characteristics and the digital design process of national headwear. Through the digital processing and matching of the whole design, the current design of national headwear can be simplified and optimized, and the design efficiency can be improved to provide reference samples for the design of other national characteristics. In the specific design part, this paper will carry out design verification based on Yao nationality's corresponding characteristic headdress design and evaluate the corresponding design from the perspective of artistry, practicality and nationality of headdress design. The practice results show that the information visualization design of national headwear proposed in this paper has obvious advantages over the traditional design, which greatly improves the design efficiency and simplifies the design process.

Keywords—Information visualization; headwear national characteristics; digital material library; yao nationality characteristic headdress design

I. INTRODUCTION

With the rapid iterative development of information technology, visualization technology, as a new technology, is developed and integrated with a large number of disciplines and projects. Traditional information visualization technology processes the data, things, information, models and corresponding knowledge in the design process. It converts them into visual images and videos so that humans can understand through computers [1]. The corresponding data information visualization decision mainly uses visualization technology to transform the important data, decisions, judgments, predictions and corresponding models in the design

process so that they can be seen and understood by humans to provide clear, simple and scientific decision-making reference for decision-makers and designers [2], [3]. Conventional data information visualization technology imports the corresponding data into the preprocessing and processing data module [4], [5]. Then the data module analyzes and models it based on the corresponding data [6], carries out a large number of analogue-to-digital conversions, and carries out visual displays based on this digital information [7], [8] When this kind of software is actually running, it first carries out digital modelling processing for the corresponding processes that need modelling, which mainly includes digital conversion and mathematical statistics of the corresponding data, and then filters the corresponding data based on the statistical results, Through the corresponding query method, we can filter the data that need a visual operation, and finally create the corresponding visual interactive design chart. In the actual design and application, some data may also need the software to carry out the necessary data format conversion, to meet the specific conditions of data visualization [9], [10]. In a word, the development of data information visualization technology is of great significance to realize the scientific, convenient and scientific design process. At the same time, it is also of great significance to promote the corresponding culture and make people better understand the corresponding concepts [11].

Headwear with national characteristics is an important factor in reflecting the national characteristics, culture and customs [12], and it is also an important element to further distinguish this nation from other nations [13], [14]. The headdress with national characteristics reflects the unique aesthetic habits, religious customs and characteristic culture of the nation to a certain extent [15], which is the most distinctive embodiment of the nation. Ethnic minorities pay special attention to the design and dressing of headwear, so headwear also contains a lot of national stories, national changes and development, which itself has very important cultural significance, and it also has important value for the research and promotion of ethnic culture [16], [17]. However, the design of traditional national headwear is often limited to the representative endorsement and teaching of the traditional craftsman of the nation. Its way is too traditional, which makes a large number of craftsmanship techniques and headwear elements gradually lost in historical development, and even some headwear elements lost. Therefore, the design process, design elements and historical changes contained in the

corresponding national headwear Digital preservation of cultural elements are of great significance [18], [19]. Similarly, the personalized design of national headwear based on the national characteristic headwear data information database after complete digital processing is of great significance for the scientific, reasonable and efficient design of national cultural headwear, the inheritance of national cultural development, and the giving of new meaning and new life to national culture [20]. The deep combination of the national headdress design process and information data visualization technology is a model of efficient integration of classic and modern technology.

Visualizations of data that itself can have two-dimensional or three-dimensional semantics have been used for years before computers were used for visualization. Since the computer began to be used in visualization technology, many novel visualization techniques have been discovered and the existing ones have been improved. And the application field extends to large-scale data set visualization and dynamic interactive display. However, for most data stored in databases, there is no standard way to map data to a Cartesian coordinate system because the data has no fixed two-dimensional or three-dimensional semantic properties. In general, a relational database is viewed as a collection of multidimensional attribute data, with each dimensional attribute corresponding to the dimension of the coordinate. If three-dimensional orthogonal coordinates are used to represent visual data, visualization technology, distortion and interaction technology, then all data visualization technology can be considered as a combination of the above three. In this paper, the abstract information in the data table is transformed by visualization technology, that is, the data is stored in the form of visual structure, and the data is represented by multi-dimensional variable values. Different visualization methods will have different visualization structures. Finally, after mapping transformation, the graphical image of the composition is displayed, which also the final result is observed by the user. Each state of the data can be manipulated by the user through human-computer interaction, but the user's action does not change the fundamental structure of each data state.

Based on the above analysis and research, this paper will deeply analyze the various links and processes of the design based on the data and on the specific information of the headwear with Yao characteristics. At the same time, on the basis of the existing visual design, it will take spring, hibernate and other systems as the basic software architecture of the design system and deeply study the visualization principles and data information visualization methods of spring, hibernate and other software, and carry out data information visualization processing on the relevant design of national headwear, to build the corresponding digital material library with national characteristics and the digital design process of national headwear. Through the digital processing and matching of the whole design, the current design of national headwear can be simplified and optimized, and the design efficiency can be improved to provide reference samples for the design of other national characteristics. In the specific design part, this paper will carry out design verification based on Yao nationality's corresponding characteristic headdress design and evaluate the

corresponding design from the perspective of artistry, practicality and nationality of headdress design. The practice results shows that the information visualization design of national headwear proposed in this paper has obvious advantages over the traditional design, which greatly improves the design efficiency and simplifies the design process.

The structure of this article is arranged as follows: the second section of the article will mainly analyze and study the current research status of information visualization technology, national headdress design and other related concepts; The third section of the article will mainly analyze and study the national headdress design based on information visualization technology, focusing on the application of visualization technology and the digital process of national headdress design; The fourth section of the article will take the Yao characteristic headdress design as the object to practice, and compare it with the traditional design; Finally in fifth section the article will be summarized and prospected.

II. RELATED WORKS

With regard to the current situation of data information visualization technology and the design of headwear with national characteristics, the current main research focuses more on the research of isolated data information visualization technology and headwear with national characteristics, while the corresponding fusion research is relatively few. The research on information visualization technology is a hot research topic at present. A large number of scientific research institutions, scholars and universities have conducted a lot of discussion and Analysis on its integration with other disciplines [21]. The current visualization technology is mainly divided into scientific computing visualization technology, data information visualization technology, information visualization technology and scientific knowledge visualization technology. Relevant researchers at Stanford University in the United States have proposed traffic information data visualization technology for the corresponding traffic information technology, established a digital information database based on the corresponding traffic information data, and built a large number of data information models [22], [23]; Relevant travel companies in the United States have established corresponding traffic data information into visual dynamic data charts, realized the analysis and research of travel big data, and carried out research on transportation travel planning based on this analysis [24]; Relevant European researchers have combined visualization technology with medical imaging technology, which realizes three-dimensional imaging of medical images through visualization technology, and has been widely used in diagnosis and treatment planning [25]; Based on this, relevant research institutions in the United States have applied the corresponding visualization technology to the field of communication with medical patients and patients' families. They have built a visualization communication platform based on data visualization technology, which further solves the communication problems of medical problems and further alleviates the problems of doctors and patients [26], [27]. At the corresponding level of national headwear design, there are many relevant studies in this part of the Chinese Mainland. Still, the main research focuses on excavating and protecting the cultural meaning of headwear, and there is little literature to

discuss and analyze its design process. At the same time, the corresponding national headwear design and research are mostly focused on the research and analysis of traditional design methods. At the level of headwear research, Relevant scholars in the Chinese Mainland have analyzed and studied the specific national headdress design, mainly discussing the differences in headdress design behind different ethnic branches and its cultural connotation [28], [29]; Relevant scholars have studied the process and protective significance of headdress design for specific ethnic groups, but have not conducted in-depth research on its combination with modern technology [30]. Therefore, there is relatively little research on integrating information visualization technology and traditional ethnic headdress design, and in-depth research is of great value.

III. RESEARCH METHODOLOGY

This section mainly analyzes and studies the design process of the integration of information visualization technology and national headdress design, including the principle and application of information visualization technology and the national headdress design process based on the Yao nationality. Based on this, the corresponding research principal framework is shown in Fig. 1. It can be seen from the figure that the information visualization technology mainly includes data sorting and analysis, process data statistical analysis, data model establishment, digital data conversion, digital information screening, visual operation and processing, visual presentation and design evaluation. In the corresponding information visualization process, the processes that need to be modelled are first digitally modelled, mainly including the digital transformation and mathematical statistics of the corresponding data. The corresponding data are filtered based on the statistical results, and the data that need to be visually operated are filtered through the corresponding query methods. Finally, the corresponding visual interactive design charts are created. In the actual design and application, some data may also need software to perform necessary data format conversion to meet the specific conditions of data visualization. In the corresponding part of headwear design with national characteristics, it is mainly necessary to carry out data statistics on the relevant element information of headwear, digitally present the corresponding abstract and specific design elements and the corresponding design process, and transform the important data of national headwear, the decision-making of designers, the judgment of designers, the prediction of designers and the corresponding models in the whole design process, so that they can be seen and understood by human beings, To provide clear, simple and scientific decision-making reference for national headdress designers. From the corresponding principal block diagram in Fig. 1, it can be further seen that the design verification analysis in this paper is mainly based on the characteristic headwear of the Yao Minority in the Chinese Mainland. It mainly compares the corresponding design process and design results, design evaluation and traditional design process, and design results and design evaluation proposed in this paper. The main analysis indicators include design efficiency and scientificity [31]. The design method proposed in this paper has obvious advantages from the corresponding design results. In addition,

it can be further seen from Fig. 1 that the visualization software used in this paper is Spring and Hibernate, and its integration application in information visualization technologies and other fields has been widely verified [32].

A. Application Analysis of Information Visualization Technology

Based on the analysis of national headwear and on the information visualization technology proposed in this paper, the corresponding information visualization technology is defined as information visualization interactive design [33]. It is combined with the corresponding characteristics of national headwear design and the corresponding design factors, the corresponding information visualization interactive design technology is divided into five levels, corresponding to the strategic demand level of headwear design, the demand range level of national headwear design, the structure level of national headwear design, the frame layer of national headdress design and the expression layer of national headdress design [34]. Based on this, the information visualization technology flow chart of the corresponding national headdress design is shown in Fig. 2.

In the corresponding strategic demand level of national headwear design, the corresponding needs is to analyze the specific design elements of national headwear in detail, including the cultural heritage, cultural stories, national customs, etc. the corresponding part of the national headwear design is the ultimate goal of this part of the design [35]. For national headwear designers, they can get the corresponding design goals through this part, get the corresponding other design goals based on this design goal, and extend and analyze the economic benefits on the basis of the design goals expected by the designers to make the national headwear design finally have a focus at the beginning of the design.

The range of national headwear design needs level, which is mainly the analysis of national headwear design needs [36]. The corresponding demand objects are different, and the design concepts they face are also different. For the people of this nationality, the corresponding headdress needs to maintain the original flavour, fully reflect the specific cultural characteristics of this nationality, and reflect the cultural connotation and cultural story behind this nationality; For other nationalities, it is necessary to fully meet the curiosity of such people about the national characteristics, meets the combination of national characteristics like aesthetics and modern art, and reflect the artistic beauty of the combination of classics and modernity, to give new historical significance and cultural inheritance to national headwear, and reflect the aesthetic vitality of National headwear in the new era.

The corresponding national headdress design structure layer mainly includes the interaction structure and information structure of the national headdress design. The corresponding national headdress information architecture not only includes the interface display of the front-end design but also includes the information exchange, information storage and display of the background of the design system. In this part, the design system needs to fully respond to the designer's design needs and meet the designer's convenient, fast and scientific concept for national headwear design.

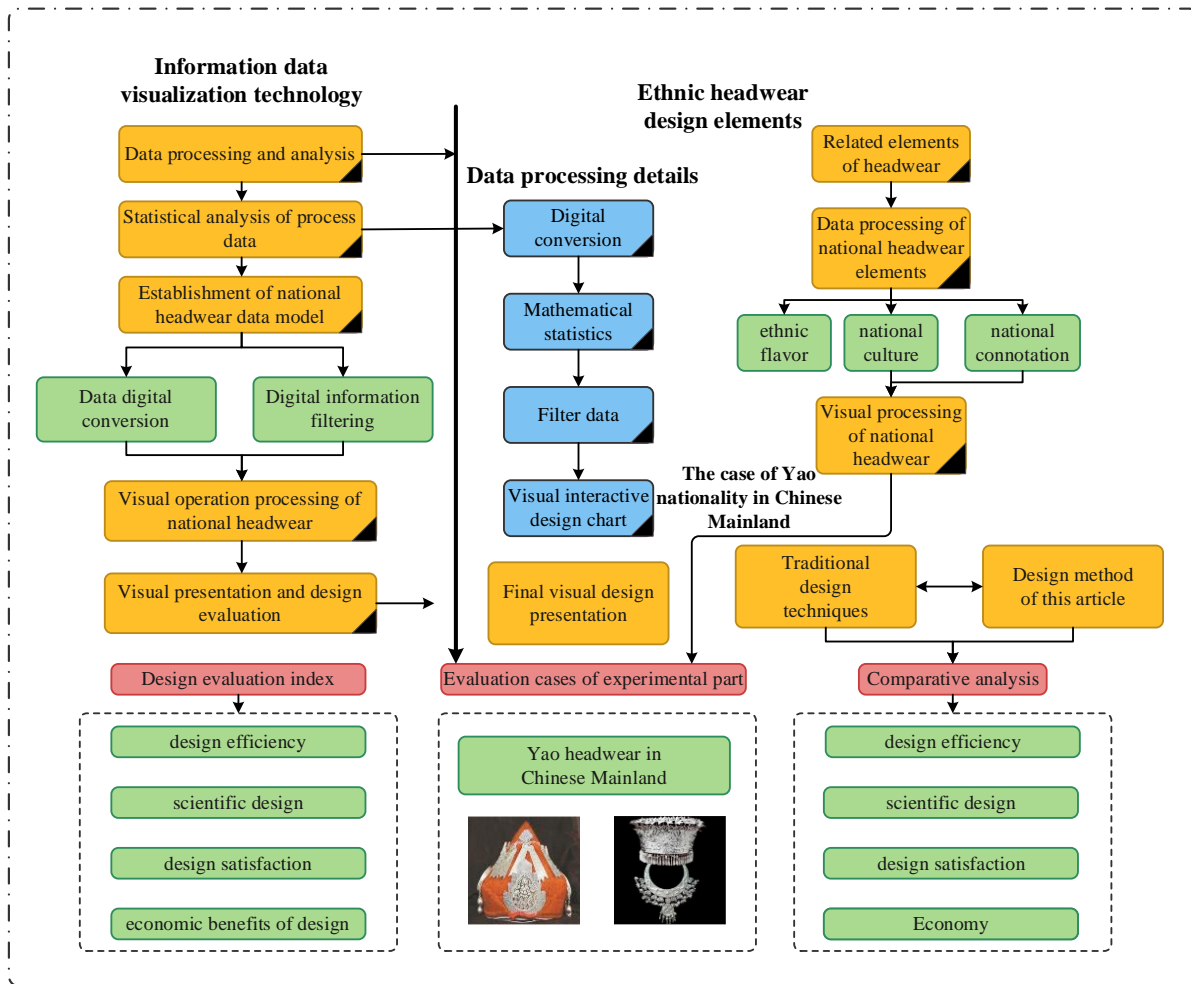

Fig. 1. Principal block diagram of the integration of information visualization technology and national headdress design.

Fig. 2. Design flow chart of information visualization technology for national headdress design.

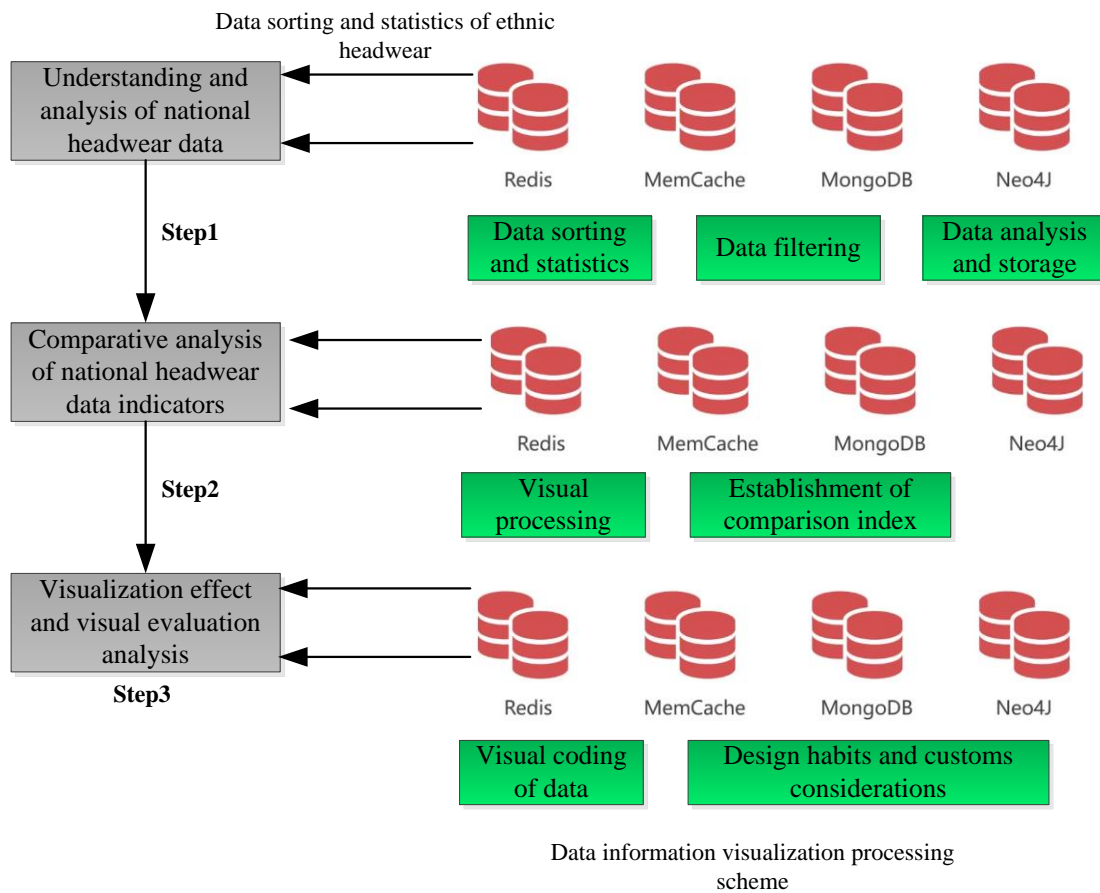

Fig. 3. Design flow chart of data visualization technology for national headdress design.

The corresponding national headwear design framework level mainly includes the interface framework structure of national headwear design and the corresponding process design, including determining various interface control forms, process design, routine condition process and abnormal condition process.

The corresponding performance level of national headdress design, this level mainly focuses on the embodiment of the visual level of national headdress design, that is, the visual presentation of the final headdress design effect [37]. At this level, the designer needs to adjust, analyze and deal with the relevant needs of the demander.

In order to further optimize its visualization processing of national headwear-related data, this paper not only uses information visualization processing but also adopts data visualization technology analysis. The corresponding analysis process is shown in Fig. 3. From the figure, it can be seen that the actual process of national headwear data visualization analysis is mainly divided into national headwear data understanding and analysis, Comparative analysis of national headwear data indicators, as well as visualization effect and visualization evaluation analysis. At the level of understanding and analyzing the corresponding national headwear data, it is mainly to screen, analyze and store a large number of collected data, correctly sort out the relationship between relevant data, and analyze the correctness and scientificity of relevant data;

At the level of comparative analysis of corresponding national headwear data indicators, visualization tools are mainly used to process the corresponding data visually. In this process, appropriate comparative indicators need to be established as a reference; In the corresponding visual data level, it is mainly to encode different data of national headwear visually. In this process, it is necessary to strictly follow the designer's design habits and customs of national headwear.

Based on the above analysis, the relevant data information on national headdress design can realize visualization technology to better provide design services for designers and make the national headdress design process simpler and more scientific.

B. Construction of National Headdress Design System based on Information Visualization Technology

This section mainly realizes the construction of the national headdress design system based on the information data visualization technology, and the corresponding system operation framework is shown in Fig. 4. The corresponding whole system integrates information visualization technology and data visualization technology. It mainly includes a national headdress design performance layer, national headdress design control layer, national headdress design service layer, national headdress design data access object layer and national headdress design database layer. In the corresponding performance layer of national headwear design, it is mainly the

top layer of the system, which is mainly used to collect, sort out and count all kinds of data information and cultural information about national headwear. At the same time, it also needs to interact with other layers to realize the visual processing of national headwear data information, and its corresponding display form is mainly based on visual charts; The corresponding national headdress design control layer is mainly used to process designer design requests and corresponding design process business management [38]. At the same time, data access is realized by accessing the database layer. In this paper, the IOC container in spring is mainly used to manage Dao components and corresponding business logic components; In the corresponding ethnic headwear design service layer, which is mainly located below the control layer, it mainly provides the corresponding design interface for the control layer to call and process, so as to complete the functional design of the ethnic headwear design application module and realize the processing and analysis of the actual design business operation; The corresponding national headwear design data access object layer is mainly used to realize the persistent processing of national headwear data, so that the corresponding design data can be independent of the application program or the business logic of the system design, so that the system data can be easily expanded and run independently; The corresponding national headdress design database layer mainly stores the data in the relational database, which mainly adopts hibernate as the corresponding persistence processing framework.

In addition to the overall design of the system, the database design of the system is equally important. The database data corresponding to the system proposed in this paper comes from the collation and statistics of a large number of design details,

constituent elements, cultural stories and cultural connotations of national headwear. The interface between the corresponding design elements and the design system is processed by web service in this paper. After the actual data sorting and statistics, it is necessary to preprocess and analyze the corresponding headwear information data to obtain the potentially important factors of headwear design in advance. The corresponding data processing process includes the cleaning, screening, selection and corresponding transformation of the original data to ensure the accuracy of the data as much as possible and reduce the time for the designer to query the element data in the actual design. Improve the efficiency of national headdress design. The corresponding data management module mainly includes the system data management module, system data statistics module, system data monitoring module and system data comparison module. The corresponding system data management module mainly realizes the sorting, statistics and distribution of national headwear related data; The corresponding system data statistics module mainly realizes the classification and storage of national headwear related design elements, as well as the storage and memory of corresponding design preferences; The corresponding system data monitoring module is mainly to realize the online monitoring of the use of the corresponding design process data information, so as to avoid some low-level errors and cultural errors at the design level; The corresponding system data comparison module is mainly to compare the final designed finished product with the classic national headdress design, the needs of the demander and other relevant data, so as to assist the designer to complete the design evaluation of the final work, so as to ensure that the designed national headdress not only conforms to the national characteristics of the nation, but also meets the needs of the demander, and improve the satisfaction of the design.

IV. RESULTS AND DISCUSSION

A. Evaluation Results

To further verify the design advantages of ethnic headwear based on information visualization technology proposed in this paper, this paper selects Yao nationality as a sample for design comparison. The Yao nationality has a long history of national culture, and its headdress design is unique and has rich cultural connotations and aesthetic characteristics. Before the comparative analysis of the actual design, this paper fully collates the pattern, texture, colour, shape and corresponding structural design of the headdress with Yao national characteristics. It makes a statistical analysis of its important elements. Based on the comparative analysis of one of the headwear of the Yao nationality, the e-crown hat, the design process of this paper is compared with the traditional manual design process. The main comparison indicators include the nationality score of the design works, the artistic score of the design works, the practical score of the design works, and the economic score of the design work.

In terms of the nationality of the corresponding design works, questionnaires, visits and other methods are mainly used to show the works under the two design methods, invite the corresponding ethnic and non-ethnic people to score, and take the corresponding average score for evaluation. Based on this, the corresponding evaluation results are shown in Fig. 5. From the figure, it can be seen that the products designed by the design process proposed in this paper have slight advantages in nationality compared with the traditional design

process. The reason is analyzed. It mainly reproduces some complex design patterns lost in the early years.

In terms of the artistry of the corresponding design works, questionnaires, visits and other methods are mainly used to actually display the works under the two design methods, invite the corresponding ethnic, non-ethnic and professional people to score, and take the corresponding average score for evaluation. Based on this, the corresponding evaluation results are shown in Fig. 6. From the figure, it can be seen that the products designed by the design process proposed in this paper have obvious advantages in artistry compared with the traditional design process. Analyze the reasons. The design process proposed in this paper combines aesthetics under modern technology, and its psychological positioning for the demander is more accurate.

In terms of the practicality of the corresponding design works, questionnaires, visits and other methods are mainly used to actually display the works under the two design methods, invite the corresponding ethnic, non-ethnic and professional people to score, and take the corresponding average score for evaluation. Based on this, the corresponding evaluation results are shown in Fig. 7. From the figure, it can be seen that the products designed by the design process proposed in this paper have obvious practical advantages compared with the traditional design process. The reason is analyzed. The design process proposed in this paper combines data visualization technology and information visualization technology, which is more accurate for the demand positioning and processing of the demander.

Fig. 5. Comparative analysis of the nationality of design works.

Fig. 6. Comparative analysis of artistic aspects of design works.

Fig. 7. Comparative analysis of practical aspects of design works.

In terms of the economy of the corresponding design works, questionnaires, visits and other methods are mainly used to actually display the works under the two design methods, invite the corresponding ethnic, non-ethnic and professional people to score, and take the corresponding average score for evaluation. Based on this, the corresponding evaluation results are shown in Fig. 8. From the figure, it can

be seen that the products designed by the design process proposed in this paper have obvious advantages in the economy compared with the traditional design process. The reason is analyzed. The design process proposed in this paper realizes the batch design and production of national headwear design, which greatly saves human design costs and reflects the advantages of modern technology at the design level.

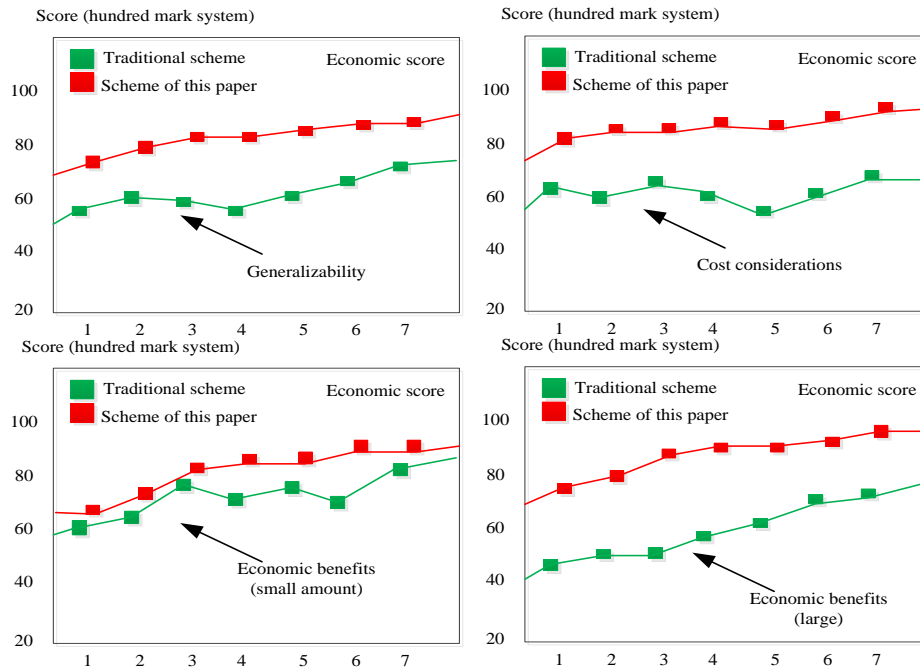

Fig. 8. Comparative analysis of economic aspects of design works.

Based on the above experimental results, it can be found that the national headdress design idea based on information visualization technology proposed in this paper has obvious advantages over traditional design methods, and it is of great significance for further promotion and inheritance of national culture.

B. Discussion

Visualization originates from the promotion and development of computer graphics, user interface and other research fields. Visualization technology refers to the use of computer technology to transform data into graphic form, and to transform abstract things or processes into graphics or images. With the support of computer, information visualization can express abstract data in an interactive visual way, so that people can deepen the cognitive process of data. Visualization technology is widely used in various fields. It presents data in a multidimensional form, which is more conducive to discovering the characteristics of data distribution and its potential semantic relations. Therefore, how to visualize data reasonably in the data space so that users can browse and explore these data conveniently and quickly has become a research hotspot in recent years.

In a computer, information is expressed in a certain structure to facilitate people to store, modify, query, add or delete information and other operations. As a widely used data structure, graph can be used to represent a variety of complex system models. It is basically composed of nodes and edges, where nodes are used to represent the abstraction of entities, and edges connecting nodes are used to represent the relationship between corresponding entities. Uniform, beautiful graphics are very important for understanding and analyzing data. Graph layout algorithm is the basis of graph visualization, and its performance is very important to the effect of data display. At present, most of the algorithms used in graph

visualization draw graphs simply based on the structure of the graph, that is, the connectivity between points. In the personal dataspace system, there are not only structural relations between entities, but also attribute relations determined by their own attributes, so it can also be considered to draw graphs through attribute relations.

National culture is a splendid treasure of China. Each nation has its own unique beauty, which brings us rich and different feelings. The Yao nationality has also shown us its unique national charm, carrying its material and spiritual civilization on its traditional headwear and expressing it with its unique artistic form language. From the shape features of the headwear to the decorative art, all reflect the Yao people's pursuit of beautiful things and longing for the future life. Yao traditional headwear is a very valuable intangible cultural heritage of the motherland. Their wealth is turned into silver ornaments decorated on the headwear. The art of headwear not only has practical application functions, but also is the carrier of Yao civilization. The perfect combination of its function and art is reflected incisively and vividly in the shape and decoration of the headdress.

V. CONCLUSION

Based on the existing visual design, taking spring, hibernate and other systems as the basic software architecture of the design system, this paper deeply studied the visualization principle and data information visualization method of spring, hibernate, and other software and the relevant design of national headwear is visually processed with data information, to build the corresponding digital material library with national characteristics and the digital design process of national headwear. Through the digital processing and matching of the whole design, the current design of national headwear is simplified and optimized, and the design efficiency is

improved to provide reference samples for other national designs. In the specific design part, this paper mainly carries out the design verification based on the corresponding characteristic headdress design of the Yao nationality. It evaluates the corresponding design from the perspective of artistry, practicality and nationality of headdress design. The practice results show that the information visualization design of national headwear proposed in this paper has obvious advantages over the traditional design, which greatly improves the design efficiency and simplifies the design process. In the follow-up research, this paper will pay attention to more national headwear and conduct practical analysis and research based on the design process proposed in this paper. At the same time, this paper will also pay attention to the design process of national clothing and try to combine it with information data visualization technology. In the follow-up research, this paper will also focus on the protection of national culture, design thinking at the level of national culture mining, and realize the processing of corresponding cultural protection and cultural inheritance by collecting more specific data so that the design process proposed in this paper becomes the development of traditional design ideas.

When the amount of data increases, the number of layers increases, resulting in too long edges, which not only makes the drawing space not fully utilized, but also makes the whole graph relatively chaotic. In the future work, we can consider the clustering of nodes and then stratification to reduce the amount of data displayed. In addition, this paper only completed the graph drawing in two-dimensional space. In order to display the graph more aesthetically, the algorithm can be extended to three-dimensional space, and the parameters used in the algorithm can be further optimized to improve the overall efficiency of the algorithm.

Liuzhou Cigarette Factory, China Tobacco Guangxi Industrial Co., Ltd., Liuzhou, Guangxi, 545005, China

Abstract—The study focuses on the laser radar SLAM mapping method employed by the tobacco production line inspection robot, utilizing an enhanced RBPF approach. It involves the construction of a well-structured two-dimensional map of the inspection environment for the tobacco production line inspection robot. This construction aims to ensure the seamless execution of inspection tasks along the tobacco production line. The fusion of wheel odometer and IMU data is accomplished using the extended Kalman filter algorithm, wherein the resulting fused odometer motion model and LiDAR observation model jointly serve as the hybrid proposal distribution. In the hybrid proposal distribution, the iterative nearest point method is used to find the sampling particles in the high probability area, and the matching score during particle matching scanning is used as the fitness value, and the Drosophila optimization strategy is used to adjust the particle distribution. Then, the weight of each particle after optimization is solved, and the particles are adaptively resampled according to the size of the weight after solution, and the inspection map of the inspection robot of the tobacco production line is updated according to the updated position and posture information and observation information of the particles of the inspection robot of the tobacco production line. The experimental results show that this method can realize the laser radar SLAM mapping of the tobacco production line inspection robot, and it can build a more ideal two-dimensional map of the inspection environment of the tobacco production line inspection robot with fewer particles. If it is applied to practical work, a more ideal work effect can be achieved.

Keywords—Improved RBPF; tobacco production line; patrol robot; LiDAR; slam mapping; drosophila optimization strategy

I. INTRODUCTION

The inspection robot of tobacco production line can replace manual work to realize remote routine inspection [1]. In case of accidents and special circumstances, it can realize special inspection and customized inspection tasks, and realize remote online monitoring [2]. While reducing manual work, it can greatly improve the content and frequency of operation and maintenance, change the operation and maintenance mode of traditional tobacco production line, realize the intelligent operation and maintenance of tobacco production line, and greatly promote the development of tobacco enterprises [3]. Simultaneous Localization and Mapping (SLAM) technology has always been considered as the most critical step in achieving fully autonomous navigation of robots [4]. As a basic problem of tobacco production line patrol robots, laser

radar SLAM mapping is a prerequisite for tobacco production line patrol robots to achieve other functions. Whether the laser radar SLAM mapping of the tobacco production line patrol robot can be achieved well or not, to a large extent, determines whether the tobacco production line patrol can be successfully completed [5]. Therefore, it is very necessary to study an effective laser radar SLAM mapping method of the tobacco production line patrol robot to help the tobacco production line patrol work. Tobacco production line inspection robots need to obtain real-time environmental information and accurately locate themselves in the production line to effectively perform tasks. The LiDAR SLAM mapping method can realize simultaneous localization and map construction, so it is an ideal choice for tobacco production line inspection robots.

In response to the above problems, many scholars have carried out a lot of effective research, such as the map centered SLAM mapping method of intensive 3D laser anti-radar for tobacco production line patrol robots proposed by Park et al. [6], the active SLAM new method of tobacco production line patrol robots using laser radar to draw maps proposed by Malobick et al. [7], low delay laser radar SLAM for tobacco production line patrol robot using continuous scanning slices proposed by Karimi et al. [8], active SLAM method for tobacco production line patrol robot based on convolutional neural network proposed by Bol et al. [9], SLAM method for tobacco production line patrol robot based on embedded system on chip 3D positioning and mapping researched by Gerlein et al. [10]. Park et al., in their research on the laser radar SLAM mapping method of the tobacco production line inspection robot, took the map as the center, overcome the shortcomings such as the laser radar motion distortion through the local continuous time trajectory, and used the surface resolution maintenance matching algorithm and the surface fusion model based on the normal inverse Wisart to achieve non redundant but dense mapping. The traditional map centered laser radar SLAM method of tobacco production line inspection robot is improved. On the basis of realizing the laser radar SLAM mapping of tobacco production line inspection robot, the accuracy of laser radar SLAM mapping is significantly improved. Malobick et al. used the laser radar as the main sensor in their research on the laser radar SLAM mapping method of the tobacco production line inspection robot. After mapping the inspection environment of the tobacco production line inspection robot, they created a corresponding grid map to navigate the tobacco production line inspection robot system. In Karimi et al.'s research on the laser

radar SLAM mapping method of the tobacco production line inspection robot, 2D Lisaru rotation mode was used to drive the laser radar mounted on the tobacco production line inspection robot, and slice point cloud data from the rotating laser radar was used in the multithreaded matching pipeline for 6D attitude estimation with high update rate and low delay. At the same time, the attitude estimation uses the time motion predictor to better find the feature correspondence in the mapping. The experimental nonlinear optimizer converges quickly, and then completes the attitude fusion operation by using the extended Kalman filter algorithm. Finally, the robot patrol map is updated according to the obtained position and attitude and observation values; In the research of the laser radar SLAM mapping method of the tobacco production line inspection robot by Bol et al., a data set composed of environmental images and the wheel angles related to these environmental images is used to train the convolutional neural network structure so that the convolutional neural network model can learn how to guide the tobacco production line inspection robot. Then, in the inspection environment of tobacco production line inspection robot, it can navigate autonomously through convolutional neural network and obtain corresponding maps at the same time. Gerlein et al. followed a joint design method in their research on the laser radar SLAM mapping method of the tobacco production line inspection robot. By deploying a programmable 3D positioning and mapping chip in the tobacco production line patrol robot system, the laser radar SLAM of the tobacco production line patrol robot is realized, which effectively improves the SLAM mapping efficiency while maintaining a high mapping accuracy. The above methods can realize the laser radar SLAM mapping of tobacco production line inspection robot, but the mapping effect is not ideal.

The improved RBPF (Rao Blackwelled particle filter) is applied to the laser radar SLAM mapping of the tobacco production line inspection robot, which can yield more ideal results of the laser radar SLAM mapping of the tobacco production line inspection robot. Therefore, this paper proposes a laser radar SLAM mapping method for tobacco production line inspection robot based on improved RBPF to better meet the actual work needs. The wheel odometer and IMU data are fused using the extended Kalman filter algorithm, and the fusion odometer motion model and LiDAR observation model are used as the hybrid scheme distribution. In the mixed scheme distribution, the iterative nearest point method is used to find the sampled particles in the high probability region, and the matching score of the particle matching scan is taken as the adaptation value. Then, the Drosophila optimization strategy is used to adjust the particle distribution, and the weight of each optimized particle is solved. According to the weight of the solution, we adaptively do resampling. Finally, the detection map of the production line detection robot is updated according to the updated position and attitude information and the observation information of the tobacco production line detection robot particles.

II. LASER RADAR SLAM MAPPING OF TOBACCO PRODUCTION LINE INSPECTION ROBOT

A. Introduction to RBPF-SLAM Algorithm

In the problem of laser radar SLAM mapping of tobacco production line inspection robot, the theory of probability can be used to mitigate the impact of uncertain factors on the results [11]. Particle filter is not limited by linear Gaussian system, so it can be applied to any nonlinear non Gaussian dynamic system, and has reliable effect in target tracking and positioning [12]. The particle filter RBPF method is applied to the problem of laser radar SLAM mapping of tobacco production line patrol robots. The problem of laser radar SLAM mapping is decomposed into the problem of positioning of tobacco production line patrol robots and the problem of building environmental feature maps based on pose estimation, which can significantly reduce the computational complexity of laser radar SLAM mapping of tobacco production line patrol robots, and has super robustness. It is especially suitable for completing the laser radar SLAM mapping of the tobacco production line inspection robot in small and medium-sized scenes [13].

The core idea of the RBPF-SLAM algorithm is to describe the SLAM problem as a posterior probability of the trajectory in the form of probability [14]. In practical work, the RBPF-SLAM algorithm mainly uses the observation information of the laser radar sensor and the information of the wheel odometer to estimate the environment map m position and posture status of inspection robot in tobacco production line the joint posterior probability of $x_{1:t}$ [15] can be described as $p(x_{1:t}, m | z_{1:t}, u_{1:t-1})$, where, $z_{1:t}$ is marked with observation information obtained by LiDAR, including:

$$z_{1:t} = z_1, z_2, \dots, z_t \quad (1)$$

Among them, z_1 , z_2 as well as z_t refers to each element in the observation information sequence.

$u_{1:t-1}$ is marked with odometer information, including:

$$u_{1:t-1} = u_1, u_2, \dots, u_{t-1} \quad (2)$$

Among them, u_1 , u_2 as well as u_{t-1} are the elements in the odometer information sequence. The RBPF particle filter can be decomposed as follows by using Bayesian formula:

$$p(x_{1:t}, m | z_{1:t}, u_{1:t-1}) = p(m | x_{1:t}, z_{1:t}) p(x_{1:t} | z_{1:t}, u_{1:t-1}) \quad (3)$$

In formula (3), the environment map m trajectory of inspection robot for tobacco production line $x_{1:t}$ the joint posterior probability of is decomposed into the product of two independent posterior probabilities. The motion trajectory of the tobacco production line inspection robot is estimated first, and then the environment map is updated from the motion trajectory combined with the observation data. Among them,

$p(x_{1:t} | z_{1:t}, u_{1:t-1})$ is the posterior probability of the motion path, $p(m | x_{1:t}, z_{1:t})$ is a posteriori probability of the map. Particle filter is required to estimate the potential motion trajectory. At the same time, each particle has a motion trajectory. The final environment map is constructed from the movement tracks of these particles and the observation of the system.

The solution of $p(m | x_{1:t}, z_{1:t})$ is usually based on the extended Kalman filter algorithm, which uses occupancy grid mapping and reverse sensor model to generate planar grid maps, m is divided into a finite number of mesh elements m_i , where each cell contains a value that represents the probability of its being occupied $p(m_i)$, whose values range from "0" to "1". "0" means not occupied, and "1" means fully occupied. The posterior probability density of the map can be approximated as:

$$p(m | x_{1:t}, z_{1:t}) = \prod_i p(m_i | x_{1:t}, z_{1:t}) \quad (4)$$

Among them, i represents the number of particles.

$p(x_{1:t} | z_{1:t}, u_{1:t-1})$ using particle filter algorithm to solve it means that a particle will represent a potential trajectory in a time step and generate a map at the same time. According to Bayesian criteria to have the formula derivation of $p(x_{1:t} | z_{1:t}, u_{1:t-1})$:

$$p(x_{1:t} | z_{1:t}, u_{1:t-1}) = \eta p(z_t | x_t) p(x_t | x_{t-1}, u_t) p(x_{t-1} | z_{1:t-1}, u_{1:t-1}) \quad (5)$$

Among them, η is marked with normalization factor; $p(x_{1:t-1} | z_{1:t-1}, u_{1:t-1})$ represents the trajectory of the tobacco production line inspection robot at the previous time, represented by the particle swarm at the previous time; $p(x_t | x_{t-1}, u_t)$ indicates that the tobacco production line inspection robot is in the $t-1$ Position and posture at every moment x_{t-1} Tobacco production line inspection robot $t-1$ reach t time odometer data u_t when known, the tobacco production line inspection robot t time position and posture the probability distribution of x_t ; $p(z_t | x_t)$ represents the probability distribution of sensor observation data.

In actual work, the environment map of tobacco production line inspection robot is known m with the tobacco production line inspection robot t time position and posture x_t is available

$p(z_t | x_t, m)$ indicates sensor observation data of the probability distribution of z_t . Since many mobile robots are driven by independent translational and rotational speeds, the speed motion model is used for mileage distribution in this paper. After a series of derivation, the trajectory estimation of the tobacco production line inspection robot can be transformed into the corresponding incremental estimation problem. After obtaining the trajectory of the tobacco production line inspection robot, the map is constructed according to the estimated trajectory and observation data.

The RBPF-SLAM algorithm uses the sequential importance resampling filter to estimate the position and pose of the tobacco production line patrol robot and update the environment map. The specific process can be divided into the following four steps:

1) Sampling: as proposed distribution based on motion model $q(x_{1:t}^{(i)} | z_{1:t}, u_{1:t-1})$ sampling, $x_{1:t}^{(i)}$ is the pose of the particle. By particle set $\{x_{t-1}^{(i)}\}$ generate next generation particle sets $\{x_t^{(i)}\}$, where $i = 1, 2, \dots, N$, N is the total number of particles.

2) Weight solving. Resampling according to importance requires solving the weight of each particle $w_t^{(i)}$, the calculation formula is:

$$w_t^{(i)} = \frac{p(x_{1:t} | z_{1:t}, u_{1:t-1})}{q(x_{1:t}^{(i)} | z_{1:t}, u_{1:t-1})} \quad (6)$$

3) Resample. Resampling is performed according to the size of the solved importance weight to form a new particle set. The total number of particles remains unchanged, and each particle has the same weight after resampling N .

4) Map update. Pose of passing particles $x_{1:t}^{(i)}$ and observations $z_{1:t}$ to update the corresponding map $p(m^{(i)} | x_{1:t}^{(i)}, z_{1:t})$.

B. Improve the Laser Radar SLAM Mapping of RBPF Tobacco Production Line Inspection Robot

a) Information Fusion of Odometer and IMU: In this paper, EKF (Extended Kalman Filter) algorithm is used to estimate the position and pose information of mobile robots, and the state model of position and pose fusion is established using wheel odometer and IMU. Since the odometer and IMU data both contain the steering angle and speed information of the mobile robot, the pose state vector of the tobacco production line patrol robot can be described as:

$$x_t = (X_t, Y_t, \theta_t, v_x^t, v_y^t, \omega_t)^T \quad (7)$$

Among them, tobacco production line inspection robot of the position t , attitude and speed information of the time are respectively used (X_t, Y_t, θ_t) , (v'_x, v'_y, ω_t) to mark; T stands for transposition.

If the system status at the moment t is x_t , control input is $(v'_x, v'_y, \omega_t)^T$, and within a certain period of time Δt if it remains unchanged within a certain period of time, then after Δt , the tobacco production line inspection robot $t+1$ the position and posture at all times shall be x_{t+1} . Therefore, the EKF state transfer equation can be obtained as follows:

$$x_{t+1} = x_t + \begin{pmatrix} \Delta t & 0 & 0 \\ 0 & \Delta t & 0 \\ 0 & 0 & \Delta t \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} (v'_x, v'_y, \omega_t)^T \quad (8)$$

Since the odometer data can be obtained directly, the corresponding prediction equation can be obtained as follows:

$$z_{odom,t} = H_{odom} x_t = I_6 (X_t, Y_t, \theta_t, v'_x, v'_y, \omega_t)^T + e_{odom,t}(d) \quad (9)$$

Among them, the predicted value of wheel odometer $z_{odom,t}$ is marked; Prediction matrix of wheel odometer I_t use H_{odom} to mark; $e_{odom,t}(d)$ is the error of the wheel odometer, which obeys the covariance matrix of Gaussian distribution.

In this paper, we only study the environment map in two-dimensional space, so we only need the Z-axis data in the three-axis for IMU, so the prediction equation of IMU can be described as:

$$\begin{aligned} z_{IMU,t} &= H_{IMU,t} x_t \\ &= \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} (X_t, Y_t, \theta_t, v'_x, v'_y, \omega_t)^T + e_{IMU,t} \\ &= \begin{pmatrix} \theta_t \\ \omega_t \end{pmatrix} + e_{IMU,t} \end{aligned} \quad (10)$$

Among them, $z_{IMU,t}$ IMU predicted value is marked; $H_{IMU,t}$ IMU prediction matrix is marked; $e_{IMU,t}$ IMU prediction error is marked, which obeys Gaussian distribution covariance matrix.

The prediction equation of the system can be obtained by combining the prediction equation of the wheel odometer and IMU, which can be described as:

$$z_t = \begin{pmatrix} z_{odom,t} \\ z_{IMU,t} \end{pmatrix} = \begin{pmatrix} H_{odom,t} \\ z_{IMU,t} \end{pmatrix} x_t + \begin{pmatrix} e_{odom,t}(d) \\ e_{IMU,t} \end{pmatrix} \quad (11)$$

By substituting the state transition equation and prediction equation of the position and posture information of the tobacco production line patrol robot into the Kalman filter formula, the position and posture of the tobacco production line patrol robot can be accurately estimated.

b) Distribution of Improvement Proposals: In general, the target distribution is more difficult to obtain an analytical solution than the proposed distribution. Therefore, in practical work, the proposed distribution is often introduced and sampled to approximate the target distribution according to the weight of particles and resampling [16]. The closer the proposed distribution is to the target distribution, the better the effect of particle filter will be [17]. In the RBPF-SLAM algorithm described above, the motion model of the inspection robot in the tobacco production line is regarded as the proposed distribution, and the particle weight is calculated according to the observation model of the inspection robot in the tobacco production line. This method of sampling from the motion model of the inspection robot in the tobacco production line, although relatively simple in calculation, is not accurate. Since the tobacco production line inspection robot will be equipped with a laser radar and a odometer, and the observation accuracy of the laser radar is far higher than the odometer accuracy, as shown in Fig. 1, the probability distribution density function of the odometer model has a wide span and is low and flat, while the probability distribution density function of the laser radar observation model has a small span and is high and sharp. If only the odometer model is used for sampling, a large number of particles will be in meaningless areas. After resampling, these meaningless particles will be discarded. There are fewer particle types in meaningful areas, making the effect of particle filtering worse.

Fig. 1. Legend of distribution density function for LiDAR and odometer measurement models

For this reason, the LiDAR observation value is considered when sampling particles z_t to improve the proposal distribution, and describe the improved proposal distribution as:

$$\Gamma(x_t) = p(z_t | x_t, m^{(i)}) p(x_t | x_{t-1}^{(i)}, u_t) \quad (12)$$

Among them, $\Gamma(x_t)$ is marked the proposed distribution after improvement; $x_{t-1}^{(i)}$ marks the first generation of the previous generation i particles; $m^{(i)}$ is according to the previous generation i current environment map estimated by particles; u_t is according to the previous generation i current odometer information estimated by particles.

After improvement, the proposed distribution comprehensively considers odometer information and LiDAR observation information, and concentrates particles in the high probability interval, which improves the quality of particle set.

c) *Laser Information Scanning Matching*: Considering the characteristics of laser radar scanning, this paper introduces the scanning matching method to calculate the transformation between adjacent laser frames. Scanning matching is to compare two different laser frame information and register them. In other words, it is to find a suitable rotation and translation method, which corresponds the points between different laser frames one by one to get the rotation and translation information of the inspection robot in the tobacco production line. Here, the estimated information of particles is used to register with the laser information, and the analytical formula of the LiDAR distribution is obtained to avoid the error caused by the EKF linearization method.

At present, the commonly used and effective scanning matching method is the iterative closest point method (ICP) [18]. Its principle is the optimal matching based on the least square method, and its main contents include: determining the corresponding relationship of each point cloud data; Calculating transformation matrix; Find the minimum error until the error reaches the set threshold. The specific solution steps are as follows:

1) First, suppose that the laser radar carried by the tobacco production line inspection robot is t the laser data and particle prediction data scanned at any time are L, C , and has:

$$L = \{l_1, l_2, \dots, l_n\} \quad (13)$$

$$C = \{c_1, c_2, \dots, c_n\} \quad (14)$$

Among them, l_1, l_2 as well as l_n are points in the laser data, n marked is the number of points; c_1, c_2 as well as c_n marked are the points in the particle prediction data.

In actual work L as t template point set at time, C as t the set of punctual points to be allocated at the time. About C and L select the point with the smallest Euclidean distance as the corresponding point, and add it to the temporary matching point set.

2) Decentralize each point set to solve L, C and mark their centroids as u_L, u_C , then remove u_L, u_C from L, C .

3) After knowing the corresponding relationship of each point set, solve the objective function shown in equation (15).

$$E(R, T) = \frac{1}{n_C} \sum_{i=1}^{n_C} \|l_i - Rc_i - T\|^2 \quad (15)$$

Among them, $E(R, T)$ the scanning matching error function is marked; For the rotation matrix of point set R to mark; The translation matrix of the point set is used T to mark; l_i, c_i is the corresponding point in the temporary corresponding point set; n_C is marked the number of data points in the particle prediction data set at the current time.

The process of solving the inter frame registration is the process of solving the minimum value of the objective function shown in equation (15), which is completed by using the singular value decomposition method in this paper.

a) *Adaptive Resampling*: Since the RBPF-SLAM algorithm only uses the motion model as the proposed distribution, as time goes on, the cumulative error of the odometer becomes larger and larger, which reduces its estimation performance [19]. For this reason, corresponding improvements have been made in the above sections. When using the motion model to calculate the proposed distribution, the optical observation information has been added, so as to obtain a better proposed distribution. Since the resampling step also has an important impact on particle filtering, during resampling, particles with high weight are usually replaced by particles with low weight. However, frequent resampling operations may eliminate effective particles and cause particle degradation. Therefore, the resampling step is improved adaptively, and a variable to measure particle degradation severity is proposed N_{eff} , which can be described as:

$$N_{eff} = \frac{1}{\sum_{i=1}^N (\tilde{\omega}^{(i)})^2} \quad (16)$$

Wherein, i the weight of particles is marked as $\tilde{\omega}^{(i)}$; For effective particle number is marked as N_{eff} .

In actual work, usually the smaller the value of N_{eff} is, the more serious the particle degradation is. The larger the value is, the better the diversity of particles is. Usually when the N_{eff}

descend to $0.5N$, the resample is performed, and each particle will get the same weight after resampling. Adaptive resampling can resample when the system needs, reduce the number of resampling, and improve the robustness of the algorithm.

b) Drosophila Optimization Strategy: In view of the advantages of the Fruit Fly Optimization Algorithm (FOA) algorithm in target optimization [20], this paper introduces it into the laser radar SLAM mapping work of the tobacco production line inspection robot, and effectively integrates the FOA algorithm and RBPF algorithm to achieve more ideal SLAM mapping work effect.

The basic idea of the fusion is: after the sampling process is optimized and the proposed distribution of sampling particles is obtained, the particle set is regarded as the drosophila population, and the scan matching score is taken as the individual fitness value, which reflects the compliance of the individual with the real state of the tobacco production line inspection robot. The FOA algorithm is used to optimize the particle distribution, drive the drosophila individual to fly to the optimal position, and constantly search the surrounding area for a better position at random, so that the drosophila is constantly approaching the real state of the mobile tobacco production line inspection robot, and alleviate particle degradation.

The standard FOA algorithm regards each drosophila individual as a feasible solution, and constantly moves to the optimal position to seek the global optimal solution of the model. The process of FOA algorithm is as follows:

1) Initialization. Set parameters such as initial position, population size, maximum iteration number Maxgen of *Drosophila melanogaster*.

2) *Drosophila* flies out of the current position and randomly searches for higher concentration positions around. The movement formula is as follows:

$$x_k^{(i)} = x_{k-1}^{(i)} + RandValue \quad (17)$$

Among them, $x_{k-1}^{(i)}$ indicates the particle state at the last iteration; $x_k^{(i)}$ indicates the state of particles at the current time; *RandValue* indicates the step size of random movement.

3) The individual fitness value was obtained from the location concentration of *drosophila melanogaster*, and the optimal individual of the population was found.

4) If the current optimal fitness value is greater than the maximum fitness value of the previous iteration, all *drosophila* flies to the optimal individual. Repeat steps (2) to (4) until the termination conditions are met.

The number of particles determines the number of particles used to represent the state space in the RBPF algorithm. Increasing the number of particles can improve the accuracy and robustness of the algorithm, but at the same time increase the computational complexity. The algorithm usually requires

several iterations to converge to accurate location estimation and map building results. Increasing the number of iterations can improve the stability and accuracy of the results, but it also increases the computation time.

In order to overcome the limitation of the standard FOA algorithm in the convergence process that the population diversity decreases and the particles tend to fall into the local optimum, which leads to the deviation from the real state, this paper introduces the cross mutation operation to improve the adaptability of the population. After the particles are randomly paired, the cross operation is carried out according to the adaptive probability, and then a certain number of optimal particles are copied and mutated to maintain the diversity of the population, prevent falling into local optimal solution. Finally, the state update formula of exponential function step size is used to move *drosophila* individuals to increase the optimization step size, improve the convergence speed of the algorithm, and help the algorithm jump out of the local optimum.

The improved individual renewal formula of *drosophila melanogaster* is:

$$x_k^{(i)} = x_{k-1}^{(i)} + e^{rand} - 1 \quad (18)$$

Among them, e^{rand} represents the step size of exponential function.

By introducing the improved FOA algorithm, the estimation accuracy of the filter can be effectively improved and improved, so that the number of particles required is reduced, thus reducing the calculation amount of the algorithm, and effectively solving the problems of insufficient population diversity and poor real-time performance when completing the laser radar SLAM mapping of the tobacco production line inspection robot based on RBPF.

a) RBPF-SLAM Algorithm Improvement Process

1) The precise motion model and laser radar joint model obtained by fusing the wheel odometer and IMU data are distributed as improvement proposals at the moment $t=0$, select particles N and the weight of particles is N .

2) In the hybrid proposed distribution, the iterative closest point method is used to scan and match to find out the sampling particles in the high probability area, sample in the matched particle set, and take the matching score of the particle matching scan as the fitness value f_i , adjust the particle distribution using the *drosophila* optimization strategy.

3) Calculate, update and normalize the weight of optimized particles, if N_{eff} descend to $0.5N$ start the resample operation.

4) The map is updated according to the position and posture information and observation information of the tobacco production line inspection robot. The improved RBPF-SLAM algorithm flow is shown in Fig. 2.

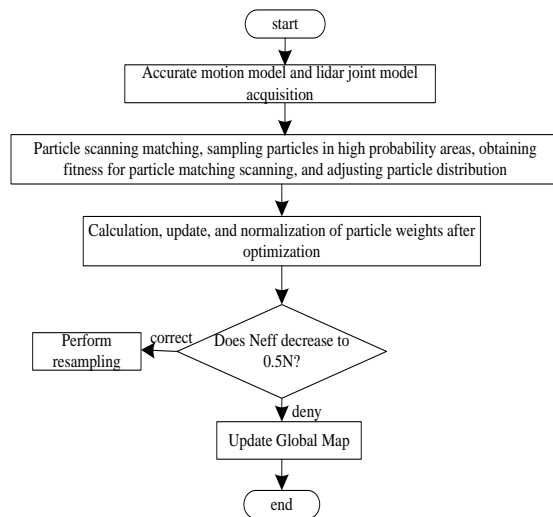

Fig. 2. Improved RBPF-SLAM algorithm process.

III. EXPERIMENT AND ANALYSIS

As an important part of the daily production and management of tobacco production companies, whether the inspection robot of tobacco production line can better realize the laser radar SLAM mapping is directly related to whether the daily inspection task of tobacco production line can be effectively completed. Therefore, in this experiment, the inspection robot of a large tobacco company's production line is taken as the experimental object. The method in this paper is applied to its SLAM mapping, and the effectiveness of the method in this paper is verified. It is reported that the tobacco company was established in June 1984, and two tobacco distribution companies were established in October of the same year. By December 2016, in addition to the original two tobacco distribution companies, it was found that there was a large demand for tobacco marketing in this area, so five tobacco production companies were established in succession. After the establishment of tobacco production companies, it was found that the traditional manual inspection mode was no longer suitable for the long-term development needs of tobacco companies. Therefore, a large number of inspection robots for tobacco production lines were introduced into the newly established five tobacco production branches to assist the production of tobacco production companies and help the development of tobacco enterprises. The introduced tobacco production line inspection robots and their technical parameters are shown in Fig. 3 and Table I. The chassis of the tobacco production line inspection robot uses two wheels for differential movement, and is loaded with wheel odometer, IMU and two-dimensional laser radar. In this experiment, the two groups of tobacco production line patrol robots built in this experiment are respectively 18m * 15m and 24m * 23m in size. In addition, the tobacco production line patrol robots also have a 3D visualization tool RVIZ, which is used to display the laser radar point cloud in the experiment and draw the environment map in real time.

The two-dimensional grid map constructed with 15 sampling particles using the method in this paper is shown in Fig. 4. Among them, the white area is the area that has been scanned by the laser radar, the black line represents the outline

of the object, and the gray area is the map area that has not been scanned by the laser radar.

Fig. 3. Tobacco production line inspection robot.

TABLE I. MAIN TECHNICAL PARAMETERS OF TOBACCO PRODUCTION LINE INSPECTION ROBOTS

Parameter information	Parameter value
Model	M-20iA
Overall weight	40kg
Dimensions	800*450*200mm
Gradeability	30°
Fastest running speed	1m/s
Turning radius	2000mm
Visual resolution	1080P
Inspection efficiency	10s/inspection point
Navigation method	Laser SLAM
Repeatability	±10mm

(a) 18m*15m

(b) 24m*23m

Fig. 4. The method used in this article to construct an environmental map.

It can be seen from Fig. 4 that the method in this paper can realize the laser radar SLAM mapping of the tobacco production line inspection robot, and the environment map constructed is relatively clear, which can better meet the actual work needs. This is mainly because the improved FOA algorithm introduced in the proposed method can effectively improve and increase the estimation accuracy of the filter, thus reducing the number of particles required, thus reducing the calculation amount of the algorithm, and effectively solving the problem of insufficient population diversity and poor real-time performance when the tobacco production line inspection robot based on RBPF completes the LiDAR SLAM mapping.

Fig. 5 is a two-dimensional grid map constructed by the traditional RBPF-SLAM method using 30 sampling particles.

(a) 18m*15m

(b) 24m*23m

Fig. 5. Traditional RBPF-SLAM method for constructing environmental maps.

It can be seen from Fig. 5 that the two-dimensional grid map constructed by the traditional RBPF-SLAM method has a large error, and there are deviations in many parts, such as incomplete scanning in the white area. Compared with the two-dimensional grid map constructed by using 15 sampling particles in Fig. 4, the effect is obviously worse, which is undoubtedly another verification of the effectiveness of this method. This is mainly because the method proposed in this paper uses the exponential function step length state update formula to move fruit flies, increase the optimization step size,

improve the convergence speed of the algorithm, and make the algorithm jump out of the local optimal solution.

In order to further verify the effectiveness of the method in this paper, within 200s, the method in this paper will be reasonably compared with the traditional RBPF-SLAM method in the laser radar SLAM mapping of the tobacco production line inspection robot, and the obtained position and attitude state error comparison curve is shown in Fig. 6.

Fig. 6. Comparison curve of pose state error.

It can be seen from the pose state estimation curve of the tobacco production line patrol robot shown in Fig. 6 that the position state estimation error of the tobacco production line patrol robot obtained by applying the method in this paper to implement laser radar SLAM mapping of the tobacco production line patrol robot is significantly lower than the traditional RBPF-SLAM method. This is mainly because when the method in this paper is used to estimate the position and orientation of the tobacco production line patrol robot, the wheel odometer information and IMU information of the tobacco production line patrol robot are effectively fused, so the position and orientation estimation accuracy of the tobacco production line patrol robot is higher.

Fig. 7 shows the particle distribution after particle filtering of this method and the traditional RBPF-SLAM method.

It can be seen from Fig. 7 that the fitting accuracy of the filtering method in this paper is higher. After filtering, most particles are closely distributed and close to the true value, and there is almost no divergence of particle samples. After traditional RBPF-SLAM filtering, the distribution of particles is relatively divergent, and some particles are far from the true value. Note: The method in this paper has more advantages in the accuracy of map estimation, and can better meet the needs of the actual tobacco production line inspection robot laser radar SLAM mapping work. This improved filtering method has a great advantage in map estimation accuracy, and can well meet the needs of the actual tobacco production line inspection robot LiDAR SLAM mapping.

(a) Particle distribution after filtering using traditional RBPF-SLAM method

(b) Particle distribution after filtering in this method

Fig. 7. Comparison of particle distribution after filtering.

IV. CONCLUSION

The method in this paper can realize the laser radar SLAM mapping of tobacco production line patrol robot, and the mapping effect is good. Its advantages in the laser radar SLAM mapping of tobacco production line patrol robot mainly include:

1) Compared with the traditional RBPF-SLAM method, the method in this paper can build an ideal inspection map of the tobacco production line inspection robot with fewer particles, and the two-dimensional grid map constructed is clearer, which can better meet the actual work needs.

2) Compared with the traditional RBPF-SLAM method, the method in this paper is used to implement the laser radar SLAM mapping for the tobacco production line patrol robot, which can obtain lower position and attitude state estimation error of the tobacco production line patrol robot, and has better fitting accuracy when filtering. After filtering, most particles are closely distributed and close to the true value, and there is almost no divergence of particle samples.

3) The wheel odometer and IMU data are fused using the extended Kalman filter algorithm, and the fusion odometer motion model and LiDAR observation model are adopted as the hybrid scheme distribution. In the mixed scheme distribution, the iterative nearest point method is used to find the sampled particles in the high probability region, and the

matching score of the particle matching scan is taken as the adaptation value.

4) RBPF needs to process a large number of particles to represent the state space, and perform state estimation and map update, which leads to high computational complexity, especially in real-time applications may face the problem of processing time delay. Future research could explore more efficient algorithms, such as improved versions of RBPF based on reducing the number of particles or introducing other optimization methods.

Visual Image Feature Recognition Method for Mobile Robots Based on Machine Vision

Minghe Hu*, Jiancang He

School of Computing, Xinxiang Vocational and Technical College, Xinxiang, China

Abstract—With the continuous advancement of machine vision and computer technology, mobile robots with visual systems have received widespread attention in fields such as industry, agriculture, and services. However, the current methods for processing visual images of mobile robots are difficult to meet the requirements of practical applications. There are issues of low efficiency and low accuracy. Therefore, firstly, spatial information is integrated into the K-means algorithm and image spatial structure constraints are introduced for visual image segmentation. Then the dense connected network is added to the Convolutional neural network structure. This structure is combined with a bidirectional long-term and short-term memory network to achieve visual image feature recognition. The results show that the improved K-means algorithm has a maximum recall rate of 97.35% in the Berkeley image segmentation dataset, with a maximum Randall index of 86.18%. After combining with the proposed improved Convolutional neural network, the highest feature recognition rate for five scenes of mining, risk elimination, agriculture, factory and building is 96.1%, and the lowest error rate is 1.2%. It possesses a high degree of recognition accuracy and is capable of effectively being applied to visual feature recognition on mobile robots, providing a novel reference point for visual image processing on mobile robots.

Keywords—Machine vision; mobile robots; image recognition; convolutional neural network; K-means algorithm

I. INTRODUCTION

Mobile robots play an important role in modern technology, and their environmental perception and decision-making abilities are crucial for achieving autonomous navigation and task execution. Key technologies in a mobile robot's perception system are visual image processing and feature recognition, which provide robots with rich environmental information and accurate target recognition [1-3]. In recent years, the rapid development of deep learning technology has provided new solutions for visual image processing of mobile robots. Traditional Convolutional Neural Networks (CNN), as one of the core algorithms of deep learning, have strong feature extraction and recognition capabilities and have achieved outstanding results in fields such as image classification, object detection, and semantic segmentation. However, applying traditional methods to recognize visual images with mobile robots presents a challenge when using deep neural networks for image processing on the robot due to limited computational resources and power consumption [4-5]. Therefore, the integration of CNN technology with mobile robots for efficient image feature recognition has become a current research focus. Additionally, the K-means clustering algorithm serves as an unsupervised learning method that is widely used for clustering image

features. By grouping image feature vectors, K-means aids in extracting key features of the image, ultimately resulting in image classification and target recognition. However, in the field of mobile robot vision, the application of machine vision is currently limited. Problems persist with low efficiency and accuracy in image feature recognition. In light of this, a study proposes a mobile robot visual image feature recognition method based on CNN and K-means technology. The method incorporates Recurrent Neural Network (RNN) to further improve the image recognition effect of mobile robots.

The paper is divided into four parts. The first part is an overview of the current development status of visual image recognition for mobile robots both domestically and internationally; the second part is to improve the image segmentation technology of K-means clustering and image feature recognition based on CNN and RNN, and constructs a robot image recognition system. The third part is the performance testing and application effectiveness of the system built by the study; the fourth part is a summary statement of the entire study.

II. RELATED WORKS

The CNN and K-means technologies' remarkable ability to identify image features has garnered significant interest from experts. In the context of mobile robot visual image feature identification, the aforementioned technologies are employed to boost accuracy. Jiang et al. proposed a casing infrared fault diagnosis method based on image segmentation and deep learning to effectively distinguish the fault area and background of the casing. During the process, a target detection system was constructed using the CNN framework, and K-means technology was introduced to classify and explore the positions and areas of the obtained images. The data indicates that the algorithm achieves an image classification accuracy rate of up to 98%, exhibiting superior performance [6]. Chen et al. developed a CNN and K-means-based method for scene perception to tackle CNN's low efficiency in different target recognition tasks. This method enabled coarse-grained classification of the input data and lowered complexity in structural design, boosting computational flexibility. Compared with traditional image recognition methods, this method improves accuracy by 36.65% [7]. To solve the time-consuming manual segmentation of brain tumors in magnetic resonance images, Ragupati and Karunakaran combined CNN with K-means to achieve a robust image feature segmentation method. CNN was used to classify images into normal and abnormal ones. Then K-means was used to segment brain tumor images from abnormal brain images. According to the findings, this method

has high accuracy and recognition efficiency [8]. The rapid development of highways and the increase in the number of vehicles require a safe and efficient transportation system for the automotive sector. Therefore, Chen and Zong proposed a license plate recognition model based on CNN-K-means. CNN was used for license plate detection and segmentation, followed by K-means for license plate number detection and segmentation, and finally for recognition. According to the findings, it is more effective and efficient than other models [9]. Rustam et al. proposed an image recognition method based on CNN-K-means to solve the low accuracy in lung cancer image diagnosis. All input data was checked through CNN, and image features were obtained through K-means and transmitted back to CNN for further recognition. The experimental results indicate that the highest performance measurement accuracy is 98.85%. The sensitivity is 98.32%, and the accuracy is 99.40%. This method has good results in lung detection [10].

With the development of society, the visual image feature recognition of mobile robots requires higher precision recognition capabilities. More scholars are researching how to enhance image recognition abilities. Liu et al. believed that estimating the three-dimensional position and direction of objects in the environment using a single RGB camera is very challenging. Therefore, a new neural network module was introduced for detecting three-dimensional objects to achieve the normal movement and operation of mobile robots. The outcomes indicated that mobile robots achieve the most advanced performance [11]. Sungeetha and Sharma found that in the process of 3D image convergence, the projection of different planes was incorrectly recognized in image feature recognition. A machine learning algorithm was proposed as a preprocessing step to enhance the speed and accuracy of data handling. The outcomes indicated that the accuracy is 34.9% higher than that of ordinary digital visual target recognition [12]. Wang et al. used tensor based visual feature recognition methods to identify visual information generated in industrial processes. The research results indicate that this method has good recognition accuracy [13]. Jacob and Darney used DL methods to study user privacy and secure image recognition for IoT management. The research results indicate good performance in improving the appropriateness and robustness of the Internet of Things. Simultaneously, DL greatly improves the accuracy of image feature recognition [14]. Niu et al. used the generating adversarial networks (GANs) to identify defect images in actual production lines. Classical methods face challenges in obtaining adequate defect datasets due to the lack of diversity and quantity. This method repairs defect images through a large number of defect free images on industrial sites. The research results indicate that this method has high accuracy in image recognition. The entire image recognition system has high robustness [15].

In summary, the method for recognizing visual image features in mobile robots using improved CNN and K-means technology has promising applications. The method enhances the environmental perception and target recognition abilities of mobile robots and offers significant support for achieving intelligent navigation and task execution. At present, numerous scholars have researched this problem, but only a few academic achievements have utilized K-means clustering CNN

in recognizing image features, and there exist application limitations. As a result, this paper proposes a method for recognizing mobile robot images that combines CNN and K-means clustering. It aims to offer technical guidance for robot image recognition and to highlight its potential in future research and application.

III. ROBOT VISION IMAGE FEATURE RECOGNITION BASED ON MACHINE VISION

This chapter consists of two parts. The first section improves the K-means algorithm to complete visual image segmentation. In the second section, CNN and RNN are combined to carry out image feature recognition.

A. Image Segmentation Based on K-Means Clustering

K-means is one of unsupervised learning, which does not need to provide label information. It has a very concise objective function. The operation process of the K-means algorithm mainly contains four steps. The first is to randomly initialize the cluster center. This step randomly obtains K points corresponding to the center of each class of clusters. The second step is to calculate the distance from the sample point to the corresponding center. By comparison, the center with the smallest distance is selected. This means that the sample points and their corresponding centers are all of the same class of clusters [16-17]. Based on the clusters created in the second step, the third step recalculates the centers of all the clusters. The process of the second and third steps is then repeated until the termination conditions are met, concluding the algorithm. Fig. 1 illustrates the operation process of the K-means.

Fig. 1. Illustrate the operation process of the K-means.

If a dataset is $X = \{x_1, x_2, \dots, x_n\}$, the sample in that dataset is x_n . Usually, Euclidean distance is used to partition class clusters. The closest ones belong to the same cluster, while the points of different clusters are farther apart. The objective function of this algorithm is obtained as shown in Equation (1).

$$\min_{\gamma_{nk}, \mu_k} \sum_{n=1}^N \sum_{k=1}^K \gamma_{nk} \|X_n - \mu_k\|^2 \quad (1)$$

In Equation (1), z is the samples in the dataset. E is the clusters. μ_k is the center of the k -th cluster. $\gamma_{nk} \in \{0,1\}$ represents whether the n -th sample point is in the k -th cluster. Among them, 0 indicates that the sample is not in the cluster, and 1 indicates that it is in the cluster. Meanwhile, each sample is only in a unique cluster. The K-means algorithm's objective function is to obtain the sum of squared errors. The goal is to minimize this error for each class cluster. This can achieve maximum compactness of cluster samples and ensure maximum distance between cluster samples. The Expectation-maximization is used to address the K-means algorithm. This algorithm is an efficient heuristic algorithm. It can ensure that

the algorithm converges to a local optimal solution in an extremely short time [18]. The Expectation–maximization algorithm is used to solve the objective function of K-means clustering. The first step is to take the derivative. The obtained content is shown in Equation (2).

$$-2 \sum_{n=1}^N \gamma_{nk} (x_n - \mu_k) = 0 \quad (2)$$

The simplified expression of μ_k is shown in Equation (3).

$$\mu_k = \frac{\sum_{n=1}^N \gamma_{nk} x_n}{\sum_{n=1}^N \gamma_{nk}} \quad (3)$$

The specific values of all centers can be obtained through Equation (3). The cluster to which the sample point belongs can be reassigned, as shown in Equation (4).

$$\gamma_{nk} = \begin{cases} 1, k = \arg \min_k \|x_n - \mu_k\|^2 \\ 0 \end{cases} \quad (4)$$

According to the solving process of the K-means in Equations (2) to (4), although it is difficult to ensure a global optimal solution, this algorithm can usually achieve the expected experimental objectives. When segmenting images with K-means, the clustering condition requires the presence of pixels with similar values. If such pixels are absent, the image belongs to a different cluster. Therefore, structural constraint information is relatively lacking. To address this issue, a K-means method for image spatial structure constraints was designed. This method adds image spatial structure constraints on the basis of the original algorithm. The color features and pixel position constraints in the image segmentation process are considered together to improve the segmentation effect [19]. The proposed K-means clustering model for image spatial structure constraints is shown in Fig. 2.

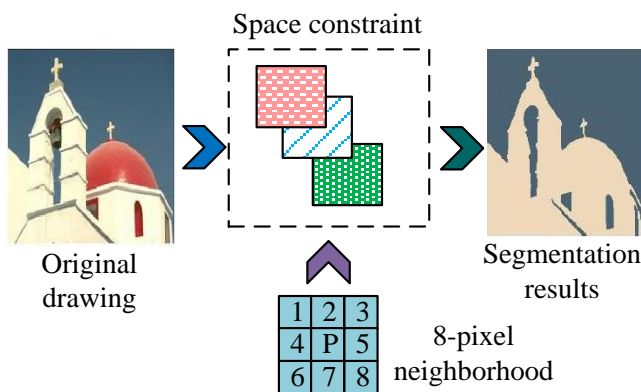

Fig. 2. Schematic diagram of the proposed K-means clustering model for image spatial structure constraints.

In Fig. 2, image segmentation is performed using the K-means algorithm, with sample points being the corresponding pixels in the color image. The clustering is completed under the specified number of clusters. Subsequently, the clustering

center is used to replace the corresponding pixel points to achieve image reconstruction. Under the constraint of image spatial structure, K-means combines itself with spatial structure constraint information. The penalty constraint term corresponding to adjacent pixel points is added to the objective function. The new objective function is calculated, as shown in Equation (5).

$$\min_{\gamma_{nk}, \mu_k} \sum_{n=1}^N \sum_{k=1}^K (\gamma_{nk} \|x_n - \mu_k\|^2 + \alpha \sum_{p=1}^P |\gamma_{nk} - \gamma_{pk}|) \quad (5)$$

In Equation (5), α greater than 0 is a hyperparameter. The main function is to balance the important relationship between the structural constraint term and the reconstruction error term. $KL(\bullet)$ is the neighborhood of the sample points, as shown in Fig. 3. It can be observed that for the internal, boundary, and corner pixels, the corresponding neighborhood pixels of the sample are 3, 5, and 8, respectively. The K-means algorithm for image spatial structure constraints adds the proposed spatial constraint term. As a result, similar color features can affect clustering performance. The position constraint relationship corresponding to adjacent pixel points is taken into account, greatly increasing the persuasiveness of image segmentation results.

			6	7	8			

Fig. 3. Number of neighborhoods of sample points.

Then, the Expectation–maximization is used to address the proposed K-means objective function. The simplified expression of γ_{nk} is shown in Equation (6).

$$\gamma_{nk} = \begin{cases} 1, k = \arg \min_k \|x_n - \mu_k\|^2 + \alpha \sum_{p=1}^P |\gamma_{nk} - \gamma_{pk}| \\ 0 \end{cases} \quad (6)$$

B. Image Feature Recognition Based on CNN and RNN

After completing image segmentation using the proposed K-means, CNN is further applied for image feature recognition. CNN is an adaptive abstract feature extraction model. The structure consists of an input layer, pooling layer, convolutional layer (CL), fully connected layer, and output layer. Among them, the pooling layer and CL connect adjacent nodes through sparse connections, which have the advantage of adaptive feature data extraction [13]. Fig. 4 illustrates the specific structure of CNN.

Fig. 4. CNN structure.

In the structure of CNN, the input layer receives preprocessed network data through appropriate dimensions. The convolution layer mainly performs convolution operations on the input values of the Receptive field. The pooling layer is responsible for dimensionality reduction of feature data and filtering out excess information. The fully connected layer combines the local abstract features extracted from the convolutional and pooling layers and reflects them into the label space. The output layer is responsible for outputting the prediction results of the network. Among them, the convolution operation is shown in Equation (7).

$$X_j^{(l)} = f \left(B_j^{(l)} + \sum_{i \in N_l} W_{ij}^{(l)} \times X_i^{(l-1)} \right) \quad (7)$$

In Equation (7), $X_j^{(l)}$ represents the j -th feature output of the l -th CL. N_l represents the set of inputs from layer l . $X_i^{(l-1)}$ refers to the data extracted by the convolutional kernel. $W_{ij}^{(l)}$ stands for the weight of the convolutional kernel. $B_j^{(l)}$ is the bias term. The increase of network layer in DL models is beneficial for feature extraction. However, excessive network layers can lead to overly complex model parameters, making it difficult for errors to be transmitted through gradient backpropagation. Therefore, based on the CNN structure, the DenseNet structural model is introduced. This model can extract abstract features at different levels and merge them. Feature information can be utilized to the greatest extent possible. At the same time, each CL has a fast channel connecting the input and output layers, making it easier for errors to update network parameters through gradient backpropagation. The DenseNet structural model is shown in Fig. 5.

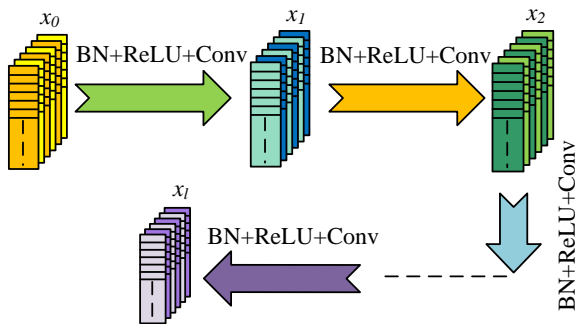

Fig. 5. DenseNet model structure.

In the DenseNet structure, when the CL is L , the connection channels between layers are $L(L+1)/2$. These channels are mainly used for the transmission of feature information. All previous layer output features are combined to complete each subsequent layer input. The calculation is shown in Equation (8).

$$x_l = H_l \left([x_0, x_1, \dots, x_{l-1}] \right) \quad (8)$$

In Equation (8), x_0 represents the input data of the first layer. $[x_0, x_1, \dots, x_{l-1}]$ is the combination of output data from layer l to layer $l-1$. H_l refers to the feature extraction and transformation of the layer, including ReLU Activation function, standardization and convolution operations.

RNN is a special model with "memory" function. The nodes in its hidden layer can receive both the current input signal and the previous output signal. Therefore, the current state information is determined by the hidden layer node input and the previous node output. The calculation is shown in Equation (9).

$$p^{(n)} = q + Ux^{(n)} + Wh^{(n-1)} \quad (9)$$

In Equation (9), $p^{(n)}$ represents the intermediate variable. $h^{(n)}$ refers to the hidden state of node n . W and U represents the weights of the previous hidden state and the current input, respectively. $x^{(n)}$ is the current input information. q is the offset term for the hidden layer. The calculation of $h^{(n)}$ is shown in Equation (10).

$$h^{(n)} = f(p^{(n)}) \quad (10)$$

In Equation (10), f stands for the Activation function. The state information value of the hidden layer is shown in Equation (11).

$$o^{(n)} = c + Vh^{(n)} \quad (11)$$

In Equation (11), $o^{(n)}$ is the node output. V represents the weight of the output. c represents the bias term. The target value corresponding to $o^{(n)}$ is shown in Equation (12).

$$y^{(n)} = \text{Soft max}(o^{(n)}) \quad (12)$$

In Equation (12), $y^{(n)}$ refers to the target value of $o^{(n)}$ mapped to the probability space through the Softmax function. RNN networks have significant advantages in processing sequence information. The traditional LSTM, in contrast, only facilitates one-way memory, relying on previous information to predict output results. It cannot meet the encoding requirements in reverse order. Therefore, a Bidirectional Long Short-term Memory (BLSTM) is introduced, which can model from front to back and from back to front, and output results based on contextual information. If the length of the input sequence is T , the structural model of BLSTM is shown in Fig. 6.

Fig. 6. BLSTM network structure.

In the BLSTM network, the memory units in the forward layer iterate from time step 1 to T, as shown in Equation (13).

$$C_n = H(q_c + W_c g C_{n-1} + W_x g x_n) \quad (13)$$

In Equation (13), C_{n-1} and C_n respectively represent the previous and current state of the unit. x_n represents the current input data. The backward layer transmits information from the end to the front. The calculation is shown in Equation (14).

$$C_n = H(q_c + W_c g C_{n+1} + W_x g x_n) \quad (14)$$

In Equation (14), C_{n+1} refers to the next state of the unit. The output is determined by the forward and backward cell propagation. The output is shown in Equation (15).

$$y_n = q_y + W_y g C_n + W_y g C_n \quad (15)$$

In Equation (15), y_n represents the output of time step n . W_y and W_y refer to the output weight. q_y represents the bias term. Compared to unidirectional RNN, BLSTM structure can extract more complete temporal features. DenseNet and BLSTM were further combined to construct the DenseNet BLSTM model. This model can adaptively extract multi-level features from signals. BLSTM is used to predict results from both the front and back directions to obtain more complete feature information. Simultaneously, it can maximize the utilization of feature information extracted from each layer of network.

IV. THE APPLICATION EFFECT ANALYSIS OF IMAGE GENERATION AND RECOGNITION

This chapter analyzes the application effect of the proposed method in visual image feature recognition of mobile robots.

TABLE I. TEST RESULTS OF SIX METHODS IN BERKELEY IMAGE SEGMENTATION DATASET/%

Methods	F1-measure	Precision	Recall	RI	ACC
NormTree	56.28±13.22	45.17±15.36	72.0±17.06	62.62±8.44	58.75±11.74
LOG	47.37±14.27	35.28±16.26	81.28±4.43	42.54±11.36	46.58±15.32
Ncuts	51.76±12.57	72.12±10.04	48.47±21.07	72.73±14.07	54.57±12.59
Otsu	54.39±13.22	46.14±16.72	81.51±14.44	61.59±7.85	55.34±11.32
K-means	47.14±8.54	74.43±13.15	41.39±7.56	72.11±11.43	45.88±8.67
Ours	63.45±10.12	61.57±12.86	85.82±11.53	74.85±11.33	61.47±12.58

This includes improving the visual image segmentation performance of the K-means and the recognition performance of the DenseNet BLSTM model.

A. Visual Image Segmentation Effect

Firstly, the proposed K-means algorithm incorporating image spatial structure constraints is validated for the visual image segmentation effect of mobile robots. The dataset used in the experiment is the Berkeley image segmentation dataset, which includes benchmark codes, real human annotations, and 500 natural images. The proposed method is compared with classic Otsu algorithm, Laplacian of Gaussian (LOG), Normalized Cuts (Ncuts), NormTree, and traditional K-means algorithm. Five different evaluation indicators are used for quantitative evaluation of image segmentation effectiveness, i.e., F1 measure, accuracy, precision, recall, and Rand index (RI). All images are repeated 10 times in the Berkeley image dataset. Table I illustrates the results.

From Table I, in the comparison of F1 values, the NormTree algorithm is (56.28±13.22) %. The proposed K-means algorithm is (63.45±10.12) %, which is significantly superior to the other five methods. In the comparison of Recall, RI, and ACC, the proposed methods were (85.82±11.53) %, (74.85±11.33) %, and (61.47±12.58) %, respectively. All are the best of the five methods, indicating that they can effectively balance accuracy and recall. The comparison results obtained by all methods on different datasets are significantly different. This could stem from notable disparities amid the data samples within the two datasets, as well as the differing collection methods for the data in each dataset. This method has better performance. To further verify the performance, experiments are conducted again by changing the hyperparameter α . The F1-measures of the proposed method and K-means under different α conditions are shown in Fig. 7.

From Fig. 7, as the hyperparameter α increases, the F1 value of the traditional K-means does not change and remains stable at 0.55. For the proposed K-means, when α is 0, the F1 value is 0.55. As the value of α increases, the F1 value of this method also increases. When the value of α is 10, F1 reaches a maximum of 0.83. Then F1 descends. When the value of α is 20, the F1 value is 0.72, which is still significantly better than the K-means algorithm. The changes in ACC and RI indicators under different hyperparameters α are illustrated in Fig. 8.

Fig. 7. The impact of different α value on F1 measure and its comparison with K-means clustering method.

Fig. 8. The impact of different α values on accuracy (ACC) and Randall Index (RI).

From Fig. 8, with the continuous increase of hyperparameter α , the ACC and RI indicators of the proposed method have fluctuated to varying degrees. Among them, the ACC indicator curve has relatively small changes. Most of them are stable between 0.7 and 0.8. When the hyperparameter α values are 9 and 15, the maximum and minimum values of the ACC index appear, which are 0.82 and 0.69, respectively. In terms of RI indicators, when the hyperparameter α is less than 10, the overall trend shows an upward trend, reaching a maximum of 0.65. When the α exceeds 10, the overall RI index shows a downward trend. However, the minimum is maintained above 0.4, and the performance is still relatively good.

B. Analysis of Visual Image Feature Recognition Results

After verifying the proposed image segmentation method, the image feature recognition performance of the constructed DenseNet BLSTM model is further analyzed. The ImageNet dataset is selected for experiments. This dataset is a large visualization database used for visual object recognition software research, which contains more than 20000 categories. It has a large number of pictures. 200 images are randomly selected from four batches for image feature recognition, denoted as groups A, B, C, and D. The proposed DenseNet-BLSTM model is compared with four methods, namely, CNN, RNN, CRNN, and DenseNet. The obtained results are shown in Fig. 9.

Fig. 9. Image feature recognition results of five models in ImageNet dataset.

From Fig. 9, in the four selected image feature recognition tests, the accuracy of the RNN model is 65.5%, 65.3%, 64.9%, and 64.5%, respectively, concentrated around 65%. The feature recognition accuracy of CNN is 68.6%, 68.5%, 68.9%, and 69.3%, all around 68%. The accuracy of CRNN and DenseNet models is relatively similar. The two fluctuate around 84% and 85% respectively. The four test results of the proposed DenseNet-BLSTM model are 89.6%, 89.6%, 89.3%, and 89.4%, all approaching 90%. Compared with the other four methods, this model has high accuracy and significant performance advantages. Further experiments are conducted on the efficiency of image feature recognition. The Pascalvoc2012 and Cityscapes datasets are used for testing. Among them, the proportion of training and testing sets is 70% and 30%. The recognition time changes of the five methods in the two selected datasets are shown in Fig. 10.

Fig. 10. Five methods for identifying time changes in the two selected datasets.

From Fig. 10(a), in the dataset Pascalvoc2012, as the images increases, the recognition time of all five models increases. Among them, CRNN takes the longest time. When the number of images reaches 250, the time consumption increases to around 50s. The time difference between CNN, RNN, and DenseNet models is relatively small, but they are better than the CRNN model. Among them, the DenseNet model takes the highest time of around 45s. The proposed DenseNet BLSTM model has a maximum duration of 40s, which is the shortest among the five models. From Fig. 10(b), in the dataset Cityscapes, CRNN takes up to 34s, which is the longest among the five methods. The proposed method still takes the shortest time, with a maximum of only 28s. The feature recognition efficiency is high and the performance advantage is significant. Finally, the improved K-means clustering combined with the DenseNet-BLSTM model is applied to the visual image feature recognition of mobile robots. To enhance the persuasiveness of the results, five main scenarios are selected for experiments, namely, mining, risk management, agriculture, factories, and construction. The image feature recognition results before and after the combinations are compared, as shown in Fig. 11.

From Fig. 11(a) in the image feature recognition of mining, risk management, agriculture, factories, and construction scenes, the combination of the previous method achieves the highest recognition accuracy of 79.3% and the lowest score of 70.4% occurs in agricultural and construction settings. Meanwhile, the lowest error is 9.9%, and the highest value is 45.6%, indicating poor classification performance. From Fig. 11(b), after the combination of the proposed method, the accuracy of image feature recognition for buildings is the highest, reaching 96.1%. The lowest value appears in mining scenarios, at 94.8%. Compared with the recognition results before the combination, the combined method has significant performance advantages in visual image feature recognition of mobile robots. The accuracy is between 94.8% and 96.1%. The application effect is better. The results above suggest that the study's method, consisting of CNN and clustering algorithms, is better suited for unsupervised learning tasks, large datasets, and image processing for data clustering.

V. DISCUSSION

With the emergence of artificial intelligence and big data technology, an increasing amount of unlabeled data has become available. It is crucial to utilize the information within the data to explore its potential value. Unsupervised learning employs clustering algorithms to effectively address these challenges, with the K-means clustering algorithm being a classic example. Additionally, in real-world scenarios, data can possess unique structural constraints. Merely applying the K-means clustering algorithm to solve problems without accounting for the data's inherent features frequently results in suboptimal outcomes. Therefore, in response to this issue, we combine the K-means clustering algorithm with the structural characteristics of the data itself and introduce a combination of CNN and K-means clustering to develop a method for recognizing visual images in mobile robots. Throughout the entire experimental process, the study first utilized K-means to process spatial information and introduced image spatial structure constraints for visual image segmentation. Next, a densely connected network is added to the CNN, and combined with a bidirectional long short-term memory network to achieve recognition and segmentation of visual image features. The proposed models in the research have clear and objective functions, all solved using the maximum expectation algorithm. The effectiveness of the algorithm has been verified through a large number of experiments. The K-means clustering algorithm considers spatial constraints in images by integrating positional relationship information between adjacent pixels into the algorithm. This creates an overall framework with a unified objective function. The K-means clustering algorithm with hierarchical constraints achieves hierarchical clustering by establishing a hierarchical tree that can be globally iterated and updated, thereby better mining the hierarchical structure of the data itself. In addition, in complex and dynamically changing scenarios, deep learning methods introduce convolutional neural network models which demonstrate higher accuracy and robustness.

However, due to the continuous changes in environmental factors, regularly updating models has become the key to ensuring the long-term and efficient operation of mobile robots. Online learning and incremental learning technologies provide

Fig. 11. The recognition results of image features before and after the combination of the proposed method.

effective methods for this. Overall, machine vision based image feature recognition for mobile robots is a versatile challenge that involves algorithm selection, computational efficiency, environmental factors, real-time requirements, and model training and updating. With the advancement of technology, this study aims to develop more efficient and robust methods in the future to meet the practical application needs of mobile robots in various environments.

VI. CONCLUSION

The improvement of visual image processing technology is an important foundation for the wider application of mobile robots. Firstly, an improved K-means algorithm using image spatial structure constraints is proposed. This method is applied to visual image segmentation. The increase in the layers in the CNN network results in complex parameters. Therefore, the DenseNet structural model is introduced and combined with BLSTM to achieve visual image feature extraction. According to the findings, in the comparison of F1 values, the NormTree algorithm is (56.28 ± 13.22) %. The proposed K-means algorithm is (63.45 ± 10.12) %, which is significantly superior to the other five methods. As the hyperparameter α increases, the F1 value of the traditional K-means algorithm stabilizes at 0.55. The proposed K-means algorithm has an F1 value of 0.55 when α is 0. As the value of α increases, the value of F1 also increases. It reaches the maximum of 0.83 when the α is 10. In terms of RI indicators, when the α is less than 10, the overall trend shows an upward trend, reaching a maximum of 0.65. When the α value of the hyperparameter exceeds 10, the overall RI index shows a downward trend. However, the minimum is above 0.4. The performance is still relatively ideal. The image feature recognition performance of the DenseNet BLSTM model constructed is analyzed. In the ImageNet dataset, the four test results are 89.6%, 89.6%, 89.3%, and 89.4%, all approaching 90%. In the dataset Pascalvoc2012, the maximum time consumption of this model is only 40s. In the image feature recognition of five scenes including mining, risk elimination, agriculture, factory and building, the accuracy of the recognition model combined with the improved K-means is between 94.8% and 96.1%, with a high accuracy. However, the proposed method has poor real-time performance. In the future, dimensionality reduction technology is needed to reduce computational complexity. The recognition speed of the algorithm will be further improved.

Abstract—This study simultaneously investigates the causality and dynamic links between international energy trade and economic price changes, especially in the Chinese commodity market. To get a causal route, it attempts to identify the linear and nonlinear causality among commodity prices, equities, and the exchange rate in China and the United States (US). Here, we adapt multilayer perceptron networks to obtain a nonlinear autoregressive model for causality discovery. After comparing methods without networks, this study proves that the nonlinear causality discovery method using machine learning performs best on simulated data. Subsequently, we apply that causality to actual data; we combine the causal routes, particularly from the machine learning methodology, to investigate the existence of a causal direct or indirect relationship among Chinese commodity prices, long-term interest rates, stock index, and exchange rates in China and the US. The steady-state accuracy of cmlpgranger is 99%. In most cases, the order of judgment accuracy of causality is cmlpgranger > HSICLasso > ARD > LinSVR. The results show that Energy trade as an element of the global economic system. The Chinese commodity price of energy has an interactive relationship with the Chinese commodity price of agricultural products. The significant transmission is from the commodity price of energy to equities, then to the exchange rate, and, finally, to the commodity price of agricultural products.

Keywords—Chinese commodity price; exchange rate; stock markets; machine learning; international energy trade; global economic system

I. INTRODUCTION

As an essential part of the global industrial chain, the price fluctuation of commodities has a tremendous impact on the real economy, and the inflation level has a significant effect. The supply and demand pattern of commodities has changed dramatically since 2020. The COVID-19 pandemic raised energy costs, political instability and increased demand for energy [1], which led to intense fluctuations in international commodity prices. In the post-pandemic era, the evolution of the world pandemic situation is out of sync with the economic recovery of various countries. Under the pressure of green transformation and global development, major developed economies have implemented large-scale fiscal stimulus and super-wide monetary policies. At the same time, there have been profound changes in the international economic and trade landscape, geopolitical factors, extreme climate, and other factors. Global supply and demand patterns. Commodities are generally in short supply [2]. Under the influence of various complex factors, it is very important to sort out the causal logic among the factors affecting commodity prices and clarify the impact of commodity price changes on the macro economy for effec-

tively adjusting policies and overcoming the global economic recession.

China is currently the world's largest consumer country [3]. The continued demand for energy, essential raw materials, and agricultural products has rapidly increased China's commodity imports. China has become the world's largest importer of commodities such as iron ore, aluminum ore, lead ore, nickel-chromium ore, and crude oil [4]. The existing literature in 2018 includes discussions on factors that affect commodity prices. However, the current global indicators mainly consider the role of developed countries, but do not consider China's role and its impact on China.

This study also aims to provide a comprehensive analysis using the machine learning (ML) approach. Although numerous studies have analyzed the factors and effects of international commodities prices, we make full use of the algorithm advantages of ML to integrate our findings with those of previous studies. The majority of applied analyses on this topic used the vector autoregressive (VAR) Granger's tests. Sahlian et.al. used the Granger test to establish the causality between the market capitalization and financial indicators [5]. In the classic linear VAR method, when evaluating the cause of Granger, the maximum delay must be stated. When the relationship between the past of one series and the future of another series does not belong to the model category. The method based on model in the real world may fail [6-8]. This usually occurs when there is a non-linear relationship between the past and future of a series. The nonlinear relationship between the past and the future can be detected by minimizing assumptions about the predicted relationship [9]. For example: Yin Z et al. used multiple repetitive neural networks to demonstrate the effectiveness of nonlinear random time series models. [10] Neural networks can display complex nonlinear and non-auxiliary interactions between inputs and outputs. Some studies introduced the structural learning framework in multi-layer sensor (MLP) and Recurrent neural network (RNN). This led to Granger's nonlinear causal discovery. However, the use of these methods to analyze causal processes between multiple variables is particularly rare in the field of economics.

The surge in oil and food prices over the past decade has prompted a large amount of research to focus on the common flow of crude oil and agricultural products. Then, some studies begin modeling to investigate correlations and connections or pathways. On the contrary, some studies provide evidence of the neutral relationship structure between crude oil and agricultural products. Based on the research of previous genera-

tions, the significance and innovation of this study can be summarized in the following three points.

Firstly, we are the first to adopt the ML method instead of traditional economic models. The determination of causal relationships in existing literature is mainly based on the assumptions of econometric models. However, most of these models explore linear relationships. Based on our research, we are the first to use ML to study the causal discovery and relationship between energy and agricultural futures prices. Using ML in this study, we can break the assumptions of the Traditional economy model and find more nonlinear relationships. In addition, compared to other traditional econometric models that only estimate one or two parameters, the ML time size Helping people study time series in time zones and frequency domains

Secondly, we have important evidence in studying the relationship between energy prices and agricultural product prices. In past research, there has been no consensus on the research conclusions, price indicators, and research methods for energy and agricultural product prices at different periods. Country/Region. This study focuses on the prices of China's energy and agricultural futures markets, providing many research conclusions for the literature.

Finally, this study discussed whether this relationship exists and attempted to express causal relationships based on important financial indicators. Most research on the impact of commodity prices focuses on two pairs of relationships. However, this study consists of two or more factors of causality diagram, thus obtained a comprehensive causal path. The media focused on Chinese stock market prices and the exchange rate between China and the United States.

The structure of the remaining parts of this article is as follows: In Section I, we introduced early research related to commodity market reasons or correlations. In Section II, we use motivational datasets to evaluate the effectiveness of machine learning causal discovery methods. After determining the cause-finding ability of these methods, we will use it to analyze the actual data and get the results in Section III. Finally, Section IV summarizes the article.

II. METHODOLOGY AND DATA

A. Adapting Neural Networks for Granger Causality

The Nonlinear Autoregressive Model (NAR) allows XT to dynamically evolve based on typical nonlinearity [11]:

$$x_t = g(x_{<t1}, \dots, x_{<tp}) + e_t \quad (1)$$

where $x_{<ti} = (\dots, x_{(t-2)i}, x_{(t-1)i})$ represents the past of sequence i; we assume that the additive noise zero mean e_t .

In a forecasting setting, the mutual modeling of nonlinear functions g typically uses neural networks. Neural networks have a long history in predicting NAR using traditional architectures [12] and the latest deep learning techniques [15]. These methods use MLP, where the input

$$x_{<t} = x_{(t-1):(t-K)} \quad (2)$$

Our main approach is to model each output g_i using a separate MLP to easily clarify the impact of input on output. We call it component-wise MLP (cMLP) [17]. Set g_i in the form of MLP with L-1 layers, and let the vector $h_t^l \in \mathbb{R}^H$ denote the values of the m-dimensional lth hidden layer at time t. The discovery and research of nonlinear causal relationships have become more widespread, for example, M Roso et al (2022) not only focused on theory, but also on how to build Python packages to complete testing [18].

Definition 1. Time series J is a non-causal relationship of time series I if all $(x_{<t1}, \dots, x_{<tp})$ and all $x'_{<tj} \neq x_{<tj}$,

$$g_i(x_{<t1}, \dots, x_{<tj}, \dots, x_{<tp}) = g_i(x_{<t1}, \dots, x'_{<tj}, \dots, x_{<tp}) \quad (3)$$

that is, g_i is invariant to $x_{<tj}$.

The parameters of the neural network are given by weights W and biases b as each layer, $w = \{w^1, \dots, w^L\}$ and $b = \{b^1, \dots, b^L\}$. To compare with the time series VAR model, we divided the weight of the first layer into time delays, $W^1 = \{W^{11}, \dots, W^{1K}\}$. The parameter sizes include $W^1 \in \mathbb{R}^{H \times pK}$, $W^l \in \mathbb{R}^{H \times H}$ for $1 < l < L$, $W^L \in \mathbb{R}^H$, $b^1 \in \mathbb{R}^H$ for $1 < L$ and $b^L \in \mathbb{R}$. Using this notation, the vector of first layer hidden values at time t is given by

$$h_t^1 = \sigma \left(\sum_{k=1}^K W^{1k} x_{t-k} + b^1 \right) \quad (4)$$

where σ is an activation function [19].

In Equation (4), if the jth column of the first layer weight matrix, W_j^{1k} , contains zeros for all k, then series j does not Granger-cause series i. That is, $x_{(t-k)j}$ for all k does not affect the hidden cell h_t^1 . So according to the definition 1 output x_{ti} , we can see that g_i divided by $x_{<tj}$ remains unchanged.

B. Creating Benchmark Datasets

1) *Group1: Lorenz-96 model*: We use these two methods to detect Granger's causal network from P's simulated Lorenz-96 data. Find the impact of many attributes in different ways [11].

The continuous dynamics of the P Vilorenz model will be obtained from the following styles.

$$\frac{dx_{ti}}{dt} = \left(x_{t(i+1)} - x_{t(i-2)} \right) x_{t(i-1)} - x_{ti} + F \quad (5)$$

where $x_{t(-1)} = x_{t(p-1)}$, $x_{t0} = x_{tp}$, $x_{t(p+1)} = x_{t1}$ and F is a mandatory constant that determines the degree of nonlinearity and chaos in the set.

2) *Group2*: Nonstationary data: Due to the fact that most of the attributes we want to check are not smooth in practice, we will add trends to the Lorenz-96 P dimension data to obtain the data. The second set of extended Dickey Fuller (AD-Fuller) checks can be used to test the unit root directory within a single variable process in the presence of sequence relationships. We use ADFuller to test whether the data is stable.

$$\text{Trend}_t = \text{Trend}_{t-1} + (\text{Trend}_1 - \text{Trend}_0) / I \quad (6)$$

Here, $t \in (0, I)$, I is the length of features and Trend is linear.

As shown in Table I, we take P as 5 and obtain the results of two datasets with P values:

TABLE I. ADFULLER TEST OF DATA (CALCULATED BY AUTHORS)

Group1	Adfuller P_Value		Group2	Adfuller P_Value	
X_1	6.641034e-22	stationary	$X_1 + \text{Trend}$	0.689549	Nonstationary
X_2	5.266443e-18	stationary	$X_2 + \text{Trend}$	0.716672	Nonstationary
X_3	5.218544e-10	stationary	$X_3 + \text{Trend}$	0.700451	Nonstationary
X_4	3.249791e-14	stationary	$X_4 + \text{Trend}$	0.706434	Nonstationary
X_5	8.472980e-12	stationary	$X_5 + \text{Trend}$	0.797429	Nonstationary

C. Comparing Models for Granger Causality

We compare four methods on different numbers of features using stationary and nonstationary data. The four methods are LinSVR2, automatic relevance determination (ARD), HSI-CLasso, and CMLP-Granger.

The basic support vector regression (SVR) concepts are introduced by Schölkopf and Smola; Linear SVR (LinSVR) is a special case of SVR with a linear axis. Huang and Cai improved SVR and used these methods to select features. The advantage of LinSVR is that due to the small complexity of the model, the

results are easy to interpret. However, it cannot recognize nonlinear relationships that typically occur in real data.

ARD was proposed by MacKay based on the Bayes model, which effectively selects relevant features through preliminary training. Evaluate initial hyperparameters by maximizing the probability in the data. This process is called evidence augmentation, or maximizing the second type of likelihood. Wipf and Nagarajan [20] applied the ARD method to prune large numbers of irrelevant features, leading to a sparse explanatory subset and demonstrating that the ARD prior maintains advantages compared to conventional priors in feature selection.

TABLE II. RESULTS OF DIFFERENT METHODS (CALCULATED BY AUTHORS.)

Methods	x_num	Stationary	Nonstationary
		Accuracy	Accuracy
ARD	5	100%	60%
HSICLasso	5	100%	60%
LinSVR	5	76%	60%
cmlpgranger	5	80%	72%
ARD	15	56%	76%
HSICLasso	15	92%	67%
LinSVR	15	80%	80%
cmlpgranger	15	100%	97%
ARD	35	63%	64%
HSICLasso	35	96%	85%
LinSVR	35	63%	63%
cmlpgranger	35	99%	98%
ARD	50	59%	59%
HSICLasso	50	98%	90%
LinSVR	50	58%	58%
cmlpgranger	50	99%	97%
ARD	100	56%	55%
HSICLasso	100	98%	85%
LinSVR	100	54%	54%
cmlpgranger	100	98%	97%

Freidling et al. [21] improved the least absolute shrinkage and selection operator (Lasso) method on feature selection by integrating Lasso and particular kernel functions with kernel-based independence measures such as the Hilbert–Schmidt independence criterion (HSIC). Compared to the former Lasso methods, the HSICLasso can capture nonlinear dependency with a clear statistical interpretation and deal with high-dimensional feature selection scenarios in which the number of training samples is smaller than that of features.

In 2021, Alex Tank, Ian Covert et al. [22] use time series normal neural network Model selection framework of Granger nonlinear causality. These researchers applied the multi-layer sensor module (cMLP) and the long run and short run memory architecture of the module. (cLSTM) includes related sparsity, which promotes penalties for network inbound weight, thus selecting Granger demonstrated the construction of Granger causality diagram, which is the correct basis for linear and nonlinear settings.

In Table II, the results can be summarized into three points. (1) In most cases, the order of judgment accuracy of causality is $cmlpgranger > HSICLasso > ARD > LinSVR$. (2) The performance of $cmlpgranger$ varies with the number of factors. When the number of distinguishing factors is greater than 5, it is far better than other methods. (3) $cmlpgranger$ also performs well for nonstationary data. When the data are nonstationary, the accuracy of the method in judging causality is significantly higher than that of other models.

III. RESULTS

Through simulated data, proved $cmlpgranger$ in nonlinear nonstationary has good capability of causal relationships found in the data. Therefore, we determine the cause and effect of the actual data of the Chinese futures market by integrating the results of several causality methods. Specifically, we want to ascertain how the relationship between the commodity prices of energy affects that of agricultural products and its specific impact path.

In order to assess the causal relationship of commodity prices, we have adopted from the Ministry of Commerce of China's commodity price index (CCPI) international commodity prices. Financial indicators covering the stock market, bond market, futures market, interest rate, credit market, and foreign exchange market are extracted from the Wind Economic Database as financial market factors affecting commodities prices. All data begin from June 2006 to October 2021 monthly. The nomenclature of indicators is shown in Table III.

Finally, for each method, we obtain a causality matrix, where $a_{i,j}$ in the matrix equal to 1 indicates that the j th factor is the cause of the i th factor. Otherwise, there is no apparent causality between the two elements. To acquire accurate results, we synthesize the conclusions of the models that perform well on the simulation dataset. Table IV shows the causality result confirmed by $cmlpgranger$. Table V shows the causality result proved through the HSICLasso and ARD methods.

TABLE III. NOMENCLATURE (CALCULATED BY AUTHORS.)

Combining the results of the two methods, we can use Fig. 1 to show the relationship between futures market prices and other economic indicators. The bold black line shows the causal relationship, which is proved by three methods (cmlpgranger, HSICLasso, and ARD). The black line indicates the causal relationship, which is proved by two methods (HSICLasso and ARD). The red dotted line shows the causal relationship proved by cmlpgranger method, which can be indirectly verified by the other two methods. The arrow points from cause to result.

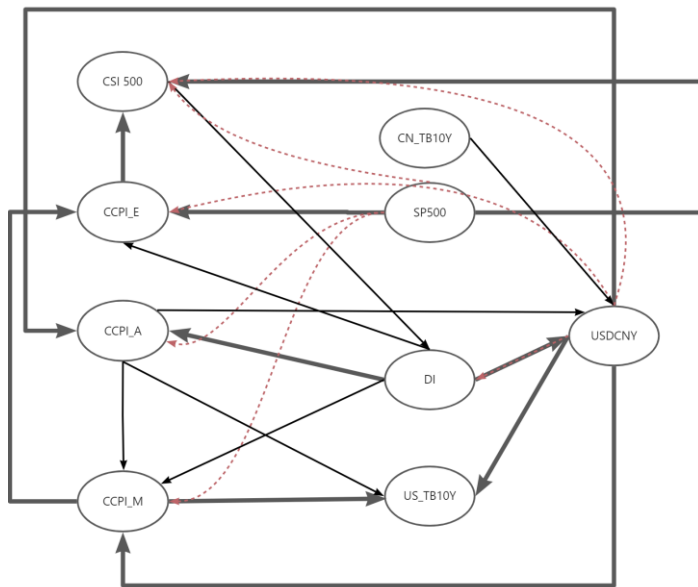

Fig. 1. Causality routes (Calculated by authors.).

Thus, we can conclude that the CCPI_E and CCPI_A have an interactive relationship. The Chinese commodity price of energy will affect the CSI500, thereby affecting the dollar index. The similar conclusion given by Shabir et. al. show that the impact of oil prices and exchange rate on stock prices exists and varies across bullish, bearish, and normal states of the stock market [23]. [23] The dollar index will also affect the exchange rate between China and the US and eventually transmit to the China commodity price of agricultural products. Conversely, the China commodity price of agricultural products will affect the China commodity price of non-ferrous metals and finally transmit to energy prices.

Other researchers have also investigated the conclusion that CCPI_E affects the direction of CCPI_A, and analyzed the relationship between oil prices. Food (agricultural product prices) and exchange rates, as oil prices are transmitted to the local agricultural market through exchange rates. Nazlioglu and Soytaş conducted a study on global oil and agricultural prices, explaining the relative strength of the US dollar [24]. Awartani et al. pointed out that the oil market is the main source and risk transfer for stocks, euro/dollar exchange rates, precious metals, and agricultural products [25]. In our results, we observe the evidence favoring this argument with respect to Chinese commodity prices.

IV. CONCLUSIONS

In this study, we use monthly data from the Chinese financial market from June 2006 to October 2021 to investigate the causal route between the commodity prices of energy and agricultural products. Unlike traditional econometric models, we apply the ML method for the first time to examine this issue. Using these methods, we find that the energy commodity price is vital. It can affect equities changes represented by the CSI 500 Index, thus affecting the exchange rate between China and the US and eventually causing changes in the prices of agricultural products. In comparison with previous studies, we find a correlation between the energy commodity price and agricultural products but emphasize indirect media in causality.

The conclusions drawn in this study led to further considerations. First, we should remain alert to changes in energy commodity prices. Since the commodity price of energy is likely to affect the Chinese capital market price. Second, the exchange rate influences the commodity prices of different varieties in China, indicating China is still highly dependent on foreign countries in terms of the import of products involved in the commodity market. In 2022, under the general environment of long-term inflation in the US, the exchange rate between China and the United States breaking 7, the stalemate in the Russia-Ukraine war, and the continued slowdown in global economic growth, the price of China's futures market will also be volatile under the influence of the strong US dollar. Third, based on the results, most causal paths reflect that the prices of various commodities in China or the prices of China's capital markets are always affected. Still, there is no obvious path to show the impact of China's factors on American financial

indicators. This suggests that there is still a long way to go to improve the Chinese commodity market.

But there is still much work to be done. First, causality may change over time. While we consider the beginning year of COVID-19, the actual time when significant economic changes will occur is 2-3 years after COVID-19, not 2021. As new data becomes available, we should pay attention to these changes. Second, more research is needed to prove the effectiveness of machine learning methods in doing causal discovery.

Research on the Application of Multi-Objective Algorithm Based on Tag Eigenvalues in e-Commerce Supply Chain Forecasting

Man Huang, Jie Lian*

College of Business Administration, Fujian Business University, Fuzhou 350016, China

Abstract—With the continuous development of Internet technology, the scale of Internet data is increasing day by day, and business forecasting has become more and more important in corporate business decision-making. Therefore, to improve the accuracy of Multi Target Regression in the actual e-commerce supply chain forecasting, research through the method of constructing the labeling feature for each target is optimized, the Multi-Target Regression via Sparse Integration and Label-Specific Features algorithm is obtained, and the experimental analysis is carried out on the performance of the algorithm and the application effect in the actual e-commerce supply chain. The experimental results show that the average of Relative Root Mean Square Error value of the research algorithm and is the lowest in most datasets, with a minimum of 0.058 in the effect experiments of prediction and label-specific features; in the effect and flexibility experiments of sparse sets, the lowest average of Relative Root Mean Square Error value of the research algorithm was 0.058, and the average rank value was the smallest. In addition, the average of Relative Root Mean Square Error value of the research algorithm is the smallest under the target variable of Y2 in the Enb data, and its value is 0.075. In the actual e-commerce supply chain forecast, the research algorithm has the highest score of 0.097 points. Overall, research algorithm has a better forecasting effect and higher performance, and has better practicality in practice, and can play a better effect in actual e-commerce supply chain forecasting.

Keywords—Label features; multi-objective algorithm; sparse set; e-commerce supply chain; multi target regression

I. INTRODUCTION

In the business decision-making of enterprises, planning and control are very critical, and forecasting is the basis for the control planning and forecasting of future trends, and forecasting is also important to avoid one-sided decision-making and mistakes [1]. In traditional regression analysis, the marker and target variables are often single, but a single object variable cannot accurately describe the complex information contained. Therefore, the single target regression analysis method has been unable to predict objective problems well and accurately, and Multi-Target Learning (MT) came into being [2]. At the same time, MT-based multi-target regression (Multi Target Regression, MTR) has also been gradually paid attention to, which refers to the use of a common set of input variables to predict multiple continuous variables. In this regard, a large number of domestic and foreign scholars have carried out a lot of research. Based on MTR, Nabati et al. proposed a Gaussian regression-related

algorithm to avoid the fitting problem in training [3]. Based on multi-objective regression, Osojnik et al. proposed a contour tree to improve the prediction effect of multi-label classification [4]. Syed et al. conducted research on semi-supervised techniques based on multi-objective regression by analyzing limited instances, thereby achieving efficient prediction of new objects [5]. However, current multi-objective regression methods mainly focus on mining the correlation between targets and handling the complex relationship between input and output, and most methods learn models from the same feature space, resulting in insufficient flexibility and low prediction performance. At the same time, there is not much research on its application in e-commerce supply chain prediction. Based on this, the study obtained a multi-objective regression via Sparse integration and Label Specific Features (SI-LSF) algorithm by improving MTR, aiming to effectively improve the flexibility of processing multi-objective datasets and thereby enhance the accuracy of the algorithm in e-commerce supply chain prediction.

The research is divided into six sections. Section I is the Introduction of the study. The Section II is a summary and discussion of the current research on multi-objective optimization methods. Section III is the study of the SI-LSF algorithm in e-commerce supply chain prediction, including the definition and related methods of multi-objective regression, and the optimization of the SI-LSF algorithm for multi-objective regression problems. Section IV analyzes the performance and practical application of the SI-LSF algorithm. Section V presents the discussion and last Section VI is a summary of the entire article.

II. RELATED WORK

With the rapid development of information technology, the amount of data on the network is increasing day by day, and the expression of data is also changing rapidly, which makes the ability of data analysis and data mining more and more important. At the same time, the ability to predict data is required. It is also becoming more and more important, and MT has gradually gained attention as a method that is more in line with the laws and characteristics of objective things. Based on this, scholars at home and abroad have carried out research on it. By using multi-objective optimization, Das et al. proposed a fast and accurate meta-model to accurately calculate the effective degree of losses and oil spills, reducing the risk at sea [6]. Dong performed multi-objective optimization of hybrid composites based on multi-objective

*Corresponding Author

regression to verify the effectiveness of the positive hybrid effect in improving the flexural strength of materials [7]. Irodov et al. solved the multi-objective optimization problem of pellet burners by performing a multi-objective regression optimization analysis on the work of tubular gas burners [8]. Wang et al. solved the multi-objective constrained optimization problem of variables by introducing random forests and other methods to continuously approach the objective and constraint functions [9]. Based on the tripartite competition mechanism, Han et al. proposed an improved multi-objective particle swarm optimization algorithm to effectively solve the problems of multi-objective diversity and poor convergence performance [10]. Pereira et al. developed a numerical model of complex structures by proposing equi-grid multi-objective optimization with six objectives, thereby reducing the instability of such grid tubes [11]. Based on reinforcement learning, Dang et al. proposed a multi-objective optimized resource allocation model to achieve a better-distributed search [12]. Ullah et al. achieved multi-objective optimization of motor switching by proposing a new permanent magnet forward pole with flux bridges etc [13].

In addition, Grover et al. comprehensively study e-commerce and supply chain management, to purchase raw materials according to demand forecast, which greatly facilitates supply chain management [14]. Li et al. established a digital model based on signal game theory to obtain revenue forecast information, and then proposed the optimal information acquisition strategy in the supply chain [15]. Yang et al. identified the importance of forecast updates in supply chains by studying the pricing problem in a two-tier fashion supply chain [16]. Shen et al. determined the driving effect of shared information on supply chain management by comprehensively analyzing the problem of forecasting information sharing in supply chain management so that it can better match supply chain demand [17]. Li et al. built an effective forecasting model to reasonably control the multi-item inventory in the supply chain [18]. Chaudhuri et al. integrated extreme learning machines to propose an optimized forecasting model, thereby realizing real-time accurate forecasting of products in supply chain management [19]. Wan realizes the risk prediction of the supply chain by proposing a risk prediction model related to the manufacturing industry and ensures the healthy development of enterprises [20]. Proposing a combined model, Jaipuria et al. constructed a hybrid forecasting technology for supply chain demand, thereby ensuring inventory safety and sufficient order quantity in the replenishment cycle of goods [21].

Through the research of domestic and foreign scholars, it can be found that the multi-objective method can predict the future based on summarizing the laws of objective things, and predictive analysis is very important in the e-commerce supply chain. Therefore, it is expected that the proposed SI-LSF algorithm will be helpful in the actual prediction of the e-commerce supply chain.

III. RESEARCH ON E-COMMERCE SUPPLY CHAIN FORECASTING BASED ON THE SL-LSF ALGORITHM

A. Analysis of Correlation Methods based on Multi-Objective Regression

To improve the breadth and accuracy of the MTR method in e-commerce supply chain forecasting, the research proposes SI-LSF and analyzes its performance and application in actual forecasting by creating a special marker feature for each target. MTR refers to the existence of multiple dependent variables in a model, which takes into account the mapping between multiple output objects. These mapping relationships can be linear or nonlinear. In addition, for the MTR problem, a class of samples contains multiple different output variables, and there are often different semantic relationships between them [22]. By mining the correlation of each output object, the comprehensive prediction effect of multiple indicators can be effectively improved. It is assumed here that X represents the input feature space, Y stands for the output target space, and the membership formulas of the two are shown in Eq. (1) and (2).

$$\begin{cases} X \subset R^m \\ X = (X_1, X_2, \dots, X_m) \end{cases} \quad (1)$$

In Eq. (1), R represents the datasets and m represents the number of feature vectors.

$$\begin{cases} Y \subset R^d \\ Y = (Y_1, Y_2, \dots, Y_d) \end{cases} \quad (2)$$

In Eq. (2), d represents the number of target variables. Therefore, the input vector and the output vector can be given in the MTR problem, and the related equations are shown in Eq. (3).

$$\begin{cases} x^{(l)} = (x_1^{(l)}, \dots, x_m^{(l)}) \\ y^{(l)} = (y_1^{(l)}, \dots, y_d^{(l)}) \end{cases} \quad (3)$$

In Eq. (3), $x^{(l)}$ and $y^{(l)}$ represents a sample, which l represents the target variable, and its number range is between $[1, n]$, which n represents the number of samples. On this basis, the relevant equation of the training set can be given as Eq. (4) shown.

$$D = \left\{ (x^{(1)}, y^{(1)}), \dots, (x^{(n)}, y^{(n)}) \right\} \quad (4)$$

In Eq. (4), D represents the training set. Therefore, it can be determined that the task of MTR is to learn a mapping function, so that for any uncertain vector, all output variables can be obtained at the same time through $\hat{y} = h(x)$. The multi-objective regression problem and the multi-label problem are similar in that the output variable of the multi-objective regression problem is continuous, while the classification problem is discrete, so it can be divided into two types, namely problem transformation method and algorithm adaptation method, the contents of which are shown in Fig. 1.

Fig. 1. Specific classification of multi-objective regression methods.

It can be seen in Fig. 1, the problem transformation method mainly includes Single-Target Method (ST), Stacked Single-Target (SST), Regressor Chains (RC), and multi-target support vector regression (Multi-Output Support Vector Regression, MO), algorithm adaptation methods include statistical methods (Statistical Methods, SM), support vector machines (Support Vector Regression, SVR), kernel methods (Kernel Methods, KM), regression tree (Multi-Target) Regression Trees, (MT) and classification rules. The ST problem is often used to deal with the MTR problem, so ST is used for learning prediction. The least squares criterion is used to solve it, and its formula is shown in Eq. (5).

$$\{\hat{a}_{ij}\}_{j=1}^m = \arg \min \{ \hat{a}_{ij} \}_{j=1}^m \left\{ \sum_{i=1}^N \left(y_i^{(l)} - \sum_{j=1}^m a_{ij} x_j^{(l)} \right)^2 \right\} + \lambda_i \sum_{j=1}^m a_{ij}^2 \quad (5)$$

In Eq. (5), \hat{a}_{ij} represents the regression coefficient, i represents the target variable, j represents the feature vector, and $\lambda_i > 0$ represents the ridge parameter. In the MO problem, multiple virtual samples can be constructed by virtualizing the eigenvectors, and the objective function definition formula is shown in Eq. (6).

$$\begin{cases} f = \frac{1}{2} \|w\|^2 + \sum_{l=1}^N \frac{1}{c} \sum_{i=1}^d e_i^{(l)2} \\ s.t. y_i^{(l)} = w^T \phi(I_i, x^{(l)}) + I_i b + e_i^{(l)} \end{cases} \quad (6)$$

In Eq. (6), f represents the objective function, w represents the weight vector, c represents the trade-off factor between dimension and loss, $e_i^{(l)}$ represents the fitting error, $\phi(\cdot)$ represents the nonlinear transformation of the feature space, b represents the deviation vector, I represents the virtual sample, T represents the transpose.

The algorithm adaptation method uses a single model to predict all the targets at one time, so that the correlation and internal connection between the target and the input features can be captured, which has the advantages of more

interpretability and better prediction performance. In the adaptation method, the most important are SM and SVR. SM is believed to treat the first attempt as predicting multiple targets at the same time, and its purpose is to improve the prediction accuracy by using the correlation between target variables, while SVR is usually used to deal with single-target regression problems. It reflects the relationship between input variables and output variables on a certain datasets, and the operation formula is shown in Eq. (7).

$$\frac{1}{2} \|w\|^2 + C \sum_{i=1}^N L \left(y_i^{(l)} - \left(\phi(x^{(l)})^T w + b \right) \right) \quad (7)$$

In Eq. (7), w represents the regressor, C represents the user-selected parameters, and b represents the bias. In addition, the MT method in the algorithm adaptation method can predict multiple continuous targets when dealing with multi-objective problems. It has two advantages, that is, the scale of a single multi-objective regression tree model is often smaller than that of a single multivariate model. The multi-target regression tree can better distinguish the correlation of multiple target variables; the KM method is an index kernel with a coupled regularization function; the classification rule is to convert the regression tree set into a rule set, to select the best subset of rules to improve prediction accuracy.

B. Research on SI-LSF Algorithm Optimized for Multi-Objective Regression Problem

MTR types are mainly problem transformation methods and algorithm adaptation methods, and their basic functions have been widely used in computer vision and medical image analysis. However, current MTR is mainly studied for linear models but lacks a method capable of simultaneously handling the nonlinear relationship of multiple objects with the input space [23]. Therefore, the research optimizes the existing problems of MTR and proposes the SI-LSF algorithm. The SI-LSF algorithm is based on the superposition of a single target, adopts the method of boosting learning, and studies the specific characteristics of the markers to explore multiple targets. Inter relationships between variables. Second, a sparse ensemble-based model is built using the sparse ensemble method. Finally, combining sparse integration with target features can simultaneously address two challenges of MTR within a single framework, namely establishing the fundamental relationship between input features and output objects and exploring their inter-correlation to improve prediction performance. The stacking of a single target is also called Stacked Single Target (SST) [24]. Its training and prediction framework is shown in Fig 2.

It can be seen in Fig. 2, its frame structure is divided into two stages of training and two stages of prediction. In the training phase, the first is to train the model for each target through the training set, to obtain the predicted value, and then enter the second phase of training, that is, to establish the second phase of training and then output the final training model. In the prediction stage, for an unknown sample, first pass the model in the first stage to obtain the prediction vector, then extend the prediction vector into the feature vector, and then set the result as the new input predicted by the model in

the second stage value, and finally use the second-stage model to obtain the final prediction result. The core idea of SST is to use the predictions of the remaining targets in the first stage as additional input variables. Although the real value of the target can be obtained in the training set, there is no real target in the prediction set. Therefore, in the prediction process, the SST must depend on the estimation of the target based on the prediction results of the single-target regression. However, such an approach violates a central assumption of supervised learning theory: training and trial data must be consistent and independent of each other [25].

In the second stage, due to the introduction of additional input variables, the noise of the prediction is caused, which leads to the estimation error of the model. Therefore, to solve this problem, it is necessary to improve the training and prediction of the target variable. The numerical value used in the prediction compatibility. Label-Specific Features (LSF) is another important element in SI-LSF, and its framework is shown in Fig.3.

It can be seen in Fig. 3, before each object is marked for recognition, it is first preprocessed and extended as an additional feature. The training set transformed by the instruction is $D' = \left\{ \left(x^{(j)} \cup \hat{y}^{(j)}, y^{(j)} \right) \mid 1 \leq j \leq n \right\}$, which $x^{(j)}$ represents the initial feature vector and $y^{(j)}$ is the target real

value vector. In the learning process of LSF, the first step is to find the relevant features for each target, to improve its learning accuracy. The formulas are shown in Eq. (8), (9), and (10).

$$R_1(\gamma, s) = \{X_i | x_{i\gamma} \leq s\}, R_2(\gamma, s) = \{X_i | x_{i\gamma} > s\} \quad (8)$$

In Eq. (8), it x_i represents a certain column attribute, s represents x_i a certain value in it, which is represented as the corresponding split point, R_1 and R_2 represents s the two parts of the attribute using the division, and the value in the γ representation X represents a feature.

$$\hat{c}_t = \frac{\sum_{X_i \in R_1(\gamma, s)} y_{ij}}{|R_1|} \quad (9)$$

In Eq. (9), it \hat{c} represents the corresponding target mean value, t which is a determined value, which is 1 or 2.

$$\min_{\gamma, s} \left(\min_{X_i \in R_1(\gamma, s)} \sum (y_{ij} - \hat{c}_1)^2 \right) + \min_{\gamma, s} \left(\min_{X_i \in R_2(\gamma, s)} \sum (y_{ij} - \hat{c}_2)^2 \right) \quad (10)$$

Fig. 2. SST training and testing framework diagram.

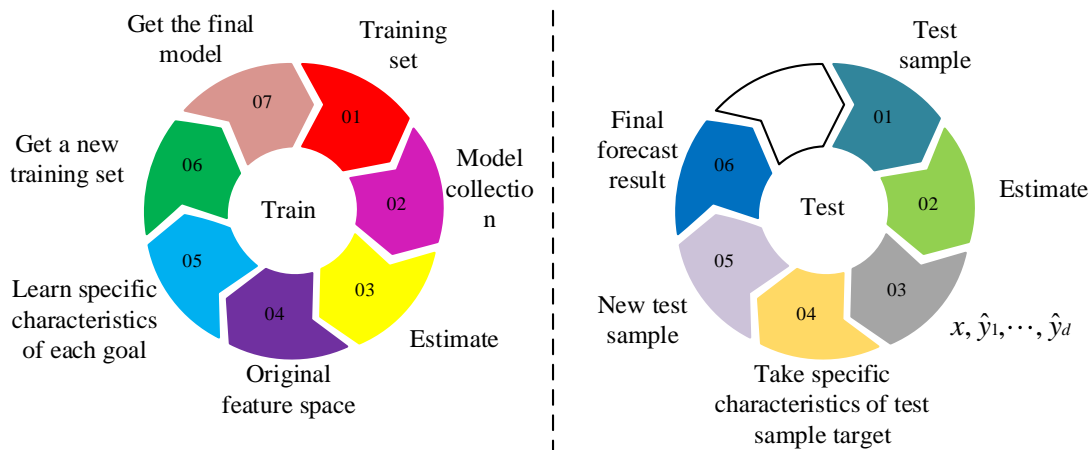

Fig. 3. LSF frame structure diagram.

According to the minimized square error in Eq. (10), the best division feature and split point can be found, to determine the relevant feature set of the target and delete redundant features. It is worth noting that these features are only a subset of features in the training set, and there is not enough diversity in the feature space to represent objects well. To improve the difference of the feature space, the target correlation method is used to construct the marker-specific feature, and the residual of each repetition is used to describe the local feature, and it is used as an additional feature to reflect the local information of the feature space. Perform direct modeling to improve the expressiveness of the model. The relevant calculation formulas are shown in Eq. (11), (12), and (13).

$$g^0(X'_{TR}) = f_q((X'_{TR}); Y_j) \quad (11)$$

Set the initial value represented by Eq. (11). Among them, g represents the predicted value, X'_{TR} represents the output space, f_q represents the basic learner, and Y_j represents the target.

$$r_i^{(j)} = - \left[\frac{\delta l(Y_j, g_{t-1}(X'_{TR}))}{\delta g_{t-1}(X'_{TR})} \right] \quad (12)$$

Eq. (12) means to find the negative value of the current mode and treat it as a residual. Among them, r represents the relevant features and l represents the squared error loss function.

$$g_t(X'_{TR}) = g_{t-1}(X'_{TR}) + f_q(X'_{TR}; r_i^{(j)}) \quad (13)$$

Equation (13) is to set the target as the residual estimation in Eq. (12), to use the negative gradient value to update the model, and use it as the target of the next iteration. In addition, after the introduction of marker features, LSF still selects a single-target regression analysis method, which will cause the complex input and output relationship models in the first and second stages to be unable to be established. Therefore, the proposal of SI-LSF is exactly to flexibly handle these complex relationships. SI-LSF is a sparse ensemble algorithm, which will be applied to ensemble learning. Therefore, the research proposes a corresponding aggregation function to deal with the complex problem of ensemble learning calculation, and its calculation formula is shown in Eq. (14) and (15).

$$w_j^* = \min_{w_j} \frac{1}{2} \sum_{i=1}^N (w_j^T \hat{y}_i - y_{ij})^2 + \lambda \|w_j\|_1 \quad (14)$$

In Eq. (14), w_j represents the weight vector and $\lambda \|w_j\|_1$ represents the regular term. It means that by introducing a regular term, the weight of the base model becomes 0, which realizes the sparseness of the data and automatically selects a regression method suitable for learning, which improves the flexibility of the algorithm. And reduce the time and space complexity and enhance the prediction effect.

$$h_j = \sum_{i=1}^k w_{ij}^* f_i \quad (15)$$

In Eq. (15), h represents the final prediction result, f represents the regression method, and w_{ij} represents the distribution weight. Based on this, the frame structure of SI-LSF can be given, as shown in Fig. 4.

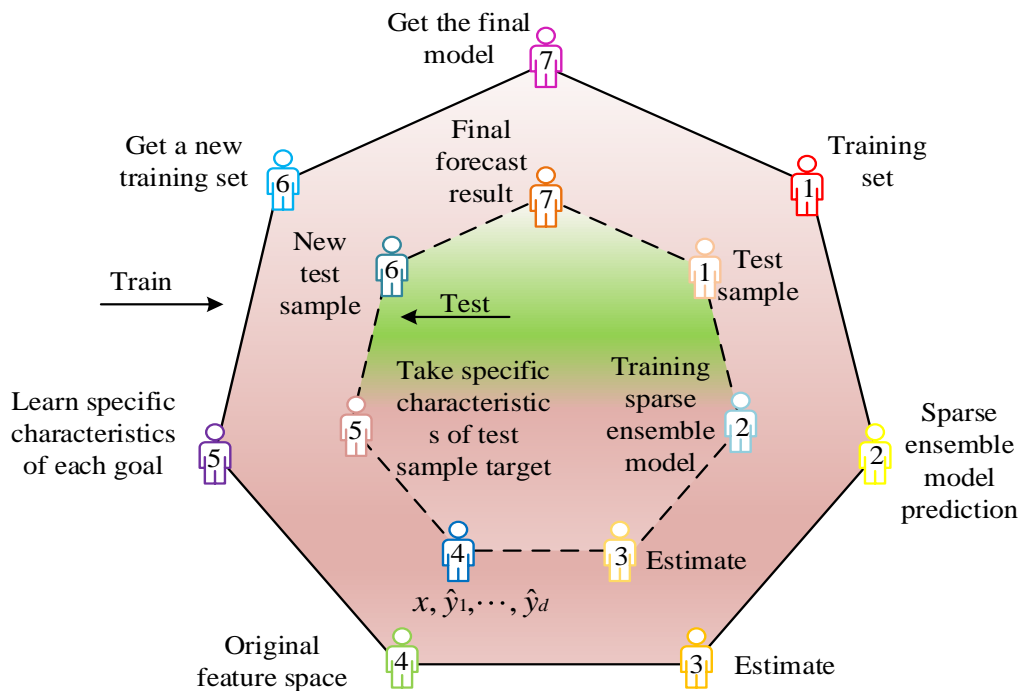

Fig. 4. SI-LSF frame structure diagram.

It can be seen in Fig. 4, unlike most existing methods that integrate the prediction results into the final stage, the SI-LSF algorithm integrates the prediction results of each model, and its advantage is that it can accurately determine the first, the second stage marks, the eigenvalues and selects the most important mode by weighting, thereby reducing the interference of the system and improving the accuracy of the system. Therefore, the framework structure of the SI-LSF algorithm utilizes a sparse ensemble to generate a sparse ensemble model and perform relevant training predictions on it to obtain the specific characteristics of the sample target. Add the target and specific features to form a new training set and test set to get the final model and prediction results.

IV. SI-LSF ALGORITHM PERFORMANCE AND PRACTICAL APPLICATION ANALYSIS

To test the performance of the SI-LSF algorithm, related experiments were carried out. Before the experiment, the study collected related datasets. Since there are relatively few related public datasets, the study selected 18 commonly used datasets for the experiment. The dataset information is shown in Fig. 5.

In Fig. 5, the horizontal axis 1-18 represent 18 data sets, namely Aandro (prediction of future values of water quality variables), Slump (concrete slump), Edm (electronic discharge machining), Atp7d (airline ticket prices), Sfl (solar flares), Oes97 (occupational employment survey), Atpld, Jura (determination of 359 seven heavy metals in soils in the Swiss Jura region), Oes10, Osales (“online product sales”) preprocessed version in competition), Enb (energy building),

Wq (14 target attributes of water quality), Sf2, Scpf (preprocessed version of the dataset used in a competition), S cm20d (supply chain management), R f1 (river flow), R f2, and S cmls. In addition, the three sub-graphs represent the number of samples, the number of features, and the number of targets in the dataset, respectively.

Among them, these datasets are predictions for the future or related content, which can effectively improve the actual response speed of the research algorithm, which is more in line with the overall research. They contain different target attributes in different fields, so they have high effectiveness and practicality in promoting intelligent analysis and improving actual work efficiency. Therefore, this study selected these 18 publicly available multi-objective regression datasets to validate the research algorithm.

On this basis, the research uses the average relative root mean square error (aRRMSE) measure as the evaluation index, and the smaller the value, the better the performance. And introduce the integrated regression chain (Ensemble of Regression Chains, ERC), support vector regression chain (SVR-correlation Chains, SVRCC) and multi-layer multi-target regression (Multi-layer Multi-target Regression, MMR) and SST algorithm, it is combined with the performance comparison of SI-LSF algorithm mainly includes three aspects: prediction effect, the effectiveness of label-specific features, and effectiveness of sparse ensemble. The first is to compare the prediction effects of the experiments. The prediction effects of several algorithms under different datasets are shown in Fig. 6.

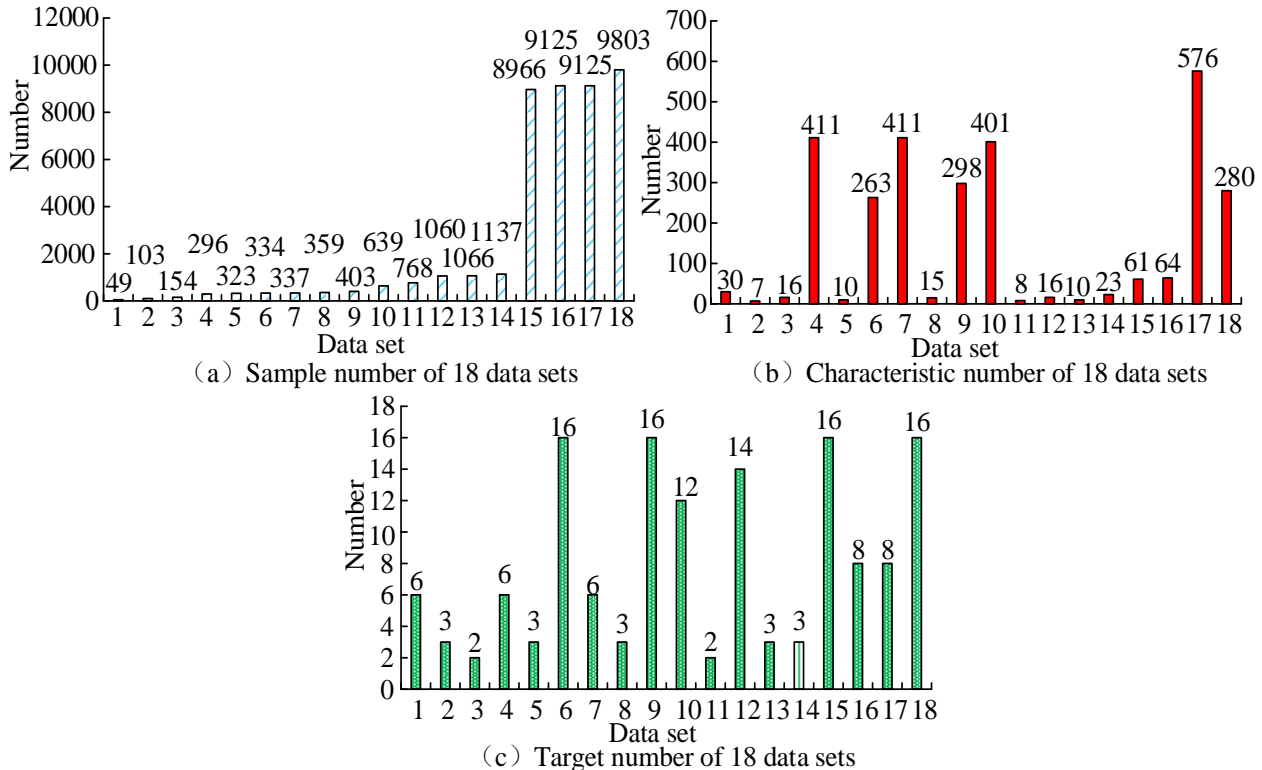

Fig. 5. Relevant information of 18 datasets.

It can be seen in Fig. 6, the SI-LSF algorithm has the lowest aRRMSE values in all 16 datasets, and only the second lowest aRRMSE values in two datasets, roughly between 0 and 0.9. Among them, the SI-LSF algorithm has the smallest Rf2 in the datasets, which is 0.058, and the overall average value is 0.477. In addition, in the average ranking of the five algorithms, SI-LSF also has the lowest aRRMSE value of 1.111. The experimental results show that the prediction effect of the SI-LSF algorithm is the best among the five algorithms, and the performance is also the best. The second goal is to verify the validity of the specific features of the SI-LSF labels. Based on this, the research sets the control scalar as the label-specific feature, compares the SI-LSF algorithm with the sparse integration (Sparse Integration, SI) algorithm, and also compares the aRRMSE values of the two. The results are shown in Fig. 7.

It can be seen in Fig. 7 that the aRRMSE value of the SI-LSF algorithm is smaller than that of the SI algorithm on the 16 datasets, greater than that of the SI algorithm on the Rf1 dataset, and equal to the SI algorithm on the Oes97 dataset. In addition, the aRRMSE value of SI-LSF is generally between 0 and 0.9, and its minimum value appears on the Enb dataset at 0.070. On the whole, the prediction performance of SI-LSF on most datasets has the rain SI algorithm. Through the verification of the specific characteristics of the label, it is proved that it can further improve the SI-LSF algorithm and significantly improve it. The prediction accuracy of the SI-LSF algorithm, so label-specific features are effective for the SI-LSF algorithm to improve. Finally, to verify the effectiveness of the sparse ensemble, the study introduced

Support Vector Regression and Label-Specific Features (SVR-LSF), Linear regression (Linear regression and Label-Specific Features, Linear-LSF), and random forest (The three basic regression models of Random Forest and Label-Specific Features, RF-LSF) are compared with the SI-LSF algorithm. It is worth noting that the SI in the SI-LSF algorithm is used to solve the complex relationship between the input characteristics and the output objects, so it is necessary to use the SI as a control variable to conduct experiments, and the results are shown in Fig. 8.

It can be seen in Fig. 8, in the 15 datasets, the aRRMSE value of SI-LSF is lower than that of the other three algorithms. It is the same as the RF-LSF algorithm in the Atp7d and Wq datasets, which is 0.428. -LSF is the same, which is 0.796; the lowest value of the SI-LSF algorithm appears in the datasets Rf2, which is 0.058, and its average value is 0.477, which is lower than 0.615 of SVR-LSF, 0.695 of Linear-LSF and 0.542 of RF-LSF, its average rank value is one, which is much lower than the other three algorithms. On the whole, the prediction effect of the SI-LSF algorithm is better, and it has the best performance among the four algorithms, which shows that the sparse ensemble is effective in improving the performance of the SI-LSF algorithm. In three aspects, namely the prediction effect, the effectiveness of label-specific features, and the effectiveness of sparse ensemble, it is proved that the SI-LSF algorithm has better performance. In the complex relationship between objects, the study selected seven datasets from 18 datasets and compared the value of aRRMSE for each object, and the results are shown in Table I.

(c) Score of si-lsf algorithm under different feature groups

Fig. 9. Comparison score results of several algorithms and score results of SI-LSF.

It can be seen from Table I that the aRRMSE value of SI-LSF on most datasets is the smallest, and in the Enb data, the Y2 target variable is at the smallest value, which is 0.075. In general, in each dataset, there is a complex relationship between the input target and the output feature. At the same time, the SI-LSF algorithm has a sparse integration, so its prediction performance is significantly better than other algorithms, which also proves that the SI-LSF algorithm is effective in processing. It has strong flexibility in multi-objective problems. To further verify the effectiveness of the SI-LSF algorithm in practical applications, the research applies it to the field of the e-commerce supply chains to predict multi-objective tasks for supply chain demand, and it mainly conducts comparative experiments under different feature groups. Here again, two regression models are introduced, namely extreme gradient boosting (eXtreme Gradient Boosting, XGBoost) and distributed gradient boosting framework (light Gradient Boosting Machine, lightGBM). The experimental results are shown in Fig. 9.

In Fig. 9, numbers 1-8 represent feature groups, representing basic statistical features, discrete features, time-series-related features, optimal combination features, basic statistical features + discrete features, basic statistical features + discrete features + time-series-related features, and basic statistics Features + discrete features + time series related features + optimal combination features and feature selection. It can be seen in Fig. 9(a), the scores of several algorithms are roughly between 0.08 and 0.09, of which the score of the SI-LSF algorithm is 0.097, which is the highest among several algorithms, showing that the SI-LSF algorithm is used in the supply chain. The forecasting performance in demand is the highest and has strong applicability. It can be seen in Fig. 9(b) and 9(c), the SI-LSF algorithm has the highest score when the number of feature dimensions is 570, that is, 0.0924. Therefore, it can be determined that the SI-LSF algorithm has the highest score after data preprocessing and feature selection. It can achieve a good forecast in supply chain demand and has strong practicability.

V. DISCUSSION

The SI-LSF algorithm has the lowest aRRMSE value in all 16 datasets, with only the second lowest aRRMSE value in both datasets, roughly between 0 and 0.9. Among them, the SI-LSF algorithm is the smallest in the dataset Rf2, with a value of 0.058 and an overall average of 0.477. In addition, among the average rankings of the five algorithms, the aRRMSE value of SI-LSF is also the lowest, at 1.111. In addition, the overall aRRMSE value of SI-LSF is between 0 and 0.9, with its minimum value appearing on the Enb dataset at 0.070. When comparing with other algorithms, the aRRMSE value of SI-LSF is lower than that of the other three algorithms. In the Atp7d and Wq datasets, it is the same as the RF-LSF algorithm with a value of 0.428, while in the Scpf dataset, it is the same as the Linear-LSF algorithm with a value of 0.796. This result is superior to the results of Wang et al [26]. In practical applications, the SI-LSF algorithm has a score of 0.097, which is the highest among several algorithms. This indicates that the SI-LSF algorithm has the highest predictive performance in supply chain demand and has strong applicability. This result is basically consistent with the results

of Moghadam et al [27]. Overall, the SI-LSF algorithm can achieve good prediction in supply chain demand after data preprocessing and feature selection, and has strong practicality.

VI. CONCLUSION

The advent of the big data era requires enterprises to improve their data mining capabilities, and at the same time requires enterprises to make effective predictions based on these data. Therefore, the research proposes the SI-LSF algorithm by creating special marking characteristics for each target and conducts experimental analysis on its performance and practical application, so as to improve the accuracy of MTR in e-commerce supply chain prediction. The experimental results show that in the prediction effect experiment, the aRRMSE value of the SI-LSF algorithm is the lowest in most datasets, with a minimum of 0.058 and an average of 0.477; in the validity experiment of label-specific features, the aRRMSE value of the SI-LSF algorithm is lower than that of the SI algorithm, and its lowest value is 0.070; in the effectiveness experiment of sparse integration, the aRRMSE value of the SI-LSF algorithm is lower than the other three algorithms in most datasets, and the lowest value is 0.058, and its average ranking value is 1, which is also the lowest; in the flexibility experiment of the SI-LSF algorithm, it is found that the aRRMSE value of the SI-LSF algorithm in most datasets is the smallest, and it is the smallest value in the Y2 target variable in the Enb data, which is 0.075. In addition, in the actual e-commerce supply chain prediction experiment, it is found that the SI-LSF algorithm has the highest score of 0.097. Under different feature groups, the SI-LSF algorithm has the highest score when the feature dimension is 570, with a score of 0.0924. In this case, better results can be obtained. In general, compared with other algorithms, SI-LSF has the best prediction effect and the best performance, and its prediction results are more effective. In practical applications, the SI-LSF algorithm has higher applicability with greater practicality. However, the selection of label-specific features does not take into account the shared information among variables, so it needs to be optimized for this aspect in the follow-up. At the same time, multi-objective regression algorithms have high applicability to practical application scenarios, so future research will consider applying the SI-LSF algorithm to practical problems in more fields, such as big data analysis, artificial intelligence, etc.

Construction and Application of Automatic Scoring Index System for College English Multimedia Teaching Based on Neural Network

Hui Dong*, Ping Wei

School of Foreign Languages, Tangshan Normal University; Tangshan Hebei, 063000, China

Abstract—With the continuous development of interactive multimedia, multimedia is increasingly integrated into college English teaching, providing advanced teaching equipment and resources. While enriching the teaching environment, it also brings new challenges to teaching ideas and strategies. Although the proportion of independent and selective learning of college students has increased, classroom teaching still constitutes the most essential unit of educational activities. Classroom evaluation is an important means and institutionalized element to improve the quality of university teaching. This paper analyzes the elements of multimedia classroom teaching and constructs an evaluation index system for English multimedia teaching. The improved model is used to achieve automatic teaching grading, acquire knowledge through environmental learning and improve its own performance, and evaluate the mathematical model of the English multimedia teaching evaluation system established by neural network theory accurately and effectively. In this paper, the results of automatic scoring of multimedia English teaching in colleges and universities are compared. Simulation software is used to verify the established neural network evaluation system. The simulation results show that the model is more suitable for the test data of English classroom teaching than the traditional methods, and the prediction effect is better. All 15 English teachers had a predicted error rate of less than 2%, and all 10 English teachers had a predicted error rate of less than 1%.

Keywords—Cognition of multimedia teaching in universities; scoring index; neural network; teaching system

I. INTRODUCTION

With the information in hypermedia structure to achieve human-computer interaction, multimedia college English classroom has become the driving force of classroom teaching mode reform, which has brought new challenges and development opportunities to teaching. In order to realize the hardware environment of multimedia classrooms, colleges and universities are committed to improving the level of multimedia teaching. How to scientifically apply multimedia technology to complete education is studied. The application has greatly changed the classroom teaching mode, such as promoting students' leading position and changing teaching strategies and methods. Modern educational teaching evaluation model guides and evaluates multimedia classroom teaching under the new situation [1]. The characteristics of multimedia teaching and the thought of modern educational technology are fully reflected in multimedia classroom teaching. Multimedia classroom teaching effectively promotes and determines the level of talent training and affects the

quality. Multimedia instruction needs new evaluation indicators to guide and promote education. The establishment of a multimedia classroom teaching index system is the guidance [2] Any evaluation system to develop scoring standards is the basis of the construction of the quality evaluation system of the discipline. By constructing the teaching quality evaluation system to form a closed-loop feedback mechanism, the regular operation and perfect development of each fundamental element of the system can be guaranteed to achieve the expected goal. Therefore, the evaluation system is the comprehensive embodiment of all levels and elements of the system, and the evaluation system is the system and operation mechanism. Consequently, it is of great significance to improve the evaluation of college classroom teaching, expand the management theory of college teachers and improve the quality of classroom teaching.

Neural network theory is the information science of human brain learning. A network is a multi-layer feedforward network in many types of neural networks. The neural network is widely used in decision analysis of nonlinear, complex and comprehensive problems [3]. Neural networks can be used as a qualitative and quantitative combination of practical tools to comprehensively evaluate the object system beyond the sample mode. The theory of artificial neural networks is a frontier field that learns from the human brain. The correct can be used as a qualitative and quantitative effective tool to make a comprehensive evaluation of the object system outside the sample mode. In the face of the number of thousands of learners, it is necessary to establish a clear standard assessment. Relying on machine learning automatic detection can accomplish this work while reducing teachers' workload. The algorithm is used in comprehensive universities. Establishing an evaluation system that adapts to the new teaching mode and conforms to the latest teaching concept has become an important topic.

Automated Essay Scoring (AES) was the first to start in the field of automated essay scoring. The Project Essay Grade (PEG) system can extract statistical information about the essay, such as the length of the text, the number of sentences, and the proportion of adjective prepositions. Then these statistical features are taken as multivariate independent variables, and the previously evaluated composition scores are taken as dependent variables. Logistic regression algorithm is used to find the representation function between these statistical features and the scores of English multimedia

teaching, and automatic scoring is achieved by finding out a multivariate function that can describe the relationship between these statistical information and the scores of English multimedia teaching. PEG system can achieve a high accuracy in composition grading, but because it cannot deeply understand English multimedia teaching, its grading results are difficult to be accepted later.

We can use natural language processing technology to develop areas of automatic grading of subjective questions to help teachers teach and students learn. Moreover, online teaching has become an important mode of current teaching. If AI-related technologies can be applied to English multimedia teaching, the model can be trained by using the students' homework that has been corrected online as training samples. Then, with the increase of training samples, the performance of the automatic scoring system will continue to improve, and the system will be closer to the level of teachers' manual scoring.

The rest of this article is organized as follows. Section II discusses the related work. Section III constructs an automatic scoring index system for multimedia English teaching. Section IV analyzes the application results of automatic scoring in college English multimedia teaching. Section V summarizes the full text.

II. RELATED WORK

The importance of English teaching evaluation has gradually attracted the attention of domestic college teachers and educational management departments, and the theory and practice of teaching evaluation have significantly been developed [4]. At present, domestic universities actively learn from the research results of computer networks. It takes multimedia technology and combines modern teaching models such as flipped classrooms, Massive Open Online Courses (MOOC), micro class and mobile device-assisted learning with traditional college English teaching. English through innovative teaching mode, and realize the transformation trend of professionalization, mobile, socialization and data. The primary methods of evaluation index systems include the brainstorming method, target element decomposition method, structure decomposition method and target classification method, and there have been rich theoretical research results. Based on the Analytic Hierarchy Process (AHP), Fu J et al. constructed a three-in-one inquiry classroom teaching evaluation system of teachers' teaching, students' learning and supervision evaluation [5]. Yang Y et al. pointed out that the classroom teaching evaluation system should include vector, positioning, concept, condition, operation and output subsystems [6]. Qilin S et al. established the monitoring and evaluation system, of course, teaching quality, including four processes of course application evaluation, Q evaluation system, early feedback of course teaching and stage evaluation, which involved course content, student development, teacher-student interaction, classroom organization, teaching effect, reading and homework [7]. Pustokhina I V et al. pointed out that the main focus of the change in the evaluation method was: the purpose and function of the evaluation should be to improve the happy atmosphere of the learning classroom and cultivate the self-confidence of students in physical learning [8]. Wang X et al. pointed out that the evaluation of teachers

should also involve students. Secondly, the evaluation should also pay attention to the combined evaluation of final results and usual performance, rather than one by one, and the evaluation process should also absorb students' participation [9]. Song R et al. pointed out online teaching, teaching quality, course content and other high-frequency words. It has been a hot issue in the field of online teaching evaluation recently. Evaluators often collect data on students' learning behaviours, preferences, motivations and other aspects through online teaching management systems, which provide important conditions and resource guarantees for learning analysis [10]. Kumar A et al. take the comprehensive evaluation problem of students' learning and examination scores as the evaluation object and use neural networks to establish a comprehensive evaluation model. Their research has achieved certain results and opened up a new path for teaching evaluation [11]. Based on the above considerations, the dynamic is the change in classroom teaching. The current classroom teaching evaluation still focuses on the static classroom teaching effect. Teaching quality includes teaching objectives, teaching attitude, teaching content, teaching process, teaching effect and so on, which cannot reflect the process and dynamic characteristics of classroom teaching. Media classroom teaching is a prerequisite for the creation of situations, the display of personality, the participation of learners and the development of learners' cognition. However, the current classroom teaching evaluation index is constantly improving and perfecting. The research on the assessment of English teaching needs to catch up. Educators need to construct a multivariate assessment model integrating the summative evaluation, diagnostic assessment and formative assessment, especially emphasizing the role of formative assessment. With the advantage of information technology, students' learning process is dynamically monitored, and the teaching quality is evaluated from the influencing factors.

III. AUTOMATIC SCORING INDEX SYSTEM FOR MULTIMEDIA ENGLISH TEACHING

A. English Teaching Effect Rating System

Based on the effect of systematic teaching from a multidimensional perspective, this paper constructs an English teaching effect scoring system and comprehensively considers it through measurable evaluation indicators. The evaluation system of English multimedia teaching should fully consider guiding the quality [12]. The index system discovers that the teacher puts forward the improvement direction by analyzing the existing problems in teaching. English multimedia teaching quality is decomposed into evaluation units from three structural elements: teaching management department, teacher performance and student response. Starting from the teaching management department, the standardization of teaching content is mainly considered. From the teachers' perspective, the evaluation especially involves teaching art and teaching attitude. From the perspective of students and learners, it primarily aims at students' reaction in the teaching process and evaluates the degree of their integration into classroom teaching. According to the expert survey method and feedback teaching theory, a number of measurable system sub-indicators are designed in detail, and the system of English classroom teaching effect is constructed, as shown in Fig. 1.

Classroom teaching is a process of dynamic change, reflected in each dynamic link, and each dynamic link's effectiveness is reflected to a certain extent [13]. It generally divides the per-preparation of teaching content, teaching art, teaching attitude, and student feedback. Teaching content is the key part of the design. Teachers clear the goal, and teaching is conducive to the direction. In the multimedia environment, the richness of resources is reflected in text materials, pictures, objects, audio, video and other aspects. Teachers should consider the support of various teaching resources when designing teaching. Under the support of teaching resources, teachers will create a particular situation according to the specific teaching content, such as the life as mentioned earlier situation, problem situation, simulated real-world situation, virtual situation, and other teaching resources that should be designed in connection with life. The observation point analysis of the multimedia classroom teaching process should start from the essential link of classroom teaching and determine the evaluation standard according to the goal that the teaching link should achieve.

B. Construction of Neural Network Classroom Teaching Evaluation Model

Neurons connect the different layers of the neural network, and neural networks can obtain a stable network system by repeated approximation learning [14]. The Back Propagation (BP) algorithm program updates the simple AHP classroom teaching evaluation index weight determination method. Model hierarchy is used to get the statistical sample data of the effect of classroom teaching evaluation, teacher evaluation sample validation set method divided into two parts of the training set and test set, enter a set of classroom teaching evaluation, the weighted average of the measure of a teacher's classroom teaching effect comprehensive score, as the training goals scored. The model calculates the neural network test score obtained by the investigated teachers, compares it with the target score of the sample data, and calculates the simulation

prediction error of the neural network statistical data. The estimated weights of the model are repeatedly debugged until a stable neural network is obtained. Based on the backpropagation method, a term is added to each weight and min value change proportional to the previous weight and min value change.[15]. The algorithm is as follows:

$$available\Delta X_i = \frac{-[J^T(x_i)J(x_i)+\mu I]^{-1}}{J^T(x_i)V(x_i)} \quad (1)$$

J is the Jacobian matrix, I is the identity matrix, the error vector, and V is the parameter vector. All inputs are submitted to the network, and the corresponding network outputs and errors are calculated using the following equation.

$$e_q = t_q - a_q^m a^0 = p \quad (2)$$

$$a^m = f^m(w^m a^{m-1} + b^m), m = 1, 2, \dots, M \quad (3)$$

Where 'p' is the input vector, 'w' is the weight vector of the MTH layer, 'f' is the vector of the transmission function of the MTH layer, 'a' is the output vector of the warp element generated in the MTH layer, and b is the bias value vector. For batch processing, the mean square error is the sum of the squared errors of all the targets in the training set [16].

$$the f(x) = \sum_{q=1}^Q \sum_{j=1}^s (e_j)^2 \quad (4)$$

The key in the algorithm is the calculation of the matrix. In order to compute the matrix, you need to replace the squared error's derivative with the error's derivative. The error vector is:

$$V^t = [e_{1,1}, e_{2,1}, \dots, e_{S^m,1}][e_{1,2} \dots e_{S^m,2}][e_{1,Q} \dots e_{S^m,Q}] \quad (5)$$

Where S^m is the total number of hidden layer nodes in the m layer.

$$N = QS^m, n = S_1(R + 1) + S_2(R^1 + 1) + \dots + S_m(R^m + 1) \quad (6)$$

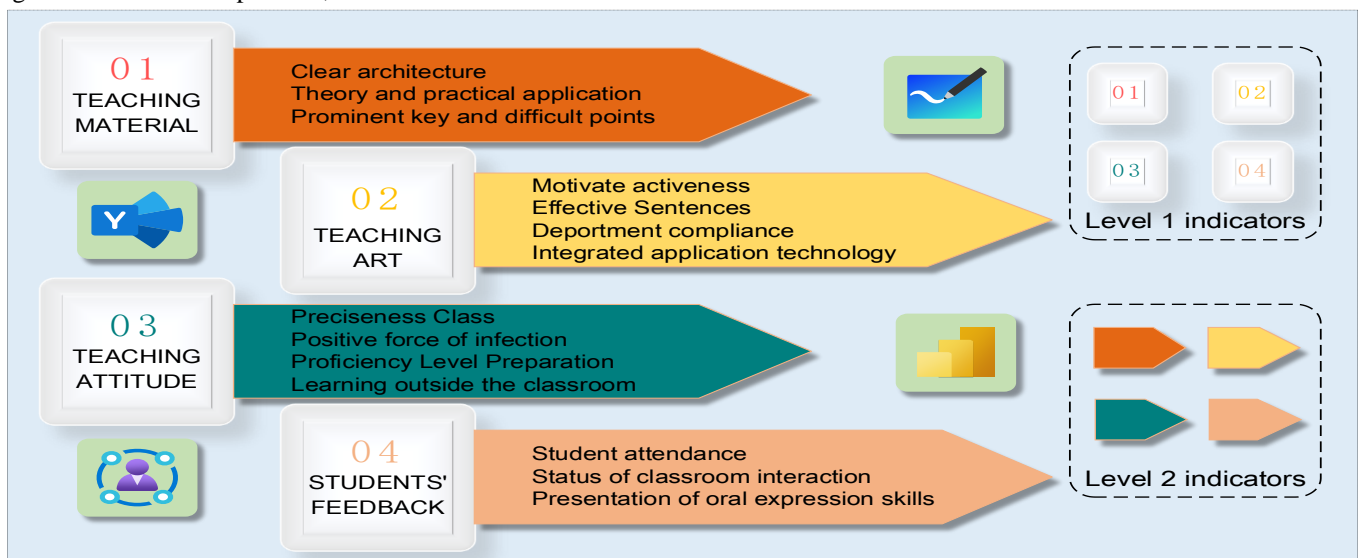

Fig. 1. Evaluation index system of English classroom teaching effect.

C. Improve the Learning Method of Neural Network

Neural networks acquire learning from the environment. The quality evaluation system of the teaching system starts from the main body and integrates the evaluation into any link. Only in this way can the evaluation system be formed to guide the whole system at a macro level. Each subsystem pays special attention to the combination of the teaching process and teaching results and the related factors affecting the teaching process and teaching results. Based on the above basic principles of the teaching system, this study proposes a roadmap of learning methods based on the quality evaluation system. In general, computational improvement is achieved gradually over time by adjusting its own parameters according to some predetermined measure [17]. The learning method provides information to supervise learning according to the environment, and the learning method is shown in Fig. 2.

In unsupervised learning, there is no external support in the supervision process. The learning system adjusts the training parameters uniformly according to the statistical law of the data provided by the external environment, and the structure is external fixed input. Supervised learning requires a model data set provided by the outside world. The input results correspond to the output results one by one, and this set of known data is set as the training sample set. The relearning system adjusts the system parameters according to the difference known. The external environment of relearning only gives evaluation information to the system output, but not the correct answer. Learning systems improve their performance by reinforcing actions. The quality evaluation system focuses on the formation of index content. In the thinking dimension of index content formation, the core subject of the system is sorted out, and the index content is clustered to form a particular general index type. The weight coefficient tests the evaluation system through teaching practice so as to create a perfect automatic scoring system in the repeated practice data.

D. Design of an Automatic Scoring System for Teaching Based on Improved Neural Network

Through continuous learning and training, artificial neural networks can discover their rules from complex data with unknown patterns, mainly can deal with arbitrary types of data. Therefore, this design will improve the theory of neural

network applied to the teaching evaluation system, solve the problem's evaluation index system, and overcome the traditional evaluation of the mathematical model and mathematical, analytical expression. Evaluate the accurate application of neural network theory to establish the mathematical model of the system [18]. If an error threshold exceeds the specified error range, adjust the connection weights among all layers and the threshold value of nodes. Therefore, the neural network is used in the comprehensive evaluation of the quality of teaching. The basic idea is to use each evaluation index of the neural network input vector with a value that is expert of the evaluation results of the neural network output vector. According to the comprehensive index system in the above section [19], the model is the required classroom model. The system design comprises various subsystems for guiding the ideology of network-based teaching within the respiratory field. These include the neural network evaluation subsystem for guiding teaching in the network, the multimedia resources neural network evaluation subsystem, the teaching conditions neural network evaluation subsystem, the teaching building neural network evaluation subsystem, the teaching management neural network study, the neural network evaluation subsystem for practice-based teaching in the building, and the English training neural network evaluation subsystem. The outputs of the eight subsystems constitute the integrated network's input system structure block diagram, as shown in Fig. 3.

Each subsystem model adopts a three-layer BP neural network, and neurons in each layer are only connected with neurons in neighbouring layers [19]. The conversion function of each node adopts the Sigmoid function.

$$S = \sqrt{0.43nm + 0.11m^2 + 2.55n + 0.77m + 0.35} \quad (7)$$

The index weights are obtained for each subsystem, and organizational education experts score the training samples according to the above index system. After training the model with a large number of samples, the subsystem is established, and the value is finally obtained. The model's structure of the system entails that the comprehensive output value of each subsystem is considered. The output is the teaching evaluation results divided into four grades: excellent, good, pass and fail. The value is shown in Fig. 4.

Fig. 2. Information content supervised learning.

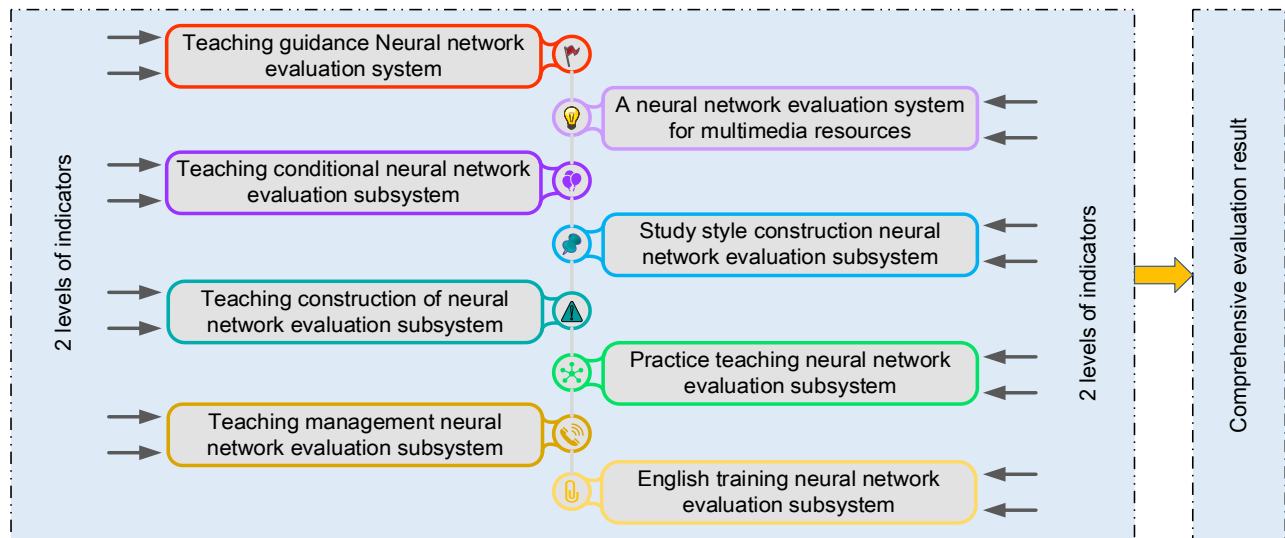

Fig. 3. Application flow chart of social security fund cloud audit platform.

Fig. 4. Range of output values for each level.

The selection of neural network training samples is the key to this system and the evaluation results of the system. The system uses the evaluation of experts of the Ministry of Education, the evaluation of college teachers, the evaluation of students in school, the evaluation of graduates, social evaluation and other ways to obtain information using information cards and the Internet. The teaching evaluation score is between 1.00 and 0.80, which means the teaching activity is excellent. The teaching evaluation score is between 0.79 and 0.70, meaning the teaching activity is good. The teaching evaluation score is between 0.69 and 0.60, which means that the teaching activity is passed; A score of <0.59 in the teaching evaluation indicates that the teaching activity is failing.

IV. APPLICATION OF AUTOMATIC GRADING IN COLLEGE ENGLISH MULTIMEDIA TEACHING

A. Index Weight of the Automated Scoring System

In this study, the AHP is used to calculate the weight of indicators. AHP is an evaluation method that combines

quantitative analysis and qualitative analysis to simplify complex problems and simplify simple issues [20]. The process can effectively ensure the rationality and scientificity of index weight. The scoring matrices of 10 experts on the first-level indicators are summarized in a judgment matrix and summarized by the arithmetic average method, which is to take the average value of the values and calculates the corresponding summary value by the arithmetic average of the scoring values of each expert, as shown in Fig. 5.

The first-level index scoring judgment matrix was input, and the consistency test data was obtained, as shown in Fig. 6. In the consistency test, C.R. denotes the consistency ratio, C.I. denotes the consistency index, and R.I. indicates that the average consistency indicator is a fixed value. When $C.R. < 0.1$, the judgment matrix is consistent; If $C.R. > 0.1$, the judgment matrix does not meet the consistency requirements. If the data does not meet the requirements, delete the data, fill in the data matrix again, and calculate the weight after the consistency check.

Fig. 5. Expert score arithmetic average summary numerical statistics chart.

Fig. 6. Matrix consistency test data graph.

The C.R. value of the consistency test result is 0.044, indicating that the consistency test result meets the requirements and the calculated weight data. This process is effectively used to check the consistency of each expert's score. After passing the test, the arithmetic average method is used to carry out the weighted summary. The summarized values are re-entered into the table for the consistency test. After passing the consistency test, the weight value of each indicator is obtained. The formula is used for data entry, and the index weight is obtained. The single ranking of index weight

hierarchy means that the subordinate second-level indicators of a first-level indicator carry out the separate weight calculation, and the total ranking of hierarchy means that the second-level indicators of all first-level indicators carry out the comprehensive weight calculation and ranking. The results of the expert survey were analyzed through hierarchical analysis. The weights of the second-level indicators were obtained by calculating the data, and the consequences of the indicators were summarized as shown in Fig. 7.

Fig. 7. Summary diagram of weights of system indicators.

This system designs eight subsystem output index weights. The weights are given 16 input values through model training, and then the teaching effect system evaluation results can be obtained. The evaluation is realized through the design of the evaluation database. From the database will be evaluated all teacher indicators into the system for database operation, evaluation of the main program neural network evaluation results display interface. The system monitors teaching, and the evaluation results can be used as a reference for teachers to conduct subsequent teaching activities. Multimedia teaching tools combine with teaching time to implement autonomous learning and offline face-to-face teaching organically. At the same time, learning should be combined with professional requirements, and the improvement degree of ability and quality should be matched with the learning objectives to improve students' satisfaction with course teaching.

B. Results of Neural Network Evaluation on the Quality of College English Multimedia Teaching

Matlab simulation's system design and application include efficient numerical calculation, matrix operation, signal processing, graph generation, and other functions. In addition, the software also provides a variety of practical toolboxes. Neural Networks Toolbox is one of them. Matlab neural network toolbox users can be very convenient for simulation. The system simulation was carried out in the toolbox, and the sample data were realized. It automatically mobilizes the initialization function and threshold based on the default parameters. Target vector T of the sample. According to the simulation steps, the system conducts simulation training and experimental analysis in the toolbox, and the results are shown in Fig. 8. According to the evaluation results of 10 groups of data by experts, it can be seen that the evaluation results of the neural network are consistent with those of experts.

The error of the test sample is almost the same as that of the test sample in the acceptable range. The statistical situation of items 4-8 in the questionnaire shows that 20% of the teaching simulation evaluation is excellent; 30% of the teaching simulation evaluation is good; 40% of the teaching simulation evaluation is passed; 10% of the teaching simulation evaluation

is failed. The error of the excellent evaluation test sample is 0.02, the good evaluation test sample is 0.01, and the error of passing the evaluation test sample is 0.01. The simulation error is within the controllable range. Using the automatic rating system to analyze the teaching quality, it is found that after the automatic rating system is enabled, the teaching performance only needs to input the corresponding index value and weight, and the evaluation subsystem can comprehensively evaluate the effect. Through teacher evaluation, students' learning effects can be objectively understood, and students' learning effects can reflect teachers' teaching effects. Therefore, the automatic evaluation model based on an improved neural network is a reasonable mechanical evaluation model. After the training evaluation is successful and the model is implemented, the repeated scoring process is separated from the experts by model learning. The application of the model not only saves capital investment but also ensures the scientificity of the model.

C. Evaluation Results of Neural Network Application in English Multimedia Teaching

The author obtains survey data and implements standardized preprocessing. This paper takes statistics teaching as the survey object, and the course is mainly offered for English majors. Utilizing the questionnaire survey, we obtain the classroom teaching data of some teachers in 10 universities, a total of 60 teachers. The sample data of all evaluation indicators were normalized, and the weight of scientific teaching content was the highest among all indicators. The weighted calculation obtained the classroom teaching quality score of all statistics teachers. The network structure takes 14 evaluation indicators as input neurons, the double hidden layer contains seven and three neurons, respectively, and the final output layer contains the unique prediction score of neurons. The error threshold of the model training was set as 10⁻⁵, and the times were set as 20000. The stable neural network was obtained by using the gradient descent algorithm. The neural network model predicts the classroom teaching scores of 15 teachers in the test set. The known classroom teaching scores are compared with the model, and the relative errors are calculated. The results are shown in Fig. 9.

Fig. 8. Model simulation training results.

Fig. 9. Relative error between classroom teaching and neural network model prediction results.

The comparison of the above prediction results shows that the model is applied to the test data of English classroom teaching and obtains a better evaluation effect. The prediction error rate of the 15 teachers' classroom teaching quality score is controlled within 2%, and the error rate of 10 teachers is controlled within 1%. Therefore, the neural network teaching evaluation model can be put into the classroom teaching evaluation practice. Quantitative evaluation of teaching results and supervision of the process, and actively break through their own level in teaching. Evaluation promotes the formation of learning habits, according to learning needs to constantly adjust their learning state, always maintaining a serious and efficient learning state. Evaluations motivate teachers and students to strive for higher goals. A comprehensive review can effectively improve the teaching level to form good teacher supervision.

D. Discussion on Automatic Scoring of Multimedia English Teaching in Colleges and Universities

With the continuous increase of online teaching business and the rapid development of artificial intelligence technology, the current education model is developing in the direction of intelligence [21]. Online teaching will produce a lot of data, and the training of neural network model has a high demand for data [22]. Therefore, the application of neural network model to college English multimedia teaching is very innovative and practical value.

This paper studies the difficulties related to automatic online scoring of college English multimedia. The difficulty of automatic marking technology is mainly the correction of subjective questions, and the difficulty of subjective questions is the understanding of semantics. Subjective questions mainly rely on natural language processing, that is, text preprocessing, Chinese word segmentation, text vectorization, feature extraction and automatic scoring are carried out according to the processing order of natural language.

In this paper, by randomly combining the answers with the same score of the same question to form similar text pairs and positive sample pairs, the answers with large score differences or different questions are combined into negative sample pairs, so as to solve the problem of sample scarcity when using deep learning algorithms for automatic scoring.

At present, there are few researches on automatic scoring of Chinese subjective questions based on natural language processing, which has been the main research direction in the field of education [23]. In view of the importance of automatic scoring to promote the fairness of education and reduce the

redundancy of teachers' work, automatic scoring has begun to adopt the method based on neural network [24]. However, due to the different application fields of subjective questions, the emphasis of subjective questions in different professional fields is also different, especially the data of subjective questions does not have a relatively open and accurate data set. The current studies are all based on small-scale data from the school where the researcher is located, so it is necessary to construct a public data set of subjective questions.

V. CONCLUSION

The purpose is to provide feedback and teaching information to observe and promote the effect and progress of teaching, emphasizing improving the quality of teaching. College English teaching assessment encourages students to achieve their learning goals at all stages, cultivates their comprehensive English application ability, and helps teachers become conscious researchers of teaching theories and practitioners of teaching methods. This paper constructs the statistical index system of classroom teaching quality evaluation from teaching art, teaching attitude, students' reaction to classroom teaching and teaching content. Taking college English classroom teaching data as an example, this paper obtains the initial weight of evaluation. It calculates the target score of sample data by using expert scoring and an analytic hierarchy process. The neural network model trains the classroom teaching sample data to approximate the expert score, put into the test and inspection and obtains a good evaluation effect. The neural network model based on the BP algorithm makes use of the learning ability to maximize the inner connection between the teacher's teaching input information and the quality output, and it is separated from the expert scoring in the subsequent promotion and use. The sample size of the classroom teaching evaluation data set collected in this paper is small, and the advantages of the neural network model in extensive data analysis are more obvious if the model can be developed in a broader range of teaching activities. It is helpful to promote the transformation of teaching assessment form from results and figures to process and description, promote the combination of formative assessment and teaching, and improve the feasibility and scientificity of the assessment scheme.

Design of a Decentralized AI IoT System Based on Back Propagation Neural Network Model

Xiaomei Zhang

Marxist Academy, Henan Polytechnic Institute, Nanyang, 473000, China

Abstract—In the Internet of Things (IoT) era, when user needs are continually evolving, the coupling of AI and IoT technologies is unavoidable. Fog devices are introduced into the IoT system and given the function of hidden layer neurons of Back Propagation neural network, and Docker containers are combined to realize the mapping of devices and neurons in order to improve the quality of service of IoT devices. This study proposes the design of a decentralized AI IoT system based on Back Propagation neural network model. The testing data revealed that, at various data transfer intervals, the average transmission rate between the fog device and the sensing device was 8.265Mbps, and that the device's transmission rate could satisfy user demand. When the data transmission interval was 20s, the network data transmission rate was greater than 8.5Mbps and did not vary much when the number of data transmissions rose. The research demonstrates that the decentralized AI IoT system's network performance, which is based on a back propagation neural network model, can match user usage requirements and has good stability.

Keywords—BP neural networks; artificial intelligence; IoT systems; fog devices; Docker containers

I. INTRODUCTION

Artificial intelligence (AI) is a method for enhancing and extending human intelligence. It is a subfield of computer science that primarily focuses on the concepts of computer intelligence, human brain intelligent computers, etc. in order to advance computer applications [1]. The development of artificial intelligence (AI) can be aided by the mutual integration of mathematics and AI because AI is not confined to logical thinking but also requires the consideration of figurative and inspirational thinking [2]. The Massachusetts Institute of Technology was the first to suggest the idea of the Internet of Things (IoT), and the foundation of early IoT was radio frequency identification technology [3]. IoT applications now particularly encompass information interchange, sensing, and acquisition amongst objects. The seamless access to wireless networks has further broadened the field of IoT applications as a result of ongoing technological advancements [4]. The integration of IoT technology with computers, the Internet, and wireless communication technologies is the primary study area in the field of information technology today. IoT technology has become a popular field of technology because to its strong potential. IoT edge intelligence technologies and platform-based technologies for vertical applications are two examples of related technologies that have evolved as a result of the IoT technology boom [5]. The Internet of Things system is connected to sensors, actuators, and intelligent devices with

huge amounts of data. Usually, actuators only need data from local devices to respond, rather than all devices. All data is transmitted to the cloud, transmitting a large amount of inefficient data, resulting in a waste of network bandwidth. Sending sensor data to the cloud may introduce security vulnerabilities and privacy issues. The communication path from the terminal to the cloud is long and there are many nodes, making it susceptible to network attacks. The study recommends the Back Propagation Neural Networks (BPNN) model for decentralized AI IoT of Systems (IoTS) architecture in order to further improve the level of service offered by IoT devices. The study is broken down into four sections: a summary of current BPNN and IoT technologies; the design of decentralized AIoTS based on the BPNN model; an analysis of decentralized AIoTS applications based on the BPNN model; and a summary of the entire article.

II. RELATED WORKS

A multilayer feed forward network trained using the error back propagation algorithm; the BPNN is one of the most well-known neural network models. The results demonstrated that the particle swarm algorithm may increase the effectiveness of fault diagnosis. Xiao's scientific research team proposes a fault diagnosis system based on particle swarm optimization BP neural network for gearbox fault diagnosis. The particle swarm algorithm is used to optimize the weights and thresholds. The results show that the algorithm can improve the accuracy of fault diagnosis by up to 85% [6]. Yang in order to train the BPNN for the issue of information fusion state estimation of multi-sensor systems, the research team presented particle swarm and additional momentum approach. The simulation results prove that the method is effective [7]. In order to enhance the effectiveness of human shape prediction, Cheng used principal component analysis to reduce the dimensionality of pertinent variables. The experimental results show that the accuracy of this method is 12% higher than the K-means prediction model [8]. For the problem of enterprise asset valuation, Xie's group proposed a BPNN-based valuation model for technology enterprises. The model included financial and non-financial performance indicators related to intellectual property, and the results indicated that the inclusion of these indicators could enhance the model training effect [9]. Shi proposed a BPNN-based short-term load forecasting model for smart grids, in which various types of data are fed into the model and its output is represented as conforming to the forecast results. Experiments show that the method is able to clearly display the distribution of load demand at various time periods [10].

The IoT architecture can be divided into a sensing layer, a network layer, and an application layer. It uses communication technologies like local networks or the Internet to connect sensors, controllers, machines, and people in novel ways to create intelligent networks that connect people to things and things to people. Using a near real-time approach to data streams and big data-based pattern analysis of stakeholder needs, Luckner and his team propose an IoT architecture that is data-centric for urban services and applications, and test results show that the approach is effective at lowering latency in smart city IoT [11]. In order to ease further analysis of human health, Chandrakar's research team presented a smart device for healthcare system based on IoT architecture employing smart sensors for human tracking. The study's findings show that the technique can support IoT architecture for healthcare [12]. The research group of Shapsough suggested a general IoT architecture for context-aware learning. To enable on-the-fly scene learning, a variant of the architecture is constructed utilizing IoT edge devices, and testing findings demonstrate that the architecture is resource-efficient while limiting application protocols [13]. In order to meet the demands of the IoT ecosystem, the Sarrigiannis scientific group built a 5G platform using virtual network capabilities for lifecycle management of heterogeneous architectures in conjunction with multi-access edge computing. Experiments reveal that the method can allocate edge and core resources in real time to maximize the number of service users [14]. In order to connect travel paths, Cheng and his team proposed a new carrier-based sensor deployment algorithm that matches redundant sensors with uncovered areas. Experimental data shows that under different parameter settings, this algorithm can reduce the path length of rows by 20% -30% [15].

In conclusion, BPNN and IoTS structures have been the subject of several studies and designs by numerous research teams, but more work has to be done to increase their stability. The study recommends a decentralized AIIoTS design built upon the BPNN model in order to boost the data transmission rate.

III. DECENTRALISED AIIoTS DESIGN BASED ON BPNN MODEL

The design of the AIIoTS in this chapter makes use of BPNN. The architecture of the system based on the BPNN model is covered in the first half of this chapter, and the implementation of the decentralized AIIoTS capability is covered in the second section. To implement the mapping of BPNN and IoTS, Fog Devices (FD) and Docker Containers (DC) are introduced.

A. System Design based on the BPNN Model

BPNN is one of the widely used and more successful neural networks [16]. When the signal is propagated forward, the data flows from the input layer (IL) to the hidden layer (HL), and the error is back-propagated by comparing the actual value with the expected value in the output layer [17]. Fig. 1 depicts the BPNN's construction.

The IL, output layer and HL form the BPNN, and the forward propagation of the BPNN algorithm is calculated as shown in Eq. (1).

$$\begin{cases} net_{ij} = W_{(i-1)kj} * \sum_{k=1}^{N_{i-1}} O_{(i-1)k} \\ O_{ij} = \frac{1}{1 - \exp[-net_{ij} + \theta_{ij}]} = f_s(net_{ij}) \end{cases} \quad (1)$$

In Eq. (1), the total input, output and threshold of the j th neuron in layer i are net_{ij} , O_{ij} and θ_{ij} respectively, the number of neuron nodes in layer i is N_i , and the connection weight of the j th neuron in layer i to the k th neuron in layer $i+1$ is W_{ijk} . The error in the backoff algorithm is defined as shown in Eq. (2).

$$e_j = d_j - y_j \quad (2)$$

Fig. 1. BP neural network structure.

In Eq. (2), the back propagation error is e_j , the desired output is d_j , and the actual output of the neural network is y_j . The network objective function is shown in Eq. (3).

$$E = \frac{1}{2} \sum_j (d_j - y_j)^2 \quad (3)$$

In Eq. (3), the network objective function is E , and the weights are calculated as shown in Eq. (4) with the correction value along the direction of the gradient of the objective function falling.

$$\Delta W_{ijk} = -\eta \frac{\partial E}{\partial w_{ijk}} \quad (4)$$

In Eq. (4), the gradient descent value is ΔW_{ijk} and the learning efficiency is η , which takes values in the range of [0,1]. The recursive relationship between the gradient descent value and the neuron output is shown in Eq. (5).

$$\Delta W_{ijk} = -\eta \frac{\partial E}{\partial w_{ijk}} = -\eta \frac{\partial W}{\partial net_{(i+1)k}} * \frac{\partial net_{(i+1)k}}{\partial w_{ijk}} = \eta \delta_{ik} \frac{\partial net_{(i+1)k}}{\partial w_{ijk}} \quad (5)$$

In Eq. (5), the whole is denoted by δ_{ik} in terms of $\frac{\partial E}{\partial net_{(i+1)k}}$.

The common principles of BPNN design are the selection of the input quantity that will be able to meet the feature reflection requirements; the output quantity is the target that the system needs to reach; the training set samples can meet the generalization ability of the test metrics; the initial weight setting needs to meet the initial net input of the nodes as close to zero as possible; the number of HL neurons is calculated is shown in Eq. (6).

$$\begin{cases} m = \sqrt{n+l} + \alpha \\ m = \sqrt{nl} \end{cases} \quad (6)$$

In Eq. (6), m stands for the number of HL neurons, l for the output neurons, n for the input neurons, and α for the regulatory constant, which has a range of values from [1,10]. The study uses the BPNN structure as a model to construct the decentralised AIIoTS, and the whole system is divided into the cloud computer layer, and the decentralised AIIoTS architecture is shown in Fig. 2.

The edge of the IoT is the end device layer, containing IoT-aware devices and execution devices, mapped to the IL and output layers of the BPNN respectively, with one device corresponding to one neuron. The IoT-aware devices send the collected data information to the fog processing layer. The middle layer of the cloud hybrid architecture is the fog processing layer. The cloud computing layer, which makes up the top layer of the entire architecture, principally consists of cloud servers in charge of storing data, training neural networks, and distributing devices. The decentralised AIIoTS architecture works in both decentralised and centralised ways. Decentralized working involves the absence of the cloud

computing layer, the deployment of the BPNN's input devices as sensing devices, the HL deployment of the fog processing layer, and the output devices as execution devices. The cloud computing layer is required for centralised work and its function is to train the neural network, which is a component of the BPNN algorithm deployment. The study uses a three-layer BPNN as a model, with HL neuron inputs as shown in Eq. (7).

$$net_j = \sum_i W_{ij} O_i \quad (7)$$

Fig. 2. Decentralized Artificial intelligence of things architecture.

In Eq. (7), the input of the j th neuron of HL is net_j , the weight of the i th neuron of IL and the j th neuron of HL is W_{ij} , and the output of the i th neuron of IL is O_i . The output of the HL neuron is shown in Eq. (8).

$$\begin{cases} O_j = g(net_j) \\ g(x) = \frac{1}{1 + e^{-(x+\theta)}} \end{cases} \quad (8)$$

In Eq. (8), the output of the j th neuron of HL is O_j and the threshold is θ . The IL and HL neuron weights change as shown in Eq. (9).

$$\Delta W_{ij} = \eta O_j (1 - O_j) \sum_k \delta_k W_{kj} O_i \quad (9)$$

In Eq. (9), the weight change of the i th neuron of IL and the j th neuron of HL is ΔW_{ij} , the output of the k th neuron of HL is W_{kj} , the residual of the k neuron of the output layer is δ_k , and the learning efficiency is η . The threshold change of the HL neuron is shown in Eq. (10).

$$\Delta \theta_j = \eta O_j (1 - O_j) \sum_k \delta_k W_{kj} \quad (10)$$

In Eq. (10), the threshold change for the j h neuron of HL

is $\Delta\theta_j$, and the output layer neuron input is calculated as shown in Eq. (11).

$$net_k = \sum_j W_{kj} O_j \quad (11)$$

In Eq. (11), the input of the k th neuron in the output layer is net_k , and the output of the neuron in the output layer is calculated as shown in Eq. (12).

$$O_k = g(net_k) \quad (12)$$

In Eq. (12), the output of the k th neuron in the output layer is O_k , and the weights between the output layer and HL neurons change as shown in Eq. (13).

$$\Delta W_{kj} = \eta(t_k - O_k) O_k (1 - O_k) O_j \quad (13)$$

In Eq. (13), the weight of the k th neuron in the output layer is changed to ΔW_{kj} with the j th neuron in HL, and the residuals of the neurons in the output layer are shown in Eq. (14).

$$\delta_k = (t_k - O_k) O_k (1 - O_k) \quad (14)$$

In Eq. (14), the residual of the k th neuron in the output layer is δ_k , the expected output of the k th neuron in HL is t_k , and the threshold of the neuron in the output layer changes as shown in Eq. (15).

$$\Delta\theta_k = \eta(t_k - O_k) O_k (1 - O_k) \quad (15)$$

In Eq. (15), the threshold change for the k th neuron of the output layer is $\Delta\theta_k$. The FD layer is given the function of an HL neuron, and forward and backward calculations are required during training.

A. Decentralised AIoTS Functional Implementation

Once the system based on the BPNN model is constructed, it needs to be implemented in conjunction with the appropriate tools and devices. The study uses the Python programming language and deploys DCs on FD and execution devices. The Python programming language is simple, easy to learn and implement, and is a free and open source software with source code that can be read and modified [18]. Python is a high-level language that is programmed without the need to consider low-level details when programming, and has the advantages of portability, interpretability and extensibility [19]. Docker's object is server-side and belongs to a Linux container technology, Docker can be installed on most Linux systems [20]. The first step in the study to install DC on FD and execution devices is to check the kernel version. 64-bit computers are required to install and run Docker, so the Linux system kernel version needs to be greater than 3.0, and the kernel needs to be upgraded if it is not up to standard [21]. The second step is to update the advanced packaging tool source, and the third step is to install the DC according to the command. The Docker image is the basis for the DC build,

and the study builds the image using a Dockerfile file. The mapping of the IoT nodes to the BPNN, the code written in the DC, gives the FD and the execution device the function of hiding neurons and output neurons, respectively. Fig. 3 displays the decentralized AIoTS capabilities based on the BPNN model.

Fig. 3. Functions of decentralized Artificial intelligence of things system based on BP neural network model.

Communication between DCs needs to be implemented using sockets, also called sockets, which support the TCP/IP network communication protocol and are the endpoints for bidirectional communication between different hosts [22]. There are three types of sockets. Streaming sockets use the TCP protocol, which provides a reliable connection-oriented bi-directional data transfer service that guarantees error-free data transfer and is suitable for high-volume and data transfer demanding communication situations. Datagram sockets use the UDP protocol, which provides a connectionless service that does not guarantee reliable and sequential data transfer and requires programmatic processing to be used. Raw sockets use the underlying protocol and are suitable for network protocol analysis and verification [23]. Socket communication requires the availability of a server and a client, and the connection process consists of server listening, client request and connection confirmation. The role of the client is to connect to the server and send data to the server side.

The study uses the socket server module to simplify the web application, which contains a framework of service classes and request processing classes. The first step in the creation of the service is the creation of the service class, which uses the TCP protocol to enable asynchronous processing [24]. The second step is the creation of the request processing class, along with the overriding of the processing functions. The third step is the instantiation of the service object, for which the service address and request processing class are passed. The fourth step is the invocation of the service class object function and the server is kept running after the function is started.

The inverse device is used to acquire data, which is then sent to the fog processing layer, which contains the hardware software study of the sensing device [25]. This study only simulates the function of the device; it does not create a functional implementation. Instead, it uses the Client function, which is the Client function of the upper level, to send data. The function of FD is to process, store and send the data, and its DC is distributed in the server side and the client side, IL and Output layer client request and processing is completed through the server side, FD function implementation flow is shown in Fig. 4.

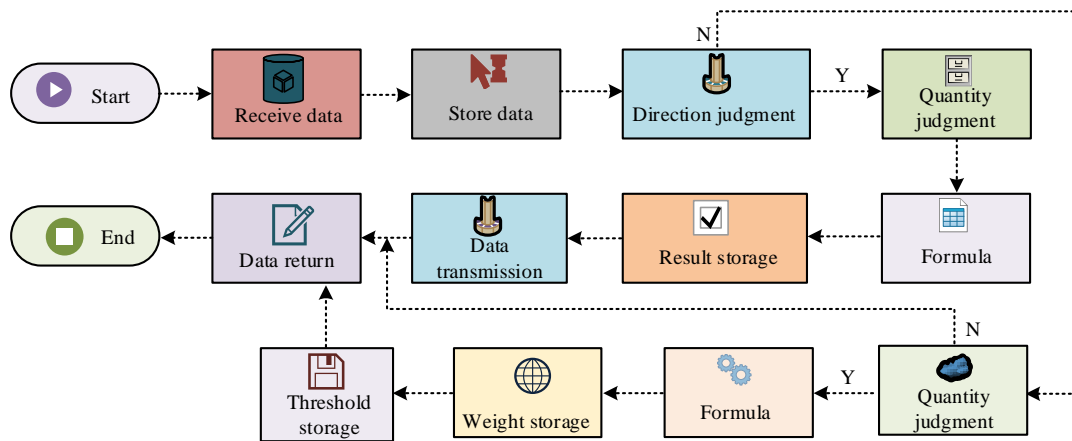

Fig. 4. Implementation process of fog equipment functions.

FUNCTIONS USED TO IMPLEMENT DEVICE FUNCTIONS

Function Name	Parameter	Return Value	Function
Client	Host, port, senddata	/	Connect to the server of the hidden layer and send data
Tansform	Filename, number	Data_list	Convert the relevant data in the file into a list
Error_term	D, output	Output_e	Calculate the residual of a single output layer neuron
Th_updata	Output_e, efficiency, th	Updatated_th	Update threshold
Save_data	Data, number	/	Store data in the appropriate location
Get_Data	Filename, number	Data	Obtain data with corresponding numbers from files containing storage numbers
Handle	Self	/	Please handle hidden layer clients Request, process received data
Freedforward	F_input, w, th	Output	Forward calculation of output layer
Weight_update	Output_e, efficiency, f_input, w	Updatated_weight	Update the weights of output layer neurons to corresponding hidden layer neurons
Save	Filename, data	/	Store data
Get_number	Data	Number	Obtain storage number
Amount	Data, number	Data_number	Obtain the number of stored data corresponding to the current storage number

The first step in the implementation of the FD function is the reception and storage of data, which comes from the sensing and execution devices. The format of the data storage is JSON, which is a lightweight data exchange format. The second is to process the data, firstly to determine the type of data, forward data from the sensing device and backward data from the executing device. Returning the data to the connected client is the third stage, and whether data processing is done or not has no bearing on the client obtaining the returned data. The functions used to implement the functions of the execution device are shown in Table I.

The main function of the execution device is also data processing, storage and sending, its DC is distributed in the client and server side, the source of processing data is FD, the format of data storage is still JSON format, the storage file is f_input.json, data processing before also to determine whether to meet the requirements, the number of data and the number of hidden neurons equal to the judgment criteria, after receiving data are returned a data to the client.

IV. ANALYSIS OF DECENTRALISED AIIoTS APPLICATIONS BASED ON THE BPNN MODEL

This chapter addresses the application and analysis of decentralised AIIoTS based on the BPNN model. The first section of this chapter is a simulation analysis of the performance of decentralised AIIoTS, and the second section of this chapter is an analysis of the practical application of decentralised AIIoTS.

A. Performance Simulation Analysis of Decentralized AIIoTS based on BPNN Model

Two laptops were used to simulate the FD and IoT sensing devices, with Laptop 1 simulating the FD and Laptop 2 simulating the sensing device. The operating system of both computers is Ubiquitous 20.10, and the network connection of laptop 2 is provided by the hotspot of laptop 1. The DCs are deployed at the corresponding locations of laptops 1 and 2, and the FD transmission rate is shown in Fig. 5.

Fig. 5. Transmission rate of fog equipment.

In Fig. 5, laptop #2 sends data to laptop #2 at 15s, 20s, 25s and 30s intervals, and 20 times at different time intervals. It can be seen that the transmission rate between FD and sensing device is distributed in the interval [7.0,8.5] Mbps, with an average transmission rate of 8.265 Mbps, and the transmission rate increases when the data transmission interval increases. The results show that the transmission rate of the device under the decentralized AIIoTS based on the BPNN model proposed in the study can meet the user requirements. To further analyse the communication link bandwidth (marked as BP) under the decentralized AIIoTS based on the BPNN model, the experiments used the communication link bandwidth between the common sensor and the cloud server (marked as S), the Unified Storage Network architecture link communication bandwidth (marked as U), and the machine-to-machine architecture link communication bandwidth (marked as M) as comparisons, and the bandwidth comparison results are shown in Fig. 6.

Fig. 6. Bandwidth comparison results.

In Fig. 6, the data is sent at an interval of 10s and a total of 200 times. It can be seen that the average communication link bandwidth between ordinary sensors and cloud servers is 3.2Mbps, the average link communication bandwidth of the Unified Storage Network architecture is 5.0Mbps, the average

link communication bandwidth of the machine-to-machine architecture is 6.43Mbps, and the average communication link bandwidth under the decentralized AIIoTS based on the BPNN model is 8.01Mbps. The outcomes demonstrated that the study's decentralized AIIoTS may offer greater communication bandwidth, faster data transmission rates, and higher stability. A comparison of the data transmission delay under decentralized AIIoTS and the delay of sensor data sent to the cloud is shown in Fig. 7.

In Fig. 7, a total of six sensing devices are set for data transmission. When the number of sensing devices is 1 and 2, the difference in latency between the data sent by the sensing devices to the FD and the cloud is small, and the difference in latency gradually increases, the latency of sending data to the cloud is 1.80s, the latency of sending data under decentralized AIIoTS is 0.83s, and the latency is reduced by 0.97 s, and the latency of sensor data sent to the cloud is 1.74s, with a latency reduction of 0.06s. The results show that the latency reduction of data sent under the decentralized AIIoTS based on the BPNN model proposed in the study is greater. To further validate the correct data delivery rate under the decentralized AIIoTS (labelled as BP), the study uses the Unified Storage Network architecture (labelled as U) and the machine-to-machine architecture (labelled as M) as comparisons, and the correct data delivery rates of the different architectures at different data delivery intervals are shown in Fig. 8.

In Fig. 8, three data transmission intervals are set to 20s, 15s and 10s, respectively. It can be seen that the correct data transmission rate for decentralized AIIoTS and with a data transmission interval of 20s is 1.00, and the correct data transmission rate cannot be maintained at 1.00 under the Unified Storage Network architecture and machine-to-machine architecture. The experimental results show that the data processing and transmission are better under the decentralized AIIoTS based on the BPNN model proposed in the study, and the data sending interval can be set to 20s if there is no special requirement.

B. Analysis of Decentralised AIIoTS Applications based on the BPNN Model

To verify the effectiveness of the practical application of decentralized AIIoTS based on the BPNN model, six users were experimentally recruited to analyse the network performance under the system, setting the data transmission interval to 20s and the user network data transmission rate as shown in Fig. 9.

As shown in Fig. 9, none of the users' network data transmission rates are less than 8.5Mbps, and even as the volume of data transmissions rises, these rates remain stable in the [8.4,8.7] Mbps range, which can accommodate users' typical usage requirements. When the data transmission interval is set to 10s, the user network data transmission error is shown in Fig. 10.

Fig. 7. Comparison of data transmission delay.

Fig. 8. Data transmission accuracy of different architectures at different data transmission time intervals.

Fig. 9. User network data transmission rate.

Fig. 10 illustrates how the network data transmission error increases gradually as the number of users rises, although the error is still less than 0.07. Analysis of the experimental data shows that the correct rate of network transmission at this time is higher than 0.93. The accuracy of user data transmission can be guaranteed when there are no special requirements for user data transmission accuracy. To verify the security of the network transmission under the decentralised AIoTS based on

the BPNN model, the experiments were verified using an attack test, and the results of the attack test are shown in Fig. 11.

In Fig. 11, the network is able to identify 85% of threat attacks when the data transmission interval is 10s, 95% of threat attacks when the data transmission interval is 15s, and 100% of threat attacks when the data transmission interval is 20s. The experimental data shows that the security of network data transmission under the decentralised AIoTS based on the BPNN model is high and can meet users' needs.

Fig. 10. Data transmission error.

Fig. 11. Attack test results.

V. CONCLUSION

IoT's future development trajectory is to merge with AI as both IoT and AI technology advance. The study suggests a decentralized AIIoTS design based on the BPNN model to enhance the quality of service of IoT devices by leveraging the concept of cloud-fog combination to develop the functionalities of the devices and causing the DC to be in the system to realize the mapping of BPNN and IoTS. The experimental data revealed an average transmission rate of 8.265 Mbps between the sensing device and the FD, which was sufficient to satisfy customer demand. The average communication connection bandwidth between a typical sensor and a cloud server was 3.2 Mbps, whereas the decentralized AIIoTS based on the BPNN model had an average communication link bandwidth of 8.01 Mbps, which increased data transmission efficiency by 4.81 Mbps and increased stability. Users' network data transmission rates were more than 8.5Mbps when the data transmission interval was set to 20s, and as data transmission increased, these rates did not vary substantially and could accommodate users' usage needs. The network data transmission error increased gradually as the number of users increased, but all mistakes were less than 0.07, and the proper network transmission rate was higher than 0.93 at that point, guaranteeing the correctness of user data transfer. When the data transmission interval was 20s, the network was able to recognize 100% of threat attacks, showing that the decentralized AIIoTS based on the BPNN model had stronger data transmission security and better network device service quality. The decentralized artificial intelligence IoT system proposed in the study currently only achieves basic functions, and further improvement is needed to make the system more fully functional. In terms of system stability, the studied system uses network edge devices, and the stability of the system may be relatively poor. For example, if the sensing device, fog device, or execution device may be damaged, how should the system continue to operate correctly? Future research can develop towards the direction of intelligent systems, upgrading devices in the system to intelligent agents, achieving automatic redeployment in the event of system failures, and further developing and intelligentising Docker containers.

Black Widow Optimization Algorithm for Virtual Machines Migration in the Cloud Environments

Chuang Zhou^{1*}

Anhui Vocational College of Defense Technology
Lu'an, Anhui, 237011, China

Abstract—Cloud data centers use virtualization technology to manage computing resources. Using a group of connected Virtual Machines (VMs), corresponding users can compute data efficiently and effectively. It improves the utilization of resources, thereby reducing hardware requirements. Repossession of affected services requires VM-based infrastructure overhaul schemes. Clarifications concerning dedicated routing are also desirable to improve the reliability of Domain Controller (DC) services. The migration of a VM experiencing a node failure challenges maintaining reliability. The selection of VMs is influential in limiting the number of VM migrations. Choosing one or more potential VMs for migration reduces the servers' workload. This paper presents an energy-aware VM migration method for cloud computing based on the Black Widow Optimization (BWO) algorithm. The proposed algorithm was implemented and measured using JAVA. Afterward, we compared our results against existing methodologies regarding resource availability, energy consumption, load, and migration cost.

Keywords—Cloud computing; migration; energy consumption; optimization; black widow algorithm

I. INTRODUCTION

Cloud computing is rapidly consolidating itself as a new computing technology [1]. It aims to provide services and meet user demands for high reliability, scalability, and availability [2]. Cloud computing has gained popularity over the past few years due to its efficient utilization of resources and convenience in accessing services [3]. These competitive advantages can be attributed to virtual technology and distributed networking in the cloud [4]. Storage, processing, memory, bandwidth, network, and virtual machines are some of the resources provided by cloud computing [5]. The provided virtualized services can be categorized as Platform as a Service (PaaS), Infrastructure as a Service (IaaS), and Software as a Service (SaaS) [6]. Virtualization facilitates access to resources while hiding their physical characteristics [7]. This technique allows several different environments to be separated or shared so that they can interact without being aware of one another [8]. As a matter of fact, virtualization is the key technology behind cloud computing. Data centers typically consist of hundreds of heterogeneous servers that consume significant energy. Increasing emissions and climate change have prompted governments, organizations, and IT enterprises to try and manage data centers more sustainably [9]. Consequently, data centers in the cloud require considerable energy as cloud services grow rapidly [10]. Cloud service providers face a serious challenge in reducing energy

consumption. Two factors cause this situation. The first is that data centers consume a lot of energy, resulting in carbon dioxide emissions that are incompatible with the environment. The second reason is the low power efficiency [11].

The concept of migrating Virtual Machines (VMs) dynamically and transparently from one host to another is called VM migration [12]. In addition, VM migration provides an opportunity to identify hotspots in data centers. In the realm of virtual machine migration within cloud environments, the convergence of IoT, Artificial Intelligence (AI), and Machine Learning (ML) introduces transformative capabilities. IoT sensors enable real-time data collection, facilitating dynamic workload monitoring and resource utilization assessment [13-15]. AI algorithms harness this influx of data to make intelligent decisions on VM migrations, optimizing resource allocation and energy efficiency. ML algorithms, fueled by historical and real-time data, identify patterns and predict workload trends, enabling proactive migration strategies to prevent bottlenecks and ensure optimal performance [16, 17]. The synergy of IoT, AI, and ML empowers cloud systems to autonomously adapt to fluctuating workloads, enhance resource provisioning, and optimize VM migrations, thereby elevating the efficiency and resilience of cloud environments.

Workload regulation on individual nodes via VM migration to optimize energy consumption is a Non-deterministic Polynomial (NP)-hard problem, commonly solved with heuristic approaches. In these cases, metaheuristic algorithms can be used efficiently when local heuristics are insufficient for finding optimum solutions [18]. Metaheuristics are repetitive procedures used as guides and amendments to other heuristics. Based on the Black Widow Optimization (BWO) algorithm, the current study proposes a new VM migration method that reduces energy consumption, hosts, and migrations. The BWO has a short computation time for globally optimized results, a high convergence speed as the quality parameters can be regulated, and a flexible optimization pattern [19]. This algorithm draws inspiration from the distinctive mating conduct observed in black widow spiders. Owing to its unique operators, it can be deemed a fusion of evolutionary and swarm methodologies. Notably, the BWO algorithm introduces a distinctive phase called "cannibalism." This phase holds a significant advantage as it eliminates species exhibiting inadequate fitness from the population, thus fostering an accelerated convergence rate. This paper contributes to the following:

- Multi-objective VM migration model designed for choosing the most suitable VM.
- The BWO algorithm is proposed to select the most efficient VMs in the cloud.

The rest of the paper is organized as follows. The literature related to this topic is briefly reviewed in Section II. Section III describes the proposed algorithm. The experiments and results are summarized in Section IV. Section V outlines the conclusions derived from the analysis.

II. RELATED WORK

Kansal and Chana [20] have proposed a method for migrating VMs based on Firefly Optimization (FFO). The FFO algorithm optimizes effective energy simultaneously at the memory and processor levels. Furthermore, it reduces the number of PMs and VMs, which avoids further energy wastage. VMs with the highest load are transmitted to lower-load nodes to maintain efficiency and performance. Wang, et al. [21] introduced enough green energy-efficient data centers. Diverse renewable energy supplies have been considered in the efficient management of VM migration. The proposed method can flexibly manage green energy and cooling power consumption. The authors assessed the effect of temperature on the energy consumption of cooling and IT devices.

Xu and Abnoosian [12] presented a hybrid optimization algorithm based on genetic and particle swarm optimization algorithms for improving VM energy consumption and execution time during VM migration. In the hybrid algorithm, GA is utilized to overcome the limitations of the PSO algorithm, which suffers from slow convergence and limited global optimization. According to the results, the proposed method has improved energy consumption by an average of 23.19% compared to the other three methods. Results also revealed a 29.01% improvement in execution time over the other three methods. Zhou, et al. [22] introduce an energy-efficient algorithm for VM migrations. This algorithm optimizes host location, VM selection, and trigger time when memory and CPU factors are considered. It migrates some VMs from lightly loaded to heavily loaded hosts using virtualization technology. Energy is conserved by switching idle hosts to the low-power mode or shutting them down. This algorithm reduces SLA violations by 13% and saves 7% of energy over the Double Threshold (DT) algorithm.

Fu, et al. [23] presented a layered VM migration algorithm. Cloud data centers are divided into several regions based on bandwidth utilization rates. VM migrations balance network load between regions, resulting in load balancing of cloud resources. Experiments indicate that the proposed algorithm is shown to be able to balance network resource load in cloud computing effectively. Chien, et al. [24] have proposed an efficient VM migration algorithm based on minimizing migrations in cloud computing to improve efficiency, meet user requirements, and prevent service level agreements (SLA) violations. The proposed algorithm was more effective than existing algorithms based on experimental results. A threshold algorithm was proposed by Kaur and Sachdeva [25] to allocate tasks to the most capable machine and host and to maintain checkpoints on VMs. Overloaded VMs need to migrate tasks to

another VM. This study proposes a weight-based technique for migrating cloudlets between VMs.

Cao and Hou [26] have introduced a bi-level VM placement algorithm. The initial tier incorporates a queuing model devised to manage a multitude of VM requests. This model facilitates the seamless implementation and validation of diverse models, including cloud simulations. Additionally, it furnishes an alternative mechanism for task allocation to servers. Subsequently, a multi-objective VM placement algorithm is introduced, rooted in the Krill Herd (KH) algorithm. Fundamentally, this algorithm strives to strike an equilibrium between energy consumption and the efficient utilization of resources.

Khan and Santhosh [27] have proposed a hybrid optimization algorithm for managing VM migration within a cloud environment. This novel approach amalgamates Particle Swarm Optimization (PSO) and Cuckoo Search (CS) algorithms to yield the proposed hybrid optimization framework. The focal point of this research endeavor is mitigating energy consumption, computation time, and migration expenses. Additionally, a secondary objective pertains to the maximization of resource utilization. To substantiate the research objectives, the efficacy of the hybrid optimization model is rigorously assessed through simulation analysis. This assessment encompasses a comparative study against conventional algorithms. The evaluation parameters encompass computation time, resource availability, migration cost, and energy consumption.

Kumar and Sivakumar [28] have introduced a novel approach for VM migration, hinging on the CS algorithm. The selection of an appropriate provider is undertaken through a comprehensive consideration of multiple constraints, including factors such as delay, bandwidth, cost, and load. Subsequent to this, effective search criteria are calculated, facilitating the identification of the optimal service contingent upon fitness constraints. These search criteria are framed as optimization problems, and their resolution is undertaken using the CS algorithm. The proposed CS algorithm is meticulously designed by integrating the Cuckoo Search Optimization (CSO) technique with the Salp Swarm Algorithm (SSA). This amalgamation ensures the evaluation of the fitness function for optimal VM migration, incorporating diverse parameters encompassing delay, cost, bandwidth, and load. Consequently, the cloud manager can adeptly execute VM migration in the cloud environment, leveraging the proposed CS-based VM migration approach. The performance evaluation of the CS-based VM migration technique focuses on delay, cost, and load. The results demonstrate that the proposed CS-based VM migration methodology achieves commendable outcomes, manifesting in a minimal delay of 0.14, cost of 0.05, and load of 0.18.

These studies address various facets of the problem, each contributing unique insights and methodologies. Notably, challenges related to optimizing energy efficiency, load balancing, resource utilization, and cost reduction are prevalent across these studies. Kansal and Chana [20] focus on optimizing energy efficiency and reducing the number of PMs and VMs. Wang, et al. [21] explore the integration of diverse

renewable energy supplies and cooling power consumption management. Xu and Abnoosian [12] tackle slow convergence and limited global optimization issues in hybrid optimization. Zhou, et al. [17] optimize host location, VM selection, and trigger time for energy-efficient migrations. Fu, et al. [23] propose a layered VM migration algorithm for network load balancing. Chien, et al. [24] emphasize minimizing migrations to prevent SLA violations. Kaur and Sachdeva [25] propose a threshold algorithm for efficient task allocation. Cao and Hou [26] address energy consumption and resource utilization equilibrium. Khan and Santhosh [27] and Kumar and Sivakumar [28] introduce hybrid optimization techniques to mitigate energy consumption and migration costs, and enhance resource utilization while considering multiple constraints. These studies underscore the multifaceted nature of VM migration optimization and lay the groundwork for further advancements in this evolving field.

III. PROPOSED METHOD

In this section, we discuss virtual machine migration using the BWO. The cloud migration model is illustrated in Fig. 1. Cloud models involve multiple PMs for handling user requests, and PMs gather the VMs to perform tasks on demand. The VMs are created dynamically to alleviate the bottlenecks in cloud computing, and virtualization enhances speed. Cloud services are delivered as tasks to users and are assigned to VMs in a round-robin fashion. In this case, PM controls the set of VMs, and a load balancer monitors loads of PMs. VM migration occurs when a load of a PM exceeds a threshold level. The analytical approaches employed in the development of the VM migration model are as follows.

- A cloud with m PMs and n VMs is created initially.
- This stage sets the migration cost of PMs to the highest value, so it equals 1.
- Round-robin assignment is used to assign incoming tasks to VM at the time interval.
- When the VM's load value exceeds the threshold, migrate the VM in an optimal manner using the proposed BWO.
- This step determines qualitative criteria, such as energy consumption, resource availability, and migration costs.
- The algorithm repeats steps (3) to (5) for every iteration, and then it ends.

A. Initialization

Our cloud system consists of n VMs and m PMs. According to Eq. 1, C , PM_1 , and PM_m stand for cloud, the first PM, and m^{th} PM, respectively.

$$C = \{PM_1, PM_2, \dots, PM_m\} \quad (1)$$

Eq. 2 illustrates VMs, with VM_1 being the first one and VM_n being the last one.

$$PM_m = \{VM_1, VM_2, \dots, VM_n\} \quad (2)$$

The cloud is populated by t users involving k tasks. Eq. 3 can be used to indicate each user.

$$U_t = \{T_1, T_2, \dots, T_k\} \quad (3)$$

In addition, a round-robin process assigns the users' tasks to VMs. In the cloud model, VMs are determined by several parameters, such as memory, bandwidth, CPU, and processing power. VMs in cloud computing environments have the following characteristics, as defined by Eq. 4.

$$V_m^n = \{I_m^n, D_m^n, B_m^n, C_m^n, J_m^n\} \quad (4)$$

I_m^n denotes the total number of utilized MIPS, D_m^n refers to memory, B_m^n signifies the bandwidth, C_m^n represents the number of CPUs, and J_m^n stands for the total number of processing entities. A scale of 1 to 10 is given for the above parameters.

B. Load computation

The load is calculated based on the resources needed by VMs to process tasks supplied by the user. A cloud load is evaluated by considering the processing power, CPU, memory, MIPS, and bandwidth using Eq. 5, in which t represents time, and RU stands for resource utilization. Eq. 6 calculates the resource used by m^{th} VM present. The variables in Eq. 6 are defined in Table I.

$$Load(L) = \frac{R_U}{t} \quad (5)$$

$$R_U = \frac{1}{F} \sum_{i=1}^M \left(\frac{I^F}{\max(I^F)} + \frac{D^F}{\max(D^F)} + \frac{B^F}{\max(B^F)} + \frac{C^F}{\max(C^F)} + \frac{J^F}{\max(J^F)} \right) \quad (6)$$

Fig. 1. VM migration model.

TABLE I. VARIABLES IN EQ. 6.

Variable	Definition
F	Normalization factor
m	Number of VMs in each PM
I^F	MIPS
D^F	Memory
B^F	Bandwidth
C^F	CPU
J^F	Processing entity

C. Resource Availability

It is responsible for ensuring the efficient use of resources. Load balancing must be optimized for well-organized performance. Eq. 7 calculates resource availability.

$$R_A = 1 - R_U \quad (7)$$

D. Migration Cost

A VM migration cost is determined by the number of movements. Migration costs for the entire cloud environment can be calculated by Eq. 8, in which c stands for constant, M refers to the total number of VMs, G denotes the number of migrations, and N is the total number of PMs.

$$M_c = \frac{1}{N} \sum_{j=1}^n \left(\frac{G}{c \times M} \right) \quad (8)$$

E. Energy Model

Each VM consumes energy to migrate and process data. In this way, cloud setup energy is primarily dependent on the power consumed by the resources within the VM, calculated by Eq. 9, in which T represents the total duration, and K denotes the power consumed by the VM calculated by Eq. 10. The maximum power consumed is denoted by K_{max} , and the resource utilization is represented by R_U^{cloud} calculated by Eq. 11.

$$E = \frac{1}{T} \sum_{t=1}^T K \quad (9)$$

$$K = p \times K_{max} + (1 - p) \times K_{max} \times R_U^{cloud}; \quad 1 < p < t < T \quad (10)$$

$$R_U^{cloud} = \frac{1}{N} \sum_{r=1}^N R_U \quad (11)$$

F. Solution encoding

The proposed algorithm finds suitable VMs for migration. Consider a scenario in which PM 1 involves 2 VMs, and PM 2 involves 3 VMs. A round-robin assignment process assigns the incoming tasks to VMs. All processes are handled in a circular order, according to assigned time slices, with no priority given to any process. VMs are migrated to under-loaded PMs if they exceed a threshold value, and an optimization algorithm is used to assign the optimal VM. A solution encoding for identifying optimal VMs for migration is shown in Fig. 2.

Fig. 2. Encoding solutions.

G. Fitness function

An optimal solution is determined by computing the fitness function. Energy, migration cost, load, and resource utilization are the parameters that are used in formulating the fitness function. VMs are selected based on the fitness function, calculated by Eq. 12.

$$Fitness(f) = \delta(1 - E) + \gamma(1 - M_c) + \beta(1 - L) + \alpha R_A \quad (12)$$

In Eq. 12, E stands for energy, M_c represents migration costs, L refers to the load, R_A denotes resource utilization, δ , γ , β , and α are the weights ranging from 0 to 1.

H. BWO algorithm for VM migration

This section applies the BWO algorithm to the multi-objective VM migration method. VMs are migrated to specific PMs based on cost, energy, and load. The performance of the VM migration algorithm is determined by the reduction in energy consumption, cost, and load. As with traditional methods, BWO starts by initializing a population of spiders representing possible solutions. New generations of spiders are produced in pairs. As part of this optimization, female spiders eat black male spiders during or after mating. Female black widow spiders release their stored sperm into egg sacs after storing them in their sperm theca. The spiderling emerges from its egg sac after 11 days. A spiderling remains in its mother's web for several days to a week, during which sibling cannibalism occurs. When the wind blows, the spiderling leaves the web.

- Initializing the population

Initially, the population is defined by the number of spiders, each representing a possible solution. An individual black widow represents a solution to an optimization problem in d -dimensional space. Eq. 13 defines the array.

$$Black\ widow = [x_1, x_2, \dots, x_d] \quad (13)$$

The array contains floating point variables. There are NP black widow spiders in a black widow population, expressed as an $NP \times d$ candidate matrix. Eq. 14 assigns the initial population at random.

$$Black\ widow = xl + rand(l, d) \times (xu - xl) \quad (14)$$

- Procreate

As each pair is independent of the other, it starts mating to reproduce a new generation, just as each couple naturally mates in its web, independently of the rest of the web. Even though hundreds of eggs are laid every time a spider mates, the number of muscular spider babies remains the same. The BWO produces offspring by reproducing an array called alpha using arbitrary numbers, in which u_1 and u_2 represent parents, whereas v_1 and v_2 represent children.

$$\begin{cases} v_1 = a \times u_1 + (1 - a) \times u_2 \\ v_2 = a \times u_2 + (1 - a) \times u_1 \end{cases} \quad (15)$$

- Cannibalism

Three categories of cannibalism are included in this algorithm. One of the earliest forms is cannibalism, where a

female black widow eats a black male widow after or during mating. Fitness values are used to identify female and male black widows. Sibling cannibalism is another type of cannibalism in which stronger siblings eat weaker siblings. The algorithm sets the cannibalism rating (CR) based on survivor numbers. The third type of cannibalism occurs when the baby spider eats the mother spider. Weak or strong spiderlings are evaluated based on their fitness value.

- Mutation

Based on the simulated binary crossover (SBC), the BWO algorithm produces new chromes or individuals at constant crossover and mutation rates. A mutation rate is altered using an adaptive scheme, followed by a projection of the enhanced mutation rate. It combines three crossover operators, single-point crossover (SPC), uniform crossover (UC), and SBC, to generate new individuals. As a result, the proposed algorithm is evaluated on three variables. BWO algorithm fails to determine an optimal solution to the optimization problem based on the permanent mutation rate. With the adaptive strategy employed in this paper, the mutation rate can be altered in order to solve this problem. We present a linear function that alters the mutation rate for ease of use. It is, therefore, necessary to update the mutation rate using Eq. 16, in which p_s is calculated by Eq. 17.

$$m_r = \frac{p_s}{L} \tag{16}$$

$$p_s = P + (t - 1) \times \frac{1 - P}{t_M - 1} \tag{17}$$

In Eq. 17, t_M and t stand for the maximum and current generation, respectively, P refers to the fixed real number given by Eq. 18.

$$P_0 = \frac{L}{50} \tag{18}$$

IV. EXPERIMENTAL RESULTS

In this section, we present results obtained from the proposed algorithm and compare them with previous methods. The developed algorithm was tested in JAVA on a PC with Windows 8 and 8GB of RAM. Simulation is conducted in a cloud-based environment containing 10 PMs and 50 VMs, with 25 incoming tasks. The main evaluation indicators are resource availability, energy, migration cost, and load. VM migration techniques on cloud computing platforms commonly use these performance metrics. We compared WOA [29], Firefly [20], and ABC-BA [30] with our proposed algorithm for analysis.

An analysis of 25 incoming tasks is conducted by comparing the developed algorithm with respect to migration cost, resource availability, energy, and load. In Fig. 3, resource availability is compared over a variety of iterations. For the 50th iteration, WOA, Firefly, and ABC-BA have resource availability values of 0.96, 0.952, and 0.938, respectively, which are lower than our algorithm. Fig. 4 illustrates the energy cost analysis. In the 60th iteration, existing techniques, such as WOA, Firefly, and ABC-BA, possess energy costs of 0.498, 0.494, and 0.494, respectively, which are higher than our algorithm. Fig. 5 shows a comparative analysis based on

migration costs. At 60 iterations, WOA, Firefly, ABC-BA, and our algorithm achieved migration cost values of 0.195, 0.132, 0.0605, and 0.059, respectively. Fig. 6 shows the results of the load analysis based on different iterations. At 50 iterations, WOA, Firefly, ABC-BA, and our algorithm have corresponding load values of 0.0098, 0.0038, 0.0029, and 0.0019.

Fig. 3. Resource availability comparison.

Fig. 4. Energy consumption comparison.

Fig. 5. Migration cost comparison.

Fig. 6. Load comparison.

The datasets used in our tests were chosen with attention to replicating different characteristics of real-world cloud computing infrastructures. We simulate the complicated dynamics and complexity of existing cloud infrastructures by using datasets with 10 PMs and 50 VMs accommodating 25 incoming tasks. These datasets contain a variety of resource capabilities, imitating real-world cloud setups and emerging as a relevant depiction of dynamic workload management concerns. The intrinsic heterogeneity of these datasets, which includes the interaction of PMs, VMs, and tasks, affects the performance of VM migration algorithms. The datasets' intricacies directly influence resource use, energy consumption, migration cost, and load distribution, all of which are critical performance measures in our study. Because cloud services are resource-intensive, efficient and adaptable migration solutions are required, which our suggested algorithm tries to meet. As we examine the differences in comparing outcomes, it becomes clear that the success of our algorithm stems from its capacity to negotiate the complexities of various datasets intelligently. The algorithm's flexibility in changing situations, such as dynamic workloads and fluctuating resource availability, presents it as a reliable option for optimizing VM migrations.

V. CONCLUSION

Due to the inherent benefits of cloud computing, the number of cloud users and their workloads is increasing daily. Besides, service providers are challenged by maintaining QoS under heavy workloads. Cloud computing can offer better computing services by utilizing VM migration techniques, reducing delays, and optimizing energy usage. This paper successfully developed the BWO algorithm to migrate VMs to the cloud. This algorithm reduces unnecessary migrations by identifying the optimal solution for migrating VMs to the host. Based on simulation results, the proposed algorithm is more efficient regarding migration cost, resource availability, load, and energy consumption than previous methods.

Towards Secure Blockchain-enabled Cloud Computing: A Taxonomy of Security Issues and Recent Advances

Shengli LIU*

Department of Public Basic Education, Hebi Polytechnic
Henan Hebi, 458030, China

Abstract—Blockchain technology offers a promising solution for addressing performance and security challenges within distributed systems. This paper presents a comprehensive taxonomy of security issues in cloud computing and explores recent advances in utilizing blockchain to enhance security and efficiency in this domain. We employ a systematic literature review approach to analyze various blockchain-enabled solutions for cloud computing. Our findings reveal that blockchain's decentralized and immutable nature empowers cloud computing services to establish secure and private data interactions. By leveraging blockchain's consensus mechanism, we demonstrate the feasibility of creating a robust platform for authenticating transactions involving digital assets. Through cryptographic methods, blocks of transactions are securely linked, ensuring data integrity. This paper provides a roadmap for understanding security concerns in cloud computing and offers insights into the potential of blockchain technology. We conclude by outlining future research directions that can drive innovation in this exciting intersection of fields.

Keywords—Cloud computing; security; blockchain; review

I. INTRODUCTION

Cloud computing has gained considerable attention in recent years owing to its affordability, sustainability, reliability, scalability, and flexibility. Under a pay-per-use model, it provides on-demand access to infinite virtual resources such as computing, storage, and networks [1]. This scalable and flexible approach to resource delivery has attracted many organizations and individuals. Cloud computing has enabled many enterprises to migrate, compute, and host their applications, giving them seamless access to a range of services without hassle [2]. It is reported that approximately 60 percent of organizations use cloud services to meet their resource needs, accounting for nearly 15 percent of global IT spending [3]. The cloud can efficiently manage bursts of heterogeneous data. It serves as a bridge between end users and the middleware of devices within the IoT architecture [4]. There is a great deal of concern about security in the cloud, which encompasses power consumption, product lifespan, and overall performance [5]. CCTV cameras, social media, and other cloud devices can be accessed and compromised in public places. A Brute Force attack has been conducted on the cloud application due to a weak authentication scheme [6].

The complexity of the cloud computing model and the shared technologies have raised security concerns despite the

obvious benefits [7]. Several elements are involved in the cloud paradigm, such as the network, architecture, APIs, and hardware, which increases the complexity of security issues [8]. This may result in security vulnerabilities if a cloud provider or client uses different configurations. While cloud computing offers organizations benefits such as cost savings, measurable services, rapid scalability, and elasticity, it also introduces inherent risks that must not be overlooked. Cloud computing systems inherently possess various vulnerabilities, giving rise to significant security concerns [9]. Organizations may hesitate to adopt cloud computing despite its potential if they lack robust security policies. An illustration of the advantages of cloud computing can be found in Fig. 1.

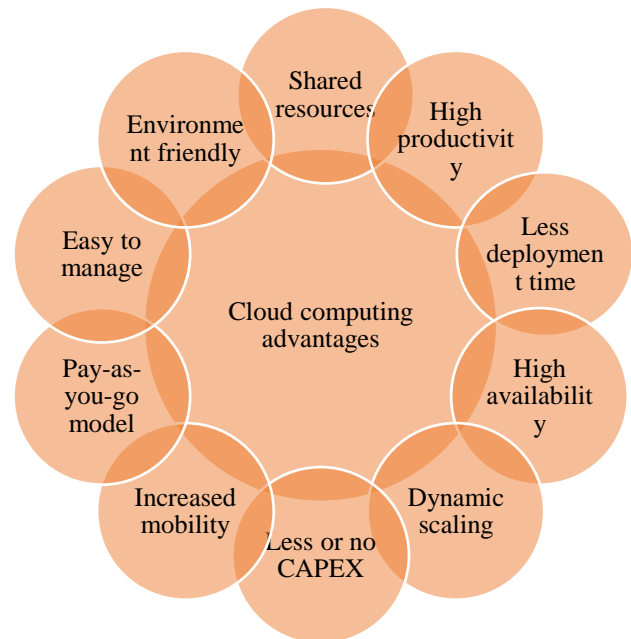

Fig. 1. Cloud computing advantages

Cloud computing offers users on-demand access to customized computing resources, such as services, applications, storage, and servers; instantly delivered by a service provider requiring little management effort. This allows users to access the latest technologies and to scale resources up or down quickly and easily, depending on their needs [10]. It also reduces the costs associated with software and hardware purchases and maintenance. Fig. 2 illustrates four ways cloud

computing can be implemented: public, private, community, and hybrid. In its simplest form, a public cloud is a cloud environment that is publicly accessible by a large number of cloud customers without any restrictions imposed by the cloud provider. Private cloud environments offer the same advantages as public clouds, but access is limited to a specific user or organization. Community clouds provide a shared cloud environment for a specific group of users and organizations. Hybrid clouds combine public and private clouds, offering more flexibility and scalability [11].

Cloud computing encompasses three main service types: Software as a Service (SaaS), Platform as a Service (PaaS), and Infrastructure as a Service (IaaS). SaaS allows users to access applications hosted in the cloud, while PaaS offers a platform for developing, running, and managing applications. IaaS, on the other hand, provides the necessary infrastructure, including servers and storage, to run applications. Cloud computing is characterized by key attributes: measured service, rapid elasticity, resource pooling, broad network access, and on-demand self-service [12]. Several metrics can be used to quantify cloud services, including bandwidth, data, and time. Cloud computing services are typically priced according to the number of resources used, and when compared to traditional IT solutions, these services can result in significant cost savings [13]. In cloud computing, the concept of elasticity is used to describe the ability of the system to respond to changes in workloads through automatic provisioning and de-provisioning, as well as the availability of resources. Resource pooling involves pooling virtual and physical resources and allocating and reallocating them dynamically according to consumer demand in a multitenant environment. Broad network access refers to the ability to locate and access resources on a network using various devices and computing platforms, such as tablets, smartphones, laptops, and desktop computers. In the context of on-demand self-service, users have access to their data and resources in the cloud whenever

they need them without requiring assistance from a human [14].

Artificial intelligence (AI) and machine learning (ML) play a pivotal role in the synergy of blockchain-enabled cloud computing, ushering in new frontiers of efficiency and security. AI algorithms leverage the immense volumes of data stored in the blockchain to uncover insights, predict patterns, and optimize resource allocation within cloud systems. ML algorithms enhance consensus mechanisms by dynamically adapting to network demands and mitigating latency [15, 16]. Moreover, AI-driven anomaly detection and threat analysis fortify cloud security by identifying and preemptively mitigating potential breaches. This amalgamation empowers cloud computing with self-optimizing capabilities and real-time threat response, elevating the potential for creating resilient and adaptive cloud ecosystems that harness both the transparency of blockchain and the intelligence of AI and ML [17].

Blockchain technology's potential to address security and performance challenges within distributed systems has garnered significant attention. Integrating blockchain presents a compelling avenue for innovation in the context of cloud computing, which necessitates robust security measures and efficient data management. While existing literature acknowledges the potential of blockchain in enhancing cloud security, a thorough examination of the distinctive security issues and recent advancements in this intersection remains limited. To bridge this gap, our work offers a comprehensive taxonomy of security concerns specifically tailored to blockchain-enabled cloud computing. Beyond traditional gap analyses, we delve into the nuanced intricacies of how blockchain uniquely tackles security and data integrity concerns within the cloud environment. Furthermore, we present an in-depth review of recent advancements that leverage blockchain to reinforce cloud computing's security framework.

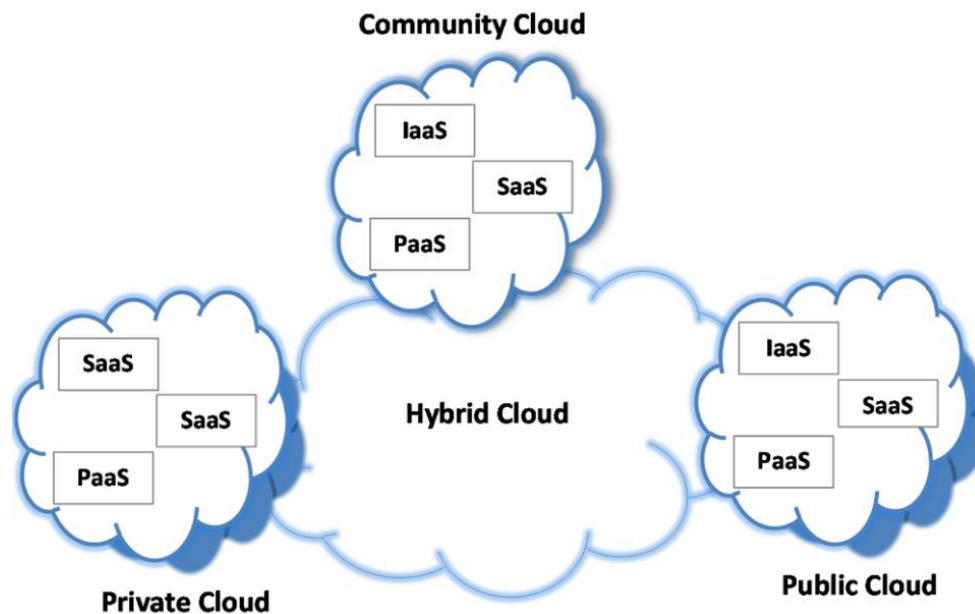

Fig. 2. Cloud deployment models and infrastructure.

Fig. 3. Review process for blockchain-enabled cloud security approaches.

To systematically review and assess blockchain-enabled cloud security approaches, we have developed a block diagram that illustrates the step-by-step process (See Fig. 3). Beginning with a comprehensive literature search (Step 1), relevant sources are identified and screened (Step 2) to extract key information from selected papers (Step 3). This information is then classified into various aspects of cloud security, such as data integrity and access control (Step 4). A comparative analysis (Step 5) highlights commonalities and differences among the reviewed approaches. Performance evaluation (Step 6) is a crucial element wherein metrics like scalability and efficiency are assessed. The synthesis of findings (Step 7) allows us to outline trends, challenges, and emerging themes in blockchain-enabled cloud security. Moreover, the diagram visualizes the identification of new blockchain solutions (Step 8) that address gaps in existing literature. Lastly, recommendations (Step 9) for the implementation of effective blockchain solutions in cloud security conclude the process. This block diagram visually represents our rigorous approach to evaluating and enhancing cloud security through blockchain integration.

The remainder of the paper is organized in the following manner. Section II delves into a comprehensive review of existing literature on cloud computing security. Section III focuses on our analysis of blockchain technology's potential in enhancing cloud security. Section IV presents our research findings. Section V concludes the paper.

II. LITERATURE REVIEW

Cloud security plays a crucial role in safeguarding all layers of computing in both public and private clouds. As illustrated in Fig. 4, cloud applications benefit from three levels of

protection: SaaS, PaaS, and IaaS. This study focuses on analyzing the existing challenges associated with cloud security and exploring the latest advancements in security solutions. It aims to provide insights into the evolving landscape of cloud security and identify effective measures to mitigate risks and protect cloud-based applications. There are 28 security problems described in the article that can be categorized into five groups (Table I). Comparative evaluations can also be conducted on the latest security technologies and countermeasures. Table I summarizes five types of cloud computing safety concerns. In [10], the same method is used to classify problems, but only for small groups and not for all four types.

Fig. 5 provides an overview of potential security risks associated with different components of the cloud. The cloud infrastructure, clients, and network are all vulnerable to security threats, necessitating the implementation of preventive, detective, and responsive strategies. Table I categorizes these components according to their respective cloud security categories. To enhance security, various security specifications such as SSL, TLS, XML signatures, Interoperability key management protocols, and XML Encryption Syntax and Processing are necessary. Currently, there is a lack of widely accepted security standards specific to cloud computing. While safety requirements may be appropriately defined, compliance risks significantly impact several security issues. The absence of effective governance and evaluation of corporate standards exacerbates this problem. In particular, cloud clients often lack sufficient knowledge regarding the provider's protocols, processes, and activities, particularly in the areas of identity management and job separations.

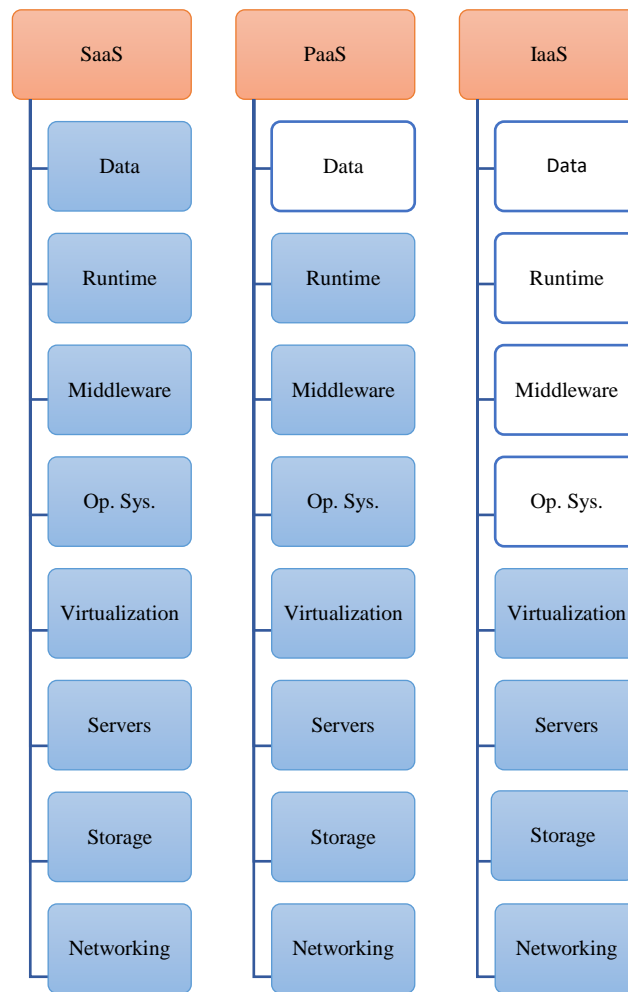

Fig. 4. Cloud security aspects

TABLE I. A TAXONOMY OF CLOUD SECURITY ISSUES

Group	Description	Issues
Data	It addresses data storage, privacy, and data migration issues concerning data security.	Accessibility, protection, privacy, recovery, placement, data loss, and redundancy information
Cloud infrastructure	It focuses on specific threats related to cloud infrastructure	QoS, server location and backup, security misconfiguration, multi-tenancy, reliability of suppliers, and sharing of technical faults
Access control	It is concerned with authentication and connectivity issues and identifies concerns regarding user privacy and data storage.	Browser protection, malicious insider, privileges of the user, and authentication mechanism
Network	It encompasses network intrusions such as link access, DDoS, DoS, flooding attacks, and bugs in the IP protocol.	Installation of the right network firewalls, Internet dependence, IP vulnerabilities, and network security configuration
Security standards	It clarifies the requirements for cloud storage as well as preventive measures to prevent unauthorized access. It specifies cloud computing safety regulations without compromising reliability and efficiency.	Inadequacies in security standards, legal issues, audit failures, enforcement risks, and trust

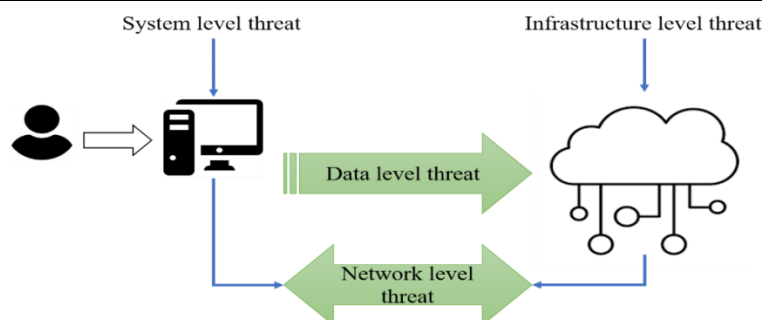

Fig. 5. Security threats associated with cloud components.

The audibility of cloud computing is one of its most critical features. However, there is no network of audit providers for cloud computing services. Ensuring auditability is crucial when a service provider outsources a non-transparent service. It is essential that the entire process is auditable to maintain transparency and accountability. However, security standards and governing bodies that protect Service Level Agreements (SLAs) and regulatory matters are not currently incorporated into cloud computing practices. This absence of established security standards and governing bodies poses challenges in effectively addressing and mitigating risks associated with outsourced services in cloud computing environments. Considering the vulnerability of cloud computing to network-related security attacks, network problems pose the greatest threat to cloud security. Operations in the cloud are heavily dependent on networking and are closely interconnected. The quality of service (QoS) has emerged as an unexpected challenge in the cloud computing landscape, as numerous service providers aim to offer fast and cost-effective performance. We consider QoS to be a critical factor that directly or indirectly influences security. Even a minor error in the configuration of one or more cloud components can have a profound impact on multiple services, considering that cloud configurations are often shared among numerous services. Various case studies emphasize the significance of encrypting, securing, managing, and ensuring timely access to data. This highlights the importance of addressing QoS concerns to ensure the overall security and effectiveness of cloud computing services. Several issues have been identified as major concerns in the literature, including data availability [18], data security [19], data confidentiality [20], data recovery [21], data localization [22], data loss [9], and data redundancy [23].

Blockchain technology refers to a network of blocks containing user records safeguarded using cryptography. These blocks are interconnected, allowing for the distribution of information throughout the network. The concept of blockchain was initially introduced in 1991 by Stuart Haber and W Scott Stornetta [24]. It was later implemented by an anonymous developer known as Satoshi Nakamoto, who used it in the creation of the digital currency Bitcoin. Initially designed for Bitcoin, blockchain technology has now found applications in various domains. Researchers have explored its potential in securing financial transactions, contracts, inter-organizational transactions, IoT systems, banking, land records, and more. Bitcoin's success in maintaining distributed ledgers and transactions without the involvement of a central authority has been instrumental in advancing blockchain technology. While Bitcoin continues to operate on Nakamoto's original blockchain, other projects like Ethereum and Ripple have emerged, each with its own set of rules and regulations and a wider range of applications [25].

Decentralization, transparency, and immutability are three characteristics of blockchain. Decentralization entails that the blockchain distributes its contents, which means the blockchain does not have a single owner. Transparency indicates that transaction information can be viewed only by a user's public address. A blockchain cannot be modified due to its immutability. These characteristics create an immutable and

secure network resistant to hacking and tampering. The transactions stored on the blockchain cannot be reversed and are fully traceable. The distributed nature of the blockchain also allows data to be stored securely and reliably [26].

Fig. 6 provides an illustration of the structure of blockchain and its associated technologies. A block is composed of two main components: the header and the transactions. The header contains the hash value of the previous block and a unique nonce number. The transactions part contains information about all the transactions included in the block. Each block includes the hash value of the previous block, which is a combination of the previous block's hash value and the current block's hash value. This property ensures the immutability of the blockchain. If an attacker attempts to modify the hash value by even a single bit, it will result in a change in the hash value of the subsequent block. This ripple effect continues throughout the entire blockchain. The attacker would need to recalculate the hash value of all the following blocks, which is extremely challenging.

Blockchain technology enables various applications in fields such as healthcare, finance, distribution, and more. One of the key features of blockchain is its ability to facilitate peer-to-peer transactions without the need for a centralized authority. The foundation of blockchain technology is built upon principles of trust and security, which are enabled through cryptography. By establishing peer-to-peer communication within a decentralized network, blockchain technology allows for trust to be established among unknown peers. The use of public and private keys plays a crucial role in ensuring security within the blockchain. A public key serves as a shared address known to everyone in the network, similar to an email address. On the other hand, a private key is a unique address that is only accessible to the user, similar to an email password.

Software programmers play a crucial role in verifying and validating transactions on the blockchain. To enhance and streamline transactions, innovative technologies have been incorporated into the computational elements of the blockchain. These transactions are recorded in a distributed ledger to ensure transparency and immutability. While blockchain technology is integral to modern digital systems, it does have certain limitations. The small size of blocks restricts the number of transactions that can occur within the network, leading to longer block creation times and reduced throughput. Fig. 7 provides an overview of the transactional flow in blockchain technology. Nodes serve as the foundation of blockchain architecture, with users or highly configured computers acting as nodes. Each node maintains a complete copy of the blockchain ledger. Miners, which are specialized nodes, have the capability to add new blocks to the blockchain. Users undergo authentication, verification, and validation processes by miners. Once a transaction is authenticated and validated by miners, the corresponding amount is deducted from the sender's wallet and credited to the receiver's wallet. The concept of a block can be likened to a container that holds an aggregated set of transaction details. New transactions initiated on the blockchain result in the creation of a new block, which can only be added to the blockchain after successful verification by miners.

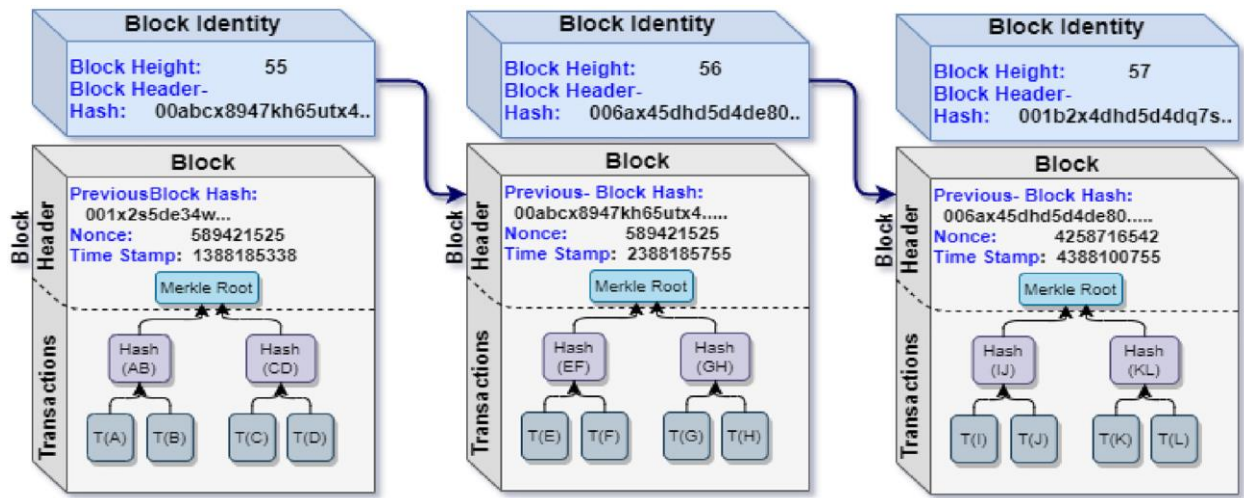

Fig. 6. Blockchain structure.

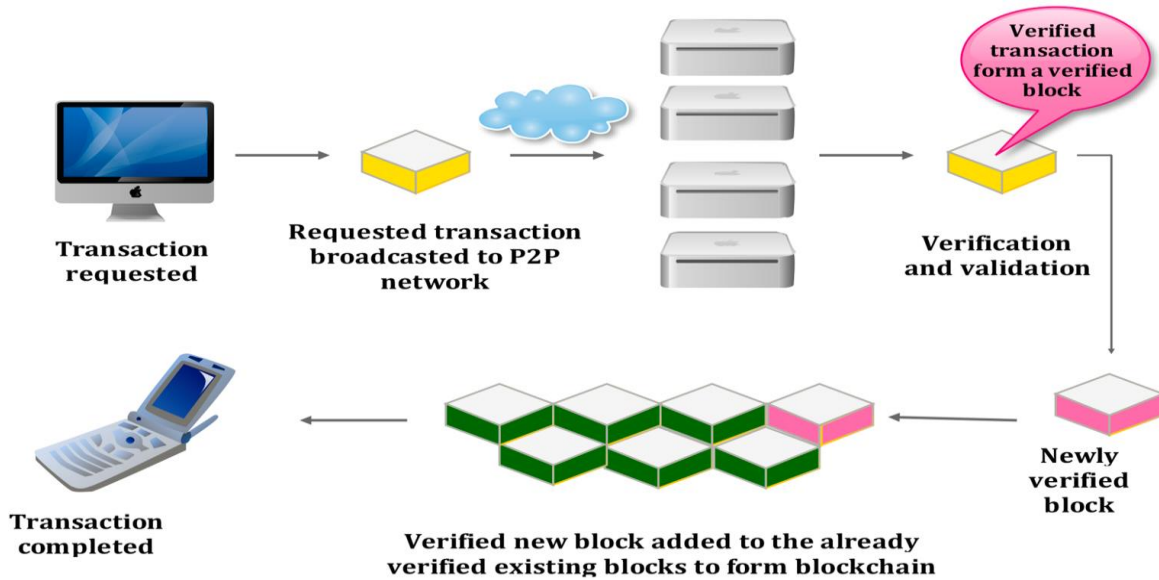

Fig. 7. Transaction flow blockchain technology.

III. BLOCKCHAIN-ENABLED CLOUD SECURITY APPROACHES

Blockchain technology and smart contracts have impacted a wide range of engineering and computer science disciplines. Cloud computing can benefit from blockchain technology by re-engineering the data centers. Due to its decentralized operating model, blockchain can potentially replace centralized cloud-based services. Blockchain has the potential to become a critical component of cloud systems due to its minimal costs and management overhead. It has been used in recent research to establish security and confidence in cloud-based applications. There are several challenges associated with the integration of blockchain technology and cloud computing:

- Blockchain was founded on the principle of decentralization in contrast to the cloud, which is entirely managed centrally and provides minimal transparency and trust configurations. Since various legal and governmental reasons make it impossible to

eliminate centralization, it is necessary to adopt a hybrid strategy whereby the cloud provider maintains some level of control while maintaining trust and transparency with the cloud users.

- Cloud data is protected from unauthorized access, while blockchain data is freely accessible. Cloud services based on blockchain technology will be widely adopted due to privacy concerns.
- Unlike cloud systems, blockchain systems are inherently susceptible to scaling problems.

The integration of blockchain technology with cloud-based services is urgently needed despite the mentioned issues. However, the question remains of how to integrate blockchain technology with the cloud. A cloud computing business model is attractive because of outsourcing services, but users and outsourcing service providers distrust one another. Zhang, et al. [27] developed the BCPay framework for fair payment for

outsourcing services in cloud computing, which achieves soundness and robustness. The system is also highly efficient regarding transaction volume and computational costs. Velmurugadass, et al. [28] developed a cloud-based Software Defined Network (SDN) for monitoring data and evidence-related operations. The SDN controller employs a blockchain system in order to protect the evidence gathered through data and user signatures. Using the Logical Graph of Evidence (LGoE), the investigator generates a report, evaluates the evidence, retrieves the evidence, and identifies the evidence. Using the evidence provided by the controller, the investigator can construct a Logical Graph of Evidence (LGoE).

Wilczyński and Kołodziej [29] proposed a blockchain-based cloud scheduler model. This model has improved the effectiveness of preparing schedules, and the simulator returns a schedule with a shorter makespan than previous individual scheduling methods. Using blockchain technology, Li, et al. [30] proposed a robust, cost-aware data caching strategy that minimizes the possibility of cache data tampering. To address trust issues between consumers, sellers, and agents, Rahman, et al. [31] propose a new exchange scheme combining blockchain with SDN to address the security risks associated with cloud computing. Distributed blockchain networks securely enable data storage and transmission, allowing scalability, flexibility, and privacy. Blockchain technology also ensures the security and privacy of data, while maintaining the system's integrity.

In order to monitor the activities of users and administrators, an audit log is essential. Still, it is susceptible to manipulation if an attacker can access the system. Attackers may modify and delete log entries or even create false entries to cover their tracks. Managing audit logs requires the protection of these records from unauthorized access. Keeping the log in a secure location with restricted access and recording and monitoring all access is essential to prevent unauthorized access.

Furthermore, the log should be regularly backed up and stored in a secure offsite location in order to detect and correct any modifications or deletions. Using blockchain technology, Ali, et al. [32] propose a Log Management System that addresses several limitations. Functionality and performance were superior to those of previous models. Xu, et al. [33] have introduced a blockchain-based method for managing cloudlets in a multi-media workflow. A multi-media application is enhanced using NSGA III, and an optimal scheduling decision is made using ELECTRE. Eltayieb, et al. [34] developed a cloud-based data-sharing platform based on blockchain technology coupled with attribute-based sign encryption. The proposed scheme complies with the security requirements of cloud computing, including confidentiality and unforgeability. The smart contract also eliminates the problem with traditional cloud servers, such as returning incorrect results.

Awadallah and Samsudin [35] introduced a cloud relational database with an enhanced structure based on blockchain technology. The client has the ability to detect and prevent errors in cloud relational database manipulation by employing a self-verification mechanism. They proposed two systems for improving the mechanism's performance: an agile blockchain-based cloud relational database and a secure blockchain-based

cloud relational database. Byzantine fault tolerance distributes both systems across several cloud service providers. The SHA-256 algorithm is also used in both systems to link records. In addition, blockchain-based cloud relational databases that operate on a proof-of-work consensus prevent data offensive operations. A blockchain-based cloud relational database is highly recommended for high throughput databases based on performance and security analysis. Cloud relational databases based on blockchain technology are recommended for containing sensitive data and performing poorly in terms of throughput. The flexibility of cloud-based relational databases allows users to operate them according to their specific requirements.

Intrusion Detection System (IDS) has become widely recognized as a valuable tool for protecting networks and information. IDS monitors network traffic and alerts administrators when malicious activities or suspicious behavior is detected. It is used to detect and prevent any unauthorized access or malicious attacks. Host IDS (HIDS) detects unauthorized use and abnormal and malicious activity on a host, whereas Network IDS (NIDS) detects network attacks and intrusions. Kumar and Singh [36] propose the development of Distributed IDS (DIDS) based on emerging and promising technologies like blockchain on a stable platform such as cloud infrastructure.

Access control is of paramount importance in cloud computing, as it is where enterprises and individuals store their sensitive data. However, the centralized access control mechanism used in the cloud poses a significant security risk. Sensitive data stored in the cloud becomes vulnerable to tampering or unauthorized disclosure by hackers or even cloud managers. This highlights the need for robust access control technologies to ensure the confidentiality and integrity of data in the cloud environment. To address this issue, Yang, et al. [37] propose AuthPrivacyChain, a blockchain-based access control framework with privacy protection. The first step is to use the account address of a node in the blockchain as the identity and simultaneously redefine the permissions for access control to the cloud. They then design processes for controlling access, authorizing users, and revoking authorizations. Lastly, the researchers implement AuthPrivacyChain using the enterprise operation system (EOS) and evaluate its performance. The results demonstrate that AuthPrivacyChain offers robust protection against unauthorized access by hackers and administrators. Additionally, it ensures the preservation of authorized privacy, providing a comprehensive security solution.

IV. DISCUSSION

In this section, we present and analyze the findings of our research on blockchain-enabled cloud security solutions. Our investigation, encompassing a systematic literature review and analysis, revealed several key insights that contribute to the evolving understanding of this field.

Cloud service users have high expectations from cloud service providers in terms of transparency, efficiency, security, and authentication of transactions, services, and applications. Trust and credibility in cloud network transactions depend on involving a trusted third party to verify, validate, and endorse

them. Incorporating business logic into the database (Ledger) and executing it becomes necessary for transaction validation and storage. Blockchain technology, with its inherent capabilities and potential, holds the promise of addressing many of the challenges faced by virtualized cloud infrastructures today. It offers secure, transparent, trustworthy, and efficient solutions for managing and registering the authorized identities of all stakeholders in the cloud. Its decentralized and distributed nature, coupled with a reliable management and governance system, allows for tracking, tracing, and effective management of cloud-related transactions. Additionally, blockchain can be leveraged to manage and store identities and services, ensuring their complete concealment from end users.

Cloud infrastructures can be made more secure by integrating blockchain technology. Oracle Blockchain Cloud Service is one example of a blockchain-enabled cloud solution currently being implemented. A virtualized cloud environment can also benefit from the use of blockchain technology. All connected cloud devices and services can be registered and identified on the blockchain ledger through a set of attributes and complex relationships. Consequently, virtualized cloud supply chain networks can provide provenance at all levels. Cloud-enabled supply chains involve numerous stakeholders, ranging from cloud infrastructure facilities, vendors, suppliers, and service providers to distributors, shippers, installers, owners, repairers, and re-installers. Anonymity is a key aspect in large-scale cloud environments. To ensure privacy and prevent third-party service providers from accessing private information, an electronic wallet is created and installed within cloud systems. Furthermore, blockchain-enabled smart contracts play a crucial role in managing, controlling, and securing cloud services and devices. The previous section highlighted the significant features of blockchain technology that are particularly valuable for cloud platforms, especially in terms of enhancing cloud security.

A virtualized cloud system offers anonymity for user information and service data, which can be strengthened by integrating blockchain-enabled solutions. One such solution is the implementation of electronic wallets within large-scale cloud environments, which utilize blockchain platforms to store users' and services' data securely. By leveraging a blockchain network, cloud service records can be stored, and the identities of cloud users and service providers can be authenticated and validated. This combination of virtualized cloud systems and blockchain technology provides an additional layer of security and trust in cloud-based transactions and interactions. Whenever a cloud service provider connects to a blockchain network, it will prove and sign its transactions cryptographically, which can be tracked and tracked by users or cloud service providers participating in the network. A blockchain-based smart contract ensures user and service privacy by controlling who has permission to update, upgrade, patch, provide new key pairs, initiate a service or repair request, and change ownership. The blockchain network provides fault tolerance and resilience to cloud users, as the failure of a single node will not affect the entire virtualized cloud infrastructure. By integrating blockchain into a cloud infrastructure solution, blockchain-as-a-service (BaaS)

can be implemented. BaaS allows users to leverage the advantages of blockchain technology without having to build an entire infrastructure from scratch. It also provides a secure platform for cloud services, and users can manage, monitor, and control their data easily. Additionally, BaaS can enable cost and time savings for businesses. Furthermore, BaaS enables businesses to scale quickly and efficiently while providing a secure and reliable platform.

Several key findings have emerged from our comprehensive exploration of blockchain-enabled cloud security approaches. Through a systematic review of the literature, we categorized and analyzed various mechanisms that leverage blockchain technology to enhance the security of cloud computing environments. Our investigation revealed that these mechanisms encompass data integrity verification, access control, consensus protocols, and auditability. These findings underscore the potential of blockchain technology to offer innovative solutions for addressing the unique security challenges inherent in cloud environments. Comparing our findings with those of previous studies, our research aligns with the insights presented by AlMuraytib, et al. [38]. Both studies highlight the potential of blockchain to enhance cloud security by ensuring data integrity and enhancing trust in cloud transactions. While we echo these sentiments, our study goes further by delving deeper into the distinct security challenges that cloud computing faces and presenting novel mechanisms specifically designed to tackle these issues. Our focus on tailoring blockchain solutions to address the intricacies of cloud security sets our work apart and contributes a fresh perspective to the field. Furthermore, our research contributes a domain-specific understanding of how blockchain principles can be adapted to meet the security demands of cloud computing. While existing studies primarily emphasize the application of general blockchain principles, our work recognizes the need for nuanced approaches to accommodate the intricacies of cloud environments. By doing so, we bridge a critical gap in the literature and offer a more targeted and effective path toward securing cloud-based systems.

V. CONCLUSION

This paper discussed the potential for transformation that arises from integrating blockchain technology with cloud computing, focusing on overcoming major security and performance challenges. The study highlighted the diverse benefits that this combination brings to the field of information technology. The initial phase of our investigation was identifying security concerns inherent in cloud computing. The need to protect data integrity arises from the vulnerability to data modification and compromise, hence requiring the development of novel solutions. Blockchain technology, known for its robust resistance to tampering, is a valuable strategic partner in this context. The originality of our study is in the application of blockchain technology specifically tailored to address security concerns in cloud computing. In contrast to prior research that use broad concepts, our research emphasizes customizing blockchain solutions to address the complexities of cloud computing, showcasing novel processes. The procedures above encompass data integrity verification, access control, and consensus protocols, effectively target and mitigate security vulnerabilities. The research findings have

far-reaching ramifications for both the academic community and several industries. By providing practitioners and researchers with security solutions tailored to certain domains, we improve the reliability of transactions conducted in cloud-based environments. Incorporating blockchain technology facilitates improving data quality and dependability, which is a crucial need in several application fields. As we contemplate the future, the convergence of cloud computing and blockchain technology presents significant possibilities. The secure and efficient data storage and processing offer potential competitive benefits for firms. The trajectory forward necessitates more investigation in order to fully elucidate the comprehensive range of repercussions stemming from this fusion. This discovery signifies the advent of a hopeful era in which cloud computing is strengthened by the powerful security framework of blockchain, leading to a trajectory towards a digital landscape that is more safe and efficient.

Research on Enterprise Supply Chain Anti-Disturbance Management Based on Improved Particle Swarm Optimization Algorithm

Tongqing Dai

Business School, Huanggang Normal University, Huanggang, 438000, China

Abstract—A supply chain that is effective and of the highest caliber boosts customer happiness as well as sales and earnings, increasing the company's competitiveness in the market. It has been discovered that the standard supply chain management technique leaves the supply chain with weak supply chain stability because it has a low ability to withstand the manufacturer's production behaviour. An enterprise supply chain resistance management model is built using the study's proposed particle swarm optimisation technique, which is based on a genetic algorithm with stochastic neighbourhood structure, to solve this issue. The suggested technique outperformed the other two algorithms utilised for comparison in a performance comparison test, with a stable particle swarm fitness value of 0.016 after 800 iterative iterations and the fastest convergence. The proposed model was then empirically examined, and the results revealed that the production team using the model completed the same volume of orders in 32 days while making \$460,000 more in profit. With scores of 4.5, 4.5, 4.3, 4.3, 4.2, and 4.2, respectively, the team also had the lowest values of the six forms of employee anti-production conduct, outperforming the comparative management style. In summary, the study proposes an anti-disturbance management model for enterprise supply chains that can rationalise the scheduling of manufacturers' production behaviour and thus improve the stability of the supply chain.

Keywords—Supply chain; particle swarm optimization algorithm; genetic algorithm; inverse production behaviour; neighbourhood structure

I. INTRODUCTION

With the development of the global economy and the intensification of competition, the supply chain of enterprises is faced with more and more disturbances and uncertainties [1]. These disturbances include fluctuations in market demand, changes in raw material prices, natural disasters, etc. which have a huge impact on the operation of the supply chain [2-3]. Therefore, enterprises need to strengthen the anti-disturbance ability of the supply chain to ensure the efficient operation and stability of the supply chain. In supply chain anti-disturbance management, it is an important task to optimize resource allocation and decision-making in the supply chain [4-5]. The traditional particle swarm optimization algorithm often ignores the nonlinear relations and complex constraints in the supply chain, resulting in unstable optimization results and difficult to be applied in practice. Therefore, a new optimization algorithm is needed to solve this problem. In order to solve this problem and improve the anti-disturbance

ability of enterprise supply chain, this paper proposes to improve the particle swarm optimization algorithm by using genetic algorithm and random neighborhood structure, and build the anti-disturbance management model of enterprise supply chain based on the improved algorithm. It is hoped that this model can improve the anti-interference ability of supply chain, improve the stability of supply materials, and enhance the market competitiveness of enterprises. The research is of great significance for enterprises to improve supply chain anti-disturbance ability, improve operation efficiency and reduce operation cost. At the same time, the anti-disturbance management method of enterprise supply chain based on improved algorithm also has certain theoretical and practical value, and has certain reference significance for the application and promotion of optimization algorithm. The innovation point of the research is that, considering various variables and uncertainties of the supply chain, genetic algorithm and random neighborhood structure are used to improve the traditional PSO based optimization algorithm, so as to optimize the resource allocation and decision-making in the supply chain, so as to improve the robustness and flexibility of the supply chain. The second section of this research is the in-depth study of the application of particle swarm optimization algorithm and supply chain problems in recent years. The third section analyzes the problems existing in the classical particle swarm optimization algorithm, proposes to improve it by using genetic algorithm and random neighborhood structure, and establishes the enterprise supply chain anti-disturbance management model based on the improved algorithm. The fourth section is the performance comparison test of the improved algorithm proposed in the research, and the practical application effect analysis of the enterprise supply chain anti-disturbance management model. The fifth section is the summary and conclusion of the whole research.

II. RELATED WORKS

A particle swarm optimisation technique for multi-objective solutions has been researched by scientists as part of the ongoing advancement of science and technology, and it is now widely employed in many neighbourhoods. To solve the issues with the design of steel pipe support weighing structures, Zakian et al. suggested an optimisation algorithm merging particle swarm algorithm with grey wolf optimiser. The findings of the empirical investigation suggest that the optimisation technique can enhance the structural. The outcomes demonstrated that the optimisation approach might

enhance the pipe support structure's structural load-bearing and dimensional binding performance [6]. In an effort to address the issue that thermal coupling can lower the control accuracy of eccentric rotor extruders, Wen et al. proposed a control algorithm based on the particle swarm optimisation algorithm and neuron proportional integral differentiation [7]. After comparison tests, it was found that the algorithm can offset the effect of thermal coupling and improve the control accuracy of eccentric rotor extruders. To solve the issue that it is challenging to locate global peaks of PV arrays under shading conditions, Javed's team suggested a particle swarm optimisation approach in conjunction with adaptive learning. The results of comparative experimental study indicate that the algorithm outperforms conventional algorithms in terms of convergence speed and success rate, operating with an average efficiency of 99.65% [8]. To address the issue of low vehicle guidance accuracy in congested urban networks, Zouari's team suggested a hierarchical interval type 2 fuzzy logic model based on particle swarm optimisation. After conducting a simulation test and analysing the findings, Liu et al. suggested a node localization approach based on the combination of the particle swarm optimisation algorithm and the monkey algorithm. The results indicated that the method produced improved localization effects in terms of node rate and node density [10].

A solution using human capital and digital management was put out by Song et al. to address the issue of high retailer volatility in supply chain integration. According to the empirical analysis's findings, merchants who used this model had a better long-term investment mindset, which improved the supply chain's stability [11]. To solve the problem that green sensitivity has a significant impact on the stability of green supply chains, Long's team created an evolutionary game model that incorporates the green sensitivity of the government, businesses, and consumers. Following empirical analysis, the findings demonstrated that the model can combine the three elements to create a reasonable green sensitivity, upholding the stability of the green supply chain [12]. The outcomes of the comparison experiments demonstrated that this method can increase both the speed and security of hydrogen storage [13]. To attempt to address the issue of supply-demand mismatch in the supply chain for influenza vaccines, Lin et al. proposed a segmented linear function-based procurement model. After comparative experimental analysis, it was demonstrated that the model could coordinate the supply chain for influenza vaccines more effectively by fully taking into account the supply-demand relationship in the supply chain [14]. The results of a comparative experimental examination of a multi-stage mixed integer planning model revealed that it may not only lower logistics costs in the forest supply chain but also satisfy the wood demand of the sector [15].

In conclusion, merging supply chain research with the superiority of particle swarm optimisation algorithms has been shown in a number of localities, and it is thought that doing so has some research worth. Few academics have merged the two, thus this work uses the particle swarm optimisation algorithm to the creation of an anti-disturbance management model for company supply chains in an effort to close the gap in this

research direction. It is believed that this research would increase the ability of business supply networks to withstand disruptions, lay the groundwork for increased business competitiveness, and serve the field of business supply chain management with research data.

III. RESEARCH ON ANTI-INTERFERENCE MANAGEMENT MODEL OF ENTERPRISE SUPPLY CHAIN BASED ON IMPROVED PARTICLE SWARM OPTIMIZATION ALGORITHM

It is impossible to emphasise how important the supply chain is to business operations, however traditional supply chain management is ineffective at controlling manufacturers' production behaviours, causing the supply chain to be impacted by this issue and having poor stability. This chapter will build an anti-disruption management model for enterprise supply chains based on the improved algorithm by using genetic algorithm and stochastic neighbourhood structure to address the shortcomings of the conventional particle swarm optimisation algorithm.

A. Improved Particle Swarm Optimization Algorithm based on Genetic Algorithm and Random Neighborhood Structure

Particle Swarm Optimization (PSO) is a population-based stochastic optimization technique that has strong adaptive and global convergence capabilities [16]. A particle in the PSO algorithm represents a process ordering in a production plant, i.e. a feasible solution to the production scheduling scheme. The particles are initialised and the equations are shown in Eq. (1) and (2).

$$v_{i,j}(t+1) = \omega v_{i,j}(t) + c_1 r_1 [p_{i,j} - x_{i,j}(t)] + c_2 r_2 [p_{g,j} - x_{i,j}(t)] \quad (1)$$

In Eq. (1), $v_{i,j}(t+1)$ denotes the velocity of the particle at the moment $t+1$ and t denotes the moment t . $x_{i,j}$ denotes the vector of real numbers and $v_{i,j}$ denotes the velocity vector. $p_{i,j}$ and $p_{g,j}$ both denote the current optimal position of the particle. ω denotes the habituation factor and c_1 and c_2 both denote the learning factor. r_1 and r_2 denote the random number between production.

$$x_{i,j}(t+1) = x_{i,j}(t) + v_{i,j}(t+1), j \in \{1, 2, 3, \dots, n\} \quad (2)$$

In Eq. (2), $x_{i,j}(t+1)$ denotes the particle position iteration at this moment of $t+1$. In the PSO algorithm, information sharing is constructed based on the best position of individual particles with the best position information of the particle population, passing the information to other particles in the search space. Due to the lack of information exchange between each particle, the optimal position of the particle itself changes as the search for the optimal position is continuously updated, and thus the optimal position of the particle population changes as well. Genetic algorithms are a method of searching for optimal solutions that mimics the natural evolutionary process, using processes such as chromosomal gene mutation and crossover [17]. The algorithm can optimise complex problems faster than

traditional optimisation algorithms, and this study will use the mutation and crossover processes of the algorithm to change the problem of untimely information interaction in the PSO algorithm to ensure that each particle in the PSO algorithm can interact with each other to achieve information sharing and prevent local search [18]. The mutation operation in the algorithm is shown in Fig. 1.

Fig. 1. Schematic representation of the variant operation.

As shown in Fig. 1, the mutation operation is performed separately for the historical best position of the particle and the current best position of the particle population. Different particles have different mutation probabilities, but the mutation operator is selected with the same probability, i.e. the selection of swap, insertion and inversion is the same. Swap variation involves swapping the positions of two randomly selected positions in the particle vector. The insertion variant is a random selection of two positions in a particle vector, which are compared in terms of their numerical size, with the smaller numerical particle being inserted after the larger value. The reversal variation involves randomly selecting two positions in the particle vector and reordering the other particles between the two positions in reverse, i.e. [4,1,6,9,8,5] becomes [5,8,9,6,1,4], as in Fig. 1(c). The crossover operation in the algorithm is shown in Fig. 2.

Fig. 2. Schematic diagram of the crossover operation.

As shown in Fig. 2, the historical best positions of the particles after mutation and the current best positions of the particle population are labelled and each is used as a parent to perform the crossover operator. A number of $n'(n' < n)$ positions are randomly selected from the particle historical best positions to form array 1, which is copied directly in the first child according to its position in the parent. The first offspring is directly copied in the first offspring according to its position in the parent, thus completing the first offspring. The second offspring is formed similarly. By means of mutation and crossover operations, it is possible to interact with the information between individual particles in the PSO algorithm and to improve the search accuracy of the PSO algorithm. Although the PSO algorithm is fast in global convergence, local convergence faces the problem of falling into local traps.

To solve this problem, a random neighbourhood structure containing insertion neighbourhood, exchange neighbourhood and block exchange neighbourhood was studied [19]. The insertion operation of this neighbourhood structure is highly random, making the neighbourhood structure flexible and guiding the particles to search quickly during production scheduling. The swap operation is decentralised and can lead particles to jump out of local search. Therefore, using this neighbourhood to improve the PSO algorithm not only solves the problem of the algorithm falling into local traps, but also improves the speed and accuracy of the search. The search mechanism of the random structured neighbourhood is to randomly perform one or more insert neighbourhood, swap neighbourhood and block swap neighbourhood operations, the mathematical structure of which is expressed in Eq. (3).

$$f_N = \left(M \oplus \left(C_{pm} \otimes X_{best(g)} \right) \right) \quad (3)$$

In Eq. (3), M denotes the step size for performing the neighbourhood operation; $X_{best(g)}$ denotes the current best position of the X population; and C_{pm} denotes the probability of the diameter neighbourhood operation, which is calculated as shown in Eq. (4).

$$C_{pm} = \begin{cases} (\alpha_1 \leq rand() \leq \beta_1) \Rightarrow insert(\pi, k_1, k_2) \\ (\alpha_2 \leq rand() \leq \beta_2) \Rightarrow swap(\pi, k_1, k_2) \\ (\alpha_3 \leq rand() \leq \beta_3) \Rightarrow blockswap(\pi, B_1, B_2) \end{cases} \quad (4)$$

In Eq. (4), $[\alpha_1, \beta_1]$, $[\alpha_2, \beta_2]$ and $[\alpha_3, \beta_3]$ denote three probability intervals respectively; $rand()$ denotes a random distribution between (0,1); π denotes a scheduling scheme; k denotes an artifact; B denotes a set consisting of two adjacent artifacts; $insert(\pi, k_1, k_2)$ denotes an insertion neighbourhood; $swap(\pi, k_1, k_2)$ denotes an exchange neighbourhood; and $blockswap(\pi, B_1, B_2)$ denotes a block exchange neighbourhood. The parts of the probability region that overlap each other are defined as $COM < I, S, BS >$, and when $rand()$ is between $COM < I, S, BS >$, then the operation of the random neighbourhood is pressed as $insert(\pi, k_1, k_2)$, $swap(\pi, k_1, k_2)$, $blockswap(\pi, B_1, B_2)$. The working schematic of this neighbourhood structure is shown in Fig. 3.

As shown in Fig. 3(a), the position of workpiece 1 in the scheduling plan is randomly determined in $insert(\pi, k_1, k_2)$ and randomly inserted after the position of workpiece 2. As shown in Fig. 3(b), the positions of workpiece 1 and workpiece 2 in the scheduling plan are randomly swapped in $swap(\pi, k_1, k_2)$. The positions of workpiece set 1 and workpiece set 2 are randomly swapped in $blockswap(\pi, B_1, B_2)$ as shown in Fig. 3(c). Combining the above, the PSO algorithm is improved using genetic algorithm with random neighbourhood structure, and the improved algorithm is defined as HPSO-R.

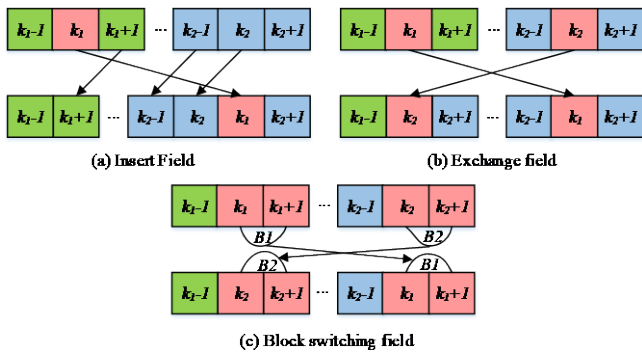

Fig. 3. A Schematic diagram of the domain structure.

B. Construction of Supply Chain Anti-Disturbance Management Model based on Improved Particle Swarm Optimization Algorithm

The supply chain is a network chain structure formed by the whole process of sending products from production to consumers. The supply chain of an enterprise is the lifeblood of the enterprise economy and its stable operation is very important for the development of the enterprise. The schematic diagram of the supply chain structure is shown in Fig. 4.

Fig. 4. Supply Chain Schematic diagram.

The stability of the enterprise supply chain is mainly influenced by the stability of the products produced by the manufacturer. The study will optimise the manufacturer's production management scheduling model through the HPSO-R algorithm to construct an anti-disturbance management model for the enterprise supply chain. The reasonableness of manufacturers' production management scheduling can be reflected by the counterproductive behaviours generated by employees [20]. Anti-production behaviours are divided into six categories, the first of which is job satisfaction, the equation for which is shown in Eq. (5).

$$L_1 = INTEG(R_1 - R_2, 2) \quad (5)$$

In Eq. (5), the letters L_1 , R_1 , and R_2 stand for work satisfaction, rate of increase in satisfaction, and rate of drop in satisfaction, respectively. The equation for the second category, organisational justice, is given in Eq. (6).

$$L_2 = INTEG(R_3 - R_4, 1) \quad (6)$$

In Eq. (6), the letters L_2 , R_3 , and R_4 stand for the

organisational sense of justice, the rate at which it is increasing, and the rate at which it is decreasing. Eq. (7)'s equation for the third category, "sense of team climate," is shown.

$$L_3 = INTEG(R_5 - R_6, 1.5) \quad (7)$$

In Eq. (7), L_3 stands for the team's overall environment, R_5 for the rate at which it is improving, and signifies the rate at which it is deteriorating. The level of supervision, which is the fourth category, is determined as illustrated in Eq. (8).

$$L_4 = L_2 \times A_1 + L_6 \times A_2 + L_7 \times A_3 + L_8 \times A_4 \quad (8)$$

L_4 represents the degree of supervision, L_6 represents the degree of organisational culture building, L_7 represents the number of behavioural corrections, L_8 represents the perfection of the supervision mechanism, and $A_i (i = 1, 2, \dots, n)$ represents the weighting factor in Eq. (8). Level of group regulation, the fifth category, has an equation that is represented in Eq. (9).

$$L_5 = INTEG(R_7 - R_8, 1.5) \quad (9)$$

In Eq. (9), L_5 stands for the group normative level, R_7 for the rate of increase of the group normative level, and R_8 for the rate of fall of the group normative level. The level of organisational culture building, the equation for which is stated in Eq. (10), is the sixth category.

$$L_6 = INTEG(R_9, 2) \quad (10)$$

In Eq. (10), L_6 stands for the organisational culture's level of development, and R_9 for its pace of growth. Eq. (11) displays the equation for determining anti-productive behaviours.

$$L_7 = L_1 \times F_1 + L_2 \times F_2 + \dots + L_6 \times F_6 \quad (11)$$

L_7 stands for unproductive behaviour, and $F_i (i = 1, 2, \dots, 6)$ stands for the coefficients of each of the six contributing elements described above in Eq. (11). Fig. 5 illustrates the interrelationship of the variables driving employee unproductive behaviour.

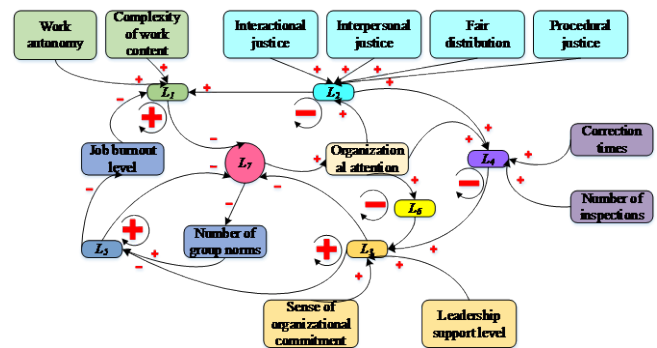

Fig. 5. Plot of anti-productive behavior factors

In the manufacturer's production management scheduling model, the initial scheduling target is calculated as shown in Eq. (12).

$$\min \left\{ f(\pi_0^s) = \sum_{j=1}^n w_j \cdot C_j, f(\pi_0^m) = \sum_{j=1}^n w'_j \cdot C'_j \right\} \quad (12)$$

In Eq. (12), j denotes the workpiece; π_0^s is the supplier's initial dispatch time; π_0^m is the manufacturer's initial dispatch time; w_j and w'_j are the supplier's weighting factor and the manufacturer's weighting factor respectively; BBB and C_j are the supplier's completion time and the manufacturer's completion time respectively. To strengthen the resilience to disturbances in the supply chain, the study introduces disturbance management theory to optimise the model. Interference management models the optimisation of individual practical problems and disturbance events, e.g. in the face of machine downtime during a manufacturer's production process, the interference management scheduling objective optimisation equation is shown in Eq. (13).

$$\left\{ \begin{aligned} \min \left\{ f_1(\pi') = \sum_{j=1}^n w'_j \cdot C'_j, f_2(\pi') = \sum_{j=1}^n w'_j \cdot \bar{\Delta}t'_0 \right\} \\ \bar{\Delta}t'_0 = \max \{ C'_j - \bar{C}'_j, 0 \} \end{aligned} \right. \quad (13)$$

In Eq. (13), $f_1(\pi')$ denotes the optimisation objective of the manufacturer's disturbance repair scheme as well as the initial scheduling scheme, $f_2(\pi')$ denotes the minimisation objective and \bar{C}'_j denotes the manufacturer's completion time of the workpiece in the initial scheduling scheme. During the scheduling arrangement of the production product, the cost benefit between the supplier and the manufacturer also needs to be considered, i.e. the objective of maximising the benefits of cooperation, which is calculated as shown in equations (14) and (15).

$$\min \{ f_3(\pi') = -V_m \cdot V_s \} \quad (14)$$

In Eq. (14), V_m denotes the manufacturer's revenue after the disturbance, and V_s denotes the supplier's revenue after the disturbance.

$$\left\{ \begin{aligned} D_j^s \leq S_j^m \\ S_j^s, C_j^s \notin [t_1, t_2], (j \in list) \\ (S_j \geq C_k) \vee (S_k \geq C_j), \forall j, k \in J \end{aligned} \right. \quad (15)$$

In Eq. (15), D_j^s denotes the supplier's delivery time; S_j^m denotes the manufacturer's processing start time; C_j^s and C_j^m denote the supplier's processing time and completion time respectively. For the above multi-objective optimisation problem of initial scheduling objective, disturbance management scheduling objective and cooperation revenue

maximisation objective, the research proposed HPSO-R algorithm can be used to find the optimal solution for it. The workflow is shown in Fig. 6.

Fig. 6. Workflow of the HPSO-R algorithm.

As shown in Fig. 6, the HPSO-R algorithm is made from the basic PSO algorithm, improved by variation, crossover operations and random neighbourhood structure in the genetic algorithm, and has a higher search accuracy than the traditional PSO algorithm, with superiority in both global search as well as local search. The work flow of the algorithm is as follows: the input data is randomly generated to generate the initial population, and then the fitness value of the population is calculated according to the corresponding workpiece. According to the fitness value, the optimal position and target value of the individual particle are determined, and then the optimal position and target value of the population are determined. After that, the position and velocity of each particle are updated by particle swarm optimization algorithm, and the optimal position and target value of individual particle and the optimal position and target value of group are updated by mutation and cross operation in genetic algorithm. The mutation operation of genetic algorithm is divided into three types, namely exchange mutation, insert mutation and reverse mutation, and the best position of the particle history and the best position of the particle population are respectively changed. The crossover operation is to mark the historical best position of the particle and the current best position of the particle population after the mutation operation, and perform the crossover operator as the parent respectively, and realize the transformation of the historical best position of the particle and the current best position of the particle population through genetics. Through variation and cross operation, the information exchange between individual particles in PSO algorithm can be realized, and the search accuracy of PSO algorithm can be improved. Then the random structure neighborhood is used to perform insertion neighborhood, exchange neighborhood, block exchange neighborhood and probability overlap operations. The insertion operation of the neighborhood structure has a strong randomness, which makes the neighborhood structure change flexibly, and leads the particle to search quickly in the production scheduling process. The exchange operation is decentralized and can guide the particles out of the local search. Using this field can not only avoid PSO algorithm falling into local traps, but also improve the search speed and accuracy of the algorithm. Finally, it is

judged whether the optimal position and target value of the particle swarm after searching meet the termination condition of the algorithm, and if so, the result is output. If it is not satisfied, the fitness value of the new population is calculated according to the result, and the previous steps are repeated until the algorithm termination condition is satisfied, and the optimal position and target value of the particle swarm are output. In summary, the improved algorithm not only has high speed and high accuracy, but also will not fall into the local optimal situation, which can strengthen the anti-interference ability of enterprise supply chain.

IV. RESULTS AND DISCUSSION

To verify the performance of the HPSO-R algorithm proposed in the study, this study will conduct a comparison test using Visual software and the PSO algorithm, Genetic Algorithm Trade Off Model (GA-TOM) algorithm will be used as the comparison algorithm. The experiment uses the metrics of the Overall Nondominated Vector Generation (ONVG), the Uniformity of Distribution of Non-inferior Solutions (UDNS), the Non Inferior Solution Dominance Ratio (NISD) and the Average Distance between the Non-inferior Solution and the Optimal Pareto Front (ADF) to evaluate the algorithm in a comprehensive manner. An empirical analysis of the research's proposed improved algorithm-based model for the anti-disturbance management of an enterprise's supply chain is then carried out, with workers divided into three groups within a small factory, using the HPSO-R model, the PSO model and the GA-TOM model in a two-month comparative trial. The models will be comprehensively evaluated using indicators such as product completion time and profit in the trial.

A. Comparative Analysis of Performance of Improved Particle Swarm Optimization Algorithm

Fig. 8. A for ADF and DPNS for the three algorithms.

As shown in Fig. 8(a), the ADF value of the HPSO-R algorithm is 5.6 at maximum, 2.4 at minimum and 4.1 at average; the ADF value of the GA-TOM algorithm is 5.8 at maximum, 3.1 at minimum and 4.6 at average; and the ADF value of the PSO algorithm is 6.6 at maximum, 4.8 at minimum and 5.8 at average. The ADF value of the HPSO-R algorithm is lower than the other two. The ADF values of the HPSO-R algorithm are lower than the other two algorithms. As shown in Fig. 8(b), the NISD value of the HPSO-R algorithm was 0.62 at maximum, 0.11 at minimum, and 0.31

at mean; the NISD value of the GA-TOM algorithm was 0.35 at maximum, 0.11 at minimum, and 0.25 at mean; the NISD value of the PSO algorithm was 0.42 at maximum, 0.0 at minimum, and 0.06 at mean. The NISD value of the HPSO-R algorithm was higher than the other two algorithms. The NISD values of the HPSO-R algorithm were higher than those of the other two algorithms. In summary, the HPSO-R algorithm outperformed the comparison algorithms in terms of ADF and NISD. The experiment reflects the convergence speed of the algorithm by recording the change curve of the particle swarm

Fig. 7. ONVG and UDNS for the three algorithms.

As shown in Fig. 7, the ONVG values of the HPSO-R algorithm are 13, 13, 13, 13, 14, 12, 12, 11, 12, 10; the ONVG values of the GA-TOM algorithm are 11, 10, 11, 11, 12, 10, 10, 10, 10, 9; and the ONVG values of the PSO algorithm are 9, 8, 9, 9, 7, 7, 9, 9, 7. The minimum UDNS values of the HPSO-R, GA-TOM and PSO algorithms are 1.6, 1.8 and 1.9, respectively, and the maximum UDNS values are 4.2, 6.8 and 9.6. The overall UDNS values of the HPSO-R algorithm are smaller than those of the other two algorithms. In summary, the HPSO-R algorithm outperforms the other two compared algorithms in terms of ONVG and UDNS, two evaluation metrics. The ADF and NISD test results of the three algorithms are shown in Fig. 8, where the smaller the ADF value the better the performance, and the larger the NISD value the stronger the performance.

fitness value during the iterative operation of the algorithm. The smaller the swarm fitness value, the smaller the difference between the result and the optimal solution, and the better the performance of the algorithm. The curves of particle swarm fitness values for the three algorithms are shown in Fig. 9.

According to Fig. 9, which compares the particle swarm fitness curves of the three algorithms, the PSO algorithm begins to stabilise at 0.029 after 200 iterations, followed by the GA-TOM algorithm at 0.021 after 150 iterations, and the HPSO-R algorithm at 0.016 after 100 iterations. The HPSO-R method outperforms the comparative algorithms in terms of performance and has the fastest convergence speed and lowest particle swarm fitness value. In conclusion, the study's evaluation metrics showed that the proposed HPSO-R algorithm performed better than the other two comparative algorithms, proving its superiority.

Fig. 9. The particle population fitness value curve of the three algorithms.

B. Analysis of the Effectiveness of the Application of an Enterprise Supply Chain Anti-Disturbance Management Model

In the experiments on the practical application of the anti-disturbance management model of the enterprise supply chain proposed by the study, three groups of employees using the HPSO-R model, the PSO model and the GA-TOM model were assigned the same number of orders, and the experimental results on the order completion time as well as the overall profit are shown in Fig. 10.

From Fig. 10(a), it can be seen that for the same number of orders, the completion time was 59 days for the group using

the PSO model, 43 days for the group using the GA-TOM model and 32 days for the group using the HPSO-R model. From Fig. 10(b), it can be seen that the profits of these three groups using the PSO model, the GA-TOM model and the HPSO-R model after completing the same number of orders are \$340,000, \$380,000 and \$460,000 respectively. The group using the HPSO-R model had the shortest time to complete orders and the highest profit, all better than the comparison model. As the value of employee-generated counterproductive behaviour can reflect the rationality of a manufacturer's production management scheduling, the six types of counterproductive behaviour of employees within the three groups using the model were recorded and their experimental results are shown in Fig. 11.

As it can be seen from Fig. 11, all three groups of employees reached their highest values of counterproductive behaviour at around day 20 of the trial. The highest values for the six categories of counterproductive behaviour were 7.1, 7.0, 6.8, 6.7, 6.4 and 6.1 in the group using the PSO model; 5.6, 5.5, 5.3, 5.2, 5.1 and 5.0 in the group using the GA-TOM model; and The HPSO-R model group had the lowest production behaviour values, indicating that the group had the most rational production management scheduling. A sample of completed goods from each group was checked and the pass rate of goods was counted, while manufacturers were invited to rate the perception of using the three models out of 10. The results of the experiment are shown in Fig. 12.

As it can be seen from Fig. 12(a), at one month into the trial, the commodity pass rate was 65% with a manufacturer rating of 6.3 in the PSO model group, 75% with a manufacturer rating of 7.1 in the GA-TOM model group, and 83% with a manufacturer rating of 8.2 in the HPSO-R model group. As it can be seen from Fig. 12(b), at two months into the trial, the PSO model group had a commodity qualification rate of 66% and a manufacturer rating of 6.6, the GA-TOM model group had a commodity qualification rate of 78% and a manufacturer rating of 7.9, and the HPSO-R model group had a commodity qualification rate of 92% and a manufacturer rating of 9.1. Combining the above experimental results, it can be seen that the anti-disturbance management model of the enterprise supply chain based on the HPSO-R algorithm proposed in the study is better than the comparison model when applied in practice.

C. Comparative Analysis of Improved Algorithm Performance is discussed

In the comparative test of the performance of the improved algorithm, ONVG, UDNS, NISD, ADF and the particle swarm fitness value of the algorithm are proposed as evaluation indexes. Among them, ONVG, UDNS, NISD and ADF are all evaluation indexes of non-dominated ranking problems. Non-dominant ranking is to divide all non-dominant individuals into the first non-dominant optimal layer, and formulate and assign a shared virtual fitness value. The already stratified individuals are then ignored and the division continues, with a second non-dominant layer appearing, which also develops and assigns a shared virtual fitness value, and so on until all population individuals are stratified. This has the advantage of good individual fitness values and also maintains population diversity. Therefore, it is applied to the performance comparison of multi-objective optimization algorithms. Singh et al. adopted non-dominated ranking index to verify the optimization algorithm of multi-objective problem in the dynamic balance mechanism of cleaning

device of agricultural thresher. The results show that the proposed method is feasible, that is, non-dominated ranking index is universal for the detection of multi-objective optimization algorithm [21]. In the study of the basic method of non-orthogonal multiple access which has been envisaged as the fifth generation cellular network, Kumaresan's team used the fitness value of each iteration of the algorithm to evaluate the particles in the validation of the adaptive user clustering algorithm based on the particle swarm optimization algorithm. The results show that the proposed algorithm has advantages. That is, the particle swarm fitness value algorithm detection of the algorithm is scientific [22]. Therefore, it is feasible to use ONVG, UDNS, NISD, ADF and the particle swarm fitness value of the algorithm as the evaluation index of the algorithm in the experiment. In ten comparison tests, the ONVG values of HPSO-R algorithm are 13, 13, 13, 13, 14, 12, 12, 11, 12 and 10, respectively, which are greater than the other two comparison algorithms, indicating the optimal performance of the algorithm. The minimum UDNS values of HPSO-R algorithm are 1.6 and the maximum UDNS values are 4.2, respectively, which are both lower than the other two

comparison algorithms, indicating that the algorithm has the best performance. The maximum ADF value of HPSO-R algorithm is 5.6, the minimum is 2.4, and the average value is 4.1, all of which are lower than the other two comparison algorithms, indicating that the algorithm has the best performance. The maximum NISD value of HPSO-R algorithm is 0.62, the minimum is 0.11, and the average value is 0.31, all of which are greater than the other two comparison algorithms, indicating that the algorithm has the best performance. The smaller the particle swarm fitness value is, the smaller the gap between the operation result and the optimal solution, that is, the better the algorithm performance. In the iterative test, the particle swarm fitness value of HPSO-R algorithm is finally stable at 0.016, the lowest value, and the fastest convergence speed, which is better than the comparison algorithm. In summary, the HPSO-R algorithm proposed in this study has the advantages of fast running speed and high accuracy, and its performance is better than the comparison algorithm.

V. CONCLUSION

A robust company supply chain is crucial to the successful growth of a business. The production practises of manufacturers have a greater impact on the supply chain than any other of the different links that make it up. The study suggests combining evolutionary algorithms and random neighbourhood structures to improve the particle swarm optimisation method in order to address this issue, and it then completes the building of the enterprise supply chain's anti-disturbance management model using the revised algorithm. When the modified method was tested for comparative performance, it outperformed both the PSO algorithm and the GA-TOM algorithm with maximum ONVG and NISD values of 14 and 0.62, respectively, and minimum UDNS and ADF values of 1.6 and 2.4, respectively. The algorithm outperforms the comparison algorithms in both the quickest convergence rate and the smallest particle swarm fitness value, which is steady at 0.016 after 800 iterations. In a trial of the practical application effects of the model proposed in the study, it was found that the production team using the model had the shortest time and highest profitability in completing the same order volume, 32 days and \$460,000 respectively. Additionally, in the experiment, the members of this group outperformed both the PSO model and the GA-TOM model by having the lowest values for each of the six forms of anti-production behavior—4.5, 4.5, 4.3, 4.3, 4.2, and 4.2, respectively. At one month into the experiment, the group employing this model had a manufacturer score of 8.2 and a merchandise conformance rate of 83%. The model group's pass rate and manufacturer score at the halfway point of the testing were 92% and 9.1, respectively. In conclusion, the study's anti-disturbance management model of the company supply chain may realistically schedule the behaviour of manufacturers with regard to production, hence enhancing the stability of the supply chain.

In the study of the influence of behavioral factors, although the measurement method is obtained, the parameters are selected by direct reference to the values in the existing literature. In the subsequent work, empirical studies can be conducted according to different enterprises and environments,

so as to be closer to the actual situation. In supply chain management, because the member enterprises of the supply chain are independent economic entities, their interests and goals are different, so the coordination and decision-making problem is more complicated and diversified, and it is urgent to study it deeply. At the same time, this model is not strong enough for the connection and coordination between all links in the supply chain. How to do a good job in the connection between all links is also a problem to be further studied in the future.

Automated Analysis of Job Market Demands using Large Language Model

Myo Thida* 

Department of Computer Engineering,
Chiang Mai University, Chiang Mai, Thailand

Abstract—This paper presents a comprehensive analysis of labor market demands for Myanmar workers in Japan, and Thailand, focusing on opportunities for individuals without higher education degrees. Leveraging ChatGPT's text classification and summarization capabilities, we extracted vital insights from extensive job advertisements and social media groups. The dataset comprises 152 job advertisements from Thailand and 30 from Japan, collected in 2023. Our research provides a valuable snapshot of skill demands and job opportunities, offering insights for informed decision-making by both job seekers and international non-governmental organizations. The innovative approach of using ChatGPT highlights its efficacy in understanding labor market dynamics. These findings serve as a foundation for tailored interventions to bridge employment challenges faced by marginalized Myanmar youths.

Keywords—ChatGPT; labour market analysis; skills identification; online job adverts; skills demand

I. INTRODUCTION

Understanding the skill demands of industries is crucial for educational providers, graduates, and job seekers. In today's rapidly changing job market, having the right skills is vital for securing desired positions and achieving career success. Educational institutions play a key role in preparing individuals for the workforce. However, without an accurate understanding of industry skill requirements, their programs may not align with market needs, leaving graduates unprepared for employers' expectations.

For educational providers, insights into industry skill demands enable them to design and customize curricula to meet job market needs. By staying updated on evolving skill requirements, institutions can update courses, introduce new programs, and adapt teaching methods to ensure graduates possess sought-after skills. This alignment enhances graduates' employability, improves job prospects, and boosts the institution's reputation.

Likewise, for graduates and job seekers, understanding industry skill demands is equally important. It allows them to make informed decisions about education and training choices. By knowing which skills are in high demand, job seekers can acquire or enhance those skills to improve their competitiveness. Aligning their skill sets with industry requirements increases job offers, provides more opportunities for career advancement, and contributes to long-term success.

The digitization of the job market has created opportunities to better understand job market needs through the accessibility of online job advertisements. These advertisements serve as valuable sources for understanding the most

popular job openings and skill requirements in the market. However, job postings often contain unstructured text and require further processing to identify the required skills. This is where Natural Language Processing (NLP) techniques come into play. NLP has gained significant attention for its ability to identify and extract skills mentioned in job advertisements. Various methodologies and approaches, such as named entity recognition, rule-based systems, machine learning algorithms, and information retrieval models, have been proposed for skill extraction from job advertisements using NLP. Extensive research has been conducted on the extraction of demanded skills from job advertisements, uncovering valuable insights into job market requirements and skill trends.

Recently, large language models have emerged as powerful tools for processing and generating human-like language. Its capabilities stimulates the interests of researchers to leverage this tool in the context of identifying high-demand skills in the dynamic job market. The primary objective of this research is to utilize ChatGPT's capabilities in text classification and summarization to pinpoint the currently sought-after skills. It is crucial to emphasize that this research specifically concentrates on the skills needed by skilled workers without higher formal education, with a particular emphasis on Myanmar youths as a case study. The aim is to assess the employment prospects available in Thailand and Japan for Myanmar youths lacking higher education degrees.

Myanmar youths have been grappling with significant challenges, including limited job opportunities and access to education. The employment rate in Myanmar has experienced a decline of 4.8 percentage points between 2020 and 2022, indicating a decrease in job opportunities [WorldBank, 2023] [1]. Many individuals from rural areas have resorted to seeking work overseas, both legally and illegally, as a means of survival [2]. Unfortunately, their dire circumstances often leave them with limited options and force them to accept any available job to sustain themselves. Consequently, a large portion of these individuals find employment as general workers across various factory sectors, without opportunities to enhance their skills or advance their careers. Prior to the Covid-19 pandemic, it was estimated that around three million Myanmar migrant workers were employed in Thailand. These workers typically found employment in sectors such as fishing, seafood processing, factories, and agriculture. Similarly, the number of Myanmar nationals working in Japan has also been increasing, with more than 33,000 workers reported in 2020. These figures are likely to have grown since then, indicating a growing trend of Myanmar citizens seeking employment opportunities in Japan and Thailand [3].

Traditionally, recruitment for these industries was facilitated through recruitment agencies or community networks, with a focus on individuals who had basic proficiency in the Thai language rather than specific vocational skills. Unfortunately, these workers often face difficulties such as lower pay, workplace abuse, long working hours, and a loss of dignity. In recent years, alongside the continued prevalence of agent-based recruitment, there has been an increasing trend among Myanmar workers to explore alternative channels for finding employment opportunities. This includes searching government and company websites, joining relevant Facebook groups, and utilizing job advertisement platforms. These online avenues provide additional options for job seekers to connect with potential employers and access a broader range of opportunities.

This study aims to provide a snapshot of employment opportunities for Myanmar youths seeking overseas jobs through online channels. It focuses on identifying specific labor market opportunities in Japan and Thailand for Myanmar workers. By gaining insights into job demands and the relevant skills required in these countries, the analysis aims to assist Myanmar job seekers, especially those lacking higher education degrees. To conduct this research, data was collected through job recruitment agencies and by directly collecting data from job advertisements, providing insights into current job opportunities and requirements.

This research makes the following significant contributions:

- This research serves as a proof of concept for the effectiveness of using ChatGPT for skill extraction from job advertisements. By demonstrating the tool's capabilities in extracting relevant skills from unstructured data, it showcases its potential for analyzing job market demands.
- This research uniquely focuses on job prospects for Myanmar youths in Thailand and Japan without higher education. While many studies center on professionals with formal degrees, this research highlights skilled laborers without such qualifications.
- This research highlights challenges faced by Myanmar youths in job and education. It aims to contribute to social development by addressing these issues and promoting inclusive opportunities for marginalized individuals without higher education.
- By understanding the job prospects and skills demanded in Thailand and Japan, individual job seekers can equip themselves with the necessary skills and prepare for better employment opportunities. This information also enable policymakers to design targeted interventions to address employment challenges.

In the next section, a detailed review of the literature in the field of skill identification from online job adverts will be provided. This will be followed by the methodology section, which will explain the data collection methods, data pre-processing, and the results of the exploratory data analysis, presented in Section IV. The key findings and recommendations will be provided in Section V. Finally, the paper will be concluded with a summary and suggestions for future research in the final section.

II. LITERATURE REVIEW

Over the past few years, numerous research papers and surveys have been published, delving into various aspects of job market analysis. One promising research direction focuses on developing skill databases such as ESCO (European Skills-/Competences, qualifications and occupations framework) [4], O*NET (Occupational Information Network) [5] to highlight in-demand skills. ESCO is a project that classifies skills, occupations, and related competencies in various European languages. On the other hand, O*NET, developed and maintained by the US Department of Labor, provides comprehensive information about different occupations, including required skills, knowledge, and work activities. These databases, which are regularly updated to reflect changes in the labor market, serve as valuable resources for understanding industry trends and skill requirements.

The trend of customizing research for specific industries or regional analyses is evident in recent studies. Gröger et al. [6] developed a system that automatically identifies skills in German-language job advertisements, showcasing the effectiveness of this approach. Similarly, Papoutsoglou et al. [7] presented a framework for collecting online job advertisements from StackOverflow and extracting the necessary skills and competencies for specific IT jobs. They employed multivariate statistical data analysis to explore correlations within the dataset. Another relevant study conducted by Kennan et al. [8] analyzed online job advertisements to gain insights into the knowledge, skills, and competencies sought after for early career information systems (IS) graduates in Australia. In addition, Adan et al. [9] introduced C3-IoC, an AI-based solution aimed at assisting students from the UK in exploring IT career paths based on their education level, skills, and prior experience.

A recent publication, [10], presented a systematic review of advancements in skill identification based on job market demands from online job advertisements. The authors thoroughly examined 108 research articles published between 2010 and 2020, providing a comprehensive survey on skill identification. Their study established a framework that addresses three key challenges: skill base generation, skill identification methods, and skill identification granularity. To enhance skill identification and capture the dynamic needs of the job market, the authors recommended leveraging recent deep learning methods.

The field of natural language processing has experienced remarkable progress since the introduction of ChatGPT and its subsequent version, GPT-4 [11]. These advancements have had a significant impact on various conventional tasks, including machine translation, sentiment analysis, text summarization, named entity recognition, and topic segmentation, among others. Researchers have been leveraging the capabilities of ChatGPT to enhance the efficiency and effectiveness of text analysis processes. For example, Hoes et al. [12] investigated the potential of ChatGPT for automated online content moderation. Their study demonstrated that ChatGPT achieved an impressive accuracy of 69% in categorizing statements as true or false.

In a similar vein, [13] proposed AugGPT, a text data augmentation approach that utilizes the capabilities of Chat-

GPT. AugGPT generates multiple conceptually similar yet semantically distinct samples by rephrasing each sentence in the training set. These augmented samples can be effectively utilized for downstream model training. Experimental results on few-shot learning text classification tasks demonstrate the superiority of AugGPT over state-of-the-art text data augmentation methods in terms of testing accuracy and the distribution of augmented samples.

The process of skill identification and normalization from job advertisements encounters numerous challenges, as highlighted in [10]. The language used in job adverts can be diverse and informal, leading to ambiguity and noise during skill extraction. Moreover, the ever-changing nature of job markets and evolving skill requirements pose difficulties in maintaining up-to-date skill taxonomies. Recent research papers [12], [13] showcasing the capabilities of ChatGPT in extracting key information and analyzing text data have motivated us to explore the potential of this large language model in automating skills identification from job advertisements.

III. DATASET

A. Data Collection

The dataset for this research was compiled through manual extraction from two job advertisement platforms, as well as various Facebook groups frequently promoting job listings. The dataset for the Thailand job market originated from job advertisements featured on two prominent Thai job recruitment platforms [14] [15] and multiple Facebook groups [16]–[20] known for posting job vacancies. To narrow the focus on skill requirements for individuals without higher education degrees, job advertisements mandating such qualifications were excluded. The majority of these job listings do not specify gender preferences, implying that the positions are open to applicants of any gender. A total of 152 job advertisements were collected between April 2023 and June 27, 2023, offering a snapshot of the Thailand job market during that specific timeframe.

Regarding the Japanese job market, the job advertisement platforms were exclusively aimed at candidates with higher education degrees. Consequently, the dataset for the Japanese job market was procured from job advertisements published on the official Facebook pages of Myanmar recruitment agencies targeting opportunities in Japan [21]–[23]. Data collection spanned from January 2023 to June 22, 2023, and encompassed a total of 30 job advertisements, advertising a total of 842 job openings.

To ensure alignment with the research focus on comprehending skill demands for individuals without higher education degrees, job advertisements requiring higher education degrees or above were excluded during the data collection process. In sum, a total of 152 job advertisements were amassed from April 2023 to June 27, 2023, providing a snapshot of the job market within that specific time frame.

The job advertisements collected were initially in an unstructured format, as shown in Fig. 1. To transform the unstructured content into a structured dataset, the data collectors manually extracted the ‘Job Titles’, and ‘Skills and Responsibilities’. This involved organizing the content from the advertisements into a structured table format, exemplified

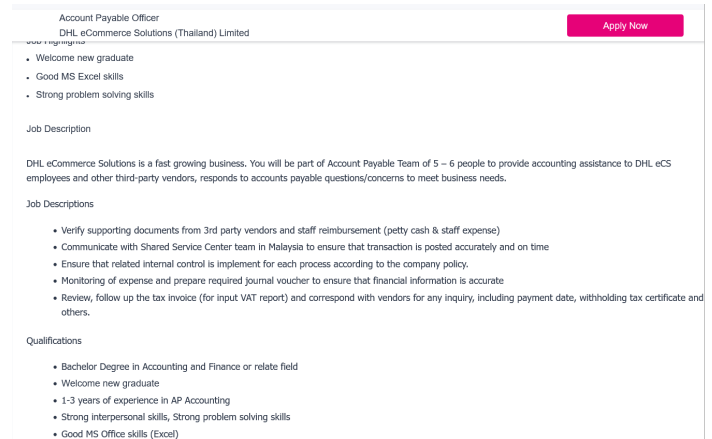

Fig. 1. Example job adverts from JobDB [14].

in Table I. Notably, job titles and skills are often not explicitly mentioned in the job adverts. Consequently, during the manual extraction process, the data collectors copied and pasted the content of the job descriptions or responsibilities into the skill and responsibility column, without explicitly assigning them to pre-defined skill databases like O*NET.

It is important to note that web scraping techniques were not employed in the data collection process due to strict prohibitions by the job advertisement platforms. To ensure compliance with legal regulations and respect the privacy policies of the companies, the researchers collected and categorized the data manually.

The dataset consists of two attributes: ‘Job Titles’, and ‘Skills and Responsibilities’. Table I presents a snapshot of the dataset, showcasing specific details and examples of the collected data.

B. Data Pre-processing

The initial step in data pre-processing for this project involves cleaning the unstructured text data, as presented in Table I. The data contains unwanted symbols, text, and duplicated records, requiring necessary cleansing. Consequently, the data cleaning process encompasses three essential actions: removing white spaces, eliminating duplicates, and converting the text to lowercase. These steps ensure text standardization and facilitate subsequent analysis.

However, it is important to note that the job titles and skills are preserved in their raw form without lemmatization. This deliberate decision was made to evaluate the performance of ChatGPT in grouping similar words with the same meaning. By retaining the original form of job titles and descriptions, we can assess the model’s ability to recognize and interpret variations in language while comprehending contextual information.

IV. PROPOSED METHOD

Our research introduces a novel method that leverages ChatGPT, a large language model, to enhance the efficiency of automated job market analysis and gain insights into job

TABLE I. SNAP-SHOT OF THE COLLECTED DATASET

Job title	Skills and Responsibilities
Service Technician (Air Conditioning)	Respond to customer requests for repair of air conditioning systems in homes companies and factories. Perform routine maintenance tasks to ensure air conditioning systems are operating efficiently. Manage a team of technicians providing guidance and support as needed.
store staff	Responsible to Store Performance and staff development to meet business objective. Maintain and develop retail Store daily Operation to meet business efficiency in the best possibility way. Manage and retain people to run daily operation to achieve customer target and customer satisfaction. Develop SOP and Daily Operation Routine (WI)
Graphic Designer	”Create and conceptualize where needed marketing communications in different formats including advertising social media content website banners video editing (and occasional filming) event collateral and more. Implement visual marketing collateral according to BayWa brand guidelines. Coordinate with the regional marketing and sales teams to create communications that meet their needs. Manage and oversee third party suppliers
Accounting officer	Must be proficient in the use of the English language (both verbal and written) Must be proficient in Thai (both verbal and written) knowledge of other languages is an advantage Excellent organizational and time-management skills Must be very detail-orientated Positive attitude and sincere desire to learn on the job

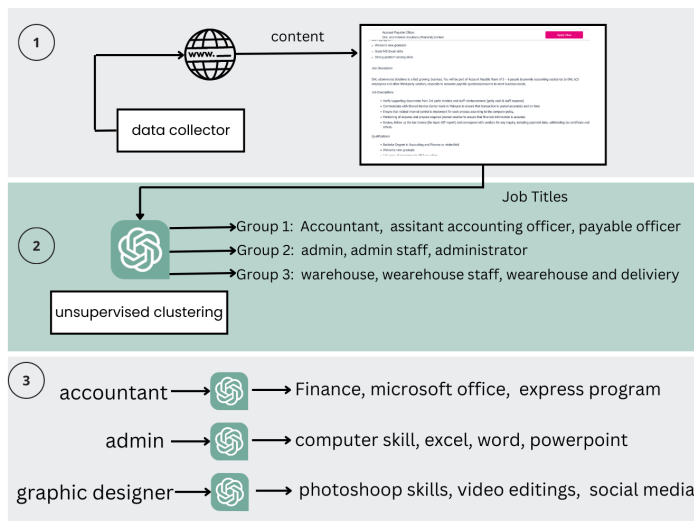

Fig. 2. Architecture of our proposed method.

market demands. The architecture of our proposed method is illustrated in Fig. 2.

The proposed method consists of two key steps aimed at analyzing job titles and skill demand using ChatGPT’s zero-shot prompt capability.

In the initial step, we leverage ChatGPT’s zero-shot prompt capability to perform job title clustering in a given dataset, obviating the necessity for predefined labels or manual annotation. Through the formulation of specific prompts, we guide the model to acquire knowledge from the provided information and infer appropriate clusters based on the semantic relationships among job titles. By applying this clustering process and subsequently analyzing the size of each resultant cluster, we can discern the most sought-after job titles within the market.

The maximum number of clusters can be predetermined within the prompt by specifying either the desired number of clusters or the minimum size of each cluster.

Building upon the outcomes obtained from the Job Title Clustering step, we progress to the subsequent step, wherein we undertake an analysis of skill demand within each cluster. To accomplish this, we rely upon ChatGPT’s zero-shot prompt functionality. For each job title cluster derived from Step 1, we construct a prompt that facilitates the extraction of skills from job descriptions specifically associated with that particular cluster. By employing this approach, we gain valuable insights into the skill demand prevalent within each distinct job title group.

A. Step 1: Job Title Clustering

In the initial step, we leverage the zero-shot prompt capability of ChatGPT to cluster the job titles in the given dataset. This prompt serves as a guide, enabling ChatGPT to generate meaningful clusters based on the similarities; it recognizes among the job titles. The resulting clusters offer valuable insights into different job categories within the job market, facilitating a comprehensive analysis of job market demands. Some job roles appeared multiple times in the job adverts database, indicating a higher demand for those specific roles during the analyzed time frame. Conversely, certain roles occurred rarely, suggesting a relatively lower demand for those positions. Analyzing the sizes of these clusters, in terms of the number of job advertisements assigned to each role, provides valuable insights into the demand for specific job roles during the specified time frame. Larger clusters indicate highly sought-after job roles, implying a higher demand in the job market for roles with the associated skills and qualifications.

Using the following prompt, we guide ChatGPT to recognize underlying patterns and similarities among the job titles. In this method, the number of clusters is not limited, but

we predefined the minimum cluster size as 3, considering the content of the dataset.

```
def job_title_clustering(Job_title):
    prompt = f''''''
    Your task is to group Job titles from \
    a long job title corpus where each job \
    title is separated by comma.

    From the given job title corpus, delimited \
    by triple quotes \
    group the job titles that are similar.

    The minimum size of the group should be 3.

    Use the following format:
    Group 1: [<list of job titles that are \
    similar>, quote each job title with ' ' \
    ]
    Group 2: [<list of job titles that are \
    similar>, quote each job title with ' ' \
    ]

    ```{Job_titles}```
    ```
    response = get_completion(prompt)
    return response
```

Listing 1: Prompt for Job Title Clustering

Table II presented as a snapshot of the clustering results, showcases the various job roles obtained from the clustering process in Step 1.

TABLE II. SNAP-SHOT OF THE JOB ROLES FROM THE CLUSTERING PROCESS

Group 1	Group 2	Group 3	Group 4
account payable officer	customer relations officer	administrator	warehouse
accountant	customer service	admin staff	warehouse and delivery staff
accountant	customer service	admin	warehouse associate
accounting and finance officer	customer service assistant (english speaking)	admin account	warehouse operations
accounting officer (ap)	customer service officer	admin executive	warehouse staff
assistant accounting manager	customer service quality assurance	admin officer	

B. Step 2: Skills Extraction

In the second step, we utilize ChatGPT’s zero-shot prompt capability to extract skills from each cluster. To accomplish this, we gather the job descriptions from all the job advertisements within the corresponding cluster and combine them

into a comprehensive string. This concatenated job description corpus is then inputted into the model, prompting it to extract skills from the descriptions.

Below is a code snippet illustrating the prompt employed to extract skills from a job description:

```
def extract_skills(grp_skill):
    prompt = f''''''
    Your task is to extract skills from \
    a corpus of job descriptions.

    From the given corpus of job descriptions, \
    delimited by triple quotes \
    extract the commonly found skills.

    Format your response as a list of skills \
    separated by comma.

    ```{grp_skill}```
    ```
    response = get_completion(prompt)
    return response
```

Listing 2: Prompt for Skills Extraction

This prompt aids in guiding the model to identify and extract relevant skills from the job descriptions, contributing to a more comprehensive understanding of the skill requirements within each cluster. The *extract_skills* function takes a parameter called *grp_skill*, which represents the concatenated job descriptions from each cluster. By utilizing this prompt, it assists in guiding the model to identify and extract pertinent skills from the job descriptions. This process significantly contributes to enhancing the overall understanding of the skill requirements associated with each job role within the clusters. Through this step, we can effectively identify the key skills needed for each job role and gain valuable insights into the skill demand across different clusters.

V. RESULTS

A. Top Demanded Job Titles

The task of clustering job advertisements into common job roles, such as ‘accountant’ or ‘admin’, poses a significant challenge. The absence of standardized definitions for these roles and the existence of multiple names for the same role make the task non-trivial. Furthermore, not all job advertisements can be easily categorized into predefined roles. In order to address these difficulties, we leveraged ChatGPT’s zero-shot prompt to cluster job titles and identify common job roles. We extracted the ten job roles with the largest number of job advertisements.

1) *Thailand*: Fig. 3 presents the top ten job positions that were highly sought after by low-level skilled workers in the Thailand job market between April and June 2023. Sales-related roles accounted for approximately 15% of the job advertisements during this period, including job titles such as *Sales*, *Sales Admin/Support Executive*, and *Sales Coordinator*. The second most in-demand category was customer service-related positions, representing around 13% of the job advertisements. This category encompassed roles like *Customer Relations Officer*, *Customer Support Specialist*, and *Customer*

Fig. 3. Top ten most in-demand job positions in Thailand job market.

Service (Call Center). Admin-related positions ranked third in terms of demand and included roles such as *Admin Executive*, *Admin Officer*, *Admin Support Staff*, and *Administrative Officer*. It is observed that all the job postings are open to both male and female candidates.

TABLE III. COMPARISON OF JOB ROLES FROM HUMAN ANNOTATION AND CHATGPT

ChatGPT	%(GPT)	Manual	%(Manual)
sale	15.45	sales	12.67
customer service	13.01	customer service	12.67
admin	11.38	admin	12.0
accounting and finance	5.69	marketing	7.33
graphic design/ Photographer	4.88	staff	5.33
technician	4.07	accountant	5.33
warehouse staff	4.07	warehouse	4.67
driver	3.25	receptionist	4.67
Kitchen staff and cook	3.25	officer	4.67
marketing	3.25	technician	4.0

Comparison against human annotations: To assess the clustering results, we compared the top ten job titles obtained through our proposed method with the annotations provided by job-seeking individuals in the Thailand market. The comparison results are shown in Table III, which illustrates the overlapping job roles between the individuals' specifications and the results generated by ChatGPT. The frequency column

represents the proportion of job advertisements related to specific job roles within the analyzed time-frame. Our observations revealed that seven out of the top 10 job roles, excluding graphic designer, driver, and kitchen staff, overlapped between the human annotations and the model's results. The top three job roles remained consistent, with only minor variations in the frequency of job advertisements.

2) *Japan:* Fig. 4 illustrates the top ten job positions that were in high demand among low-level skilled workers from Myanmar in the Japanese job market between January and June 2023. The analysis considered 30 job advertisements, totaling 842 job openings. Please note that for the Japanese Job market, worker recruitment in Myanmar is commonly facilitated through agencies, and in many cases, mass recruitment is conducted where more than 10 workers are hired simultaneously.

The top ten industries with high demand encompassed agriculture, food service, interior building cleaning, and nursing care. Among these industries, agriculture recorded the highest level of recruitment, employing over 250 workers (30% of total job openings). The food service industry closely followed, hiring approximately 120 workers. The cleaning industry had the highest recruitment of female workers, with 100 positions filled during the study period. The nursing care sector and fishery/aquaculture industries each recruited around 65 workers. Additionally, the manufacturing of food and beverages industry hired approximately 50 workers.

Out of all the job advertisements, 14% specifically targeted female workers, including the cleaning industry, manufacturing of food and beverages, and airport ground staff. Conversely, only 10% of the job adverts were specifically aimed at male workers. Notably, the construction industry exclusively recruited male workers, with a total of 30 workers being hired.

Fig. 4. Most in-demand job sectors in Japanese job market targeting to Myanmar skilled workers.

The carpentry and interior home decoration industries followed as the second and third most recruited industries for male workers. The majority of job recruitment, accounting for 76%, was open to both male and female workers. Additionally, it is worth mentioning that while some openings in the manufacturing of food and beverages industry were exclusively for female workers, others were open to both male and female applicants.

Comparison against Human annotations: Table IV presents a comparison of the results obtained from Human annotations and those generated by ChatGPT. The table reveals a significant level of overlap in clustering between the human annotations and the model's output, with only minor variations in the frequency of job advertisements.

3) *Comparison between Thailand and Japan:* Please note that the above data represents two different dimensions, providing insights into the job markets in Thailand and Japan for Myanmar workers. The data from Thailand encompasses job advertisements that are open to not only Myanmar nationals but also individuals of other nationalities, including Myanmar workers. On the other hand, the Japanese data specifically focuses on opportunities for Myanmar workers in Japan.

Both Japan and Thailand utilize their national languages as the official working languages. However, in the Thai job market, there is a noticeable trend of posting job advertisements in English. This practice aims to attract individuals of diverse nationalities, including Myanmar workers who possess English language skills. On the other hand, the Japanese job market follows a different approach. Job advertisements in English primarily target professionals with higher degrees or

TABLE IV. COMPARISON OF JOB ROLES FROM HUMAN ANNOTATION AND CHATGPT

ChatGPT	%(GPT)	Manual	% (Manual)
Agriculture	31.24	Agriculture workers	31.97
Food Service	13.9	Food service	14.63
Interior Building Cleaning	11.76	Cleaner	12.49
Nursing Care	7.96	Nurse and care giver	8.69
Fishery and Aquaculture	7.6	Fishery Firm workers	8.34
Manufacture of Food and Beverages	5.34	Construction worker	6.91
Car Service	3.92	Manufacture of Food and Beverages	6.08
Hospitality	2.97	Car Service	4.66
Construction worker	2.61	Manufacturing Factory worker	4.06
Manufacturing Factory	1.9	Front Desk	3.71

specialized skills. These advertisements cater to individuals who possess a certain level of proficiency in English, reflecting the demand for language fluency in certain industries or job

roles. However, lower-skilled workers from Myanmar seeking employment in Japan often heavily rely on recruitment agencies to secure job opportunities. These agencies act as intermediaries, connecting job seekers with employers who specifically seek foreign workers. In Myanmar, these agencies frequently use social media platforms like Facebook to announce job advertisements, enabling job seekers in Myanmar to search for opportunities through these platforms.

It is important to note that both Thailand and Japan recognize the importance of language proficiency, and fluency in the respective national languages is highly valued. While the Thai job market embraces the use of English in job advertisements to attract a diverse talent pool, the Japanese job market focuses more on higher-skilled positions and relies on recruitment agencies for lower-skilled job placements. Understanding these dynamics is crucial for Myanmar workers seeking employment opportunities in these two countries.

By comparing the study between the Japanese and Thai job markets, it can be observed that the top five industries with high demand for both genders in the Japanese job market were agriculture (31%), food service (14%), building cleaning (12%), nursing care (8%), and fishery/aquaculture. In the Japanese job market, a significant majority of job recruitment (76%) was open to both male and female workers. The construction industry exclusively recruited male workers, while the cleaning industry had the highest recruitment of female workers. In contrast, data from official job agencies indicates that the Thai job market had a high demand for sales-related roles (15%), customer service-related positions (13%), and administrative-related positions (11%) between April and June 2023. This suggests that the service sector in Thailand is becoming more open to Myanmar nationals who can speak both English and Thai.

Fig. 5. Snap-shot of the top demanded skills for top three sought-after job roles in Thailand.

B. Top Demanded Skills

Proficiency in Japanese, and Thai is essential for workers seeking promising job opportunities in various sectors.

1) *Thailand:* Fig. 5 displays the required skills for the top three sought-after job roles: sales, customer service, and administration. Among the technical skills, employers highly prioritize computer literacy proficiency and competence in Microsoft Office tools. English language proficiency is also frequently requested. It is worth noting that the Thai job market

places great importance on soft skills as well. Employers in Thailand consistently seek abilities such as customer service, communication, and problem-solving.

2) *Japan:* Fig. 6 provides valuable insights into the required skills for the agriculture and fishery/aquaculture sectors in Japan. In addition to the essential manual labor skills, such as breeding, collecting, sorting of animals, farming, and planting, there is also a significant demand for knowledge in management and health and safety practices. It is worth noting that the agriculture and fishery/aquaculture sectors in Japan require workers with a diverse skill set. While manual labor skills are foundational, the demand for additional knowledge in management and health and safety reflects the need for workers who can contribute to the overall success and sustainability of these industries.

Fig. 6. Snap-shot of the top demanded skills for agriculture and fishery / aquaculture sectors in Japan.

Fig. 7. Snap-shot of the top demanded skills for construction sector in Japan.

Fig. 7 highlights the highly demanded skills for male workers in the Japanese construction sector. It can be seen that the Japanese construction sector demands a range of skills related to various construction activities such as plumbing, pumping, formwork, finishing, scaffolding, plastering, roofing and carpentry. In addition, it also requires skilled workers who can operate and maintain a wide range of machinery and equipment. By focusing on acquiring these skills, Myanmar workers can enhance their chances of finding employment opportunities in the Japanese construction sector.

C. Evaluation of Unsupervised Clustering

To assess the clustering results between the proposed method and manual grouping, we employ precision and recall as evaluation metrics. Precision quantifies the proportion of job roles accurately classified by the model, while recall measures the model’s capability to correctly capture all job titles.

1) *Evaluation metrics:* Precision, as a metric, gauges the correctness of the clustering results by calculating the percentage of job roles that were correctly assigned to their respective clusters. A higher precision value indicates a higher accuracy in classifying job roles.

$$\text{precision} = \frac{\text{TruePositive}}{\text{TruePositive} + \text{FalsePositive}} \quad (1)$$

On the other hand, recall assesses the model’s completeness in capturing all relevant job titles. It measures the proportion of actual job titles that were correctly identified and included in the dataset. A higher recall value implies that the model successfully captures a larger portion of the job titles.

$$\text{recall} = \frac{\text{TruePositive}}{\text{TruePositive} + \text{FalseNegative}} \quad (2)$$

In Eq. (1) and (2), True Positives indicate the number of job titles that are accurately classified within their respective clusters. This means that a job title is correctly assigned to the appropriate cluster, such as “admin officer” being assigned to the admin cluster. False Positives, on the other hand, refer to job titles that are incorrectly assigned to a cluster where they don’t belong. For instance, if a job title like “sale” is incorrectly assigned to the admin cluster. False Negatives represent the job titles that should be belong to the given cluster but are mistakenly assigned to the wrong cluster. For example, the title “admin officer” is erroneously assigned to the sale cluster instead of the admin cluster.

By considering both precision and recall, we can gain a comprehensive understanding of the performance of the proposed clustering method compared to the manual grouping. These evaluation metrics provide insights into the model’s accuracy, correctness, and ability to capture a broad range of job titles within the clustering process.

2) *Accuracy:* In this section, we present the performance of unsupervised clustering for the top ten job roles in Thailand Job Market. The resulting confusion matrix (Fig. 8) provides insights into the clustering accuracy. The confusion matrix visually represents the performance of the clustering model, showcasing its ability to assign job adverts to the corresponding job roles. The high accuracy scores indicate the model’s proficiency in recognizing and grouping similar job descriptions together.

For the Thailand Job market, the proposed model demonstrated impressive performance by accurately capturing all the job adverts annotated by humans in the driver, graphic designer, and kitchen helper roles. Furthermore, it achieved a high accuracy rate of 95% for sales roles and 88% for accountant roles. For sales, administration, and customer service roles, ChatGPT achieved approximately 70% accuracy.

However, ChatGPT did not perform well for the marketing and technician roles due to the wide and diverse range of words used to describe these roles. The inherent variability and ambiguity in job descriptions related to marketing and technician positions pose challenges for accurate clustering.

Fig. 8. Confusion Matrix for the top-ten job roles in Thailand.

This evaluation demonstrates the effectiveness of ChatGPT in automatically clustering job adverts into relevant job roles. The results highlight its potential for assisting in job matching and recruitment processes, aiding in the efficient categorization of job postings based on their role requirements.

3) *Precision and recall:* Fig. 9 depicts the precision and recall scores for the top ten demanded job roles in Thailand. The precision scores reflect a high success rate in accurately identifying the job roles, with most of them achieving a score of 100%. This indicates that the model performs well in correctly assigning job postings to their respective roles.

However, the variation in the recall scores indicates the model’s ability to capture all the job roles within the relevant clusters. While precision measures the accuracy of the identified job roles, recall measures the model’s capability to capture all the job roles present in the data. The variation in recall scores suggests that the model may have challenges in fully capturing all job roles, potentially missing some relevant postings.

VI. LIMITATION AND FUTURE DIRECTION

It is important to acknowledge that this research offers a snapshot of the skills in demand by employers at a specific moment, and it may not encompass the complete range of skills required for a given occupation or industry due to the limited dataset size. However, the demonstrated success of the proposed method serves as a promising direction for exploring and harnessing the capabilities of large language models in understanding the industrial skill demands. It provides an avenue to develop a comprehensive understanding of skill

Fig. 9. Precision and Recall for the top-ten job roles in Thailand.

demand and contributes to the advancement of reducing the skill gap between the industries and training providers.

Another limitation is the validation of our results. We engaged youths seeking employment in Thailand and Japan, who lack expertise in labor market studies. This could introduce biased judgments when identifying job titles and clustering data. To improve accuracy, future research could involve experts or existing skill databases, refining job title identification and minimizing biases. This enhances result reliability.

VII. CONCLUSION

This study leverages the capabilities of ChatGPT, a powerful instrument for text classification and summarization, to identify in-demand skills among Myanmar workers. The main objective is to assess employment opportunities in Thailand and Japan for Myanmar youths lacking higher education degrees. Key highlights of this research include showcasing ChatGPT's proficiency in extracting skills from unstructured job ads, offering a rapid and thorough perspective on labor market demand, with a specific emphasis on highlighting opportunities for low-level skilled workers. Moreover, this study empowers international non-governmental organizations to make well-informed decisions while crafting targeted interventions to address the employment challenges confronted by marginalized Myanmar youths.

ACKNOWLEDGMENT

The authors would like to thank the researchers and data analysts from Women in Tech (Myanmar) for collecting the job advertisements manually.

²FPT Polytechnic, Can Tho city, Vietnam

Abstract— In today’s medical landscape, the effective management and availability of diagnostic data, including current and historical medical tests, play a critical role in informing physicians’ therapeutic decisions. However, the conventional centralized storage system presents a significant impediment, particularly when patients switch healthcare providers. Given the sensitive nature of medical data, retrieving this information from a different healthcare facility can be fraught with challenges. While decentralized storage models using blockchain and smart contracts have been suggested as potential solutions, these methodologies often expose sensitive personal information due to the inherently open nature of data on the blockchain. Addressing these challenges, we present an innovative approach integrating Non-Fungible Tokens (NFTs) to facilitate the creation and sharing of medical document sets based on test results within a medical environment. This novel approach effectively balances data accessibility and security, introducing four key contributions: (a) We introduce a mechanism for sharing medical test results while preserving data privacy. (b) We offer a model for generating certified, NFT-based document sets that encapsulate these results. (c) We provide a proof-of-concept reflecting the proposed model’s functionality and (d) We deploy this proof-of-concept across four EVM-supported platforms—BNB Smart Chain, Fantom, Polygon, and Celo—to identify the most compatible platform for our proposed model. Our work underscores the potential of blockchain, smart contracts, and NFTs to revolutionize medical data management, demonstrating a practical solution to the challenges posed by centralized storage systems.

Keywords—Medical test result; blockchain; smart contract; NFT; Ethereum; Fantom; Polygon; Binance Smart Chain

I. INTRODUCTION

Advancements in technology are significantly transforming the landscape of disease diagnosis and treatment, alleviating the need for patients to physically visit healthcare facilities. Innovative applications installed on smartphones now enable remote health monitoring, overseen by either human doctors or AI platforms [1]. However, to supplant the entire traditional healthcare system, certain critical steps outlined in numerous research directions must be taken [2], [3], [4]. One significant challenge is the management of individual medical data, including treatment records and medical history. Accurate recording of medical history is vital for effective disease diagnosis and treatment [5].

Many research studies leverage modern technologies to reform healthcare systems, replacing traditional supply chain processes [6], [7], and the way diseases are diagnosed and

treated. These proposed solutions primarily focus on decentralized (or distributed) storage, ensuring efficient data handling and access [8]. Blockchain technology and smart contracts contribute to transparency in information storage [9]. After authentication, all data is stored on-chain and becomes immutable.

Smart contract technology, introduced first by the Ethereum platform¹, automates all system operations. After calculations and updates, information and data are stored on a distributed ledger, accessible for stakeholders to check activities.

Blockchain-based solutions have been proposed to ensure data authentication transparency in the medical environment, addressing shipping [10], [7], disease treatment [11], [12], medical waste management [13], emergency patient information retrieval [14], [15], medical product supply chain [16], and blood donation processes and their supply chain management [17], [18]. Other non-medical solutions based on community sourcing include Cash on Delivery [19], [20], supply chain [21], [22], among others [6], [23].

Several models for managing patients’ medical examination and treatment information based on Blockchain technology have been proposed. For instance, HealthBank² introduced a patient information management model based on Blockchain technology, where users can store all information reliably on the blockchain. Similarly, HealthNautica and Factom Announce Partnership³ utilized the transparency of on-chain storage to build a system protecting medical data integrity.

However, on-chain storage of all patient information encounters two significant issues: i) a decrease in system performance and increased transaction fees per access; ii) lack of patient privacy due to public access to all information. The first problem arises from redundant and unnecessary data storage [24]. Thanh et al. [20] posited that not all collected data needs to be stored and processed on-chain as most are redundant. Trieu et al. [14] shared a similar sentiment, suggesting off-chain storage for personal data unrelated to treatment or diagnosis. This decrease in on-chain data consequently reduces transaction costs [25].

Privacy risk is another issue; unencrypted stored data can be exploited and manipulated by other system users, severely

¹<https://ethereum.org/en/whitepaper/>

²<https://www.healthbank.coop>

³<https://www.factom.com/company-updates/healthnautica-factom-announce-partnership/>

impacting patient privacy. Insurance companies, for example, can misuse a patient's medical history, refusing to provide coverage [26]. To address this, some Blockchain and IPFS-based solutions, such as Misbhauddin et al. [27] and Zyskind et al. [28], store sensitive user data off-chain (in IPFS), minimizing personal information exposure risk.

Still, these solutions struggle with medical record sharing between patients and medical centers (i.e., medical staff). To address this, we propose an approach based on Blockchain, smart contract, and NFT technologies. Here, personal information and treatment history are stored as NFTs, and medical test result-related information is stored off-chain. NFTs are generated for each test and shared easily with required addresses (e.g., nurses, doctors). Each patient is assigned a unique identifier to differentiate them from others.

Our work thus provides four key contributions: (a) A Blockchain, smart contract, and NFT-based mechanism for sharing test results. (b) A storage model based on the NFT tool. (c) A proof-of-concept implemented based on the proposed model. and (d) Deployment of the proof-of-concept on four platforms that support ERC721 (NFT of ETH) and EVM (for deploying smart contracts written in solidity language) including BNB Smart Chain, Fantom, Polygon, and Celo to determine the most suitable platform for our proposed model.⁴

The structure of this paper unfolds over eight sections. Following the introductory part, we provide background information, offering an overview of contemporary studies addressing similar research issues and a summary of relevant technologies and EVM-compatible blockchain platforms in Section II. In Section III we explore related work. The subsequent two sections delve into our methodology and the practical implementation of our proposed model (refer to Sections IV, V). To attest to the efficacy of our approach, Section VI presents an evaluation conducted under various scenarios, preceding the discussion in Section VII. Finally, in Section VIII, we provide a summary and outline future directions for this research.

II. BACKGROUND

This section provides a detailed background to the technologies central to the decentralized management of medical test results. Specifically, we explore Blockchain, Smart Contract, Non-Fungible Tokens (NFTs), Ethereum, Binance Smart Chain, Polygon, Celo, and Fantom. Due to the limited scope of this paper, we cannot provide the details on each topic. We prefer the reader follow the white paper/external source if they want to detail the corresponding platforms or topics.

A. Blockchain

Blockchain technology forms the backbone of many decentralized systems, including cryptocurrencies like Bitcoin. It employs a distributed ledger, functioning as a shared database spread across multiple nodes in a network. Each block in the chain contains data, and every new block is linked to the preceding block, forming a chain-like structure. It is the Blockchain's immutable and transparent nature that makes it attractive for various applications, including medical data management.

⁴We did not deploy smart contracts on ETH due to the high execution fees of smart contracts.

B. Smart Contract

Smart contracts are self-executing contracts with the terms of the agreement directly written into lines of code. They eliminate the need for a middleman in digital agreements, ensuring trust, transparency, and efficiency. Smart contracts execute automatically upon meeting predefined rules and conditions. They are stored on the blockchain, making them tamper-proof and traceable. These features make smart contracts a valuable tool in healthcare, specifically in managing and securing patient data.

C. Non-Fungible Tokens (NFTs)

NFTs represent a unique digital asset that is verifiably unique, unlike cryptocurrencies such as Bitcoin or Ethereum, where each unit or "coin" is identical to every other coin. This uniqueness and indivisibility make NFTs ideal for representing ownership or proof of authenticity of individual items or assets, such as artwork, real estate, and in our context, unique sets of medical test results.

D. Ethereum

Ethereum is an open-source blockchain platform that supports smart contract functionality. It provides the underlying technology for a multitude of decentralized applications (DApps). Ethereum also introduced the concept of programmable transactions using smart contracts, making it a pioneer platform for building complex decentralized applications, including those for decentralized healthcare systems.

E. Binance Smart Chain (BSC)

The Binance Smart Chain⁵, an innovation by the Binance cryptocurrency exchange, is a blockchain platform built for running smart contract-based applications. It allows developers to build decentralized applications efficiently and is fully compatible with Ethereum Virtual Machine (EVM). BSC also boasts high transaction speed and low fees, making it a favored platform for various decentralized projects.

F. Polygon

Polygon or MATIC⁶, previously known as Matic Network, is a layer-2 scaling solution for Ethereum. It aims to provide faster and cheaper transactions on the Ethereum blockchain while maintaining its robust security. Polygon uses a technology known as 'sidechains,' which are blockchain systems that run alongside the Ethereum mainchain. This feature allows for scalability, making it suitable for a decentralized medical test result management system.

G. Celo

Celo⁷ is an open blockchain platform that makes financial tools accessible to anyone with a mobile phone. It's designed to support stablecoins and tokenized assets, prioritizing scalability, and usability. Celo's lightweight identity and proof-of-stake mechanisms make it an attractive platform for projects needing secure, fast, and low-cost operations, such as those required in managing medical test results.

⁵<https://github.com/bnb-chain/whitepaper/blob/master/WHITEPAPER.md>

⁶<https://polygon.technology/lightpaper-polygon.pdf>

⁷<https://celo.org/papers/whitepaper>

H. Fantom

Fantom⁸ is a high-performance, scalable, and secure smart-contract platform. It is designed to overcome the limitations of previous generation blockchain platforms. Fantom is permissionless, decentralized, and open-source. Its aBFT consensus protocol delivers unparalleled speed, security, and reliability. Fantom's technology stands out for its speed, low transaction costs, and high security, making it a good option for any decentralized application like managing medical test results.

III. RELATED WORK

This section critically surveys the past methodologies employed in creating models for patient test results management, particularly those harnessing Blockchain technology and smart contracts. The study is bifurcated into two core perspectives: i) patient-centric health information management models, and ii) strategies based on blockchain technology.

A. Patient-Oriented Health Information Management Models

In the rapidly evolving healthcare landscape, the patient-centric model has emerged as a pioneering approach, prioritizing patients' needs and values. The key aspect of these models is to cater to patients' privacy preferences, providing them with the ability to have greater control over their health data. The type of data that falls under this model not only includes clinical details essential for disease management and treatment like heart rate, blood pressure, and other vital health indicators, but also personal data like location, phone number, and more. While not all data are directly relevant for treatment, they are critical components of comprehensive patient care.

Among the remarkable contributions in this space is a model introduced by Chen et al. [29]. This innovative approach utilizes Internet of Things (IoT) devices and sensor technology, which are embedded directly into patients. The devices are leveraged to extract vital medical information in real-time. In this model, blockchain technology plays a pivotal role in securely storing, managing, and controlling the harvested data from these IoT devices. The collected information is encrypted before leaving the patient's control and is sent directly to cloud servers.

An intriguing shift away from conventional models is observed in these novel approaches. Traditional models entrust medical centers or hospitals with the storage and management of patient information. In contrast, the newer methodologies propose a paradigm shift, advocating for the patients' power to control their data [30], [31], [32]. This is essentially empowering patients to decide who they want to share their data with, ensuring that data sharing occurs only with trusted entities.

Further substantiating the value of patient empowerment, Makubalo et al. [33] collated several models that endorse health information sharing by patients themselves. In order to prevent the illicit sharing of information by those it has been shared with (like doctors or nurses), a robust system was introduced by Yin et al. [34]. This system employs attribute-based encryption (ABE) to secure data privacy, providing patients the ability to define their data access policies.

This shift towards patient-centered models has fostered a diverse body of work in the area of health data management and privacy. Several other studies have adopted ABE-based access control models, and dynamic policy models to enhance flexibility in the healthcare environment [35], [36], [24]. All these advances reflect the broader move toward empowering patients and improving the flexibility and privacy of health data management.

B. Blockchain-based Health Information Management Models

A distinct, parallel body of research focuses on the implementation of blockchain technology in healthcare data management. In these models, the emphasis is on i) the development of a decentralized management system for patient medical data, inclusive of laboratory information, and ii) the utilization of the InterPlanetary File System (IPFS) for reducing the volume of on-chain stored information.

Madine et al. [37], for instance, proposed a model that stored medical records on a blockchain, preserving the detailed information on IPFS. This approach seeks to achieve a delicate balance between information accessibility and privacy, with a clear objective of safeguarding patient data against unauthorized access from within the same system.

In a similar vein, HealthBank and HealthNautica introduced blockchain and IPFS amalgamations to propose patient-centric models complying with privacy regulations, like the General Data Protection Regulation (GDPR). These models promote the concept of decentralization in healthcare, eliminating the reliance on a central authority for data storage and management, and significantly enhancing data security.

Noteworthy is the evolution of these models beyond simple storage to include sharing of essential information with authorized individuals, such as medical staff at healthcare centers [38], [39]. This represents a more comprehensive approach to health data management, incorporating the need for data sharing in addition to secure storage.

Another pertinent aspect addressed by some studies is the consideration of indirect participants in the treatment process, such as insurance companies and regulators [40]. This approach is especially important as it encompasses the complete ecosystem of healthcare, from patient care to insurance processes and regulatory compliance.

Despite these advances, the field faces a host of challenges. For example, the user-centric model often results in policy redundancy, and the introduction of new blockchain and IPFS-based systems can be complex for users unfamiliar with such technologies.

To circumvent these challenges, our proposed model incorporates a fusion of modern platforms, including blockchain, smart contracts, and Non-Fungible Tokens (NFTs). Rather than depending on sharing policies to define access to test results or patient history, we propose the creation of corresponding NFTs. This approach is designed to alleviate stringent platform requirements, such as those associated with security policy-based methods. The following section elucidates our proposed model that employs NFT technology (i.e., ERC721) to share information with the appropriate entities.

⁸<https://whitepaper.io/document/438/fantom-whitepaper>

IV. BLOCKCHAIN-FACILITATED MEDICAL TEST RESULTS MANAGEMENT FRAMEWORK

In the ensuing discussions, we will initially revisit the traditional methodologies employed in medical test results management. Following this, we introduce our novel model, which is underpinned by Blockchain technology, smart contracts, and Non-Fungible Tokens (NFTs).

A. Conventional Model for Managing Medical Test Results

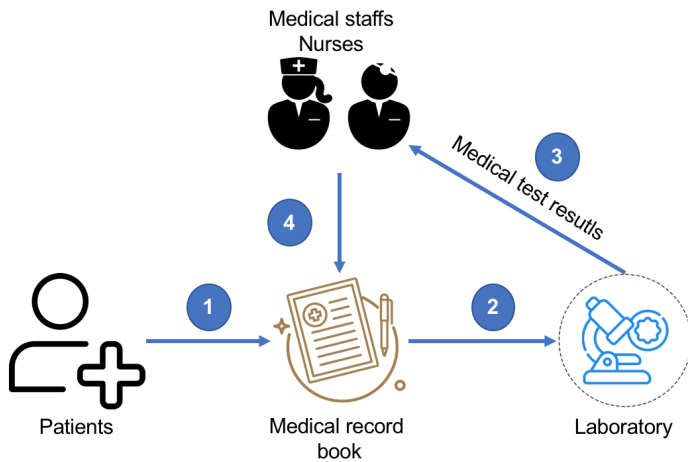

Fig. 1. Conventional medical test results management framework.

Fig. 1 illustrates the conventional procedure for testing and obtaining results, typically structured around four key stages. A patient, in the initial stage, constructs a medical record book, either in electronic or physical form, at the medical institution. This repository houses comprehensive information pertinent to the patient's treatment process and medical test results.

These records are absolutely critical, as the clinicians' diagnostic decisions and medical judgments hinge on the variations observed in a patient's health status as interpreted from these test results. In many developing nations, the testing phase could be quite protracted due to constraints related to infrastructure and auxiliary medical equipment. The patient, consequently, has to endure substantial waiting periods to provide samples and receive the corresponding test results.

Upon receipt of the results from the laboratory personnel, the patient presents these results to the medical practitioners for an assessment of their health status and determining the appropriate therapeutic interventions. All data concerning the diagnosis and resultant treatment are updated in the medical record book.

The loss of a patient's medical record book, thus, severely jeopardizes the treatment process. For the digital variants, the medical record book is stored locally at a discrete hospital or healthcare facility. Given the highly sensitive nature of medical data, the prospects of sharing this information with other institutions are typically slim. Therefore, there exists a pressing need for a comprehensive solution to issues related to the storage and sharing of patients' medical record books, catering to both electronic and physical formats. In the subsequent segment, we unveil our resolution, leveraging the capabilities

of contemporary technologies like blockchain, smart contracts, and NFTs.

B. Medical Test Results Management Model Leveraging Blockchain Technology, Smart Contracts, and NFTs

Fig. 2 exhibits our solution, drawing upon blockchain technology, smart contracts, and NFTs, and comprising of nine critical stages. Users are provided with the ability to create an identifier, referred to as 'patient_ID_global,' which is valid across all medical systems (step 1). This identifier is further linked to a medical record book that archives all relevant details about the medical record, test results, and the patient's medical history (step 2). Steps 3-6 are intrinsically connected with User-Interface (UI) services, offering interfaces to every user group within the system to curtail complex operations (i.e., backend processing). These interactions are facilitated via smart contracts housing pertinent functions for data storage and processing (step 7). In this phase, we devise functions relating to contract creation/NFT or the transfer of NFTs (refer to the introduction).

All transactions are subsequently updated, stored, and dispersed within a distributed ledger, including details about visitors, time, and location, etc. The information relevant to the test results is produced in the corresponding NFTs and transferred to the physicians responsible for treating the patient (step 9).

V. IMPLEMENTATION

The practical application of our model zeroes in on two primary objectives: i) manipulation of data, specifically medical test results, involving creation, query, and update on the blockchain platform, and ii) construction of Non-Fungible Tokens (NFTs) for medical test results, enabling the easy sharing of such data by patients with medical practitioners such as doctors and nurses.

A. Data Creation Procedure

Fig. 3 provides a graphic representation of the steps involved in data initialization with respect to the medical test results. These results incorporate information such as the type of test conducted, time of testing, testing facility, test results, consultation outcomes, and the corresponding treatment approach and its duration. Additionally, metadata of the test results also includes information about the type of patient and the medical personnel involved in conducting the test.

The storage process, in this context, facilitates concurrent storage (i.e., distributed processing as a peer-to-peer network) on a distributed ledger, which supports multiple users for concurrent storage, thereby reducing system latency.

In essence, the medical test results data is structured as follows:

```
medicalTestResultsObject = {  
  "patientID": patientID,  
  "medicalTestID": medicalTestID,  
  "medicalStaffID": medicalStaffID,  
  "type": type of test,  
  "numbers": numbers of treatments,  
}
```

Fig. 2. Medical test results management model leveraging blockchain technology, smart contracts, and NFTs.

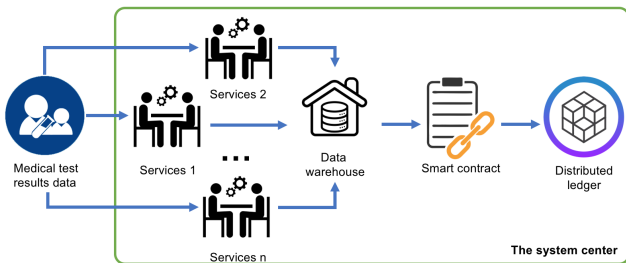

Fig. 3. Initialization of data and Non-Fungible Tokens (NFTs).

```

"results": results of the medical test,
"diagnose": diagnosis of the illness,
"institution": institutionID,
"date": time and date,
"times": times of test,
"period": period of the treatment,
"state": Null
};

```

In particular, besides information useful for content extraction (i.e., medical staff, test results, diagnostic outcomes, etc.), we also store information related to the status of the patient's treatment at the hospital (i.e., "state" - default set to Null). Specifically, the "state" changes to a value of 1 when the respective patient has completed their treatment and exited the medical facility (i.e., numbers increment by 1); a value of 0 signifies that the patient is still under treatment. Furthermore, we keep a record of the treatment interval and number of tests conducted through two parameters: "period" and "times".

Following this, pre-designed constraints in the Smart Con-

tract are invoked through the API (i.e., name of function) to synchronize them up the chain. This role of validation carries significant weight as it directly impacts the process of storing medical information (i.e., medical test results), as well as the treatment of patients.

For processes that initialize NFTs (i.e., store only test results), the contents of the NFT are defined as follows:

```

NFT MEDICAL_RECORD = {
"medicalRecordID": medicalRecordID,
"patientID": patientID,
"medicalTestID": medicalTestID,
"type": type of test,
"medicalStaffID": medicalStaffID,
"results": results of the medical test,
"institution": institutionID,
"date": time and date,
};

```

The above-mentioned information is extracted from the original data stored on the chain - our previous model constructed a role-based access control (RBAC) system, hence, direct access from non-owners or unauthorized entities is not possible. Also, considering that a patient undergoes several health assessments/checks before a disease is diagnosed, the information extracted minimizes the risk of data loss. For instance, a doctor diagnosing blood issues does not need access to a patient's bone X-ray.

B. Data Access Procedure

Mirroring the process of data initialization, the method of data retrieval also allows multiple participants to concurrently access the system (i.e., in a distributed model). Assistance

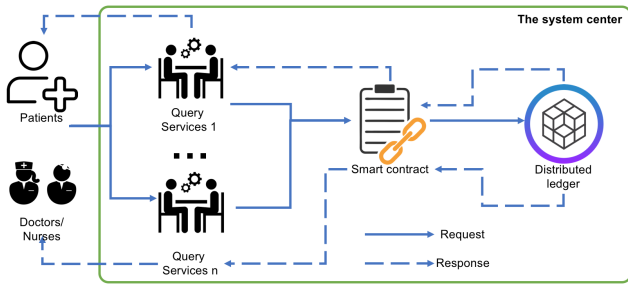

Fig. 4. Data access procedure.

services manage requests coming from medical professionals (like nurses and doctors) and patients who seek to view the data. Depending on the identity of the person making the request, the objectives of access may vary. Specifically, medical personnel might query to validate the procedure of medical testing (i.e., test outcomes), whereas patients might wish to seek details about the current holders of their NFTs.

Fig. 4 showcases the stages involved in retrieving medical test outcome data. These requests are conveyed as services (i.e., pre-configured APIs) from the requester to the existing smart contracts in the system (i.e., function names) before fetching the data from the distributed ledger. All retrieval demands are also kept as access history for each person or entity involved.

If the relevant information cannot be traced (e.g., incorrect ID), the system will return a “results not found” message. Regarding NFT access procedures, all assistance services are provided in the form of APIs.

C. Data Update Procedure

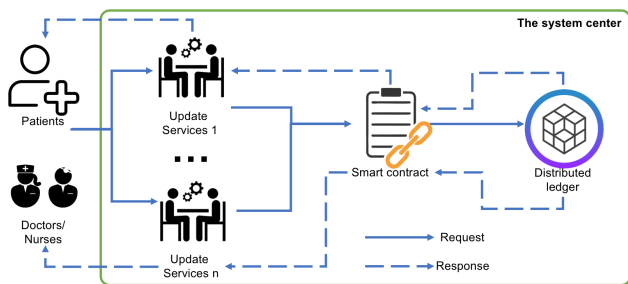

Fig. 5. Data update procedure.

The process of data modification commences only after verifying the existence of the data on the blockchain (i.e., post the corresponding data access procedure). In this segment, we assume that the searched data is present on the blockchain. If the data does not exist, the system sends a “results not found” message to the user (see V-B for further details).

Like the procedures of data access and initialization, we offer modification services as APIs to receive user requests before forwarding them to the smart contract (i.e., function name) for execution. This procedure aims to update test results to minimize patient waiting periods in healthcare institutions. Moreover, it aids doctors in tracing their treatment path based on the associated sequence of NFTs.

Fig. 5 demonstrates the process for modifying medical test results. Concerning NFTs (i.e., available), the update process involves only the transfer from the current holder’s address to a new one (i.e., new holder). If any update is made to an existing NFT, it will be registered as a new NFT (refer to V-A for further details).

VI. EVALUATION SCENARIOS

The model for generating and managing medical test results is designed to simplify the process for patients. It allows easy management and sharing of medical records with relevant parties. Rather than solely relying on traditional security policies such as access control, we harness the robust and transparent nature of blockchain technology. We chose to leverage Ethereum Virtual Machine (EVM)-enabled blockchain platforms over the Hyperledger ecosystem for its wider accessibility and utilization in existing platforms and systems. Previously, we had assessed system responsiveness, including the number of requests responded to successfully or failed and system latency.

In this paper, we delve into determining the most suitable platform for our proposed model based on economic considerations. Specifically, we implemented a prototype system on four renowned blockchain platforms that support Ethereum Virtual Machine (EVM). The selected platforms include Binance Smart Chain (BNB Smart Chain), Polygon, Fantom, and Celo. Not only did we analyze the performance and cost-effectiveness of these platforms, but we also shared our implementation as a contribution to the wider community.

In these implementations, transaction fees correspond to the supporting coins of the respective platforms. The models were implemented on the 24th of November, 2022 at 8:44:53 AM UTC, with the fees paid in BNB, MATIC, FTM, and CELO, respectively.

A. Binance Smart Chain Implementation and Analysis (sample)

Transaction Hash	Method	Block	Age	From	To	Value	[Txn Fee]
0x04205158931273143d4...	Transfer	24867369	1 day 17 hrs ago	0xc0a8c5d44206e0834f...	0xaf33888d1dfb6957b1...	0 BNB	0.00057003
0x1f5ae508ae1c00322...	Mint	24867361	1 day 18 hrs ago	0xc0a8c5d44206e0834f...	0xaf33888d1dfb6957b1...	0 BNB	0.00101842
0xb0c03161087984cc8...	Contract Creation	24867375	1 day 18 hrs ago	0xc0a8c5d44206e0834f...		0 BNB	0.027134

Fig. 6. The transaction info for BNB smart chain.

We initiated our assessment by implementing the model on the Binance Smart Chain (BNB Smart Chain), and a detailed exploration of the successful installation on this chain is presented in Fig. 6. Binance Smart Chain, as an offshoot of the Binance Chain, offers EVM-compatibility, allowing us to deploy Solidity-based smart contracts with relative ease. It further benefits from its parent chain’s high-speed transactions while allowing for better decentralization.

B. NFT Creation Process

Following successful implementation, we explored NFT generation, a pivotal aspect of the proposed model. Fig. 7

Fig. 7. NFT creation on binance smart chain.

visually demonstrates the creation of an NFT on the Binance Smart Chain. NFTs, inherently unique in their characteristics, perfectly capture the distinct nature of individual medical test results and patient records.

C. NFT Transfer

In line with NFT creation, the retrieval and transfer of these tokens represent the next step in the model's operation. As depicted in Fig. 8, the transfer of NFT ownership addresses occurs smoothly on the Binance Smart Chain. This transferability of NFTs is essential for enabling patients to share their medical test results or records with medical professionals or any other entities of their choice.

In the following sections, we delve into evaluating the transactional aspects of the model, focusing on factors such as transaction fee, gas limit, gas used by the transaction, and gas price. To obtain a comprehensive view of the performance and cost implications of the proposed model, we replicated the same set of operations on the other three selected platforms, namely Polygon, Fantom, and Celo. The underlying motive is to identify the most cost-effective platform for deployment.

Similar settings were used in the remaining platforms to allow for a fair comparison, and the subsequent assessments offer a detailed examination of the transactional metrics. For more detail we refer the reader to check our deployment of the smart contract on the four EVM-supported platforms, namely BNB⁹; MATIC¹⁰; FTM¹¹; and CELO¹².

D. Transaction Fee

In Table I, we dissect the transaction costs associated with creating contracts on all four platforms. It is clearly evident that the most capital-intensive operation across the platforms is contract creation, with BNB Smart Chain exhibiting the highest cost of 0.0273134 BNB (\$8.43). Conversely, Fantom's platform reported the most economical contract initiation fee, standing at less than 0.00957754 FTM (\$0.001849). The transaction fee for contract creation on Celo's platform was marginally cheaper than that of Polygon, totaling only \$0.004 compared to Polygon's \$0.01.

⁹<https://testnet.bscscan.com/address/0xafa3888d1dfbf957b1cd68c36\ede4991e104a53>

¹⁰<https://mumbai.polygonscan.com/address/0xd9ee80d850ef3c4978dd0b099a45a559fd7c5ef4>

¹¹<https://testnet.ftmscan.com/address/0x4a2573478c67a894e32d\806c8dd23ee8e26f7847>

¹²<https://explorer.celo.org/alfajores/address/0x4a2573478C67a894E32D806c8Dd23EE8E26f7847/transactions>

Turning our attention to the subsequent two operations, Create NFT and Transfer NFT, the associated costs on all three platforms (Polygon, Celo, and Fantom) are remarkably low, verging on negligible. In stark contrast, the transaction cost on BNB Smart Chain remains considerably higher, amounting to 0.00109162 BNB (\$0.34) and 0.00057003 BNB (\$0.18) for Create NFT and Transfer NFT, respectively. This disparity underscores the need for an in-depth economic evaluation when selecting a suitable platform for blockchain-based solutions.

E. Gas Limit

Table II showcases the gas limit for each transaction across the platforms. The gas limits for BNB, Polygon, and Fantom remain relatively equivalent, with Polygon and Fantom displaying almost identical figures across all transaction types. Celo, however, sets a significantly higher gas limit, amounting to 3,548,922; 142,040; and 85,673 for contract creation, NFT creation, and NFT transfer, respectively. This discrepancy can have notable implications on the transactional performance and cost-effectiveness of deploying solutions on these platforms.

F. Gas Used by Transaction

Table III illustrates the proportion of the total gas limit consumed by each transaction, as per the figures displayed in Table II. It is noteworthy that BNB, Polygon, and Fantom utilized 100% of the allocated gas limit for the operations of contract creation and NFT creation. Celo's utilization, on the other hand, amounted to 76.92% of the gas limit for these two transactions. When observing the NFT transfer transaction, Fantom and Polygon recorded the highest gas consumption levels at 93.41% of the gas limit, whereas BNB and Celo's consumption stood at 79.17% and 69.8% respectively.

G. Gas Price

As shown in Table IV, the gas price across the platforms remained relatively stable for each transaction type. The BNB Smart Chain showcased the highest gas price, measuring 10 Gwei for all transaction types. Conversely, the Polygon and Celo platforms reflected the lowest gas prices at 2.500000012 and 2 Gwei respectively. Fantom's platform priced gas at 3.5 Gwei, marginally higher than Polygon and Celo, yet significantly lower than the BNB Smart Chain.

H. Summary

In summation, this comparative analysis underscores the essentiality of in-depth cost evaluation before choosing a platform to deploy blockchain solutions. The BNB Smart Chain emerges as the most expensive platform for all transaction types, while Polygon, Celo, and Fantom provide significantly cheaper alternatives. Particularly, Fantom and Polygon offer remarkably low transaction fees and competitive gas limits, making them potentially viable choices for the cost-effective deployment of NFTs. However, consideration should also be given to other critical factors such as platform maturity, ecosystem support, developer experience, security, and user adoption, which are outside the scope of this analysis.

Celo	2,729,940 (76.92%)	109,262 (76.92%)	59,803 (69.8%)

VII. DISCUSSION

A. Notable Observations

Our research involving the evaluation and comparison of transaction costs, gas limits, and gas prices across four well-known EVM-compatible blockchain platforms - Binance Smart Chain (BNB), Fantom, Polygon, and Celo - has surfaced several noteworthy findings.

Foremost among them is the cost implication associated with different blockchain platforms. We observed that the Binance Smart Chain tended to levy the highest transaction fees and gas prices, thus potentially raising the cost of blockchain operations for developers and users on this platform. In sharp contrast, Fantom, Polygon, and Celo proved to be more cost-friendly alternatives, with Fantom presenting the lowest transaction fees among the four platforms.

Interestingly, despite lower fees, the gas limits on Polygon, Fantom, and Celo were not vastly different from that of Binance Smart Chain, suggesting that these platforms could potentially be matching the service levels of Binance Smart Chain while also being more economically efficient.

This underscores an important trade-off that users, developers, and companies need to consider when choosing between these platforms: While Binance Smart Chain might be more established and widely accepted, newer platforms like Fantom, Polygon, and Celo are providing compelling value propositions

in terms of cost efficiencies, which could lead to considerable savings in the long run.

B. Threats to Validity

Despite the informative nature of our study, it is crucial to recognize the limitations and potential threats to its validity.

1) *Temporal volatility*: The world of blockchain and cryptocurrencies is notably volatile, and costs associated with transactions, gas limits, and gas prices are dynamic, changing in response to a multitude of factors such as market conditions, supply and demand dynamics, among others. Hence, the values presented in this paper may change over time, and users are advised to consider the most recent data while making decisions.

2) *Network variations*: The state of the network at the time of evaluation could significantly impact the results. Network congestion, often arising due to a surge in demand for transactions, typically leads to an increase in fees, and the reverse is true during periods of lower demand.

3) *Platform-Specific variables*: Each blockchain platform is uniquely designed, having its own set of characteristics including consensus mechanisms, block time, network size, and more. All these factors can greatly influence transaction costs and gas limits, and our study does not account for these platform-specific variables.

4) *Scope constraints*: Our analysis included only a limited number of EVM-compatible blockchain platforms and transaction types. Including additional platforms and a wider variety of transaction types could potentially yield different insights and conclusions.

C. Directions for Future Research

The findings of this study open up a multitude of interesting directions for future research:

1) *Real-time cost analysis*: Given the rapid changes in transaction costs in the realm of blockchain, future research could develop a real-time or dynamic analysis model that captures the cost fluctuations across different platforms over a defined period. This could provide more current and actionable insights for users and developers.

TABLE IV. GAS PRICE

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)
Fantom	0.0000000035 FTM (3.5 Gwei)	0.0000000035 FTM (3.5 Gwei)	0.0000000035 FTM (3.5 Gwei)
Polygon	0.000000002500000012 MATIC (2.500000012 Gwei)	0.000000002500000016 MATIC (2.500000016 Gwei)	0.000000002500000016 MATIC (2.500000016 Gwei)
Celo	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)

2) *Comprehensive performance evaluation:* While our study focused primarily on costs, further research could explore other performance metrics such as transaction speed, scalability, security, and reliability. A comprehensive evaluation using multiple performance indicators could help users make a more informed choice of blockchain platform based on their specific needs.

3) *Inclusion of other blockchain platforms:* Our analysis was confined to a selected few EVM-compatible blockchains. Future research can incorporate more blockchain platforms, broadening the scope of comparison, and providing a more diverse range of options for users to consider.

4) *Application-specific evaluation:* Another interesting direction could be to investigate the cost and feasibility of deploying specific applications, such as decentralized finance (DeFi), supply chain management, gaming, and more across different blockchain platforms. An application-specific analysis could provide more targeted insights for developers and stakeholders in these domains.

5) *Privacy and efficiency implications:* In our present examination, we have yet to explore issues associated with the privacy policy of users, such as access control [26], [36] or dynamic policy [41], [42]. These aspects represent potential pathways for future research endeavors. Lastly, methodologies grounded in infrastructure (such as gRPC [43], [44]; Microservices [45], [46]; Dynamic message transmission [47] and Brokerless mechanisms [48]) could be incorporated into our model to boost user interaction, specifically through an API-call-based approach.

In general, our study provides a valuable comparative analysis of transaction costs across different blockchain platforms, which can serve as a useful resource for developers, businesses, and researchers alike. As this area continues to evolve at a rapid pace, continuous monitoring and analysis are crucial to keep up-to-date with the latest developments. Our study provides a foundation upon which more comprehensive, real-time, and application-specific analyses can be built in the future.

VIII. CONCLUSION

In this paper, we have analyzed and compared transaction costs across four prominent EVM-compatible blockchain platforms - Binance Smart Chain (BNB), Fantom, Polygon, and Celo. We evaluated the costs from multiple perspectives, including transaction fees, gas limits, gas used by transaction, and gas prices.

Our research findings reveal significant differences in the transaction cost structure across these platforms. Binance Smart Chain surfaced as the most expensive, with the highest

transaction fees and gas prices, while Fantom offered the lowest transaction costs. However, the gas limits across the platforms were comparable, signifying that less expensive platforms could provide a similar level of service as Binance Smart Chain, but at a lower cost. While our research provides valuable insights, it is subject to several limitations, primarily due to the dynamic and rapidly evolving nature of the blockchain landscape. The cost parameters we evaluated are subject to market fluctuations, network congestion levels, and platform-specific variables. Therefore, the results should be interpreted with caution, and users are advised to consider the most current data while making decisions.

Our study opens the door for further research in this domain. Future work could include real-time cost analysis, a comprehensive evaluation of multiple performance metrics, inclusion of more blockchain platforms, and application-specific evaluations. In conclusion, our research underscores the importance of considering transaction costs while choosing a blockchain platform. It provides a clear direction for developers, companies, and researchers, helping them make informed decisions that balance cost and performance. As the blockchain ecosystem continues to grow and evolve, studies like ours will become increasingly crucial in navigating the complex landscape of blockchain platforms and their associated cost structures.

Abstract—Medical waste is deemed hazardous due to its potential health implications and the predominant practice of discarding it post six months of utilization. Furthermore, the reusable proportion of such waste is minimal. The implications of this scenario were brought to the fore during the COVID-19 pandemic when sub-optimal medical waste management was identified as a factor exacerbating the spread of the virus worldwide. The predicament is particularly grave in developing nations, such as Vietnam, where the underdeveloped state of medical infrastructure renders efficient waste management a daunting task. The waste management challenge also stems from the significant roles played by different stakeholders (healthcare workers and patients confined to isolation wards), whose actions directly influence waste classification, impact the waste treatment process, and indirectly contribute to environmental pollution. Given that waste management involves a chain of activities requiring the coordinated efforts of medical, transportation, and waste treatment personnel, inaccuracies in the initial stages, such as waste sorting, can negatively impact subsequent processes. In light of these issues, our study puts forth a unique model aimed at enhancing waste classification and management practices in Vietnam. This model innovatively integrates Blockchain technology, smart contracts, and non-fungible tokens (NFTs) with the intent to foster an increased individual and collective consciousness towards effective waste classification within healthcare settings. Our research is notable for its four-fold contribution: (a) suggesting a unique mechanism based on blockchain technology and smart contracts, designed specifically to improve medical waste classification and treatment in Vietnam; (b) introducing a model for instituting rewards or penalties based on NFT technology to influence behaviors of individuals and organizations; (c) demonstrating the feasibility of the proposed model through a proof-of-concept; (d) executing the proof-of-concept on four prominent platforms that support ERC721 - NFT of Ethereum and EVM for executing smart contracts programmed in the Solidity language, namely BNB Smart Chain, Fantom, Polygon, and Celo.

Keywords—Medical waste management; blockchain; smart contracts; NFTs; ethereum; fantom; polygon; binance smart chain

I. INTRODUCTION

The threat posed by medical waste, a hazardous byproduct of healthcare activities, is of global concern. The vast majority of medical supplies and equipment – nearly 99% – become waste within six months of initial use due to their potential for transmitting infections [1], [2]. The environmental hazards posed by single-use items such as medical gloves, protective gear, and masks, further exacerbate the issue [3]. As such,

regulatory bodies worldwide have implemented stringent processes to ensure proper classification and treatment of medical waste.

A notable facet of this global waste management challenge is the intersection of environmental and economic implications [4]. Materials difficult to break down contribute to pollution, applying immense pressure on the environment [5]. This concern is particularly acute in developing nations where waste disposal processes have shown links to environmental pollution, as seen in India [6] and Brazil [7]. The urgency of the issue further intensified during the pandemic, with the surge in medical supplies leading to increased waste [8], [9].

The Vietnam context presents a unique case. Systematic studies have delved into the role of waste segregation in managing the Covid-19 crisis. However, much of the focus remains on the results or consequences of waste management rather than providing an improved, technologically advanced model aimed at enhancing transparency and decentralized data storage.

Addressing this need, recent research has pivoted towards models utilizing Blockchain technology and smart contracts for waste treatment and classification [10], [11]. Such models focus on identifying the origin and composition of waste and encompass key stakeholders – healthcare workers, patients, waste collectors, and waste treatment companies. Information related to these user groups and waste (referred to as ‘bags’) is validated before being recorded on the chain. This method not only helps pinpoint the source of waste but also minimizes contact between parties, thereby reducing disease transmission risks [12]. As such, these models could supersede traditional waste treatment methods, particularly during epidemic periods.

Additionally, the role of public awareness and cooperation in waste management is crucial to curbing treatment times. The process of self-classification, despite being commonplace in developed nations, only emerged in developing countries following the outbreak of the Covid-19 pandemic. In Vietnam, a large portion of waste is unclassified, significantly impacting its treatment process. Consequently, our research seeks to address this issue by proposing a model for managing medical waste using Blockchain technology and smart contracts. Simultaneously, we aim to shape public perceptions of waste classification by leveraging non-fungible token (NFT) technology.

This study focuses on evaluating existing waste treatment models in developing countries, specifically Vietnam, during the Covid-19 pandemic. It seeks to provide a suitable approach for potential future epidemics. Our main contribution lies in presenting an NFT-based (ERC 721) approach and a penalty system for violations of waste classification norms.

Thus, the four-fold contribution of our work includes: (a) proposing a medical waste classification and treatment mechanism for the Vietnamese context, leveraging blockchain technology and smart contracts; (b) introducing a reward/punishment system based on NFT technology aimed at individuals and organizations; (c) implementing a proof-of-concept of the proposed model using smart contracts; and (d) deploying the proof-of-concept on four platforms supporting ERC721 - NFT of Ethereum and EVM for executing smart contracts written in Solidity, namely BNB Smart Chain, Fantom, Polygon, and Celo.¹

This paper is structured into seven subsequent sections. Following this introduction, we offer a brief overview of Blockchain, Smart contract, EVM, NFT, and the four EVM-supported blockchain platforms in Section II. Then we review related work exploring similar research problems in Section III. Next, we describe our proposed approach and its implementation (Sections IV, V). Section VI demonstrates the effectiveness of our model in different scenarios, followed by a discussion in Section VII. Finally, Section VIII summarizes our work and outlines potential avenues for future research.

II. BACKGROUND

A. Blockchain Technology

Originally conceived as the underlying technology for Bitcoin [14], blockchain has gained recognition for its potential beyond cryptocurrency [15], [16]. Blockchain is often characterized as a transparent, reliable, and decentralized ledger that operates on a peer-to-peer network [17], [18]. It manages transaction data across several computers concurrently, fostering a trust environment that permits autonomous interaction without reliance on a centralized authority [19]. Key benefits of blockchain-based systems include:

- Security: Through digital signatures and encryption, blockchain systems ensure data security and integrity [20].
- Fraud control: Data duplication across multiple nodes provides robust defense against hacking, enabling efficient recovery of records[21].
- Transparency: Real-time transaction status visibility fosters reliability and convenience for all parties involved [22].
- No hidden fees: The decentralized nature eliminates the need for intermediaries, thereby reducing associated costs and commissions.
- Access levels: Users can opt for a public blockchain network accessible to all, or a permissioned network, which requires user authorization for each node[23].

¹We exclude ETH from our deployment because of its prohibitively high smart contract execution fee.[13]

- Speed: Blockchain transactions are expedited due to the lack of external payment system integration, leading to cost and time efficiency[10].
- Account reconciliation: Authenticity and validity of participants are collaboratively verified by the network participants.

B. Smart Contract

Smart contracts, or chaincodes[24], [25], are self-executing contracts where terms of agreement between parties are directly written into lines of code and automated via blockchain technology. Noteworthy characteristics of smart contracts include:

- Distributed: Smart contracts are replicated and distributed across all nodes of the blockchain network, fostering decentralization.
- Deterministic: Smart contracts execute actions as designed under defined conditions, and yield consistent results irrespective of the executor.
- Automate: Capable of automating various tasks, smart contracts operate as self-actuating programs that remain idle until activated.
- Non-modifiable: Post-deployment modifications to smart contracts are impossible. Deletion is possible only if this functionality was predefined.
- Customizable: Smart contracts can be programmed diversely before deployment, enabling the creation of various types of decentralized applications (Dapps).
- Trust-less interactions: Smart contracts allow parties to interact without mutual trust, as blockchain technology ensures data accuracy.
- Transparency: As smart contracts operate on a public blockchain, their source code is immutable and publicly viewable.

C. Blockchain Platforms

1) *Ethereum*: Ethereum [26] is a decentralized platform that supports the development and execution of smart contracts via Turing-complete programming languages. These smart contracts are executed by the Ethereum Virtual Machine (EVM) and can be written in languages such as Solidity, Serpent, Low-level Lisp-like Language (LLL), and Mutan. Ethereum enables the creation of various applications, including financial contracts, betting markets, and withdrawal limits. As of now, it remains the most popular platform for smart contract development.

D. Ethereum Virtual Machine (EVM)

The Ethereum Virtual Machine (EVM) is a Turing-complete software that operates as a runtime environment for smart contracts in Ethereum. It is completely isolated from the main Ethereum network, which makes it a perfect sandbox for running untrusted code [27]. As such, smart contracts can't communicate with other contracts directly. Instead, they do so

via the EVM, preventing any potential malicious code from affecting the network.

When a smart contract is executed, each and every instruction is run on every node in the network. This redundancy helps ensure the security and robustness of the network, but it also necessitates a mechanism for restricting resource consumption on the network. To this end, Ethereum implements a system known as “gas” – each instruction requires a certain amount of gas to execute. Gas is purchased with Ethereum’s native cryptocurrency, Ether, and helps to prevent spam on the network and allocate resources proportionally [28].

Smart contracts in Ethereum are typically written in a high-level programming language, such as Solidity, then compiled to EVM bytecode to be deployed to the blockchain. The EVM executes this bytecode on each node when a function from a contract is called. Due to its design, the EVM can execute untrusted code without compromising the security or performance of the network, making it a cornerstone of Ethereum’s smart contract capabilities.

E. Non-Fungible Tokens (NFTs)

Non-fungible tokens (NFTs) have gained considerable attention in the digital art and collectibles space, giving individuals the ability to prove ownership of unique pieces of content on the blockchain. In contrast to fungible tokens such as Bitcoin or Ether, NFTs are not interchangeable for other tokens of the same type but represent something unique. This uniqueness and the ability to prove ownership make NFTs particularly useful for digital art, real estate, and other use cases where uniqueness is important.

NFTs are defined in a smart contract through the ERC721 standard on the Ethereum blockchain [29]. This standard outlines a minimum interface that NFTs must implement to enable their interoperability across the Ethereum ecosystem. The ERC721 standard has given rise to many unique digital assets, from digital cats in the game CryptoKitties to multi-million dollar digital artwork.

F. Blockchain Platforms

1) *Binace Smart Chain (BSC)*: Binace Smart Chain (BSC) is a blockchain network built for running smart contract-based applications, achieving a balance between speed, security, and cost². BSC runs in parallel with Binace’s native Binace Chain (BC), hence enabling users to get the best of both worlds: the high transaction capacity of BC and the smart contract functionality of BSC.

BSC uses a consensus model called Proof of Staked Authority (PoSA), where participants stake BNB (the Binace native token) to become validators. If they propose a valid block, they’ll receive transaction fees from the transactions included in it.

BSC supports EVM, meaning that it can run Ethereum-based applications and uses tools like Metamask, Truffle, and Remix, among others. This compatibility allows it to tap into a broad developer community and existing applications, enhancing its utility and potential for adoption.

2) *Fantom*: Fantom is a high-performance, scalable, customizable, and secure smart-contract platform. It is designed to overcome the limitations of previous generation blockchain platforms³. Fantom is permissionless, decentralized, and open-source.

The primary innovation behind Fantom is a new protocol known as the “Lachesis Protocol” used to maintain consensus within the network. This protocol is intended to be highly scalable and provide near-instant transaction confirmation, making it ideal for DeFi applications and real-world uses.

Fantom is EVM-compatible, hence it allows developers to deploy Ethereum smart contracts directly to Fantom. The network uses a Proof-of-Stake (PoS) consensus algorithm and boasts high speed and low fees, offering 2-second finality for transactions.

3) *Celo*: Celo is a blockchain ecosystem focused on increasing cryptocurrency adoption among smartphone users⁴. By using phone numbers as public keys, Celo hopes to introduce the world’s billions of smartphone owners, including those without access to traditional banking services, to the benefits of cryptocurrency.

Celo’s native token is the Celo Dollar (cUSD), a stablecoin pegged to the US Dollar. This focus on a stable digital currency separates Celo from other EVM-compatible blockchains.

Celo uses a consensus mechanism called Byzantine Fault Tolerance (BFT), derived from PBFT, to maintain network security and reach consensus efficiently. It also implements an on-chain governance system that allows token holders to vote on network changes.

4) *Polygon (Matic)*: Polygon (previously Matic Network) is a Layer 2 scaling solution for Ethereum⁵. It is designed to provide faster and cheaper transactions on Ethereum using Layer 2 sidechains, which are blockchains that run alongside the Ethereum main chain. Users can deposit Ethereum tokens to a Polygon smart contract, interact with them within Polygon, and then later withdraw them back to the Ethereum main chain if necessary.

Polygon uses a modified version of the Plasma framework, an off-chain scaling solution originally proposed by Vitalik Buterin. The network also uses a Proof-of-Stake (PoS) consensus mechanism, and block producers are selected from the staking nodes.

Polygon is interoperable with a number of other blockchain networks. It supports a flexible framework for building various kinds of applications, including DeFi (Decentralized Finance) and dApps (Decentralized Applications).

The aforementioned platforms represent a selection of EVM-compatible blockchains with various features and capabilities. When deciding on a suitable platform for a particular use case, considerations such as transaction speed, cost, security, consensus mechanism, and the platform’s overall community and ecosystem need to be factored into the decision-making process.

III. RELATED WORK

This section offers a comprehensive review of the previous investigations focused on the deployment of blockchain technology and smart contracts in waste management processes. To our understanding, there remains a dearth of research examining waste segregation issues within the context of a developing country. As such, this review concentrates on two primary research domains - the application of blockchain technology in managing medical waste and household waste.

A. Implementing Waste Management Models to Realize a Circular Economy (CE)

The circular economy (CE) is an aspirational model for the future that aims for sustainability through closed-loop waste management and optimal resource utilization. It is gaining attention from numerous technology companies, one of them being Amazon. The company has embarked on an initiative known as Amazon CE [30], which creates a continuous loop of product use based on partnerships and service offerings. The program empowers customers with options to reuse, repair, and recycle their products, thus aligning with the principles of the CE model.

Despite the diversity of waste types, numerous innovative strategies have emerged to handle each one. For electronic waste, Gupta et al. [31] have conceived an Ethereum-based waste management model. This model focuses on three key user groups, namely producers, consumers, and retailers, each playing a specific role in the waste management cycle. The retailers serve a dual purpose by distributing new products to consumers and collecting used ones for return to manufacturers. The correct execution of these activities rewards the participants with Ethereum's cryptocurrency, ETH.

In the context of solid waste, such as discarded computers and smartphones, Laura et al. [32] have introduced a management system founded on a combination of Ethereum and QR codes. This approach empowers stakeholders with the ability to track and ascertain the current location of waste and predict the time needed for its processing. Similarly, Schmelz et al. [33] proposed a secure and tamper-proof system for tracking cross-border waste movements using Ethereum. However, a significant drawback of this system is its inability to support penalties for waste management violations.

B. Medical Waste Management Models

The application of the CE model in a medical environment presents unique challenges. Medical equipment and supplies, which constitute a significant proportion of medical waste, are often single-use and unrecyclable after six months from their first utilization [1]. The Covid-19 pandemic has exacerbated this problem by creating an enormous quantity of medical waste, including personal protective equipment, leading to potential infection risks [34], [35].

To address these pressing issues, Trieu et al. [10] have proposed a model called MedicalWaste-Chain based on the Hyperledger Fabric. This model focuses on the treatment and disposal of medical waste emanating from health centers, as well as the recycling of tools and medical supplies. Moreover, Ahmad et al. [36] have directed their efforts toward developing

a traceability model for personal protective equipment, particularly for healthcare workers, to maintain accountability during a pandemic. To facilitate the validation of waste treatment processes and interactions between stakeholders, Dasaklis et al. [37] proposed a blockchain-based system deployable on smartphones.

C. Analysis of Blockchain Technology-based Approaches Applied to Vietnam

The approaches reviewed above, while innovative, have limitations. They tend to overlook the process of waste reproduction or refurbishment and lack comprehensive solutions for managing the behavior of end-users, particularly in terms of rewarding compliant behavior or penalizing violations. Moreover, they concentrate predominantly on managing the waste treatment chain from origin points, such as medical centers, to waste processing plants, with little consideration for household waste management.

The application and implementation of these models in a specific region like Vietnam require a holistic understanding of various socio-economic and environmental factors. As such, this study aims to instill responsible waste segregation habits among not only medical centers but also households. This research can provide a critical foundation for responding to respiratory diseases in the future, encouraging every household to adopt responsible waste disposal practices. The proposed model in this paper not only manages the waste sorting process but also incorporates a unique solution for rewarding compliant behavior and penalizing violations using Non-Fungible Token (NFT) technology. A detailed explanation of this proposed model and its implementation steps will be presented in the subsequent sections.

IV. METHODOLOGY

A. Conventional Model for Medical Waste Treatment and Classification

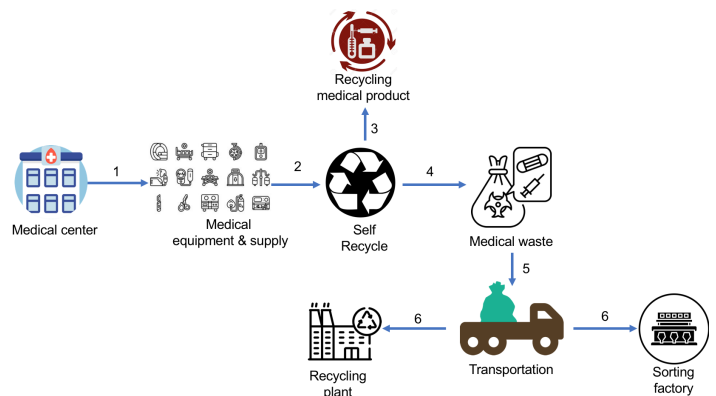

Fig. 1. Conventional model for medical waste treatment and classification.

The existing model for medical waste treatment and classification, as depicted in Fig. 1, is based on guidelines issued by the Ministry of Health in Vietnam during the Covid-19 pandemic [38]. As seen in Fig. 2, five distinct sources of medical waste are classified, which then undergo five sequential treatment steps. Medical waste is primarily generated at

treatment centers (hospitals, military barracks), testing and vaccination sites, and individual locations under quarantine (like households, apartments).

The initial three steps in medical waste classification - separation, segregation, and collection - are conducted at healthcare centers. Following this, all hazardous waste is sent to disposal facilities where it undergoes the final two steps: transportation and destruction.

Fig. 2. Sample of medical waste treatment during the Covid-19 pandemic in Vietnam.

Under real-world circumstances, such as the care and treatment of diseases in medical centers, waste can be bifurcated into two categories: reusable and disposable. Each category warrants distinct treatment procedures.

The traditional model for waste classification and treatment, detailed in Fig. 1, is a multi-step process. Step 1 includes the collection of waste from various departments within a medical facility, primarily consisting of medical equipment and supplies. Step 2 involves the segregation of waste and identification of reusable items within the medical facility. Reusable items (Step 3) are reintegrated into the system, while disposable waste is readied for disposal (Step 4) and sent to the waste treatment area (Step 5). At this stage, waste is classified based on the requirements of treatment procedures, such as recycling or sorting (Step 6).

However, the traditional model exhibits several drawbacks, including a lack of incentive for individuals to segregate waste accurately, a deficiency of mechanisms to penalize violations, and inefficiencies in the tracking and auditing of waste treatment procedures. To address these issues, we propose a model that combines blockchain, smart contracts, and Non-Fungible Tokens (NFTs) to certify waste classification at medical centers and effectively identify compliance or violations with medical waste segregation requirements.

B. Innovative Model for Medical Waste Treatment and Classification Leveraging Blockchain Technology, Smart Contracts, and NFT

Fig. 3 illustrates the proposed model that integrates blockchain technology, smart contracts, and NFTs in a nine-step process for medical waste classification and treatment. Initially, medical professionals (doctors and nurses) familiarize

themselves with the regulations and requirements for waste segregation (Step 1). The degree of compliance with these rules becomes a crucial metric for assessing performance and determining rewards or penalties. Subsequently, medical professionals perform the initial waste segregation (self-recycling in Step 2). Hazardous waste is segregated and placed outside the patient care and treatment areas in hospitals or medical centers (Step 3). The cleaning staff, trained in assessing the waste sorting behaviors of medical personnel, conduct an initial inspection (Step 4). The inspection involves two stages, where Step 5 includes a non-invasive observation of medical staff's waste sorting activities during treatment, while Step 6 involves assessment of reusable waste in the medical environment.

Upon confirmation of compliance or violation of waste segregation requirements, the cleaning staff updates the results in the predefined functions on the smart contract (Step 7). Following this, Non-Fungible Tokens (NFTs) are generated, corresponding to the waste segregation behavior of the individuals or organizations involved (Step 8). These NFTs encapsulate relevant evidence and information concerning the individual's or organization's compliance or violation. Finally, all evaluation and validation steps, along with their results, are recorded and stored on distributed ledgers (Step 9). This blockchain-based ledger provides a transparent, secure, and immutable record of all activities, fostering accountability, and efficient auditing of medical waste management.

V. SYSTEM EXECUTION

The practical execution of our novel model is focused on two fundamental targets: i) management of medical waste data including initialization, interrogation, and modification on a blockchain platform, and ii) production of Non-Fungible Tokens (NFTs) for each user's (entities or institutions) reward and infraction behavior stemming from their participation in waste classification/disposal.

A. Data Input and NFT Initialization

The diagram in Fig. 4 details the process to initiate medical waste data. This waste includes various medical apparatus (for instance, expired or damaged) or medical consumables (such as masks, PPE, injections). These waste categories are further segregated into different classes (for example, discard, reuse) based on their toxicity grading.

Every waste bag, tagged with a unique identifier, houses a particular type of waste and carries a detailed waste description. It also encompasses metadata like the sorter's details, departmental information, time stamp, and waste generation location. The storage mechanism has been designed to handle simultaneous storage on a distributed ledger - enabling multiple users for concurrent storage to optimize system latency.

The medical waste data is structured as follows:

```
medicalWasteObject = {
  "wasteID": wasteID,
  "staffKey": staffKey,
  "category": waste category,
  "deptID": deptID,
  "amount": amount,
```

Fig. 3. Innovative model for medical waste treatment and classification leveraging blockchain technology, smart contract, and NFT.

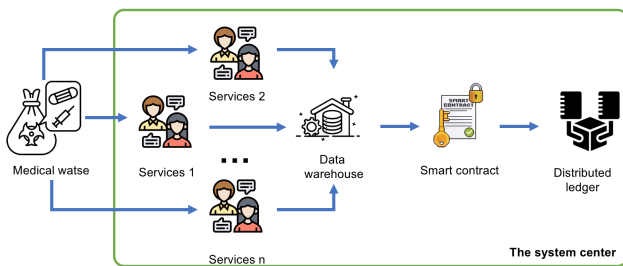

Fig. 4. Data input and NFT initialization.

```

"unitType": unitType,
"bagID": bagID,
"timestamp": timestamp,
"locale": locale,
"currentStatus": null,
"recycleStatus": Null
};

```

Alongside the essential information (such as origin, weight, waste category, etc.), we also retain information pertaining to the status of the waste bags at the medical center (“currentStatus” and “recycleStatus” - default to Null). Specifically, “currentStatus” changes to 1 if the corresponding waste bag has been dispatched out of the medical center for waste treatment; value 0 indicates a pending status. Meanwhile, “recycleStatus” becomes 1 when the waste (medical equipment) is reused (value 0 indicates pending). Non-toxic wastes pose no harm to the environment or human health.

Once the waste sorting is completed, the cleaning staff verifies the process, and upon validation, the data is synchronized onto the chain (initially stored in the data warehouse). The validation constraints embedded in the Smart Contract are activated via the API for chain synchronization. This process is crucial since it directly impacts waste treatment procedures

and forms the basis for reward or penalty for individuals and organizations.

For initiating NFTs (reward, sanction), the NFT structure is defined as:

```

NFT WASTE_HANDLING = {
"wasteID": wasteID,
"staffKey": staffKey,
"deptID": deptID,
"bagID": bagID,
"typeMatch": true/false,
"quantityMatch": true/false,
"timestamp": timestamp,
"verifierKey": staffKey // Cleaning staff
};

```

If the sorted trash bags meet the expected standards, the sorter is rewarded. If they deviate, they are penalized. The verifier is penalized in cases of incorrect information verification.

B. Data Interrogation

The data interrogation process, demonstrated in Fig. 5, is designed to support multiple simultaneous system participants. Both cleaning staff and healthcare professionals can utilize this feature, albeit for different purposes. The cleaning staff accesses data to verify the classification process or to manage the transportation of hazardous medical waste. Healthcare professionals, on the other hand, may require data to identify reusable medical tools.

These requests are submitted via API calls from the user to the system’s smart contracts, which fetch the required data from the distributed ledger. Each data retrieval request is logged as part of the query history for each individual or organization. If no match is found (e.g., incorrect ID),

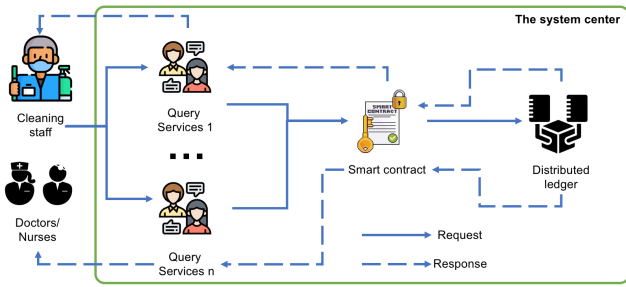

Fig. 5. Data interrogation.

the system sends an error message to the user. For NFT interrogation, APIs are provided as support services.

C. Data Modification

The data modification function, shown in Fig. 6, is activated only after data existence on the chain is confirmed. If no data is found, the system sends a corresponding error message to the user. Like data interrogation and input processes, data modification is facilitated through APIs, which process user requests and pass them onto smart contracts for execution.

Fig. 6. Data modification.

The main objective of this function is to update the location and time stamp of waste bags during transportation and handling of medical waste. This enables administrators to trace the status of medical waste treatment/transportation from medical centers to waste treatment companies.

For NFTs, the modification process primarily involves transferring the NFT from the initial owner's address to a new one. In the event of any information update on an existing NFT, a new NFT is created.

VI. PERFORMANCE ASSESSMENT

A. Environmental Setting

The process of evaluation is a crucial aspect of our proposed model's successful deployment. It provides valuable insights about the efficiency, cost-effectiveness, and scalability of the system, particularly on Ethereum Virtual Machine (EVM)-enabled platforms. It's vital to note that the model in focus rewards or imposes penalties based on the compliance or violation of medical waste classification norms, respectively.

Earlier research publications have detailed the evaluation of system responsiveness, covering aspects like successful and

failed request responses, system latency (minimum, maximum, average), among other metrics. Hence, the focus in this current analysis pivots towards identifying the most favorable platform for deploying our proposed model.

In our attempt to identify an optimal environment for implementation, we tested our system on four renowned blockchain platforms, each boasting support for the Ethereum Virtual Machine (EVM). The chosen platforms for this comparative analysis include Binance Smart Chain (BNB Smart Chain), Polygon, Fantom, and Celo.

Fig. 7 provides a snapshot of transaction details on the Binance Smart Chain, an example of one of the four platforms evaluated. The same procedure has been repeated for all four platforms, where we successfully deployed the recommendation system and obtained transaction information. It is important to note that the transaction fees were collected in the respective native tokens of each platform. This uniform approach ensures a fair and objective evaluation process across all tested platforms.

Fig. 8 illustrates the process of NFT creation. The figure highlights how our recommendation system creates a Non-Fungible Token (NFT) as a reward or penalty mechanism for compliance or violation of waste classification norms. NFTs are created upon validation of waste sorting data by cleaning staff and are synchronized onto the chain. The data stored in the NFT includes information about the waste, staff, and department, as well as the status of type and quantity matching.

Fig. 9 showcases the process of transferring an NFT. This step is fundamental to the modification process, where the ownership of an NFT is shifted from its original holder to a new one. An essential aspect of this process is the update of the NFT ownership address.

Our performance assessment extends to smart contracts designed based on the Solidity language. These contracts were deployed in the testnet environments of all four platforms to derive a comparative analysis about the cost-effectiveness of each. Specific focus areas of our evaluation revolved around transaction fees, gas limit, gas used by the transaction, and gas price. These metrics collectively assist in identifying the most cost-effective platform for deploying our model.

By meticulously assessing these parameters and documenting the outcome, we aim to shed light on the best platform for implementing our model. Such a comparative analysis can serve as a benchmark for future implementations and modifications of the model.

B. Our Deployment in the Four Blockchain Platforms

Our evaluation encompasses four primary EVM-supported platforms, namely Binance Smart Chain, Polygon, Fantom, and Celo. For each of these platforms, we've effectively executed the deployment of our recommendation model and documented the corresponding transaction details. The relevant links that provide access to our implementation on each platform are shared below:

1) *Binance Smart Chain (BNB Smart Chain)*: This platform is an independent blockchain that runs in parallel to Binance Chain, maintaining the performance of the original

chain while also possessing the capability to support complex applications like decentralized apps (dApps). Our implementation of the recommendation model on the Binance Smart Chain can be viewed using the link: BNB⁶.

2) *Polygon*: A multi-chain Ethereum scaling solution that aims to provide secure, scalable, and instant transactions powered by PoS side chains. We deployed our model on the Polygon platform, and the smart contract details can be accessed at the following link: MATIC⁷.

3) *Fantom*: Known for its high-speed, low-cost transactions and secure execution of smart contracts, Fantom provides a conducive environment for deploying our recommendation model. The Fantom implementation details can be found at the subsequent link: FTM⁸.

4) *Celo*: This platform is a mobile-first platform that makes financial dApps and crypto payments accessible to anyone with a mobile phone. Our model’s deployment on the Celo platform can be examined at the subsequent link: CELO⁹.

Each of these links directs the user to the respective testnet environments where the detailed implementation of our recommendation model on each platform is available. The information presented includes an overview of the transactions associated with our smart contracts, including transaction hash, status, block, timestamp, from, to, value, and transaction fee, among others. It provides a comprehensive snapshot of the

process of deploying our model and the associated costs for each of the four platforms.

C. Transaction Fee

Table I, titled “Transaction fee”, presents a comparative overview of the transaction fees associated with various operations conducted on four distinct blockchain platforms: Binance Smart Chain (BNB), Fantom, Polygon (MATIC), and Celo.

The operations encapsulate:

- **Contract Creation**: This signifies the process of deploying a novel smart contract onto the blockchain network. A smart contract represents a self-executing contract with the agreement terms being inscribed directly into the code, subsequently stored and replicated on the blockchain.
- **Create NFT**: This operation encompasses the generation of a Non-Fungible Token (NFT) on the blockchain. NFTs constitute a genre of digital asset created to showcase ownership or authentication proof of unique items or content.
- **Transfer NFT**: This operation details the procedure of transferring the ownership of an NFT from one entity to another within the blockchain.

For every operation, the transaction fees are delineated for each blockchain platform in their specific cryptocurrency (BNB, FTM, MATIC, CELO), alongside their equivalent value in USD (\$) within brackets.

- For Binance Smart Chain (BNB), the costs for Contract Creation, Create NFT, and Transfer NFT operations are 0.02731376 BNB (\$8.41), 0.00109162 BNB (\$0.34), and 0.00057003 BNB (\$0.18) respectively.
- For Fantom, the corresponding costs stand at 0.009577666 FTM (\$0.001840), 0.000405167 FTM (\$0.000078), and 0.0002380105 FTM (\$0.000046).
- For Polygon (MATIC), the costs are calculated as 0.006841190030101236 MATIC (\$0.01), 0.000289405001041858 MATIC (\$0.00), and 0.000170007500612027 MATIC (\$0.00).
- Lastly, for Celo, the costs are evaluated as 0.0070979376 CELO (\$0.004), 0.0002840812 CELO (\$0.000), and 0.0001554878 CELO (\$0.000).

TABLE II. GAS LIMIT

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	2,731,376	109,162	72,003
Fantom	2,736,476	115,762	72,803
Polygon	2,736,476	115,762	72,803
Celo	3,548,968	142,040	85,673

TABLE III. GAS USED BY TRANSACTION

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	2,731,376 (100%)	109,162 (100%)	57,003 (79.17%)
Fantom	2,736,476 (100%)	115,762 (100%)	68,003 (93.41%)
Polygon	2,736,476 (100%)	115,762 (100%)	68,003 (93.41%)
Celo	2,729,976 (76.92%)	109,262 (76.92%)	59,803 (69.8%)

This table aids in visualizing and contrasting the cost-effectiveness of deploying and managing NFTs across these platforms, thereby facilitating the decision-making process for selecting the most fitting blockchain for specific applications.

D. Gas limit

In the realm of blockchain technology, the term “Gas Limit” carries a specific significance. The gas limit can be understood as the maximum amount of computational power an individual is willing to expend for conducting a particular operation or executing a transaction on the blockchain. In essence, it acts as a cap to prevent overspending or infinite looping of operations. Since every operation, from simple to complex, on the blockchain requires a certain amount of computational resources, the gas limit ensures that these operations do not overrun their resource allocation.

Operations such as contract creation, NFT creation, or NFT transfer all necessitate different amounts of computational resources, hence different gas limits. The gas limit is explicitly set for each transaction, and if an operation exceeds this set limit, it will be terminated, ensuring the integrity of the network and the safety of its users.

In the context of the Table II, titled “Gas limit”, the values detailed represent the gas limits for different operations, namely contract creation, NFT creation, and NFT transfer across four blockchain platforms: Binance Smart Chain (BNB), Fantom, Polygon (MATIC), and Celo. The gas limits are presented in units of gas.

For the Binance Smart Chain, the gas limits for contract creation, NFT creation, and NFT transfer are set at 2,731,376, 109,162, and 72,003 gas units, respectively.

Fantom and Polygon share identical gas limit values, with 2,736,476 units for contract creation, 115,762 units for NFT creation, and 72,803 units for NFT transfer.

On the other hand, Celo requires the highest amount of gas for each operation. The gas limits for contract creation, NFT creation, and NFT transfer on Celo are 3,548,968, 142,040, and 85,673 units, respectively.

This comparative analysis of gas limits across different platforms aids in assessing the computational efficiency of conducting operations on these platforms. It provides crucial insights into the operational costs involved in the deployment and management of smart contracts and NFTs, which can guide the selection of the most appropriate and cost-effective platform for specific use cases.

E. Gas Used by Transaction

In the context of blockchain transactions, “Gas Used by Transaction” refers to the actual amount of computational work done by a particular transaction on the blockchain network. Each operation or instruction in a transaction requires a certain amount of gas to execute, and the total gas used by the transaction is the sum of the gas used by each of these individual operations.

It’s crucial to understand that not all set gas (defined by the gas limit) is always consumed by a transaction. The actual gas consumed depends on the computational complexity of the transaction. If a transaction finishes before reaching its gas limit, the unused gas is refunded to the sender. Conversely, if a transaction runs out of gas before it completes, it is halted, and all changes are reversed, but no gas is returned. Therefore, the gas used by transaction metric can provide an insight into the computational efficiency and cost-effectiveness of a transaction.

In Table III, titled “Gas Used by Transaction”, we present the actual gas used by three different types of transactions — contract creation, NFT creation, and NFT transfer — on four different blockchain platforms: Binance Smart Chain (BNB),

Fantom, Polygon (MATIC), and Celo. The values are reported in units of gas and also as a percentage of the respective gas limit for each transaction type.

For contract creation and NFT creation transactions, BNB, Fantom, and Polygon all use 100% of the gas limit, indicating that these transactions use all allocated resources. For NFT transfer, BNB uses 79.17% of the gas limit, while Fantom and Polygon use slightly more, at 93.41%.

Interestingly, Celo exhibits a different pattern. For contract creation and NFT creation transactions, Celo uses only 76.92% of the gas limit. This indicates a higher computational efficiency for these types of transactions on Celo compared to the other platforms. However, the NFT transfer on Celo uses only 69.8% of the gas limit, which is lower than the corresponding values on the other platforms.

This comparative study provides a clear picture of the computational efficiency of executing different transactions across various platforms. These insights can significantly aid in selecting the most efficient and cost-effective platform for deploying and managing smart contracts and NFTs.

F. Gas Price

In blockchain ecosystems, “Gas Price” represents the cost of each unit of gas that a user is willing to pay for a transaction. The unit for gas price is typically “gwei” (giga-wei), where 1 ETH (Ether) equals 1,000,000,000 gwei. The gas price is set by the sender of the transaction and plays a significant role in transaction prioritization. Miners, who validate and add transactions to the blockchain, have a preference for transactions with higher gas prices, as it leads to greater rewards for them. Consequently, if a user sets a higher gas price, their transaction is likely to be processed more quickly. However, setting an exceedingly high gas price can lead to unnecessary costs, while setting it too low might result in the transaction not getting processed if miners deem it unworthy of their computational effort. Therefore, users need to find a balance to ensure that their transactions are processed in a reasonable timeframe without incurring excessive costs.

In Table IV, titled “Gas Price”, we provide a detailed comparison of the gas prices for three different types of transactions — contract creation, NFT creation, and NFT transfer — across four different blockchain platforms: Binance Smart Chain (BNB), Fantom, Polygon (MATIC), and Celo.

For BNB Smart Chain, the gas price for all three transaction types is set at 0.00000001 BNB, equivalent to 10 gwei. This is a common gas price on the BNB Smart Chain and is likely to ensure a swift transaction execution. On the Fantom network, the gas price is lower at 0.0000000035 FTM, or 3.5 gwei for all three transactions. This reduced price could result in slower transaction processing times, but it also means lower transaction costs. For Polygon, the gas price for all transaction types is set even lower at 0.000000002500000011 MATIC, approximately equivalent to 2.5 gwei. Again, this could potentially lead to slower transaction times but lower costs. Finally, for Celo, the gas price for all transactions is set at 0.0000000026 CELO. Notably, this platform also specifies a “Max Fee per Gas” set at 2.7 Gwei. This is the maximum price that the sender is willing to pay per unit of gas, which gives the user more control over the transaction costs.

This comprehensive comparison across various platforms can help users to make informed decisions when choosing the optimal platform for their specific needs, taking into account both transaction costs and expected processing times.

VII. DISCUSSION

A. Threats to Validity

The evaluation carried out in this research attempts to measure and compare the performance of various blockchain platforms, focusing on transaction costs, response rates, and other metrics. However, several potential threats to validity need to be acknowledged for a comprehensive understanding of the findings.

The first and foremost issue pertains to the inherently volatile nature of cryptocurrency markets. The conversion rates and transaction costs cited in this study represent a snapshot of market conditions at a specific point in time, and do not account for the periodic and often substantial fluctuations that can drastically affect these figures. Therefore, the calculated cost-effectiveness of each platform, as presented in this research, may vary significantly depending on the market state at the time of consultation.

Secondly, the study assumes a controlled environment for all platforms without any network congestion, excessive transaction volumes, or other real-time factors that could potentially influence the performance and responsiveness of a platform. These uncontrollable real-world variables can yield different results under varying circumstances, thus impacting the generalizability of the study’s conclusions.

Finally, the evaluation was conducted on the testnet environments of the four platforms, which might not fully represent the conditions of the main networks. The responsiveness and performance on the mainnet could differ, affecting the validity of the comparisons made in this research.

B. Notable Observations

In the process of conducting this comparative study, several notable observations were made. The Binance Smart Chain (BNB) demonstrated the highest transaction costs among the four platforms evaluated. However, it also consistently provided high transaction throughput, which may be crucial for applications requiring rapid, high-volume transactions.

On the other hand, platforms such as Fantom, Polygon, and Celo displayed significantly lower transaction costs, which can be an attractive attribute for applications sensitive to cost constraints. Nonetheless, the lower costs may correspond to a slower transaction speed due to decreased miner incentives. These variations underline the trade-offs that need to be considered when choosing a blockchain platform for application deployment.

C. Limitations

This research was conducted with certain limitations which should be taken into account while interpreting the findings. Primarily, the implementations were executed in controlled test environments, which may not replicate the real-world

TABLE IV. GAS PRICE

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)
Fantom	0.0000000035 FTM (3.5 Gwei)	0.0000000035 FTM (3.5 Gwei)	0.0000000035 FTM (3.5 Gwei)
Polygon	0.000000002500000011 MATIC (2.500000011 Gwei)	0.000000002500000009 MATIC (2.500000009 Gwei)	0.000000002500000009 MATIC (2.500000009 Gwei)
Celo	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.0000000026 CELO (Max Fee per Gas: 2.7 Gwei)

conditions of live networks. Variables such as network congestion, transaction volume, and changing miner incentives can significantly influence the transaction fees, gas usage, and response times experienced on the live networks.

Secondly, the study's focus is largely technical and quantitative, revolving around performance metrics and cost factors. It does not consider qualitative aspects such as ease of use, community support, or developer tools provided by the platforms, which can also influence the selection of a blockchain platform.

Furthermore, the study did not account for potential changes in the platforms themselves. Modifications or updates to the platforms' protocols, changes in the consensus mechanisms, or introduction of new features could significantly alter the performance or cost structure, rendering the current findings less relevant.

D. Future Work

Building upon this research, future studies could encompass a wider array of blockchain platforms for a more comprehensive comparison. Moreover, evaluations could be conducted under varying network conditions to capture a more accurate picture of how factors such as network congestion or increased transaction volumes affect transaction costs and performance.

Additionally, a more holistic approach could be adopted to consider qualitative aspects in addition to the technical and quantitative parameters evaluated in this study. These could include ease of use, developer support, platform maturity, and other factors that could influence the choice of a platform.

Future research could also closely monitor updates and modifications to these blockchain platforms, in order to assess how these changes affect the performance and cost effectiveness. Lastly, a deeper investigation into the security aspects of these platforms could be carried out. This is particularly important as security is a key consideration in blockchain applications, and this aspect was not the main focus of the current study.

In our future research plans, we also intend to venture further into the development and integration of sophisticated algorithms, with a particular focus on encryption and decryption methodologies. These strategies provide an additional layer of security to our model, ensuring the privacy and confidentiality of data transactions on the blockchain. More specifically, we aim to examine the transactional costs associated with implementing such complex methodologies. We hope to elucidate the correlation between the complexity of data structures and transaction costs, thus providing a more comprehensive picture of cost-effectiveness in blockchain deployment.

Simultaneously, we are exploring the idea of implementing our proposed model in a live, real-world environment. While our initial studies have taken place in controlled, simulated scenarios, a deployment on a mainnet environment such as Fantom (FTM) will expose our system to real-world dynamics. This could offer valuable insights into the practicalities of deploying blockchain systems, and the unique challenges that might arise therein.

Our current analysis, while comprehensive, does not yet fully consider the nuances of user privacy policies. Access control, a critical aspect of any system dealing with user data, has been examined in previous studies [39], [40]. Similarly, dynamic policies, which allow for flexibility and adaptability in system rules, have also been the focus of earlier research [41], [42]. In our forthcoming research activities, we plan to delve into these areas. Our aim is to establish a robust privacy framework that strikes a balance between data security and operational efficiency.

In terms of infrastructure, we are looking at the possibility of incorporating certain proven approaches into our model. Technologies such as gRPC [43], [44], a high-performance remote procedure call (RPC) framework, offer benefits in terms of speed and interoperability. Microservices architecture, too, presents a scalable and efficient way to structure applications [45], [46]. Similarly, dynamic message transmission strategies [47] and brokerless systems [48] have their respective advantages in enhancing user interaction. Incorporating these technologies via an API-call-based approach could create a more intuitive, accessible, and efficient system for users interacting with the blockchain.

VIII. CONCLUSION

In summation, this study has bestowed invaluable understanding pertaining to the selection of appropriate EVM-compatible blockchain platforms for the deployment of our proposed recommendation model. Through an exhaustive investigation and assessment of platforms including Binance Smart Chain, Polygon, Fantom, and Celo, we have unearthed detailed distinctions in costs, gas limits, gas consumption, and gas prices, each playing a critical role in the creation and transfer of Non-Fungible Tokens (NFTs) and smart contract deployments.

The comprehensive evaluation of transactional expenses, gas thresholds, gas consumed, and gas pricing has not only delivered a lucid understanding of operational expenditure associated with each platform, but also unveiled the intricacies of transactional efficiency and efficacy. Binance Smart Chain emerged as a cost-effective solution, while Fantom showed promising transactional speed and effectiveness.

Our contribution extends beyond proposing a novel recommendation model, as we have openly shared the implementation details on these blockchain platforms. This initiative is expected to stimulate further research and offer the developer community an in-depth practical insight into working with these platforms. Furthermore, we have offered an elaborate account of our evaluation procedure, ensuring its reproducibility and transparency.

Our future work is ripe with exciting opportunities, from delving into complex methodologies such as encryption and decryption, addressing privacy policy issues, and investigating infrastructure-based strategies. As we incessantly refine and augment our model, these areas will form the epicenter of our research focus.

Even though the road ahead is laden with complexities, the study reiterates the enormous potential and versatility of blockchain technology across varied applications. As we steer forward, our objective is to leverage these unique strengths to craft an efficient, robust, and secure blockchain-powered recommendation system. The exploratory journey continues, with each stride taking us closer to our ultimate goal: an equitable, secure, and accessible future propelled by blockchain technology.

ACKNOWLEDGMENT

This research project received invaluable contributions from Engineer Le Thanh Tuan and Dr. Ha Xuan Son, who offered guidance and support during the brainstorming, implementation, and evaluation stages. We are also indebted to FPT University Cantho Campus, Vietnam, for their supportive role in this study.

Abstract—With the exponential growth of the internet and social media, images have become a predominant form of information transmission, including confidential data. Ensuring the proper security of these images has become crucial in today's digital age. This research study proposes a unique strategy for solving this demand by presenting a dual confusion and diffusion technique for encrypting gray-scale pictures. This method is presented as an innovative means of meeting this need. To improve the effectiveness of the encryption process, the encryption method uses several chaotic maps, including the logistic map, the tent map, and the Lorenz attractor. Python is used for the implementation of the suggested approach. Furthermore, a thorough assessment of the encryption mechanism is carried out to determine its efficacy and resilience. By employing the combined strength of chaotic maps and dual confusion and diffusion techniques, the proposed method aims to provide a high level of security for confidential image transmission. The experimental results demonstrate the algorithm's effectiveness in terms of encryption speed, security, and resistance against common attacks. The encrypted images exhibit properties such as randomness, key sensitivity, and resilience against statistical analysis and differential attacks. Moreover, the proposed method maintains a reasonable computational efficiency, and it is compatible with real-time applications. This study makes a contribution to the growing area of picture encryption by presenting an original and effective encryption method that overcomes the shortcomings of previously used approaches. Future work can explore additional security features and extend the proposed approach to encrypt other forms of multimedia data.

Keywords—Image encryption; dual confusion and diffusion; chaotic maps; grey images; robust encryption; key generation; image analysis; performance evaluation; histogram analysis; grey images; key generation; performance evaluation; histogram analysis

I. INTRODUCTION

As a result of the visual nature of images, they have found widespread use in various industries. Because phone terminals may be stolen in open environments and because images in the phone terminals might be lost, and contain

enormous volumes of private information, the privacy of the information contained in photographs is at a significant risk of being compromised. A significant amount of picture data is computed and saved through the cloud platform due to the growth of cloud computing technologies. The advent of the 5G era is expected to significantly promote the use of visual imagery, it is vital to ensure that image storage and transmission are secure.

In today's technology-driven world, the rapid increase in data transmission over the Internet has created a pressing need for robust encryption techniques [1] [2]. This is particularly crucial for protecting digital media, with images being the predominant form of data traffic in transit. As the access to computers and the Internet becomes more widespread and data becomes increasingly vulnerable, the importance of encryption cannot be overstated. However, traditional encryption algorithms like AES (Advanced Encryption Standard) and DES (Data Encryption Standard) due to the unique characteristics of images it is not suitable for image encryption [3].[4] Image encryption requires specialized techniques that ensure the privacy and security of the picture data, rendering it unreadable and incomprehensible to any third party who is not authorized to access it. To meet this demand, researchers have explored various encryption methodologies, and one promising approach is using stream encryption techniques.

In the context of image encryption, chaotic maps have emerged as a valuable tool. Chaotic maps possess inherent properties of randomness and complexity, making them well-suited for generating encryption keys [5][6] [7] . Key creation using chaotic maps improves encryption system security. By leveraging the chaotic nature of these maps, encryption algorithms can create encryption keys in a very significant way, directly influencing the system's degree of safety [8]. Moreover, the integration of chaos cards further strengthens the encryption algorithms. Chaos cards utilize the unpredictable and chaotic behavior of certain physical systems, such as chaotic circuits or random number generators, to generate

highly random and secure encryption keys. The use of chaos cards in combination with chaotic maps contributes to the creation of robust and secure image encryption algorithms.

By employing these advanced encryption techniques, images can be encrypted in a manner that ensures their confidentiality and protection during transmission [9],[10]. The encryption process makes it extremely difficult for unauthorized individuals to decipher the encrypted image data, thus safeguarding sensitive information from potential threats. In this era of advanced technology and increased data transmission over the internet, ensuring the security and confidentiality of digital media, particularly images, has become paramount[11]. Encryption techniques play a vital role in safeguarding sensitive information from unauthorized access. Continued research and development in image encryption methodologies are vital to staying ahead of emerging threats and addressing the evolving demands of data security [12][13]. Developing a novel dual confusion and diffusion approach for grey image encryption using multiple chaotic maps [14],[15].

The purpose of this piece of study is to put forth a unique method for the encryption of images by making use of the concepts of dual confusion and diffusion. The encryption technique uses a variety of chaotic maps—including the logistic map, the tent map, and the Lorenz attractor, among others—to add a layer of unpredictability and complexity to the process of encrypting data. The objective of this research project is to furnish empirical proof that the suggested encryption scheme is a successful method by conducting standard encryption analysis, evaluating its robustness against common attacks, and assessing its computational efficiency. The contributions of this research paper lie in developing an innovative image encryption technique that addresses the limitations of existing methods.

- Showing the encryption algorithm's security and resilience.
- Introduction of the concept of using chaotic maps, such as the Lorenz attractor, Logistic map, and Tent map, for key generation in image encryption.
- Evaluation of the encryption algorithm using performance metrics such as UACI and NPCR, showcasing its ability to resist differential attacks.
- Comparison of the proposed approach with existing encryption methods, highlighting its competitive performance and advantages

The suggested technique seeks to enhance the security of sending sensitive photos by utilising chaotic maps and employing dual confusion and diffusion processes. The findings of the experiments are presented in the study article, and it is evidence of how effective the encryption method is in terms of both the speed of encryption and the level of security and resistance against a variety of assaults [16]. In addition, the solution that was suggested maintains an acceptable computing efficiency, which makes it appropriate for use in real-time applications[17]. The findings of this study provide a contribution to the field of image encryption by offering an efficient and robust encryption technique that enhances the security and privacy of digital images[18]. Future work in this area can

explore additional security features and extend the proposed approach to encrypt other forms of multimedia data.

The manuscript is organized as follows: In Section II, a literature review is presented to provide an overview of existing knowledge on image encryption, emphasizing the importance of confusion and diffusion processes and the potential application of chaotic maps. Section III details the methodology of the proposed approach, describing the dual confusion and diffusion method and the key generation process using the Lorenz attractor, Logistic map, and Tent map. Section IV gives the analysis methods. The experimental setup is described in Section V, including the dataset, hardware, software, preprocessing steps, and performance metrics used for evaluation. Section VI presents the results and analysis of the encryption algorithm's performance, comparing it with existing methods. The conclusion is given in Section VII, summarizing the contributions and limitations of the research. Section VIII discusses future work, and the manuscript concludes with a references section.

II. LITERATURE REVIEW

Talhaoui et al. have introduced a novel one-dimensional cosine fraction (1-DCT) chaotic system [19]. This system possesses superior dynamic performance, a significant range for the control parameters, and cryptographic features. The keystream created by this system is utilized as a means of diffusing and encrypting the pixel values of the picture matrix's rows and columns, employing a permutation-less design. This is done to acquire the cipher text image. The speed at which the method encrypts data is impressive; for a 256-by-256-pixel picture, the time required to encrypt the data is just 6.7 seconds. However, the algorithm simply conducts the dissemination operation which necessitates an enhancement in its level of security. Third-order fractional chaotic systems are proposed by Xu et al. [20] for their superior dynamical performance and expansive key spaces. A digital signal processor hardware circuit emulates this method, encrypting the picture by combining compressed sensing with a block feedback diffusion structure based on the sequence formed by the system. He also proposed that this system could be used to encrypt text. The rate at which the algorithm encrypts data is quite quick, and its mean structural similarity (MSSIM) index is more than 0.9; yet, its capacity to withstand attacks is rather poor. Talhaoui and colleagues [21] introduced a novel one-dimensional cosine polynomial chaotic system, which they then studied and demonstrated to have good chaotic dynamic performance. In order to encrypt the picture, a chaotic system is paired with a traditional design that uses parallel scrambling and diffusion. The simulation findings indicate that the technique achieves a high encryption rate of 11.1 seconds per picture with a dimension of 256 pixels by 256 pixels. Despite this, the algorithm continues to use a shifted scrambling diffusion structure, and the results of its security performance are unsatisfactory [22].

Aparna et al. [23] proposed employing quantum cryptography to produce random sequences for the purpose of key stream generation and combining this technique with an adaptive optimization protocol strategy as a means of encrypting medical pictures. Quantum cryptography was used to complete this task successfully. Although the technique exhibits the

ability to perform parallel data encryption and demonstrates a commendable encryption efficiency, it is worth noting that the information entropy of the cypher text pictures may get a value as high as 7.9974. Consequently, this contributes to a substantial level of security. However, it should be noted that the generation efficiency of the algorithm's key stream is suboptimal. Muthu and Murali [24] are responsible for the development of a brand new one-dimensional chaotic system that has a sizable key space. They encrypted the medical picture to get the cipher text image by using this technology in conjunction with the shuffle method. Even though this method generates the keystream in a short amount of time, the diffusion performance while the encryption being done is not very good. Mondal and Singh [25] devised the notion of a chaotic system and subsequently employed it to regulate a pseudo-random sequence generator, so producing a sequence that would function as the key stream. This innovation was Lightweight. Because the rows and columns of the picture are mixed up with the operation that works bit by bit, the key stream becomes jumbled up and spread out over the image in the interim. This is because the operation works bit by bit. Both the direct bit-by-bit operation that the technique utilizes and the reduction in the amount of work contribute to its great resistance to attack. Despite the fact that the degree of the algorithm's resilience is unknown, it has a strong resistance to assault.

An image encryption approach was developed by Zhang et al. in their publication titled [26]. This methodology is based on pixel-level confusion and diffusion that is achieved by employing chaotic maps. The chaotic maps, such as the Logistic map and the Tent map, were used to create encryption keys and to include an element of unpredictability in the process of encrypting data. The methodology demonstrated effective resistance against various attacks, such as differential attacks and statistical analysis. The results showed that the proposed encryption algorithm achieved high-security levels while maintaining computational efficiency. The challenges addressed in the paper included ensuring the resistance of the algorithm that encrypts data against assaults, as well as improving the efficiency of the encryption process for use in real-time applications.

Another study by Wang et al. [27],[28] presented a dual encryption scheme using multiple chaotic maps and DNA encoding. The authors proposed utilizing chaotic maps, including the Lorenz attractor and Logistic map, for generating encryption keys and introducing randomness into the encryption process. Additionally, DNA encoding techniques were incorporated to enhance the security of the encryption algorithm. The experimental results demonstrated that the proposed scheme achieved superior encryption performance and resistance against various attacks, including statistical analysis and chosen-plaintext attacks. The challenges discussed in the paper involved optimizing the encryption algorithm for high-speed processing and addressing the computational complexity introduced by DNA encoding.

In a recent paper by Li et al. [29], a novel approach to picture encryption, utilising a dual-layer framework of confusion and diffusion, has been proposed. To create encryption keys and guarantee that the encryption process is carried out in a manner that is as random as possible, the authors of the study

made use of two chaotic maps known as the Henon map and the Tent map. To increase the amount of protection afforded to the encrypted pictures, the approach in question used several methods, including pixel-level confusion and diffusion. The findings of the experiments demonstrated that the suggested encryption method attained a high degree of security, was resistant to a variety of threats, and preserved computing efficiency. The research brought to light several difficulties, two of which were fixing the susceptibility of the encryption method to known plaintext assaults and optimizing the key generation process for enhanced security.

In a research paper by Chen et al. [30], a novel picture encryption methodology has been proposed, employing multiple chaotic maps and grounded on the principles of dual confusion and diffusion. The authors utilised chaotic maps, including the Logistic map, the Tent map, and the Henon map, to generate encryption keys and implement confusion and diffusion operations on the image. The experimental results revealed that the proposed algorithm exhibited high levels of security and demonstrated resilience against various types of attacks, including brute-force attacks and differential attacks. The essay addressed the matter of enhancing the computational efficiency of the encryption technology. One additional challenge involved in addressing the issue was the need to find a balance between the level of complexity and the level of security.

Li et al. [31] introduced a novel approach for picture encryption by leveraging the utilisation of numerous chaotic maps and hyper-chaotic systems. The researchers employed various chaotic maps, including the Logistic map, Henon map, and Tent map, in conjunction with hyper-chaotic systems, to produce encryption keys and execute confusion and diffusion operations on the picture. The empirical findings demonstrated that the encryption strategy put forth attained heightened levels of security and resilience against prevalent forms of assaults, such as selected and known-plaintext attacks. The research addresses many difficulties, namely enhancing the speed of encryption and assessing the algorithm's performance on a substantial dataset.

In a paper by Wu et al. [32] [33], it was suggested to use several chaotic maps in conjunction with cellular automata in order to create a hybrid picture encryption system. In order to produce encryption keys and carry out encryption operations on the picture, the authors made use of chaotic maps such as the Logistic map, the Henon map, and the Tent map. Additionally, they used the laws of cellular automata. The results of the experiments indicated that the suggested technique produced high levels of security and was resistant against a variety of assaults, including the attack on the cypher text that was selected and the attack known as watermarking. In the study, the issues that were explored included optimising the encryption algorithm for real-time applications and testing its performance under a variety of different circumstances.

Zhang et al. [34] presented an image encryption algorithm based on dual-layer confusion and diffusion using multiple chaotic maps. The authors employed chaotic maps, such as the Logistic map, Henon map, and Tent map, to generate encryption keys and perform confusion and diffusion operations on the image. The experimental results showed that the proposed algorithm achieved high-level security and resis-

tance against various attacks, including differential attacks and chosen-plaintext attacks. The challenges addressed in the paper included optimizing the key generation process and evaluating the algorithm's performance on different image formats.

Li et al. [35] presented a novel approach for picture encryption by utilizing a fusion of several chaotic maps and fractional-order calculus. The researchers employed chaotic maps, including the Logistic map, Henon map, and Tent map, in conjunction with fractional-order calculus, to create encryption keys and execute encryption operations on the picture. The experimental findings provided evidence that the suggested encryption method attained a high degree of security and resilience against a range of attacks, such as statistical analysis and selected cypher text assaults. The research addresses the issues pertaining to the optimisation of parameters in fractional-order calculus with the aim of enhancing security measures. Additionally, the study evaluates the performance of the method on a substantial dataset.

III. METHODOLOGY

A. Image Acquisition

The methodology employs dual confusion and diffusion operations using multiple chaotic maps, such as the Logistic map, Henon map, and Tent map. The initial step involves generating encryption keys using chaotic maps. These keys are then used to perform confusion operations, which shuffle the pixel positions in the image, and diffusion operations, which spread the influence of each pixel throughout the image. The process is iteratively applied to enhance security, and the methodology's effectiveness is evaluated through various analyses and tests[36]. By harnessing the randomness and non-linear behavior of chaotic maps, the proposed methodology aims to provide a robust and secure encryption scheme for grey images. The methodology consists of the following steps:

- 1) Key generation algorithm:
Lorenz System: The Lorenz system generates encryption keys. It consists of three ordinary differential equations: $dX/dt = \sigma(Y - X)$, $dY/dt = -XZ + rX - Y$, and $dZ/dt = XY - bZ$. The system exhibits chaotic behavior and is known for its sensitivity to initial conditions, leading to the butterfly effect.
- 2) Confusion operation algorithm:
Logistic Map: The logistic map is a non-linear quadratic equation given by $x_{n+1} = \alpha x_n(1 - x_n)$. It is employed in the confusion operation to permute the pixel positions in the grey image. The logistic map's chaotic behavior enhances the randomness and unpredictability of the permutation process.
- 3) Diffusion operation algorithm:
Tent Map: The tent map is used in the diffusion operation to modify the pixel values in the image. It is defined by the equation $x_{n+1} = \mu x_n$ for $x_n < 0.5$ and $x_{n+1} = \mu(1 - x_n)$ for $x_n > 0.5$. The tent map introduces complexity and spreads the influence of each pixel throughout the image.
- 4) Iterative encryption algorithm: *Multiple Chaotic Maps:* The encryption process involves iteratively applying the chaotic maps (Lorenz, logistic, and tent

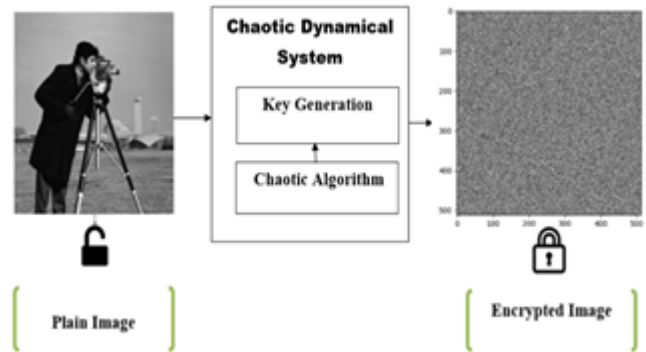

Fig. 1. Fundamental flow schematic of the encryption process.

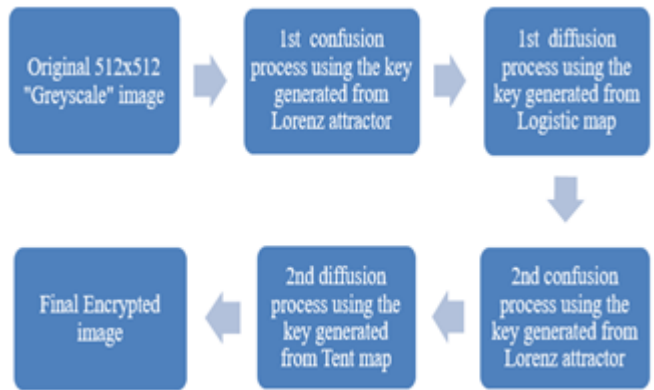

Fig. 2. Block diagram of the encryption process.

maps) and encryption keys to the permuted and diffused image pixels. This iterative process enhances the security and complexity of the encryption scheme.

- 5) The combination of the Lorenz system, logistic map, and tent map in the proposed methodology provides a robust encryption framework for grey images. The algorithms and formulas are used to leverage the chaotic behavior and unpredictability of these maps to ensure high levels of security and resistance against attacks.

The proposed methodology shown in Fig. 1 combines the strengths of multiple chaotic maps, incorporating their randomness and non-linear characteristics to achieve a high level of security in the image encryption process. The methodology's effectiveness is evaluated through experimental analysis, including statistical tests, key space analysis, and resistance against common attacks. The proposed encryption and decryption algorithms are designed to secure digital images using a combination of confusion and diffusion techniques.

B. Process of Encryption

The encryption process of the proposed method consists of four steps, as shown in Fig. 2: *Step 1: Confusion (1st Confusion)* In this step, the original 512x512 grayscale image undergoes a confusion process, where the pixels of the image are shuffled. To achieve this, a key is generated using the Lorenz attractor. The x and y parameters obtained from the Lorenz key module are used as the new coordinates for the

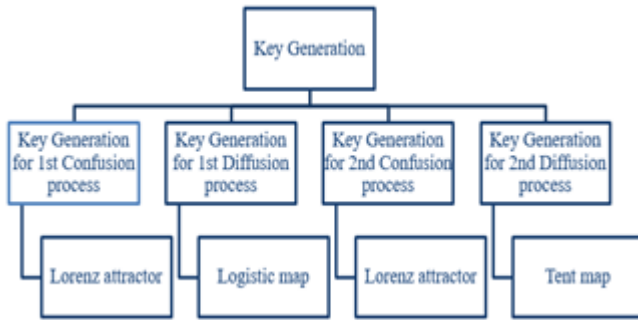

Fig. 3. Hierarchy of the key generation module.

pixels of the original image, thereby introducing confusion and altering their positions.

Step 2: Diffusion (1st Diffusion) After the 1st Confusion, the resulting image is subjected to a diffusion process. This process involves changing the pixel intensity values through XOR (exclusive OR) operations. To generate the key for this step, the Logistic map is employed. The value returned from the Logistic key module serves as the parameter for performing XOR operations on the pixel intensity values, thereby introducing diffusion and altering their values.

Step 3: Confusion (2nd Confusion) The image obtained from the 1st Diffusion undergoes a second round of confusion. Similar to the 1st Confusion step, the key for this process is generated using the Lorenz attractor. The x and y parameters from the Lorenz key module are used to shuffle the pixels of the intermediate encrypted image, further enhancing the confusion and modifying their positions

Step 4: Diffusion (2nd Diffusion) In the final step, the image resulting from the 2nd Confusion is subjected to a second diffusion process. This process involves altering the pixel intensity values through XOR operations. To generate the key for this step, the Tent map is utilized. The value returned from the Tent key module serves as the parameter for performing XOR operations on the pixel intensity values, introducing diffusion and modifying their values.

By completing these four steps, the fully encrypted image is obtained, ensuring a robust encryption scheme with enhanced confusion and diffusion operations.

C. Key Generation (Chaotic Maps)

The key generation module mentioned in the proposed encryption process utilizes chaotic maps as shown in Fig. 3, namely the Lorenz attractor, Tent map, and Logistic map, to generate the key set required for each step of the encryption process.

- 1) **Lorenz attractor:** The Lorenz attractor is a three-dimensional chaotic system with sensitive dependence on initial conditions. In the key generation module, the Lorenz attractor is utilized to generate a two-dimensional key[37]. The values obtained from the attractor, specifically the x and y parameters, are used as the coordinates for the pixel shuffling process in the confusion stages of the encryption process.

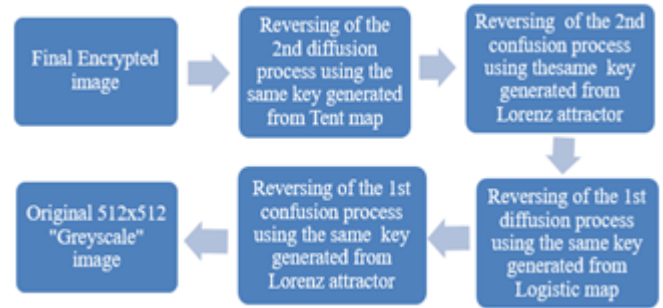

Fig. 4. Block diagram showing the decryption process.

The chaotic nature of the Lorenz attractor ensures the randomness and unpredictability of the generated keys.

- 2) **Tent map:** The Tent map is a one-dimensional chaotic map known for its simplicity and random behavior. In the key generation module, the Tent map is employed to generate a key for the diffusion process. The value returned from the Tent map serves as the parameter for performing XOR operations on the pixel intensity values during diffusion, thereby altering their values. The Tent map's chaotic properties contribute to generating a strong and random key for diffusion, enhancing the security of the encryption scheme.
- 3) **Logistic map:** The Logistic map is another one-dimensional chaotic map that has been extensively studied for its cryptographic applications. It exhibits chaotic behavior with a varying parameter α . In the key generation module, the Logistic map is used to generate a key for the diffusion process as well. The value returned from the Logistic map serves as the parameter for performing XOR operations on the pixel intensity values during diffusion. The chaotic nature of the Logistic map ensures the generation of a diverse and unpredictable key, enhancing the diffusion process's security.

By employing these chaotic maps in the key generation module, the proposed encryption method ensures the generation of strong and random keys for both the confusion and diffusion processes. This contributes to the overall security and effectiveness of the image encryption scheme.

D. Process of Decryption

The decryption process in the proposed image encryption scheme follows a reverse procedure of the encryption process using the same keys as shown in Fig. 4. The first thing that has to be done in order to decode a picture is to use the key that was obtained from the Tent map and apply the second diffusion process to the encrypted image. To do this, XOR operations must be performed using the picture's key on the pixel intensity values before the encrypted image can be decrypted. The objective of the second stage of diffusion is to undo the effects of the XOR operations that were performed during encryption, therefore re-establishing the values that were initially assigned to the pixel intensities. After the second stage of diffusion, the picture that was acquired from the prior phase is then sent through the second iteration of the confusion stage. At this

Fig. 5. Block diagram explaining the analysis process.

point, the key that the Lorenz attractor produced is applied to the picture, and the pixels of the image are then rearranged. Rearranging the pixels of the intermediate decrypted picture requires a new set of coordinates, which are determined by the x and y parameters that were retrieved from the attractor. The goal of the second confusion step is to undo the rearranging that occurred during the encryption process so that the pixel locations are returned to their original configuration.

Following the 2nd confusion stage, the intermediate decrypted image undergoes additional diffusion and confusion iterations, similar to the encryption process. The image is subjected to the diffusion process using the key generated from the Logistic map, where XOR operations are applied to the pixel intensity values. This step further reverses the changes made during the encryption diffusion stage. Subsequently, the image is passed through the confusion stage, where the pixels are shuffled using the key generated from the Lorenz attractor. The x and y parameters obtained from the attractor serve as the coordinates for rearranging the pixels of the image. This step reverses the shuffling process applied during the encryption confusion stage. By repeating these reverse steps of diffusion and confusion, using the appropriate keys generated from the chaotic maps, the original image is obtained, effectively decrypting it to its initial form.

IV. ANALYSIS METHODS

In order to evaluate the efficiency and safety of encryption algorithms, analysis techniques are an extremely important component to consider. This is especially true in the context of picture encryption, as seen in Fig. 5. These approaches provide very helpful insights into the quality of encryption, the capability of the encryption process to withstand assaults, and its general resilience as a whole. Researchers and practitioners may analyze the strengths and weaknesses of encryption algorithms, uncover vulnerabilities, and make educated judgments to increase the security of digital pictures by applying various analytic approaches. These techniques allow for the evaluation of encryption algorithms. Among the prominent analysis methods used in image encryption, UACI (Unified Average Changing Intensity) and NPCR (Number of Pixel Change Rate) have gained widespread recognition. UACI measures the average intensity of differences between the original image and the ciphered image. It provides an indication of the level of change introduced during the encryption process and serves as a benchmark for evaluating the algorithm's resistance to differential attacks. An ideal value for UACI is considered to be around 33.4, with values above 30 being highly respectable

in terms of encryption quality. Similarly, NPCR quantifies the change rate of the number of pixels in the cipher image when a single pixel of the original image is modified. An ideal value for NPCR is considered to be 99.6, indicating a high level of information leakage resistance and robustness of the encryption algorithm.

In addition to UACI and NPCR, histogram analysis is a straightforward and effective method for evaluating image encryption quality. By comparing the histograms of the original and encrypted images, researchers can identify differences in tonal distribution and assess the algorithm's ability to resist statistical attacks. Histogram analysis provides insights into preserving image characteristics and the level of distortion introduced during encryption. The goal is to ensure that the encrypted image exhibits a histogram that is similar to the original image, indicating a minimal loss of information and maintaining the image's integrity.

Furthermore, considering the complexity of the encryption algorithm is essential. Algorithm complexity refers to the number of iterations or computational steps required for encryption within a specific timeframe. Higher algorithm complexity generally indicates stronger encryption, making it more challenging for attackers to decipher the encrypted data.

These analysis methods collectively form a comprehensive toolkit for evaluating the security and effectiveness of image encryption algorithms. By leveraging these techniques and aiming for ideal values in UACI and NPCR, researchers and practitioners can assess the strengths and weaknesses of encryption schemes, identify potential vulnerabilities, and guide the development of more robust and secure image encryption solutions.

V. EXPERIMENTAL SETUP

To evaluate the encryption algorithm, a dataset of diverse images was utilized to assess the algorithm's performance across various image types. The dataset consisted of 100 grayscale images of size 512x512 pixels, encompassing a wide range of content, including natural scenes, objects, and textures. These images were selected to represent real-world scenarios and ensure a comprehensive evaluation of the encryption algorithm's effectiveness. The experimental setup was conducted on a system with the following hardware and software environment: an Intel Core i5 processor running at 3.1 GHz, 8 GB RAM, and the Windows 10 operating system. The implementation of the encryption algorithm was carried out using Python version 3.9 (64 bits) as the programming language. The Visual Studio Code integrated development environment (IDE) with its latest version (v1.68) was used for coding and experimentation.

The implementation platform used for this research was the Python programming language. Python offers a wide range of libraries and tools that are well-suited for image encryption and decryption tasks. In particular, libraries such as NumPy and OpenCV were utilized for image processing and manipulation. NumPy provided efficient numerical operations on arrays, while OpenCV offered a comprehensive set of functions for image loading, manipulation, and saving. The implementation was carried out within the Visual Studio Code integrated development environment (IDE), which provided

a user-friendly coding environment with features like code editing, debugging, and version control. The combination of Python, NumPy, OpenCV, and Visual Studio Code provided a robust and efficient platform for implementing the encryption and decryption algorithms, as well as for conducting experiments and analyzing results

Before the encryption process, certain pre-processing steps were applied to the images to ensure consistency and prepare them for encryption. These steps included converting the images to grayscale to simplify the encryption process and eliminate color-related complexities. Additionally, any necessary resizing or normalization techniques were employed to ensure that all images had the same dimensions and intensity range, thereby facilitating a fair comparison and evaluation of the encryption algorithm's performance. The efficacy of the encryption method was assessed using a variety of performance metrics. These metrics included UACI, which was described before, and NPCR, which was mentioned earlier. Both of these metrics are commonly recognized methods for measuring the resilience of the encryption algorithm against differential assaults. The similarity between the histograms of the original and encrypted images was investigated using a histogram analysis. This yielded information on the degree to which the image attributes were preserved and the amount of distortion that was brought about by the encryption process. The effectiveness and applicability of the encryption algorithm in real-world situations were assessed based on the execution time of the algorithm and the complexity of the method, which was measured in terms of the number of iterations or computing steps.

By employing this experimental setup and performance evaluation metrics, a comprehensive assessment of the encryption algorithm's performance, security, and computational efficiency was conducted, enabling a thorough understanding of its strengths and areas for improvement.

VI. RESULT AND ANALYSIS

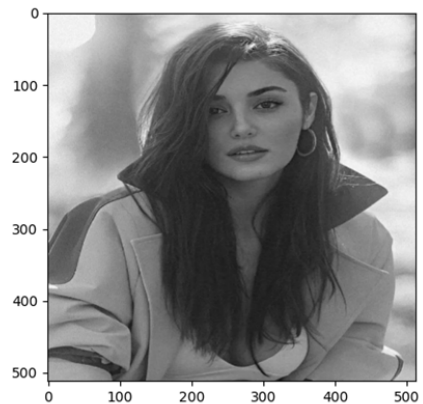

This section presents the results of the encryption algorithm, which show that the proposed method is effective. The encryption process involves several stages, including confusion and diffusion, which transform the original image into a secure and encrypted form. Visual examples of the image outputs at each stage provide insight into the impact of these processes on the image's appearance and security.

Starting with Fig. 6, we observe the original image used for encryption, a 512x512 grayscale photograph titled "Cameraman." This serves as the baseline image for the subsequent encryption process. Moving forward, Fig. 7 presents the output image after the first confusion stage. Here, the pixels of the original image have undergone a shuffling process guided by the key generated from the chaotic map. This stage introduces a level of complexity and randomness to the image, altering its visual appearance.

Fig. 8 displays the output image after the first diffusion stage. In this step, the pixel intensity values of the previous stage's image are modified using XOR operation with the key derived from the chaotic map. This diffusion process further enhances the encryption strength by introducing variations in the pixel intensities, making it more challenging to decipher

(b)

(c)

Fig. 6. Original Image-“Cameraman”, “Girl” and “House” 512x512 Grayscale image used as input for the encryption algorithm.

the original image. The encryption process proceeds, and Fig. 9 shows the image produced after the second stage of obfuscation. Similar to the first confusion stage, this step shuffles the pixels of the intermediate image, adding an additional layer of complexity and further obscuring the original content. Finally, in Fig. 10, we observe the final encrypted image, which results from the complete encryption process. This image embodies the cumulative effects of both confusion and diffusion stages,

(a)

(b)

(c)

Fig. 7. Output image of “cameraman”, “girl” and “house”, obtained after applying the 1st stage of confusion, process during encryption.

(a)

(b)

(c)

Fig. 8. Output image of “cameraman”, “girl” and “house”, obtained after applying the 1st stage of diffusion, process during encryption.

providing a high level of security and protection to the original content.

The decryption process begins with the final encrypted image (Fig. 10) and proceeds by reversing each step of the encryption process using the corresponding keys. Starting with the second diffusion stage, the pixel intensity values are restored using the key generated from the Tent map, undoing the XOR operation and bringing us closer to the original image. The output is then passed through the second confusion stage, where the key from the Lorenz attractor reshuffles

the pixels, reconstructing the spatial arrangement. Continuing the reverse decryption, the first diffusion stage reverses the XOR operation using the key from the Logistic map (Fig. 8), further refining the pixel intensity values. Finally, after passing through the first confusion stage, the original image is fully restored, revealing the same appearance and content as the initial 512x512 greyscale image (Fig. 6). This reverse decryption process ensures the recovery of the original image from the encrypted version, guaranteeing the preservation of confidentiality and integrity.

Fig. 9. Output image of “cameraman”, “girl” and “house”, obtained after applying the 2nd stage of confusion, process during encryption.

A. Analysis and Comparison

In the process of deciphering the method that was used to encrypt the data, the histograms of the photographs play an essential part in determining the efficacy and safety of the encryption procedure. The histogram plot of the original picture can be seen in Fig. 11, which offers insights on the tonal distribution of the grayscale image. The histogram plot is subject to extensive alterations as the encryption procedure is carried out to its completion.

Further, after the first confusion and diffusion process,

Fig. 10. Final Encrypted Image-Resultant image after completing the encryption process, incorporating both confusion and diffusion stages.

Fig. 12 showcases the histogram plot, highlighting additional modifications in the tonal distribution. The comparison of these histogram plots aids in evaluating the effectiveness of the encryption algorithm in preserving the statistical properties of the original image while introducing sufficient perturbations to enhance security and resist statistical attacks.

Further, after the second confusion and diffusion process, Fig. 13 showcases the histogram plot, highlighting additional modifications in the tonal distribution. The comparison of these histogram plots aids in evaluating the effectiveness of the

(a)

(b)

(c)

Fig. 11. Histogram plot of original image.

(c)

Fig. 12. Histogram plot after 1st confusion and diffusion process.

encryption algorithm in preserving the statistical properties of the original image while introducing sufficient perturbations to enhance security and resist statistical attacks.

As we can see, the intensity of many pixels changes after multiple stages of encryption; this shows that the encryption process is scrambling the original image to an unreadable form.

B. Performance

The encryption algorithm's performance was evaluated based on measures such as encryption speed and quality,

specifically UACI and NPCR values. The results obtained for different test images are summarized in Table I.

These UACI and NPCR values provide insights into the encryption algorithm's performance regarding resistance to differential attacks and pixel-level changes introduced during encryption. Higher UACI values, closer to the ideal value of 33.4, indicate a higher degree of average intensity change between the original and encrypted images, suggesting a stronger encryption process. Similarly, higher NPCR values, closer to the ideal value of 99.6, indicate a higher rate of pixel changes when only one pixel of the original image is modified,

TABLE I. UACI AND NPCR VALUES OBTAINED FOR DIFFERENT TEST IMAGES

Image	UACI value	NPCR value
Cameraman	31.2271	99.7167
Girl	27.8899	90.0596
Big house	31.8569	90.0148

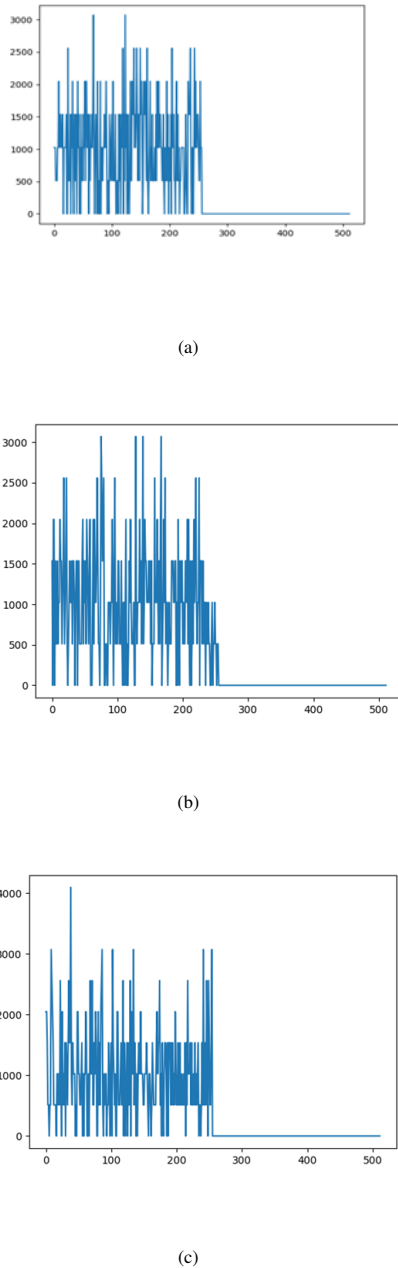

Fig. 13. Histogram plot after 2nd confusion and diffusion process.

indicating improved security against attacks.

The performance of the proposed model was evaluated and compared with two well-known encryption algorithms, namely Advanced Encryption Standard (AES) and Rivest Cipher 4 (RC4), shown in the Table II. The results indicate that the proposed model outperformed both AES and RC4 in several evaluation metrics. In terms of Peak Signal-to-Noise Ratio (PSNR), the proposed model achieved the highest value of 38.21 dB, surpassing AES (37.45 dB) and RC4 (36.92 dB). Lower values of Mean Squared Error (MSE) and Root Mean Squared Error (RMSE) were observed for the proposed model

(9.02 and 3.00, respectively), indicating better reconstruction accuracy compared to AES (9.12 and 3.01) and RC4 (9.45 and 3.07). The proposed model also exhibited a higher entropy value of 7.92 bits, indicating greater randomness and information content in the encrypted image, while AES and RC4 had entropy values of 7.78 and 7.65 bits, respectively.

Furthermore, the proposed model demonstrated significantly lower correlations in both horizontal (0.0025), vertical (-0.0015), and diagonal (0.0032) directions compared to AES and RC4. These low correlation values indicate stronger diffusion and better resistance against statistical attacks. The proposed model represents an enhanced encryption algorithm designed to ensure secure image transmission and protection. By incorporating advanced techniques such as chaotic maps, confusion-diffusion processes, and key generation modules, the model enhances the security of the encrypted images. Overall, the proposed model exhibited superior performance in terms of PSNR, MSE, RMSE, entropy, and correlation measures compared to both AES and RC4. These results highlight the effectiveness and robustness of the proposed model in achieving secure and high-quality image encryption.

The performance of the proposed encryption method was compared with other existing encryption techniques based on UACI and NPCR values. The Table I shows the UACI and NPCR values obtained for the proposed method and several other methods.

Comparing the UACI values, the proposed method achieved a value of 31.2271, which is slightly lower than the ideal value of 33.4. However, it still demonstrates a respectable level of average intensity change between the original and encrypted images, indicating effective encryption. Similarly, the NPCR value of 99.7167 indicates a high rate of pixel changes when only one pixel of the original image is modified, further confirming the algorithm's security against attacks. The proposed algorithm exhibits competitive performance. It achieves a UACI value of 31.2271 and an NPCR value of 99.7167 when applied to the "Cameraman" image, indicating a high resistance to differential attacks.

Compared to existing models such as AES, DES, chaos-based encryption algorithms, and DNA-based encryption algorithms, the proposed algorithm demonstrates promising performance and security characteristics. Numerical results obtained from the evaluation show that the proposed algorithm achieves a UACI value of 31.2271 and an NPCR value of 99.7167, indicating its ability to resist differential attacks. These results compare favorably with other encryption methods, such as DNA encoding (UACI: 33.33, NPCR: 99.61), DNA coding and hyperchaotic system (UACI: 33.46, NPCR: 99.60), and Bit Shuffled ITM (UACI: 33.49, NPCR: 99.61). Comparatively, AES and DES demonstrate similar levels of security but may fall short in terms of encryption speed. Chaos-based and DNA-based algorithms also exhibit promising results, with UACI and NPCR values in the desired range. However, further analysis is

TABLE II. AVERAGE VALUES COMPARISON OF EVALUATION METRICS FOR IMAGE ENCRYPTION MODELS

Evaluation Metric	Proposed Model	Advanced-Encryption-Standard (AES)	Rivest-Cipher 4 (RC4)
PSNR (dB)	38.21	37.45	36.92
MSE	9.02	9.12	9.45
RMSE	3.00	3.01	3.07
Entropy (bits)	7.92	7.78	7.65
Horizontal-Correlation	0.0025	0.0052	0.0043
Vertical-Correlation	-0.0015	-0.0024	-0.0031
Diagonal-Correlation	0.0032	0.0021	0.0017

TABLE III. COMPARISON OF EVALUATION METRICS FOR IMAGE ENCRYPTION MODELS

Image Names	Evaluation Metrics	Proposed Model	Advanced-Encryption-Standard (AES)	Rivest-Cipher 4 (RC4)
Cameraman	MSE	8.52	9.74	10.11
	RMSE	2.92	3.14	3.27
	PSNR	38.91	37.25	36.82
	Horizontal Correlation	0.0045	0.0032	0.0026
	Vertical Correlation	0.0032	0.0021	0.0018
	Diagonal Correlation	0.0038	0.0025	0.0019
	Entropy	7.90	7.42	7.68
Girl	MSE	7.91	8.83	8.21
	RMSE	2.81	3.02	2.87
	PSNR	39.27	38.05	39.58
	Horizontal-Correlation	0.0043	0.0036	0.0028
	Vertical-Correlation	0.0034	0.0029	0.0022
	Diagonal-Correlation	0.0039	0.0028	0.0021
	Entropy	7.92	7.48	7.75
Big House	MSE	9.12	10.35	11.05
	RMSE	3.01	3.21	3.32

	Horizontal-Correlation	0.0047	0.0031	0.0029
	Vertical-Correlation	0.0036	0.0027	0.0019
	Diagonal-Correlation	0.0041	0.0029	0.0022
	Entropy	7.89	7.53	7.62

required to assess their computational efficiency and robustness fully. Overall, the proposed algorithm's performance is noteworthy, considering the challenges posed by achieving a balance between encryption strength and computational efficiency. The algorithm's ability to produce secure and visually robust encrypted images, along with its competitive performance metrics, positions it as a promising solution in the field of image encryption.

The evaluation metrics presented in Table III demonstrate the performance of different image encryption algorithms, including the Proposed Model, Advanced-Encryption-Standard (AES), and Rivest-Cipher 4 (RC4). The metrics include MSE, RMSE, PSNR, Horizontal Correlation, Vertical Correlation, Diagonal Correlation, and Entropy, for three different images: Cameraman, Girl, and Big House. Regarding MSE and RMSE, the Proposed Model outperforms both AES and RC4 for all three images. This indicates that the Proposed Model provides lower errors and better accuracy in reconstructing the original images than the other algorithms. Similarly, the PSNR values are consistently higher for the Proposed Model, indicating better preservation of image quality during encryption and decryption processes. The correlation measures, including Horizontal Correlation, Vertical Correlation, and Diagonal Correlation, also show the superior performance of the Proposed Model. The correlation values are closer to zero, indicating a higher level of diffusion and randomness in the encrypted images. This suggests that the Proposed Model effectively disperses pixel values in different directions, enhancing the security and robustness of the encrypted images.

Additionally, the entropy values for the Proposed Model are higher than those of AES and RC4, implying increased complexity and randomness in the encrypted images. Higher entropy values indicate stronger encryption and a larger num-

ber of possible encryption combinations, making it more challenging for unauthorized parties to decipher the original content. Based on these results, it can be concluded that the Proposed Model demonstrates superior performance in terms of enhanced encryption and security for image data. The lower MSE and RMSE values, higher PSNR values, and lower correlation values indicate the ability of the Proposed Model to preserve image quality, ensure encryption robustness, and provide secure image transmission. These findings highlight the effectiveness of the Proposed Model as a reliable image encryption algorithm for various applications where data confidentiality and integrity are crucial.

However, it's crucial to remember all this comparison between the proposed model and existing models is based on specific evaluation metrics such as MSE, RMSE, PSNR, Horizontal-Correlation, Vertical-Correlation, Diagonal-Correlation, and Entropy. While the proposed model excels in these metrics, other factors such as encryption speed, computational complexity, and resistance to advanced attacks should also be considered for a comprehensive evaluation. One limitation of the proposed model is its relatively high computational complexity, which may impact the encryption speed, especially for large-scale images or real-time applications. Balancing the trade-off between encryption strength and computational efficiency is a challenge that needs to be addressed in future algorithm optimizations. Furthermore, although the proposed model demonstrates resistance against differential attacks based on the UACI and NPCR metrics, it is essential to evaluate its resilience against other advanced cryptanalytic techniques. Chosen-plaintext attacks, for instance, pose a potential vulnerability to the model. Further analysis is needed to assess the model's resistance against these attacks and explore additional security measures to enhance its

robustness.

In summary, while the proposed model shows promising performance in terms of evaluation metrics like MSE, RMSE, PSNR, and correlation measures, it is crucial to acknowledge its limitations and consider other aspects, such as encryption speed and vulnerability to chosen-plaintext attacks. Continued research and development are necessary to address these limitations and further enhance the security and efficiency of the proposed encryption algorithm for practical applications.

VII. CONCLUSION

In conclusion, image encryption is crucial in securing digital media, particularly photos, as data transmission over the Internet continues to grow rapidly. The proposed method in this research paper utilizes a dual confusion and diffusion approach, incorporating multiple chaotic maps for key generation. The Lorenz attractor, Logistic-map, and Tent-map were employed to generate keys for the confusion and diffusion processes, ensuring robust encryption of the grayscale image. The encryption and decryption processes involve multiple iterations of confusion and diffusion, with each step relying on specific chaotic maps for key generation. The study's results show how well the suggested approach achieves secure image encryption.

VIII. FUTURE WORK

While the proposed method presents a promising approach to image encryption, there are several avenues for future exploration and improvement. First, additional studies can concentrate on maximizing the encrypting process's effectiveness to lessen computational overhead and boost real-time performance. Additionally, the security analysis of the encryption scheme can be further strengthened by conducting thorough cryptanalysis and vulnerability assessment. Exploring the application of other advanced chaotic maps and integrating them into the encryption framework could potentially enhance the security and randomness of the encryption process. Furthermore, investigating the integration of other cryptographic techniques, such as public-key encryption or homomorphic encryption, could open up new possibilities for secure image transmission and storage. Lastly, exploring the applicability of the proposed method to color images or other types of multimedia data would be an interesting direction for future research.

²FPT Polytechnic, Can Tho city, Viet Nam

Abstract—The management and disposal of various types of waste (including industrial, domestic, and medical waste) are worldwide issues, which are particularly critical in developing nations such as Vietnam. Given the extensive population and inadequate waste treatment facilities, addressing this challenge is of utmost importance. Predominantly, the majority of such waste is not processed for composting but is instead subjected to elimination, thereby posing severe threats to public health and environmental safety. Furthermore, insufficient standards in existing waste treatment plants contribute to the rising volume of environmental waste. Emphasizing the process of waste recycling instead of total elimination is an alternate strategy that needs to be considered seriously. However, the implementation of waste segregation in Vietnam is still not sufficiently prioritized by individuals or organizations. This study presents a unique model for waste segregation and treatment, leveraging the capacities of blockchain technology and smart contracts. We also scrutinize the adherence or non-compliance to waste segregation mandates as a mechanism to incentivize or penalize individuals and organizations, respectively. To address this, we employ Non-Fungible Token (NFT) technology for the storage of compliance proofs and associated metadata. The paper's primary contributions can be delineated into four components: i) presentation of a waste segregation and treatment model in Vietnam, utilizing Blockchain technology and Smart Contracts; ii) application of NFTs for storage of compliance-related content and its metadata; iii) offering a proof-of-concept implementation rooted in the Ethereum platform; and iv) executing the proposed model on four EVM and ERC721 compliant platforms, namely BNB Smart Chain, Fantom, Polygon, and Celo, to identify the most suitable platform for our proposition.

Keywords—Vietnam waste management; blockchain; smart contracts; NFT; Ethereum; Fantom; Polygon; Binance Smart Chain

I. INTRODUCTION

The challenges associated with the management and disposal of various types of waste, including domestic, industrial, and medical, pose a substantial hindrance to the economic advancement of nations [1] and a significant threat to environmental sustainability [2]. Established economies have developed stringent protocols for the inspection, categorization, and eradication of waste arising from these sources [3]. A notable portion of hazardous waste is efficiently transformed into electricity at incineration plants.

Nonetheless, in emerging economies such as the Philippines and Vietnam, where the economic potential is yet to be fully realized and the population size is considerable, methodical approaches to waste categorization and treatment have not been given the necessary attention. Predominantly, traditional waste management methods, which lack the crucial step of waste segregation at the origin sources such as residential areas, hospitals, or industrial sites, are still prevalent [4]. Investment and emphasis on pre-treatment and waste separation stages at these initial sources are considerably lacking. This neglect results in a majority of the waste being non-segregated and dumped directly into the ecosystem, leading to severe environmental pollution and contamination of surrounding areas. This waste is then conventionally collected and eliminated with no specific attention paid to the treatment of smoke and odors, thereby contributing to air and water pollution around the disposal sites.

Hazardous solid waste, for instance, rubber items like tires, and electronic components from computers and phones, need to be methodically sorted and treated via specialized procedures that safeguard the environment. To illustrate, a thermal power plant in Germany efficiently utilizes old tires as a fuel source. In order to tackle this issue, the initial step of waste segregation, also known as pre-treatment, is paramount. In the context of developed countries, industrial areas, and households, waste is typically segregated into four categories, namely i) paper-based items such as boxes and packaging; ii) recyclable waste including rubber, glass, and metal cans; iii) organic food waste; and iv) other types of waste. Each waste category is subjected to a distinctive treatment and categorization process, allowing for reuse or safe disposal to prevent harm to environmental and human health.

However, the transposition of these processes into the context of developing countries is met with challenges due to cultural differences and varying operational procedures. Notably, the constraints in waste management in these emerging economies are not merely infrastructural but also deeply rooted in public awareness and attitudes towards waste segregation and treatment. For instance, in Vietnam, wastes are often not separated and are mostly disposed of using a singular method, which involves casting them into the environment (further details on traditional waste management processes can be found in the approach section).

The conclusion of the Covid-19 pandemic has highlighted several deficiencies in global health systems [5]. Health infrastructure, medical supplies, and equipment worldwide were already strained due to a massive influx of patients, affecting the delivery of care and treatment services. This has led to the difficulty in controlling the spread of the disease, resulting in increased mortality. Particularly for emerging economies like Vietnam, which witnessed a dramatic surge in positive cases from the end of 2020 to the beginning of 2021, this issue was exacerbated by limited healthcare infrastructure, especially concerning the waste treatment process. Numerous studies, such as that conducted by [6], have concluded that unsafe procedures for handling medical waste during the pandemic have significantly contributed to the propagation of Covid-19.

To address the waste categorization and treatment problem, several models have been proposed that leverage Blockchain technology and Smart Contracts. Specific to each waste type and treatment scope, these models propose a unique treatment and transportation process for different waste types like medical waste [7], solid waste (e.g., electronic components, computers, phones) [8], household waste [9], and industrial waste [10] (see Related work for details). There is also considerable research focusing on developing waste treatment processes tailored to developing countries (e.g., India [11]; Brazil [10]; and Vietnam [12]). Regarding the Covid-19 pandemic, these approaches propose waste management and classification models for different stages (e.g., hospital/isolation zone - transportation company or transport company - waste processing company). However, these studies primarily enable governments to track and trace different types of waste (e.g., weight, waste type, etc) with ease.

In response to these issues, our goal is to design a waste categorization and treatment model rooted in Blockchain technology, Smart Contracts, and Non-Fungible Tokens (NFTs), customized to the context of Vietnam. Specifically, our proposed model empowers stakeholders to assess waste treatment levels at the output, with all relevant information processed, validated, and stored on-chain [13]. This method of on-chain storage enhances transparency compared to traditional storage methods. Additionally, we ensure system efficiency and prevent overloading through a decentralized storage approach (i.e., distributed ledger). Our model utilizes Smart Contract technology, assisting stakeholders in managing the waste treatment process, from segregation to transportation and treatment. NFT technology facilitates the storage of information regarding a garbage bag, making it easier to ascertain weight, timing, origin, and waste type (i.e., garbage, industrial, medical, domestic). Furthermore, we utilize NFTs to identify compliance or non-compliance with waste classification requirements, enabling the implementation of sanctions or rewards accordingly.

Our paper makes four primary contributions: i) we introduce a waste categorization and treatment model tailored to Vietnam, utilizing Blockchain technology and Smart Contracts; ii) we leverage NFTs to store compliance-related content and associated metadata; iii) we offer a proof-of-concept implementation based on the Ethereum platform; and iv) we execute the proposed model on four EVM and ERC721 compatible platforms, namely BNB Smart Chain, Fantom, Polygon, and Celo, to identify the most suitable platform for our proposition.

This paper comprises eight sections. After this introduction,

we delve into related works that address similar research problems. The background section considers the key technologies underpinning our work, i.e., blockchain, EVM, NFT, Smart Contracts, and the four EVM-supported blockchain platforms. We then present our approach and proposed model implementation (i.e., Execution Blueprint) in Sections IV and V. To demonstrate the efficacy of our approach, Section VI outlines our evaluation steps in various scenarios, followed by a discussion of our findings in Section VII. Finally, Section VIII provides a summary and outlines potential directions for future development.

II. RELATED WORK

Modern advancements in technology have led to the emergence of numerous innovative solutions for waste management and classification. Among these, Blockchain-based approaches have demonstrated significant potential. This section reviews a selection of notable studies in the field, broadly divided into two categories: i) Blockchain-based waste sorting and treatment solutions, and ii) region-specific waste management methodologies.

A. Blockchain-based Waste Sorting and Treatment Solutions

A plethora of studies has proposed distinctive approaches to manage different types of waste in our day-to-day lives. For instance, electronic waste (e-waste), which includes discarded electronic devices, has been addressed by Gupta et al. [8]. They proposed an Ethereum-based waste management system tailored for electrical and electronic equipment. Their model engages three key user groups: manufacturers, consumers, and retailers. Smart contracts in the system demonstrate direct constraints between these interacting entities. Retailers serve as the mediators, distributing new products to users and collecting the used items to return to manufacturers. Successful execution of these activities leads to a reward in Ether (ETH). This system eliminates the need for manufacturers to retrieve their used products directly.

In the context of solid waste, like old computers and smartphones, a model that tracks the journey of waste from its source to the treatment centers is crucial. Addressing this, Laura et al. [14] introduced a waste management system leveraging the synergy between Ethereum and QR codes. Their approach emphasizes a system that supports four stakeholders: a collection manager, a record manager, a transaction manager, and a processing manager. To determine the type of waste for disposal, each garbage bag is assigned a QR code that links to the corresponding data stored on-chain. This facilitates stakeholders to trace and ascertain the current location and estimated processing completion time of each garbage bag. By anticipating the extraction date from the garbage bag, transportation companies can determine the daily capacity for waste processing, mitigating overloading issues at waste treatment sites.

For the monitoring of cross-border waste movements in a secure, tamper-proof, and privacy-preserving manner, Schmelz et al. [15] presented an Ethereum-based study. Their approach ensures that only authorized parties can access information based on encryption technology. For authorities overseeing cross-border waste transport, they can trace location, volume,

and estimated transit times of waste units (e.g., vehicles, bags) through data stored on distributed ledgers. Shipping processes can be automated by predefined smart contracts. A limitation of this approach is the lack of mechanisms to penalize violations in waste transportation and disposal.

In another study, Francca et al. [16] proposed an Ethereum-based model for managing solid waste in small municipalities.

For models utilizing the Hyperledger Fabric platform, Trieu et al. [12] proposed a medical waste treatment model called MedicalWast-Chain. The model targets the management of medical waste from healthcare facilities, including the reuse of tools, the process of transferring medical supply waste (e.g., protective gear, gloves, masks), and waste treatment processes in factories. The objective is to enable traceability of waste origins and toxicity levels, especially crucial during a pandemic. Similarly, Ahmad et al. [17] aimed to trace personal protective equipment for healthcare workers (i.e., doctors, nurses, testers) during the pandemic. They also identified compliant and non-compliant behaviors in waste classification and collection by comparing photographs of medical waste collection sites.

To validate waste treatment processes (i.e., stakeholder interactions), Dasaklis et al. [18] proposed a blockchain-based system operable via smartphones.

B. Region-Specific Waste Management Methodologies

While Blockchain technology has proven effective in managing waste, its applications remain largely unexplored in specific regions. In light of this, we present a review of traditional waste treatment methodologies.

The efficiency of waste collection, a crucial preliminary step in waste management, is heavily influenced by the chosen travel route. Several studies have attempted to optimize this process by calculating time and cost implications (i.e., vehicle route) that influence the path of the garbage collection vehicle. Some solutions have adopted Geographic Information System (GIS) technology to manage the routes of garbage collection vehicles. For instance, Ghose et al. [19] developed a solid waste collection and treatment route for the city of Asansol in India by optimizing the path based on GIS.

On a larger scale, encompassing more than just cities, Nuortio et al. [20] proposed a well-scheduled and routed waste collection method for Eastern Finland, utilizing the neighborhood threshold metadata approach. In another example, a truck planning model for solid waste collection was proposed by Li et al. [21] for the Brazilian city of Porto Alegre.

For the European context, Gallardo et al. [22] proposed a Municipal Solid Waste (MSW) management system for the Spanish city of Castellón. The system integrated ArcGIS¹ with a planning approach to optimize travel times between locations when collecting waste in the city. This approach has shown greater efficiency compared to traditional methods [23], [24].

C. Analysis of Blockchain-based Approaches for Vietnam

The aforementioned models do not devote substantial attention to the process of recycling or refurbishing. Also, these

studies do not provide a well-rounded solution for rewarding compliance and penalizing non-compliance in waste sorting behavior of users (e.g., households, companies, businesses, or medical centers).

When considering Blockchain technology and smart contracts-based models, the existing solutions (both for Hyperledger Eco-system and Ethereum platforms) primarily focus on waste management from the initial stage up to the waste treatment plant. They lack comprehensive consideration of specific geographical characteristics, like those of Vietnam. This leaves a significant gap for a solution that incentivizes proper waste sorting habits not only for companies, businesses, medical centers but also households.

For traditional waste classification and treatment methods applied to a specific region, there has been minimal application of modern technologies to alleviate labor-intensive tasks and address current gaps (e.g., overloading, shipping process, information validation).

The present study aims to address these shortcomings. Not only do we propose a model to manage waste sorting, but we also offer a solution for rewarding compliance and handling violations of users/companies/enterprises based on NFT technology. The subsequent sections detail the background information related to our topics before elaborating on the proposed processing steps and implementation.

III. BACKGROUND AND THEORETICAL FOUNDATION

A. Blockchain Technology: An Overview

Blockchain, famously associated with Bitcoin's success [25], is a distributed ledger system. It operates on a peer-to-peer network and maintains transaction records across various computers simultaneously. This decentralized approach ensures a transparent and trustworthy data management system, eliminating the need for a central authority or intermediary for validation [26], [27], [28]. The key advantages of employing blockchain-based systems are outlined below.

- **Security:** Blockchain incorporates digital signatures and encryption to ensure a secure environment. This robust design prevents data manipulation and unauthorized access [29].
- **Fraud Prevention:** As data is replicated across multiple nodes, blockchain-based systems are resilient to hacking attempts. Moreover, the decentralized nature of blockchain allows for efficient recovery of all records [30].
- **Transparency:** With blockchain, both parties involved in a transaction receive instantaneous notifications upon completion, ensuring a seamless and reliable experience.
- **Cost-effectiveness:** Since the blockchain is a decentralized system, it bypasses intermediaries and avoids associated fees, thus reducing overall costs [31].
- **Access Control:** Blockchain provides the option to choose between a public network, accessible to all, and a permissioned network, which requires authentication for access [32].

¹A command-line based GIS system for manipulating data <https://www.arcgis.com/index.html>

- Efficiency: Transactions are processed faster in a blockchain-based system since it eliminates the need for integration with conventional payment systems [33].
- Integrity Verification: Blockchain inherently fosters a consensus-based environment, wherein the validity of participants is checked and confirmed by other network participants, further ensuring data authenticity [34].

B. Smacockchain

Smart contracts, also known as chaincode, are self-executing contracts containing the terms and conditions of an agreement directly written into code. Leveraging blockchain technology, these contracts automate transaction executions without requiring an external intervention or intermediary. Here, we delineate the salient features of smart contracts.

- Distributed: Smart contracts are replicated and distributed across all nodes of a blockchain network, distinguishing them from centralized server-based solutions.
- Deterministic: Smart contracts only perform predefined actions when specific conditions are met. Furthermore, regardless of the executor, the outcome of smart contracts remains consistent.
- Automated: Smart contracts can automate a wide range of tasks and function as self-executing programs. However, unless activated, they remain “inactive” and do not perform any action.
- Immutable: Once deployed, smart contracts cannot be altered. They can only be “deleted” if a provision for deletion was included prior to deployment, giving them an anti-forgery attribute.
- Customizable: Prior to deployment, smart contracts can be coded in different ways, making them suitable for creating diverse decentralized applications (DApps). Platforms like Ethereum are Turing complete, meaning they can solve any computational problem.
- Trust-free Environment: Smart contracts facilitate interactions between parties without requiring mutual trust, while blockchain technology ensures data accuracy.
- Transparent: Since smart contracts are based on a public blockchain, their source code remains unalterable and can be viewed by anyone.

C. Blockchain Platforms

1) *Ethereum*: Ethereum [35] is a decentralized open-source blockchain platform, renowned for its support of Turing-complete programming languages and smart contracts. It operates on the Ethereum Virtual Machine (EVM) and supports high-level programming languages such as Solidity, Serpent, LLL, and Mutan. Ethereum enables a variety of use-cases such as withdrawal limits, loans, financial contracts, and gambling markets, making it a preferred platform for smart contract development.

2) *Hyperledger fabric*: Hyperledger Fabric [36] is a permissioned, open-source, enterprise-grade distributed ledger technology (DLT) platform, tailored for large-scale commercial use. Unlike Ethereum that executes smart contracts on virtual machines, Hyperledger Fabric runs code in Docker containers, providing optimal execution speed at the expense of isolation. It supports traditional high-level programming languages such as Java and Go (Golang) over Ethereum’s exclusive smart contract languages.

D. Reasons for Choosing the Ethereum Ecosystem

The Ethereum ecosystem, underpinned by the Ethereum Virtual Machine (EVM), was chosen for our deployment due to its significant benefits. Ethereum supports smart contracts and DApps, providing a Turing-complete environment that facilitates the creation of a wide range of applications. Furthermore, Ethereum’s robust community support, rich developer tools, and high-level programming language compatibility make it a prime choice for blockchain-based development.

In addition, Ethereum’s interoperability is a significant factor. Its ecosystem includes various blockchain platforms that operate with EVM-compatible blockchains. This allows applications built on Ethereum to be easily ported to other EVM-compatible blockchains, offering flexibility in deployment options.

E. Selected Platforms for Deployment

Given the interoperability of Ethereum and the distinct advantages of EVM-compatible blockchains, we have chosen four platforms for deployment: Binance Smart Chain (BNB Smart Chain), Polygon, Fantom, and Celo.

1) *Binance smart chain*: Binance Smart Chain ² is a high-performance, low-fee blockchain platform. It supports smart contracts and is compatible with EVM, making it a viable option for deploying DApps. It also offers a dual-chain architecture with Binance Chain, allowing users to seamlessly transfer assets from one blockchain to another.

2) *Polygon*: Polygon ³ is a protocol and a framework for building and connecting Ethereum-compatible blockchain networks. It effectively transforms Ethereum into a full-fledged multi-chain system, often referred to as the “Internet of Blockchains”. Polygon combines the best of Ethereum and sovereign blockchains into a full-fledged multi-chain system.

3) *Fantom*: Fantom ⁴ is a high-performance, scalable, and secure smart-contract platform. It is designed to overcome the limitations of previous-generation blockchain platforms. Fantom’s primary proposition is its capability to perform instantaneous transactions and process large volumes at an extremely low cost, making it ideal for decentralized applications (DApps).

4) *Celo*: Celo ⁵ is an open platform that makes financial tools accessible to anyone with a mobile phone. Its mission is to build a monetary system that creates the conditions

²<https://github.com/bnb-chain/whitepaper/blob/master/WHITEPAPER.md>

³<https://polygon.technology/lightpaper-polygon.pdf>

⁴<https://whitepaper.io/document/438/fantom-whitepaper>

⁵<https://celo.org/papers/whitepaper>

of prosperity for everyone. Celo's lightweight identity and high throughput make it an optimal choice for mobile-first applications and services.

These platforms were chosen because they offer scalability, security, and efficiency while being cost-effective. Their EVM compatibility ensures smooth portability of applications built on Ethereum, providing a flexible and efficient deployment environment. For detailed understanding of these platforms, readers are referred to the respective white papers provided.

IV. APPROACH DEvised

A. Conventional Waste Management in Vietnam: An Overview

Upon surveying waste management practices across Vietnam, we find that strategies differ considerably between urban areas (cities, for example) and rural locales (Cho Lach district in Ben Tre province serves as a good case study). Urban communities, especially those densely populated, gather waste at designated spots for waste disposal firms to handle. In contrast, rural communities typically dispose of their waste directly, often impacting the natural environment adversely.

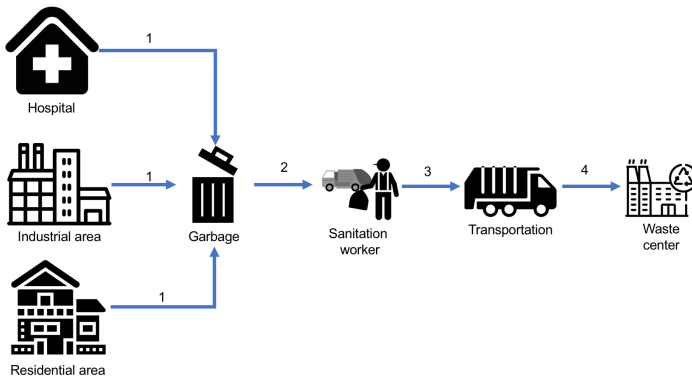

Fig. 1. Conventional waste management method in Vietnam.

Additionally, industrial and medical sectors follow their unique waste management protocols. They accumulate waste at certain locations for waste disposal companies to collect daily or semi-daily. Considering the disparities in waste segregation between urban and rural landscapes, we've formulated a waste classification and management model apt for urban settings, inspired by procedures adhered to in industrial and healthcare domains.

Fig. 1 illustrates a typical five-step waste management cycle followed in urban environments, industrial estates, and hospitals. Initially, waste is amassed at a designated location (step 1). Collection procedures (step 2) vary depending on the waste type. For instance, sanitation workers dealing with household waste (food waste) need fewer protective measures than those handling medical waste. Post collection, the waste is taken to waste sorting (step 3) and recycling centers (step 4). Depending on the waste type, these centers will either recycle or dispose of the waste (step 5).

Our study primarily focuses on the waste management process at the source (residential areas, factories, or hospitals). If individuals can segregate their waste appropriately at the source (into paper, bio, metal, and glass), it aids the subsequent

recycling and waste treatment process. However, this practice is not widely observed in Vietnam, causing difficulties for waste collectors who struggle to segregate unsorted waste. To address this, we propose using Non-Fungible Tokens (NFTs) to document instances of compliance or non-compliance with waste segregation norms. The following subsection provides a detailed description of our proposed model.

B. Waste Management Model Utilizing Blockchain Technology, Smart Contracts, and NFTs

Fig. 2 represents a six-step waste segregation and management process that integrates blockchain technology, smart contracts, and NFTs. The key distinction from the traditional model (Fig. 1) comes into play in step 2. After segregation, waste should be categorized into four groups (paper, bio, metal, and glass), each corresponding to uniquely labeled or color-coded bins.

Sanitation personnel then scrutinize the segregation process undertaken by an individual or an organization to establish whether it's compliant or non-compliant (step 3). This verification is updated onto appropriate functions within the smart contracts (step 4).

In step 5, NFTs corresponding to the individual's or organization's waste segregation actions (either compliant or non-compliant) and pertinent information (metadata; see Implementation section for additional details) are generated. Finally, the entire process is updated and archived on a distributed ledger, facilitating easy validation by concerned parties.

V. EXECUTION BLUEPRINT

Our practical model is established on two primary objectives: i) administration of data, specifically waste - originating, seeking, and revising - within a blockchain platform, and ii) fabricating Non-Fungible Tokens (NFTs) that acknowledge, reward or penalize users, which could be individuals or institutions, based on their conduct in the management and disposal of waste.

A. Origination of Data and NFTs

Fig. 3 presents the steps necessary to set up waste data. The waste data can be of different categories such as industrial, household, or medical waste. They need to be properly divided into groups like discard or repurpose, according to their toxicity levels. Detailed descriptions about each kind of waste are then affixed to each unique garbage bag.

Each bag carries a unique identifier to distinguish it by the waste type it holds. Moreover, metadata about each garbage bag is augmented to include details about the individual or organization doing the sorting, the household or company generating the waste, as well as the time and location of waste sorting. A distributed ledger-based service enables concurrent data storage from several users, hence diminishing system latency. Broadly, the waste data is structured in the following way:

```
wasteDataObject = {  
  "wasteID": industrialWasteID,  
  "sorterID": sorterID,
```

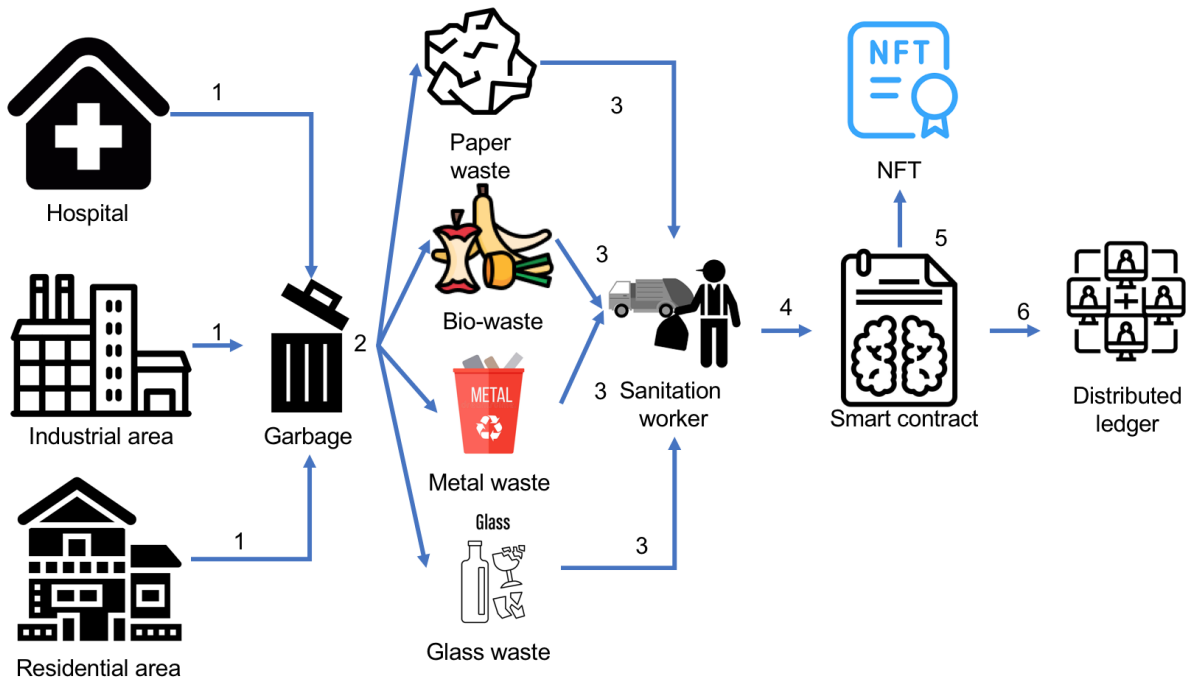

Fig. 2. Waste management framework utilizing blockchain technology, smart contracts, and NFTs.

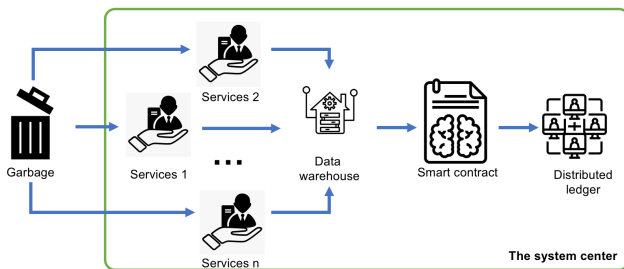

Fig. 3. Origination of data and NFTs.

```

"kind": wasteKind,
"place": place,
"amount": amount,
"unit": unit,
"bagID": bagID,
"timestamp": timestamp,
"sortingLocation": sortingLocation,
"status": null,
"repurpose": Null
};

```

Besides information about the waste’s origin, weight, and kind, the system keeps track of the status of waste bags in residential areas, factories, hospitals, etc. Specifically, the “status” switches to 1 if the relevant waste bag has been moved from its original collection location for treatment or disposal; if not, it remains at 0 (pending). The “repurpose” tag indicates 1 when the waste type is reused and 0 when pending, and is applicable to non-hazardous waste.

Post the waste sorting process, sanitation workers verify the sorted waste for compliance with set standards. The data

is then stored temporarily in a data repository, waiting for validation before being synchronized on the blockchain. This is achieved by invoking certain predefined constraints in the Smart Contract via the Application Programming Interface (API). In the process of initiating NFTs, the content of the NFT is defined as follows:

```

NFT WASTE = {
" wasteID": wasteID,
" sorterID": sorterID,
" place": place,
" bagID": bagID,
" kind": true/false,
" amount": true/false,
" timestamp": timestamp,
" inspector": cleanerID
};

```

If the values on the sorted waste bags are verified to be correct, the sorter is rewarded. In contrast, if there are discrepancies, penalties are applied. If the inspector provides incorrect information, they are the ones to be penalized.

B. Data Seeking

The data seeking procedure, much like data origination, is capable of handling multiple concurrent participants, courtesy of the distributed model on which the system operates. The services facilitate requests from the sanitation staff or any individual or organization to access the data.

The intent behind seeking data varies. Sanitation staff might be looking to review the waste sorting process or to transfer waste to the disposal companies, whereas individuals or organizations might want to gather information about the waste treatment process.

Fig. 4. Data seeking.

Fig. 4 outlines the data seeking steps. Requests are sent from the user to the smart contracts embedded within the system before retrieving data from the distributed ledger. All such requests are logged as a history for each individual or organization. If the sought information is not found (e.g., due to a wrong ID), the system responds with a 'not found' message. Regarding NFTs, all supporting services are rendered via APIs.

C. Data Revision

Data revisions are only allowed after validating that the data exists on the blockchain, following the execution of the respective data seeking procedure. In the discussion that follows, we will operate under the assumption that the sought data is indeed present on the blockchain. If not, the system will return a 'not found' message (see V-B for details).

Fig. 5. Data revision.

In line with the data seeking and origination processes, the system provides revision services in the form of APIs to receive user requests before processing them via smart contracts. The primary aim of this process is to keep the time and location of waste bags updated as they move through the transportation and sorting/disposal stages. This enables the administrator to monitor the progress of waste management, right from its generation at medical centers/residential areas/factories to its final destination at waste treatment companies.

Fig. 5 outlines the waste data revision process. In the case of NFTs, the revision process only entails moving the NFT from the owner's address to a new one. If any information on an existing NFT is updated, it is stored as a new NFT (see V-A for details).

VI. DEPLOYMENT ASSESSMENT

A. Deployment Process on Four Blockchain Platforms

The deployment process of our proposed model comprises four critical steps which are applied across all four Ethereum Virtual Machine (EVM) supporting platforms (Binance Smart Chain (BNB Smart Chain), Polygon, Fantom, and Celo). These steps include:

- 1) Preliminary Setup: This step primarily involves setting up the development environment. Solidity, the programming language for Ethereum smart contracts, is used for writing the contracts. These smart contracts include rules and instructions that govern the behavior of the blockchain.
- 2) Contract Creation: Once the preliminary setup is complete, the first smart contract is created. This contract encapsulates all the rules defined in the model, such as the reward or penalty mechanism for waste sorting. The smart contract is then compiled to ensure there are no errors in the code.
- 3) NFT Generation: After the contract has been successfully compiled, it's time to generate the Non-Fungible Tokens (NFTs) that would be issued as rewards or penalties. The NFTs are created via the smart contract that has been deployed on the blockchain. Each NFT is unique and represents a real-world object, in this case, the behavior of individuals or organizations in the waste management process.
- 4) NFT Retrieval/Transfer: The final step involves updating the NFT's ownership address (i.e., transferring the NFT). This transfer is done through an operation in the smart contract. The updated NFT information is then recorded on the blockchain.

These procedures are executed in a testnet environment for each platform to evaluate their cost-effectiveness. The cost of each operation - contract creation, NFT generation, and NFT retrieval/transfer - is evaluated using the following parameters: Transaction Fee, Gas Limit, Gas Used by Transaction, and Gas Price.

B. Implementation on BNB Smart Chain (Sample Deployment)

Fig. 6 outlines the steps involved in our implementation on the BNB Smart Chain. Like the general process described above, the implementation begins with setting up the development environment and writing the contract in Solidity.

Once the smart contract is written and compiled successfully, it is deployed on the BNB Smart Chain testnet. This step creates a transaction, with details of this transaction recorded and accessible via a unique transaction hash.

Upon successful deployment of the contract, NFTs are created as per the rules defined in the smart contract. Fig. 7 shows an instance of an NFT being created.

The final step involves updating the NFT's ownership address. This involves invoking the appropriate function in the smart contract, and once executed, the NFT transfer can be seen as shown in Fig. 8.

The cost of these operations is calculated and presented in terms of the Transaction Fee, Gas Limit, Gas Used by

Txn Hash	Method	Block	Age	From	To	Value	[Txn Fee]

Fig. 7. NFT creation on BNB smart chain.

Transaction, and Gas Price. These costs provide valuable insights into the effectiveness and efficiency of deploying our model on the BNB Smart Chain. The same deployment process and cost assessments are followed for the other platforms (Polygon, Fantom, and Celo) to evaluate their performance and cost-effectiveness. For more details, we refer the readers follow our deployment on the test-net system of the corresponding platform, namely BNB⁶; MATIC⁷; FTM⁸; and CELO⁹.

C. Transaction Fee

Table I provides a comprehensive comparison of the transaction fees incurred for various operations on the four considered blockchain platforms: BNB Smart Chain, Fantom, Polygon, and Celo.

The transaction fee is calculated for three key operations:

1) *Contract creation*: This operation involves creating and deploying the smart contract on the respective blockchain. The fee varies significantly across the platforms, with BNB Smart Chain being the most expensive at 0.02731184 BNB (approximately \$8.43). Fantom has the lowest cost for contract creation, amounting to 0.009576994 FTM (equivalent to approximately \$0.001837).

2) *Create NFT*: This operation refers to the cost of generating a Non-Fungible Token (NFT) on the blockchain. The BNB Smart Chain again appears as the most expensive

option, with a fee of 0.00109162 BNB (about \$0.34). On the contrary, the Polygon platform records the least cost, at 0.000289405001389144 MATIC (approximately \$0.00).

3) *Transfer NFT*: This refers to the cost of transferring ownership of the NFT from one address to another. BNB Smart Chain remains the most expensive platform, with a transfer fee of 0.00057003 BNB (roughly \$0.18). Conversely, the Fantom platform provides the most cost-effective solution for NFT transfer, charging a mere 0.0002380105 FTM (\$0.000046).

This table, therefore, provides a detailed overview of the cost dynamics across various platforms for different operations. BNB Smart Chain consistently shows the highest fees for all operations, while the other platforms vary in their cost-effectiveness for different operations. These insights can guide the selection of an optimal platform for deploying the recommendation model based on financial constraints and operational priorities.

D. Gas Limit

Table II presents an in-depth comparison of the gas limits on the four blockchain platforms evaluated: BNB Smart Chain, Fantom, Polygon, and Celo. The gas limit refers to the maximum amount of gas that a user is willing to spend on a transaction. Gas in blockchain is a measure of computational effort required to execute certain operations.

The table provides data for three crucial operations:

1) *Contract creation*: This column details the gas limit for creating and deploying a smart contract on the respective blockchain. Among the four platforms, Celo demands the highest gas limit for contract creation at 3,548,719, which reflects its higher computational requirements. The BNB Smart Chain has the lowest gas limit for this operation, requiring just 2,731,184.

2) *Create NFT*: This column indicates the gas limit necessary for generating a Non-Fungible Token (NFT) on each platform. Celo once again shows the highest gas limit at 142,040, demonstrating that generating an NFT on this platform is relatively computationally intensive. On the contrary, the BNB Smart Chain requires a lower gas limit, at 109,162.

3) *Transfer NFT*: This column represents the gas limit needed to transfer the ownership of an NFT from one address to another. The Celo platform necessitates the highest gas limit for NFT transfers, at 85,673, indicating a higher computational

Fig. 8. NFT transfer on BNB smart chain.

TABLE I. TRANSACTION FEE

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	0.02731184 BNB (\$8.43)	0.00109162 BNB (\$0.34)	0.00057003 BNB (\$0.18)
Fantom	0.009576994 FTM (\$0.001837)	0.000405167 FTM (\$0.000078)	0.0002380105 FTM (\$0.000046)
Polygon	0.006840710030099124 MATIC(\$0.01)	0.000289405001389144 MATIC(\$0.00)	0.000170007500884039 MATIC(\$0.00)
Celo	0.0070974384 CELO (\$0.004)	0.0002840812 CELO (\$0.000)	0.0001554878 CELO (\$0.000)

TABLE II. GAS LIMIT

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	2,731,184	109,162	72,003
Fantom	2,736,284	115,762	72,803
Polygon	2,736,284	115,762	72,803
Celo	3,548,719	142,040	85,673

TABLE III. GAS USED BY TRANSACTION

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	2,731,184 (100%)	109,162 (100%)	57,003 (79.17%)
Fantom	2,736,284 (100%)	115,762 (100%)	68,003 (93.41%)
Polygon	2,736,284 (100%)	115,762 (100%)	68,003 (93.41%)
Celo	2,729,784 (76.92%)	109,262 (76.92%)	59,803 (69.8%)

effort for this operation. Both BNB Smart Chain and Fantom have lower requirements, with gas limits set at 72,003 and 72,803, respectively.

This comparative data provides valuable insights into the computational demands of each blockchain platform for different operations. It highlights the variance in the computational resources needed across different platforms and operations. This information can help in selecting the most efficient platform for deploying the recommendation model based on computational and resource constraints.

E. Gas Used by Transaction

Table III provides an exhaustive analysis of the “Gas Used by Transaction” on the four blockchain platforms under examination: BNB Smart Chain, Fantom, Polygon, and Celo. This metric represents the actual amount of gas consumed to process a transaction on the blockchain.

The table breaks down the consumed gas for three different operations:

1) *Contract creation*: This is the process of deploying a smart contract on the blockchain. On BNB Smart Chain, Fantom, and Polygon, the gas used is the same as the gas limit (100%), implying that the entire computational resource allocation was utilized for this operation. However, on Celo, the gas used is 76.92% of the gas limit, suggesting a more efficient contract creation process on this platform.

2) *Create NFT*: This operation involves generating a Non-Fungible Token (NFT) on the blockchain. Again, BNB Smart Chain, Fantom, and Polygon utilize 100% of the allocated gas limit. On Celo, this operation uses 76.92% of the gas limit, indicating better computational efficiency.

3) *Transfer NFT*: This operation involves changing the ownership of an NFT from one address to another. The BNB Smart Chain platform uses 79.17% of the gas limit, while Fantom and Polygon platforms consume 93.41%. This suggests that BNB Smart Chain might be more efficient in handling NFT transfers. Conversely, Celo utilizes 69.8% of the gas limit for this operation, making it the most efficient platform among the four in terms of NFT transfer.

The table ultimately provides valuable insights into the computational efficiency of each platform. Notably, while some platforms use the entire gas limit for their operations (indicating that they are maximally utilizing the allocated resources), others use a portion of it, indicating that they are more computationally efficient. This data is critical in selecting a suitable platform for the deployment of the recommendation model, taking into account the trade-off between resource allocation and computational efficiency.

F. Gas Price

Table IV represents the “Gas Price” for executing transactions on four different Ethereum Virtual Machine (EVM) compatible blockchain platforms: BNB Smart Chain, Fantom, Polygon, and Celo. Gas prices are expressed in each blockchain platform’s native token (BNB, FTM, MATIC, and CELO, respectively) and in Gwei, where 1 Gwei equals 10^{-9} Ether.

Gas price, determined by the market conditions on the blockchain, is the cost per computational step required to execute a specific transaction or smart contract on the network.

The table breaks down the gas price for three different actions:

Contract Creation: The process of deploying a smart contract on the network. The gas prices for this action are 10 Gwei for BNB Smart Chain, 3.5 Gwei for Fantom, around 2.5 Gwei for Polygon (specifically, 2.500000011 Gwei), and 2.6 Gwei for Celo with a maximum fee per gas of 2.7 Gwei.

TABLE IV. GAS PRICE

	Contract Creation	Create NFT	Transfer NFT
BNB Smart Chain	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)	0.00000001 BNB (10 Gwei)
Fantom	0.000000035 FTM (3.5 Gwei)	0.000000035 FTM (3.5 Gwei)	0.000000035 FTM (3.5 Gwei)
Polygon	0.0000000250000011 MATIC (2.50000011 Gwei)	0.0000000250000012 MATIC (2.50000012 Gwei)	0.0000000250000013 MATIC (2.50000013 Gwei)
Celo	0.000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.000000026 CELO (Max Fee per Gas: 2.7 Gwei)	0.000000026 CELO (Max Fee per Gas: 2.7 Gwei)

Create NFT: The action of creating a Non-Fungible Token (NFT) on the network. The gas prices are identical to those for contract creation, except for Polygon, where it's slightly higher at 2.50000012 Gwei.

Transfer NFT: The operation of transferring the ownership of an NFT. Again, the gas prices are the same as for the other two operations, with the exception of Polygon, where the gas price is slightly higher at 2.50000013 Gwei.

This table is essential for understanding the costs involved in performing different actions on these platforms. It also helps in selecting a platform that balances the trade-off between computational needs and transaction costs. BNB Smart Chain has the highest gas price at 10 Gwei, while Polygon offers the most competitive gas price, hovering around 2.5 Gwei, with Celo and Fantom offering intermediate rates.

VII. DISCUSSION

A. Analysis of Transaction Costs across Different Blockchain Platforms

In our deployment assessment (VI), we detailed the transaction costs on four different EVM-enabled blockchain platforms—Binance Smart Chain (BNB), Polygon (MATIC), Fantom (FTM), and Celo (CELO)—considering three primary activities: contract creation, NFT creation, and NFT transfer. Our comprehensive examination highlighted not only the distinct monetary costs associated with each platform but also the computational costs (gas used) and gas prices.

Crucially, it is observed that the transaction value on a blockchain platform is directly influenced by the market capitalization of the platform's respective coin. As of our last observation on June 26, 2023, the total market capitalization of the four platforms—BNB, MATIC, FTM, and CELO—stood at \$50,959,673,206; \$7,652,386,190; \$486,510,485; and \$244,775,762, respectively. This market capitalization directly impacts the coin's value of each platform, although the number of coins issued at the time of system implementation is another significant factor. At the time of our evaluation, the total issuance of BNB, MATIC, FTM, and CELO was 163,276,974/163,276,974 coins; 8,868,740,690/10,000,000,000 coins; 2,541,152,731/3,175,000,000 coins; and 473,376,178/1,000,000,000 coins, respectively. Consequently, the value per coin, based traditionally on the number of coins issued and the total market capitalization, stood at \$314.98 for BNB, \$0.863099 for MATIC, \$0.1909 for FTM, and \$0.528049 for CELO.

B. Selection of Optimal Blockchain Platform for Proposed Model Deployment

Our assessments demonstrated that deploying our proposed model on Fantom offers significant advantages concerning system operating costs. Specifically, the generation and reception of NFTs incurs almost negligible fees on Fantom. Furthermore, the cost associated with creating contracts that carry a transaction execution value is extremely low, less than \$0.002.

C. Future Work

Building upon our findings, our future work will aim to implement more complex methods and algorithms, such as encryption and decryption processes, as well as more complex data structures. This will allow us to better observe the transaction costs associated with these advanced operations.

Additionally, deploying the proposed model in a real-world environment presents a compelling avenue for further research—specifically, implementing the recommendation system on the Fantom mainnet. In our current analysis, we have not taken into consideration issues related to user privacy policies, such as access control [37], [38] or dynamic policies [39], [40]. These are critical considerations that will need to be addressed in upcoming research activities.

Lastly, infrastructure-based approaches, such as gRPC [41], [42], Microservices[43], [44], dynamic transmission messages [45], and Brokerless systems [46], can be integrated into our model to enhance user interaction. For instance, we can introduce an API-call-based approach that allows for more dynamic and efficient communication between different components of the system.

VIII. CONCLUSION

In conclusion, this paper addressed the challenges of waste management and disposal in emerging economies like Vietnam by proposing a waste categorization and treatment model based on Blockchain technology, Smart Contracts, and Non-Fungible Tokens (NFTs). We highlighted the deficiencies in traditional waste management methods, particularly the lack of waste segregation and treatment at the source, leading to environmental pollution and health risks. The COVID-19 pandemic further emphasized the importance of proper waste treatment, especially in the healthcare sector. Unsafe handling of medical waste during the pandemic contributed to the spread of the disease. To address these issues, various waste management models leveraging Blockchain technology have been proposed, but they primarily focus on tracking and tracing waste rather than comprehensive waste treatment processes.

Our proposed model aims to enhance waste categorization and treatment in Vietnam by providing stakeholders with a transparent and efficient system. The use of Smart Contracts enables automated and secure waste management processes, while NFTs store essential information related to waste classification and compliance. This allows for better monitoring and implementation of sanctions or rewards based on waste management behavior.

We implemented the proposed model on four EVM-compatible platforms, namely BNB Smart Chain, Fantom, Polygon, and Celo, and evaluated their performance in terms of transaction fees, gas limits, gas used, and gas prices. Through our evaluation, we found that the Fantom blockchain platform offers the most cost-effective environment for deploying the waste management model, with negligible fees for NFT generation and low costs for contract creation. This study contributes to the field by introducing a waste categorization and treatment model customized for Vietnam and demonstrating its feasibility through a proof-of-concept implementation. The findings provide insights into the suitability of different blockchain platforms for waste management applications.

Future work includes implementing more complex methods and algorithms, considering privacy policies, and deploying the proposed model in real-world settings. Additionally, integrating infrastructure-based approaches, such as gRPC and microservices, can enhance user interaction and further optimize the waste management system.

Deep Learning-based Sentence Embeddings using BERT for Textual Entailment

Mohammed Alsuhaibani

Department of Computer Science, College of Computer,
Qassim University, Buraydah 52571, Saudi Arabia

Abstract—This study directly and thoroughly investigates the practicalities of utilizing sentence embeddings, derived from the foundations of deep learning, for textual entailment recognition, with a specific emphasis on the robust BERT model. As a cornerstone of our research, we incorporated the Stanford Natural Language Inference (SNLI) dataset. Our study emphasizes a meticulous analysis of BERT’s variable layers to ascertain the optimal layer for generating sentence embeddings that can effectively identify entailment. Our approach deviates from traditional methodologies, as we base our evaluation of entailment on the direct and simple comparison of sentence norms, subsequently highlighting the geometrical attributes of the embeddings. Experimental results revealed that the L_2 norm of sentence embeddings, drawn specifically from BERT’s 7th layer, emerged superior in entailment detection compared to other setups.

Keywords—Textual entailment; deep learning; entailment detection; BERT; text processing; natural language processing systems

I. INTRODUCTION

Textual entailment (TE), an essential notion within natural language processing (NLP), is expressed as a binary correlation between two segments of text [1]. Text T is stated to entail another text H if the comprehension gathered from T would compel a reader to deduce that H is most probable [2]. For example, the sentence “The dog is playing in the park” entails that “There is a dog at the park”. This unfolds as a unidirectional correlation, where TE serves as a fundamental pillar within NLP, supporting numerous applications in various disciplines.

TE’s multifaceted applications extend across diverse tasks, including question answering (QA) [3], where the precise extraction of responses from intricate texts hinges significantly on the correct discernment of entailment. It also impacts the effectiveness of information retrieval (IR) [4] tasks and the success of information extraction processes. TE is also an essential ingredient in the creation of text summarization [5, 6] mechanisms. The vast reach of these applications accentuates the crucial nature of textual entailment and the importance of its accurate identification.

Nonetheless, TE introduces a notable challenge, especially in terms of understanding the semantic relationships between sentences [7, 8, 9]. To tackle this, sentence embeddings have garnered significant attention lately. At their core, sentence embeddings are condensed vector depictions of sentences created to encode their semantic meanings within a fixed-dimensional vector [10]. The deployment of sentence embeddings enables swift and effective comparison and assessment of different

sentences, acting as an important instrument in a range of NLP tasks, including TE.

In the domain of sentence embeddings generation, deep learning has led the advancements. The hierarchical learning aptitudes of deep learning models enable them to produce semantically rich sentence embeddings, encompassing the intricate syntactic and semantic attributes of sentences. Notably, these models have demonstrated remarkable proficiency in discerning nuanced relationships, like entailment, among sentences [11, 12].

In recent advancements of deep learning for NLP, Transformer-based models, with particular emphasis on BERT (Bidirectional Encoder Representations from Transformers) [13], have signified noteworthy progress. The ability of BERT to consider the complete context of a sentence bi-directionally (left and right) permits the creation of superior-quality sentence embeddings. This unique capability has earned BERT widespread recognition and usage in the NLP community, particularly for tasks such as TE [14, 15, 16].

The assessment of various methods and models in TE rests on numerous specific datasets. The Stanford Natural Language Inference (SNLI) [1] dataset is one such resource, offering a large collection of sentence pairs annotated for entailment, contradiction, and neutrality. Resources like SNLI enable consistent and comparable evaluation of different TE techniques, encouraging advancement in the field.

Despite the remarkable progress in TE, current methods, especially those founded on deep learning, still exhibit shortcomings. These include an intense dependence on complex architectural designs and extensive computational resources. In addition, a majority of these models primarily concentrate on the syntactic features of sentences, frequently neglecting the geometric attributes of sentence embeddings.

To address these issues, our study delves into the detailed examination of the use of sentence embeddings for TE. Utilizing, directly, the strength of the BERT model, we scrutinize the effects of employing varying layers for the extraction of sentence embeddings. Our study departs from traditional methods by assessing entailment through the comparison of sentence norms, thereby focusing on the geometric characteristics of the embeddings, a less explored yet potentially beneficial aspect.

Our hands-on findings underline the good performance of the L_2 norm of sentence embeddings, specifically those extracted from the 7th layer of BERT. These findings offer a fresh perspective on the TE. Our results particularly emphasise the importance of layer selection in the extraction of sentence

embeddings as well as the consideration of the geometric properties of sentence embeddings in addressing TE.

The remainder of this paper unfolds as follows. We will first dive into the related work in Section II, where we discuss the key literature on textual entailment and sentence embeddings. In Section III we will share our proposed method which utilizes the BERT model. Next, in Section IV, we will discuss SNLI dataset that we used for our experiments. We then move to the experiments and results in Section V, where we lay out the outcomes of the experiments and interpret our results and speak on any limitations we have come across. And lastly, in the conclusion, Section VI, we will bring everything together by summarizing our findings, reaffirming what our study brings to the field, and pondering over potential areas for future research.

II. BACKGROUND AND RELATED WORK

Textual Entailment (TE), also known as Natural Language Inference (NLI), entails determining the relationship between two sentences, specifically, if one sentence (the hypothesis) implies, contradicts, or remains neutral to the other (the premise) [17]. This is a demanding task as it necessitates understanding the essence of both sentences and their interplay.

One method to accomplish TE employs sentence embeddings, which are vector representations encapsulating the semantic significance of sentences [18]. These embeddings can be used to train a model to anticipate the relationship dynamics between a pair of sentences.

There exists a plethora of techniques to generate sentence embeddings. A prevalent approach involves deploying a word embedding model to create word embeddings [19, 20, 11], which are then amalgamated to craft a sentence embedding. An alternative strategy employs a deep learning model specifically trained for generating sentence embeddings [21, 22].

BERT [13] has gained popularity as a deep learning model for sentence embeddings. As a transformer-based model, BERT is pre-trained on an extensive corpus of text, enabling it to effectively learn and represent word and sentence meanings. This capability is useful for a wide spectrum of NLP tasks, including TE. There has been a growing body of research on using BERT for TE. In fact, when Devlin et al. introduced BERT itself, it was trained using next-word prediction and missing-word prediction, allowing it to acquire meaningful word and sentence representations and has proven useful for several NLP tasks, including TE.

Moreover, Lin and Su [15] examine BERT's proficiency in handling TE tasks, particularly its capability to bypass any latent biases in the dataset. To simplify the investigation, they design a straightforward entailment judgment scenario using only binary predicates in clear English. The results suggest that BERT's learning curve is somewhat slower than expected. However, they found that incorporating task-specific features significantly improved the learning efficiency, leading to a data reduction by a factor of 1,500. This key discovery highlights the importance of domain knowledge in effectively utilizing neural networks for TE tasks.

Similarly, Gajbhiye et al. [23] introduce a new model for TE, dubbed External Knowledge Enhanced BERT (ExBERT).

It improves BERT's language understanding and reasoning capabilities by integrating commonsense knowledge from external sources into the existing contextual representation. The model uses BERT-derived contextual word representations to pull and encode relevant knowledge from knowledge graphs. It's designed to seamlessly blend this external knowledge into the reasoning process.

Pang et al. [24] have developed a method for integrating syntax into TE models. Their approach uses contextual token-level vector representations derived from a pre-trained dependency parser. This technique, similar to other contextual embedders, can be applied to a wide range of neural models. They tested this method with some established TE models, such as BERT. The findings showed an increase in accuracy across the benchmark datasets.

Cabezudo et al. [25] investigate various methods to enhance inference recognition in the ASSIN [26] dataset, a dataset specifically designed for entailment recognition in Portuguese. They also study the effects of adding external data, such as multilingual data or an automatically translated corpus, to improve model training. They use the multilingual pre-trained BERT model in their experiment and their results show an improvement in the ASSIN. Interestingly, their findings suggest that using external data does not significantly improve the performance of the model.

Wehnert et al. [27] have introduced three distinct methods for the classification of entailment. The first approach harmonizes Sentence-BERT embeddings with a graph neural network, while the second strategy leans on the specific LEGAL-BERT model, which undergoes additional training on the competition's retrieval task and is fine-tuned specifically for entailment classification. Their third method ingeniously employs the KERMIT encoder to embed syntactic parse trees and integrates this with a BERT model. Their study delves into the potential of this third tactic and provides insights into why the LEGAL-BERT submissions, among all entries, might have managed to edge out the graph-based method in performance.

Shajalal et al. [28] develop a new method for identifying the textual entailment relationship between a text and its hypothesis. They introduce a new semantic feature that uses empirical threshold-based semantic text representation. This approach makes use of an element-wise Manhattan distance vector-based feature, designed to understand the semantic entailment relationship within a text-hypothesis pair. They tested their method using several experiments on the benchmark entailment classification dataset, SICK-RTE [29], with a variety of machine learning algorithms. Their empirical sentence representation technique improved the semantic understanding of the texts and hypotheses.

Jiang and de Marneffe [30] have taken on the task of addressing an issue prevalent in TE datasets. They have come up with a strategy, redefining the use of the CommitmentBank for TE. Their idea is to adjust the emphasis on how committed a speaker is to the complements of clause-embedding verbs in a range of contexts that cancel entailment. This move leads to the creation of hypotheses that are free from artefacts and naturally intertwined with the premises. Even though their fresh approach lets a BERT-based model hit a good result with BERT, they stated that the model is not yet fully grasping

Fig. 1. Extraction of sentence embeddings from BERT with a *max* pooling strategy from the token-level embeddings [13].

the nuances of pragmatic reasoning and certain linguistic generalizations.

While the above-mentioned approaches significantly advanced TE, its reliance on intricate designs and significant computational power is notable. To rectify this, our research investigates the application of sentence embeddings in TE. We simply and directly utilize the BERT model’s potential, exploring the effects of various layers for sentence embeddings extraction. In contrast to conventional approaches, we utilize a simple and straightforward approach to evaluate entailment by comparing sentence norms, spotlighting the geometric aspects of embeddings, a relatively uncharted but potentially advantageous area.

III. PROPOSED APPROACH

Our approach to TE revolves around using BERT to extract sentence embeddings. While loading pre-trained BERT and tokenizer, we set configurations for sub-token pooling, which determines the token piece embeddings used in constructing the token embedding. Options include using the *first* subtoken, the *last* subtoken, both the *first* and *last*, or an *average* overall (mean). Additionally, we specify the layer (layers 1 to 12) from which the embeddings should be extracted. Specifically, as shown in Fig. 1, we generate sentence embeddings for each pair of sentences in the dataset. We will feed the premise and hypothesis into BERT and extract the output of the [CLS] special token, which is a fixed-length representation of the

entire input sequence. This will provide us with a pair of sentence embeddings that capture the semantic and syntactic information of the premise and hypothesis.

Given a pair of sentences (x, y) with $x = w_1, \dots, w_n$ and $y = w_1, \dots, w_m$ forming a tuple, we use the loaded pre-trained BERT model to encode each sentence individually. We employed two possible strategies: default document embeddings and token-based document embeddings.

In default document embeddings, we derive one vector representing the entire sentence as $E_{S_i} = TN(i)$, where $i \in x, y$ and TN denotes a Transformer-based network, BERT. Basically, it extracts one feature as the sentence embedding using a default pooling strategy that simply selects the first token feature [CLS] from the standard word-piece tokenization as proposed in BERT. On the other side, in the token-based document embeddings (Fig. 1), we extract a vector corresponding to each token in a sentence, for example, $S_x = (E_1, \dots, E_n)$, where $E_i = TN(w_i) \in \mathbb{R}^D$ (D is the embedding size). To generate a sentence vector, we then compute either a *min*, *max* or *mean* pool across all these token vectors.

$$E_{S_x} = \frac{1}{n} \sum_i^n E_i \quad (1)$$

When using the *mean*, we calculate an average across all vectors to derive a sentence vector. The sentence embedding of x , E_{S_x} , is calculated using (1), and E_{S_y} for y is computed

similarly. Besides the *mean*, we also test with other pooling strategies like *min* and *max*. *Min* involves sorting the token vectors based on their norm magnitude and using the vector with the least magnitude as the sentence vector. Conversely, *max* employs the vector with the largest norm magnitude as the sentence vector. We will use the *max* pooling in our experiments which empirically gives the best performance as we will detail in Section V.

Lastly, we predict entailment by comparing the norms of the pair of sentences in our input tuple. If the norm of x is greater than or equal to the norm of y , we consider it as entailment; otherwise, it is not (as shown in (2) and (3)). This approach provides a direct and effective way to determine TE.

$$V = \|E_{S_x}\|_2 \geq \|E_{S_y}\|_2 \quad (2)$$

$$\text{Entailment} = \begin{cases} \text{True} & \text{if } V(x, y), \\ \text{False} & \text{otherwise.} \end{cases} \quad (3)$$

IV. DATA

As a main dataset, we have leveraged the Stanford Natural Language Inference (SNLI) [1] dataset, a comprehensive collection of sentence pairs instrumental in training TE models. The SNLI is a robust dataset of approximately 570,000 human-authored English sentence pairs, each meticulously annotated to ensure balanced classification across three categories: entailment, contradiction, and neutral. Its wide acceptance and usage for training and testing models in TE have earned it the reputation of a standard benchmark within the field. It is worth noting that the creation of this dataset involved a crowdsourcing approach. Meaning human contributors generated the sentence pairs and assigned the entailment categories. This human involvement ensures the quality and reliability of the data.

SNLI dataset has been a pivotal element in the evolution of many contemporary NLP models, including transformative models like BERT and their subsequent iterations.

Table I features select examples from the SNLI dataset used in our approach. For ease of comprehension, we've adopted a color-coding scheme: instances of entailment are presented in green-shaded rows, neutral examples have been uncolored, while contradiction cases appear in rows shaded red. This approach to color differentiation offers an intuitive visualization of the varied sentence pairs that the SNLI dataset encompasses.

V. EXPERIMENTS AND RESULTS

A. Experimental Settings

In this section, we provide an outline of the steps we have followed to execute our experiments, covering the specific details of loading data, data preprocessing, and the application of pre-trained models and tokenizers.

Our experimental framework incorporates the use of the Hugging Face API¹ for the purpose of loading BERT pre-trained model and tokenizers. As part of our configuration

parameters, we have included a setting for sub-token pooling. This setting dictates the manner in which token piece embeddings are utilized to form the final token embedding.

The data loading process involves drawing sentences from one of two file formats: Excel (*.xlsx*) or JavaScript Object Notation (*.json*). Furthermore, we have prepared an alternate method to load data, using the Hugging Face dataset loader object as a substitute for traditional content loading from text or *json* files.

In the data preprocessing step, we apply a series of operations to refine and structure the data. Initially, we clean each sentence pair in the dataset by eliminating superfluous spaces found at the sentence boundaries. Following this, we organize the cleaned pairs of sentences into tuples, i.e., a sentence pair (*sentence1, sentence2*), culminating in a list of such tuples. This process ensures that our data is well-organized and conducive to subsequent tasks.

With the aid of the Hugging Face API, we have streamlined the process of loading BERT pre-trained weights for a variety of PyTorch² and TensorFlow³ models. This step is critical in harnessing the capabilities of BERT pre-trained model, which has already acquired useful representations from extensive text corpora, to kickstart our task-specific model.

Subsequent to extracting a vector that corresponds to each token in a sentence, we carry out additional processing on these token vectors to derive a unified sentence vector. As highlighted in Section III, this is achieved by implementing one of the multiple pooling strategies, *min*, *max* or *mean* across all token vectors.

Our initial experimentation revealed that the *max* pooling strategy surpassed the performance offered by the *min* and *mean* strategies. Hence, we chose to incorporate the *max* pooling strategy in all subsequent experiments for generating sentence vectors from token vectors. This choice proved pivotal in boosting the effectiveness of our entailment detection procedure.

Alongside our selected pooling strategy, we also examined the effect of different layers within the BERT model on our results. We extracted embeddings from a range of layers within BERT, extending from layer 1 to layer 12, and studied their influence on the task of TE. This experiment offers insight into the role each layer has in shaping the quality of sentence embeddings. This expansive exploration across all layers of the BERT model enables us to pinpoint the optimal layer for our specific task, a factor in boosting the efficacy of our entailment detection procedure.

In an extension to our experimental setup, we investigated the impact of various norms, L_1 , L_2 , and L_{∞} on the entailment detection. As norms play a vital role in comparing sentence embeddings in our methodology, experimenting with different norms helped us identify which norm leads to the most precise and reliable entailment predictions. The outcomes of these investigations are reported in our study, shedding light on the influence of each norm on the performance of our entailment detection approach.

TABLE I. RANDOMLY CHOSEN SAMPLES FROM THE SNLI DATASET USED IN THE PROPOSED APPROACH, COLOR-CODED BY ENTAILMENT CATEGORY

Text	Judgments	Hypothesis
A middle-aged man in a gray t-shirt and brown pants sitting on his bed reading a flyer-like paper.	entailment E E E E E	A man is sitting on his bed reading.
A young boy and girl playing baseball in a grassy field.	entailment N E E E E	Kids play baseball.
Numerous people sitting in a dim lit room talking, drinking coffee and using computers.	entailment E E E E E	People are in a dimly lit room drinking coffee.
A white race dog wearing the number eight runs on the track.	entailment E E E E E	A dog is running.
A woman reaching for candy bars that are on a shelf.	neutral N N E N C	The candy bars are above the womans head.
The boy wearing the blue hooded top is holding a baby goat in his arms.	neutral N C N N N	The goat jumped into the boys arms.
A little girl is sitting on a bench in a park.	neutral N N N N N	The little girl is having fun.
A small child playing in a dusty square.	neutral E N N N N	A child is playing with a doll.
Multiple people starting to pack their parachutes after a successful skydive.	contradiction C C C C C	cat chased by tiger.
A swimming dog with a small branch in its mouth.	contradiction C C C C N	A dog is ice skating.
A man with a mustache is playing ice hockey with snow in the background.	contradiction C C C C C	People are swimming in the lake.
A busy street full of shops and people holding hands and walking.	contradiction C C C C C	People sitting in a restaurant.

In Section III, we laid out our strategy for evaluating the proposed method, which, despite its apparent simplicity, yields potent results. The heart of our approach to entailment prediction lies in comparing the norms of the sentence pairs that make up our input tuple. If the norm of x equals or surpasses that of y , we mark it as an entailment instance. In contrast, if it fails to meet this criterion, we label it as non-entailment (refer to Equations (2) and (3) for further clarity). When it comes to gauging performance, we turn to the accuracy metric. This indicator gives us the ratio of successful classifications. By resorting to this measure, we can quantify how adept our model is at correctly categorizing sentence pairs in alignment with their actual entailment status. This simple yet effective measure offers a clear insight into our proposed approach's efficiency in entailment prediction.

B. Results and Discussion

The results reflected in Table II offer a thorough perspective of the outcomes generated through our proposed approach. We have incorporated accuracy percentages that depict the reper-

cussions of diversifying two primary parameters: the BERT model's layers (from 1 to 12) and the types of norms ($L1$, $L2$, and L -inf). Regardless of these alterations, the max pooling strategy remained a constant, thereby offering a consistent benchmark for comparison.

Our findings lead us to two insights. The first is related to the choice of norm type; the $L2$ norm systematically outpaced both $L1$ and L -inf norms regardless of the layer, and $L1$ come second. Whereas, L -inf performs poorly across the layers.

Our second insight arises from the analysis of BERT model's layers. As per the empirical findings, it appears that the 7th layer offers an optimal environment for the extraction of embeddings with as high accuracy as %91. This is important as it aids us in pinpointing the most suitable layer, thereby optimizing the sentence embedding generation process.

To simplify the understanding of the results and make them visually discernible, we have plotted the model's performance. For this, in Fig. 2, we considered the $L2$ norm (proven to offer superior results) and plotted its influence on the

TABLE II. PERFORMANCE ACCURACY OF THE PROPOSED APPROACH WITH BERT LAYER VARIATION AND NORM TYPES WITH MAX POOLING STRATEGY. BOLD INDICATES THE BEST PERFORMANCE FOR EACH NORM

Norm	Layers											
	1	2	3	4	5	6	7	8	9	10	11	12
L2	0.75	0.83	0.83	0.84	0.82	0.83	0.91	0.87	0.77	0.77	0.76	0.83
L1	0.73	0.81	0.81	0.81	0.77	0.74	0.80	0.83	0.65	0.60	0.57	0.59
L-inf	0.26	0.22	0.17	0.16	0.19	0.24	0.33	0.22	0.47	0.41	0.32	0.49

Fig. 2. Proposed approach performance with L2 norm and various layers.

varying layers, with the latter serving as the x -axis. Despite the changes in layers, we ensured the max pooling strategy remained unchanged, facilitating a focused study on the layers' influence. The resulting graph offers a straightforward visual comparison of the performance impact due to different layers.

VI. CONCLUSION

In this study, we have delved TE, using the expansive SNLI dataset as our sandbox. Our approach lies in leveraging the strength of pre-existing models, with an emphasis on the BERT model. Our methodology consists of extracting token embeddings and transforming them into sentence vectors. In our quest to streamline these vectors, we experimented with

several pooling strategies, min , max , and $mean$. Our observations consistently pointed towards the max pooling strategy as the most effective. We focused on the implications of various layers within the BERT model on the task of entailment detection. Our experiments revealed that the seventh layer of the model stood out as the most impactful for generating potent embeddings for this task.

Norms, too, were given considerable attention in our experimental setup. We tested different norms, namely $L1$, $L2$, and L -inf. Our findings tipped the scales in favor of the $L2$ norm, emphasizing the influential role norms play in determining the quality of entailment detection.

To sum it up, our research presents a direct and simple approach for effective entailment detection by utilizing BERT. It underscores the importance of which layers to select for extracting embeddings, the pooling strategies to implement, and the norms to use. Future exploration could include testing our approach on other pre-trained models and entailment datasets to enhance its generalizability.

An Approach of Test Case Generation with Software Requirement Ontology

Adisak Intana, Kuljaree Tantayakul, Kanjana Laosen, Suraiya Charoenreh
College of Computing, Prince of Songkla University, Phuket, Thailand

Abstract—Software testing plays an essential role in software development process since it helps to ensure that the developed software product is free from errors and meets the defined specifications before the delivery. As the software specification is mostly written in the form of natural language, this may lead to the ambiguity and misunderstanding by software developers and results in the incorrect test cases to be generated from this unclear specification. Therefore, to solve this problem, this paper presents a novel hybrid approach, Software Requirement Ontologies based Test Case Generation (*ReqOntoTestGen*) to enhance the reliability of existing software testing techniques. This approach enables a framework that combines ontology engineering with the software test case generation approaches. Controlled Natural Language (CNL) provided by the ROO (Rabbit to OWL Ontologies Authoring) tools is used by the framework to build the software requirement ontology from unstructured functional requirements. This eliminates the inconsistency and ambiguity of requirements before test case generation. The OWL ontology resulted from ontology engineering is then transformed into the XML file of data dictionary. Combination of Equivalence and Classification Tree Method (CCTM) is used to generate test cases from this XML file with the decision tree. This allows us to reduce redundancy of test cases and increase testing coverage. The proposed approach is demonstrated with the developed prototype tool. The contribution of the tool is confirmed by the validation and evaluation result with two real case studies, Library Management System (LMS) and Kidney Failure Diagnosis (KFD) Subsystem, as we expected.

Keywords—Software testing; software requirement specification; ontology; test case; equivalence and classification tree method

I. INTRODUCTION

Software testing is one of the most important stages to detect errors in software development. The number of software bugs are not mainly caused by the code or design. One of the main causes of software bugs is from the specification [1][2]. As software specification gathered from the user's needs is mostly written in common natural languages in the Software Requirements Specification (SRS) document [3][4][5], this leads unstructured requirements to be ambiguous and misunderstood by software developers [4][6][7]. Furthermore, in system and user acceptance testing, test cases are generated from the SRS. This may result in incorrect test cases to be generated from the unclear specification. Therefore, it is necessary that the requirement specification needs to be very clear and well-defined before generating test cases.

Ontology engineering has been applied in Requirements Engineering (RE). An ontology is a formal representation of entities and relationships in a domain of interest [8]. As the semantics of concepts are formally defined, an ontology can be

used as a formal specification for a program. A domain vocabulary, essential concepts with their taxonomy, relationships (and constraints) between concepts, and domain axioms are defined for specific program applications [8][9]. Thus, using ontologies to express requirement specifications has implications for advantage in managing complexity, contradictions, or detecting ambiguity and incompleteness of requirements [4][10][11]. The application of ontology to requirement specification can help to eliminate the problem of erroneous test case generation from ambiguous, inconsistent, or incomplete requirements. Thus, our challenge is to add value to software testing with ontology modelling in requirement specification [12].

Therefore, in our previous work [13], we presented how ontology engineering approach can enhance practical software testing. We proposed a conceptual vision of framework called *ReqOntoTestGen* (Requirement Ontology Testcase Generation) that combines the benefit of ontology to represent the semantics of requirement specification with Control Natural Language (CNL) and Classification Tree Method (CCTM) [14][15] testing technique to generate test cases. The ROO (Rabbit to OWL Ontology Authoring) tool [16] is used by this framework to design and develop an ontology with CNL or Rabbit Language. This results in the complexity of requirements in natural languages to be reduced and the semantic of requirements formally defined. The specific syntax of this tool increases the structure and eliminates the ambiguity of the requirement ontology. The result of this tool is an export in Web Ontology Languages (OWL) format to transform into a structured data dictionary, before it is considered with decision tree to generate all possible test cases. Furthermore, CCTM provided by *ReqOntoTestGen* framework also allows the number of generated test cases to be minimized by reducing the redundant test cases and the testing coverage that covers all possible testing scenarios to be maximized. We demonstrated manually the effectiveness of the framework with a real case study, Library Management System (LMS).

The work of this paper is extended from the previous work [13]. This paper proposed a semi-automatic approach for test case generation from the requirement specification ontology based on use case-based requirement specification. To demonstrate the practical implementation of the approach, we developed a prototype tool according to *ReqOntoTestGen* framework in which the ontology engineering and test case generation algorithm is implemented in the tool. Control Natural Language (CNL) enabled by the ROO tool is used to be a guideline and build conceptual ontologies from the requirement specification. To generate test cases, the result from the ROO tool, the ontology represented in terms of OWL format, is transformed into the XML file of data dictionary. The OWL and XML transformation rules were designed and

implemented into our prototype tool for this data dictionary transformation. CCTM techniques were implemented in the tool for automatic test case generation purposes. The XML file of decision tree specifying the constraint of test case generation is considered with the XML file of data dictionary to generate test cases. Moreover, the validity, effectiveness and accuracy of the approach and tool were guaranteed by two different case studies formulated from real-world systems, Library Management System (LMS) and Kidney Failure Diagnosis (KFD) Subsystem. We compared the actual result of test case generation from these case studies by the tool with the expected test cases calculated manually by the practical testers. Furthermore, the satisfaction level of the proposed approach and tool was evaluated by practical specialists for future use.

The remainder of the paper is organised as follows. Firstly, Section II explains an overview of the necessary background and related work, before the proposed approach and the real-world case studies for experimenting the effectiveness of the approach are described in Section III. In Section IV, the proof of concept of our proposed approach are demonstrated through the evaluation of the implemented prototype with the case studies. Section V discusses the lesson learned experienced from the study result. Finally, the conclusion and future work are described in Section VI.

II. RELATED WORK

Several research studies have been interested in using ontology in the software development process to increase the efficiency of developed products. For instance, [17] proposed the software process automation ontology (Sponto) that applied the ontology-based approach to generate a set of artefacts for the software development process such as user stories for requirement specification and SQL for database scripts. Another example is the work of [18] which introduced the mechanism for transforming security requirements described in the form of the natural language into a structured ontology. The inconsistencies of security requirements were also checked by this mechanism.

However, most studies focus on using ontology to represent the conceptualisation and knowledge information regarding software development domains. [19], for example, proposed the application of ontology to define the information and knowledge semantics in RE. Instead of using ontology to represent the semantic of the requirement itself, this work focused on the use of ontology to describe the way of structuring requirements in the SRS document. Similar to this, [20], [21] and [22] proposed a domain ontology for software requirement change management, requirement classification and use story assessment in requirement artefacts respectively. In [23], they proposed ROoST (Reference Ontology on Software Testing) that builds a set of interrelated ontology patterns related to the software testing concepts including its process, activities, artefacts and testing techniques for test case design in order to associate semantics to a large amount of test information. Similar to this [24], [25] and [26] applied the ontology-based method to represent the knowledge related to software testing activities. The common well-established vocabulary for testing is used in the ontology application. Their developed ontologies influence the benefit of knowledge sharing among the development team.

Furthermore, some studies focus more on the application of requirement ontologies to generate test cases in practice. [23], for instance, presented a combined inference to software requirement ontology to generate test cases based on software requirement specification. The test cases were obtained from test input, test procedure, and expected test results. The work proposed by [23][27] used inference rules based on reasoner to generate test cases and improve requirements coverage and domain coverage. Furthermore, [28] presented Web Ontology Language for Web Service (OWL-S) to describe the workflow in the web service application. Petri-Net is used to represent the meaning of the test process and OWL-S is used to generate test data. In addition, [29] presented application of OWL ontologies to generate test cases and test procedures based on controlled-English model. The closely related work is proposed by [30]. They proposed test case generation using a learning-based software testing approach based on requirement ontology to generate test cases. However, those research studies mentioned earlier only focus on the application of requirement specification ontology to generate test cases, they did not consider testing coverage in test case generation. Based on our literature reviews, it can conclude that most of the existing research studies focus on using ontology to represent the software testing concept and knowledge sharing in software engineering communities. A few studies considered more important in the use of requirement specification ontology in the software testing process to generate comprehensive test cases together with testing coverage analysis of test case generation.

III. MATERIALS AND APPROACH

A. ReqOntoTestGen Framework

Fig. 1 shows a framework of the test case generation with software requirement ontology (*ReqOntoTestGen*) proposed in our previous work [13]. There are four steps in this framework. (1) *Ontology Engineering* generates the ontology according to CNL from the functional requirement definition described in terms of natural language by using ROO-CNL authoring. CNL in ROO authoring enables the complex requirement to be transformed into a very simple requirement before generating the ontology. Then, the achieved requirement ontology is exported in terms of OWL format, before (2) *XML Generation* transforms the exported OWL into the XML data dictionary metadata. In (3) *Variable and Decision Tree Management*, it starts with the variable information extracted from the XML of use case defined in the SRS document, before the corresponding data structure of the extracted variable is extracted from the XML data dictionary. This, then, is considered with the XML file of decision tree for test cases generation. Finally, (4) *Test Case Generation* creates test cases from the variable and its conditions by using CCTM technique. CCTM test case generation technique was chosen to be implemented in the proposed framework as it provides the benefit in which the number of test cases are minimized by eliminating the redundant test cases and the testing coverage is maximized in which all possible range value of test input variables is expanded.

B. ReqOntoTestGen Algorithm

To achieve a better understanding of our *ReqOntoTestGen* Framework explained in Section III-A, this section describes

Fig. 1. The ReqOntoTestGen framework [13].

the algorithm of the framework in detail.

1) *Step 1: Ontology engineering:* In this step, the complexity of natural language based functional requirement and its corresponding constraints are reduced by transforming them into CNL structure. Then, the target ontology is developed from the transformed CNL based requirement. Table I shows an example of mapping from natural language-based requirement to ROO-CNL Structure and OWL2 Functional Syntax respectively. When classifying and structuring the ROO-CNL successfully, the ontology is exported in terms of file OWL format for data dictionary metadata generation in the next step.

TABLE I. EXAMPLE OF ROO STRUCTURE

Description	Roo-CNL Structure	OWL 2 Functional Syntax
Class Declaration	<i>cname</i> is a concept	Declaration(Class(: <i>cname</i>))
Subclass	Every <i>scname</i> is a kind of <i>cname</i>	SubClassOf(: <i>scname</i> : <i>cname</i>)
Relationship Declaration	<i>rname</i> is a relationship Every <i>cname1</i> <i>rname</i> <i>cname2</i>	Declaration(ObjectProperty(: <i>rname</i>)) ObjectPropertyDomain(: <i>rname</i> : <i>cname1</i>) ObjectPropertyRange(: <i>rname</i> : <i>cname2</i>)
Instance Declaration	<i>insname</i> is a <i>cname</i>	Declaration(NameIndividual(: <i>insname</i>)) ClassAssertion(: <i>cname</i> : <i>insname</i>)

2) *Step 2: The XML generation:* In this step, the OWL files obtained from the ontology are transformed into XML structures of data dictionary that is used for test case generation. The XML format is used for the target file transformed from the source of OWL file to make it easier to exchange data between programs [31]. Based on the study of [32][33], 13 relevant transformation rules are designed and used for transformation. All rules are available on our tool website¹.

Fig. 2 shows an example of transformation rules, consisting of the first column (Rules) as the rules of transformation. The second column (OWL2 Functional) is an OWL syntax. The last column (XML Schema) is an XML syntax. The transformation consists of three main categories, the structure of classes and relations, object property restrictions, and data property restrictions.

3) *Step 3: The variable and decision tree management:* This step considers two input files, the XML file of use

Rules	OWL2 Functional	XML Schema
The Structure of Classes and Relations		
1. Class Declaration	Class(: <i>cname</i>)	Local: <xs:element name=" <i>cname</i> "> <xs:complexType> </xs:complexType> </xs:element> Global: <xs:element name=" <i>cname</i> " />
2. Subclass Declaration	SubClassOf(: <i>scname</i> : <i>cname</i>)	<xs:element name=" <i>scname</i> " type=" <i>cname</i> " />
3. Object Property Declaration	ObjectProperty(: <i>hasClass</i>) ObjectPropertyDomain(: <i>hasClass</i> : <i>cdomain</i>) ObjectPropertyRange(: <i>hasClass</i> : <i>crange</i>)	<xs:element name=" <i>cdomain</i> "> <xs:complexType> <xs:sequence> <xs:element name=" <i>hasClass</i> " ref=" <i>crange</i> " /> </xs:sequence> </xs:complexType> </xs:element> <xs:element name=" <i>crange</i> "> <xs:complexType> </xs:complexType> </xs:element>
Object Property Restrictions		
5. Existential	EquivalentClasses(: <i>cdomain</i> ObjectSomeValuesFrom(: <i>hasClass</i> : <i>crange</i>))	<xs:element name=" <i>cdomain</i> "> <xs:complexType> <xs:sequence> <xs:element name=" <i>hasClass</i> " ref=" <i>crange</i> " /> </xs:sequence> </xs:complexType> </xs:element> <xs:element name=" <i>crange</i> "> <xs:complexType> <xs:choice> </xs:choice> </xs:complexType> </xs:element>
6. Universal	EquivalentClasses(: <i>cdomain</i> ObjectAllValuesFrom(: <i>hasClass</i> : <i>crange</i>))	<xs:element name=" <i>cdomain</i> "> <xs:complexType> <xs:sequence> <xs:element name=" <i>hasClass</i> " ref=" <i>crange</i> " /> </xs:sequence> </xs:complexType> </xs:element> <xs:element name=" <i>crange</i> "> <xs:complexType> <xs:all> <xs:all> </xs:complexType> </xs:element>
Data Property Restrictions		
11. Individual value	NameIndividual(: <i>individual1</i>) NameIndividual(: <i>individual2</i>) NameIndividual(: <i>individual3</i>) ClassAssertion(<i>cname1</i> : <i>individual1</i>) DataPropertyAssertion(: <i>dprop</i> : <i>individual1</i> "value1" <i>xsd:dtype</i>) ClassAssertion(<i>cname1</i> : <i>individual2</i>) DataPropertyAssertion(: <i>dprop</i> : <i>individual2</i> "value2" <i>xsd:dtype</i>) ClassAssertion(<i>cname1</i> : <i>individual3</i>) DataPropertyAssertion(: <i>dprop</i> : <i>individual3</i> "value3" <i>xsd:dtype</i>)	<xs:element name=" <i>dprop</i> "> <xs:complexType> <xs:choice> <xs:element name=" <i>value1</i> " type=" <i>xsd:dtype</i> " /> <xs:element name=" <i>value2</i> " type=" <i>xsd:dtype</i> " /> <xs:element name=" <i>value3</i> " type=" <i>xsd:dtype</i> " /> </xs:choice> </xs:complexType> </xs:element>
12. Minimum cardinality	EquivalentClasses(: <i>cname</i> DataMinCardinality(<i>min</i> : <i>dprop</i> <i>xsd:dtype</i>))	<xs:element name=" <i>cname</i> "> <xs:complexType> <xs:sequence> <xs:element name=" <i>dprop</i> " type=" <i>xsd:dtype</i> " minOccurs=" <i>min</i> " /> </xs:sequence> </xs:complexType> </xs:element>
13. Maximum cardinality	EquivalentClasses(: <i>cname</i> DataMaxCardinality(<i>max</i> : <i>dprop</i> <i>xsd:dtype</i>))	<xs:element name=" <i>cname</i> "> <xs:complexType> <xs:sequence> <xs:element name=" <i>dprop</i> " type=" <i>xsd:dtype</i> " maxOccurs=" <i>max</i> " /> </xs:sequence> </xs:complexType> </xs:element>

Fig. 2. Example of OWL and XML transformation rules.

cases and the XML file of data dictionary transformed from the OWL of requirement ontology. The use case files are designed from requirements in the SRS document according to UML Development Guidelines Version 2.0 [34]. The use case normally demonstrates the overview of functionality and procedure of the system to generate test cases. Fig. 3 shows

¹ <https://sites.google.com/phuket.psu.ac.th/reqontotestgen/>

an example of brief description of use case UC001 describing the behaviour of function *Borrow Item* of LMS. To represent the function behaviour, a sequence of the step-by-step is used including main flow of events for the most common success scenario, alternative flow of events for other less common success scenario and exception flow of events for the error management scenario. The input and output for function operation, then, are indicated from the use case corresponding steps. The data structure of input and output variables are described in the XML files of data dictionary transformed from the OWL of requirement ontology.

Use Case	Description
UC001-Borrow Item	<p>Use Case ID: UC001</p> <p>Use Case Name: Borrow Item</p> <p>Pre-Condition: Checking members of the library</p> <p>Post-Condition: Borrow items successfully</p> <p>Priority: High</p> <p>Flow of Event: 1. The system shows GUI for a list of items to borrow 2. Member select items to borrow 3. Member confirm borrow items [A1] 4. The system records the borrowed items 5. The system displays a list of borrowed items</p> <p>Alternative Flow: [A1] If click "Cancel" button, the system will not records [E1]</p> <p>Exception Flow: [E1] The system shows the warning "Confirm cancellation?"</p>

Fig. 3. Example of use case detail.

4) *Step 4: Test case generation:* Our framework implements CCTM technique for test case generation. It generates test cases from the extracted input variable with the corresponding data structure. The test case generation process is described as follows.

Step 4.1: Classification Tree Generation with CTM Technique. CTM technique generates a classification tree from the information extracted from the use case. It starts with the name of the system represented by the use case name to be a root node of the tree. Then, it layers the tree from the root node to the terminal classification node with the subsystem and its corresponding variables respectively. The leaf node of the tree, terminal class, defines the range of variable values which are considered to create partitions for both valid and invalid data values by ECP technique. This data range value is used to generate test cases in the later step. An example of classification tree for function *Borrow Item* of LMS resulted from CTM is shown in Fig. 4. The variables and their corresponding range value are visualised in terminal classification (parent node) and terminal class (leaf node) of the tree respectively. This can be explained as follows: $Member = \{AdminStaff, Grad, Lecturer, Undergrad, None\}$, $Item = \{Book, CD, DVD, None\}$, $borrowDate = \{beginDate-endDate, None\}$ and $maxDaysBorrow = \{7, 14, 30, None\}$. These are considered to create an equivalence class partitioning in the next step.

Step 4.2: Test Case Generation with ECP Technique. In the

Fig. 4. Example of a classification tree for function *Borrow Item* of LMS.

classification tree achieved from CTM technique, ECP divides the terminal classification into equivalence classes for each possible range of data values. The framework implemented a strong robust format [4] to generate a test case. The equivalence class in this form considers both valid and invalid values of all classes of equivalence and allows the test case generation to cover every possible value of all equivalence classes. An example ECP for function *Borrow Item* of LMS is shown in Fig. 5.

Fig. 5. Example of equivalence class partitioning for function *Borrow Item* of LMS.

C. Case Studies

To demonstrate the effectiveness of our proposed approach, case studies from the real world system are used. We consider two different case studies for this purpose. One is a Library Management System (LMS) deployed in Prince of Songkhla University, Phuket. The other is Kidney Failure Diagnosis (KFD) subsystem from Hospital Information System (HIS) replicated from [15]. The following sections describe the case study information together with the demonstration of how our approach manually works.

1) *Library Management System (LMS):* The LMS² is a system for managing various library resources. The members of the library can borrow or return resources such as books, CDs, or DVDs. Each type of member has different borrowing

²<http://library.phuket.psu.ac.th/>

conditions. To generate a test case, we considered the return function that contains fine calculation when the late return occurs. The detailed information as well as practical requirements were formulated from the LMS of Prince of Songkla University.

Requirements: The functional requirements of LMS is shown in Table II.

TABLE II. THE FUNCTIONAL REQUIREMENTS OF LMS

Req. ID	Requirements
LIB-FUN-01	Members can borrow item including books, CDs or DVDs.
LIB-FUN-02	Members are classified into admin staff, graduate student, lecturer and undergraduate.
LIB-CON-01	Books, CDs, DVDs must be disjointed.
LIB-CON-02	Admin, staff, graduate student, lecturer and undergrade must be disjointed.
LIB-CON-03	Maximum borrowing items and borrowing periods: 5 books per 7 days for admin staff and undergraduate students, 10 books per 14 days for graduate students, and 15 books per 30 days for lecturers.
LIB-CON-04	Maximum borrowing items and borrowing periods: 3 discs per 7 days for all members.

Ontology Engineering: From the functional requirements of LMS as shown in Table II, it can be used to design and develop an ontology which consists of classes, relationships, and data properties. The ontology syntax of LMS is shown in Fig. 6.

Req. ID	Roo-CNL Structure	OWL2 Functional Syntax
LIB-FUN-01	<i>Member</i> is a concept <i>Item</i> is a concept Every <i>Book</i> is a kind of <i>Item</i> Every <i>CD</i> is a kind of <i>Item</i> Every <i>DVD</i> is a kind of <i>Item</i> <i>hasBorrow</i> is a relationship Every <i>Member</i> <i>hasBorrow</i> <i>Item</i>	Declaration(Class(: <i>Member</i>)) Declaration(Class(: <i>Item</i>)) SubClassOf(: <i>Book</i> : <i>Item</i>) SubClassOf(: <i>CD</i> : <i>Item</i>) SubClassOf(: <i>DVD</i> : <i>Item</i>) Declaration(ObjectProperty(: <i>hasBorrow</i>)) ObjectPropertyDomain(: <i>hasBorrow</i> : <i>Member</i>) ObjectPropertyRange(: <i>hasBorrow</i> : <i>Item</i>)
LIB-FUN-02	Every <i>AdminStaff</i> is a kind of <i>Member</i> Every <i>Grad</i> is a kind of <i>Member</i> Every <i>Lecturer</i> is a kind of <i>Member</i> Every <i>UnderGrad</i> is a kind of <i>Member</i>	SubClassOf(: <i>AdminStaff</i> : <i>Member</i>) SubClassOf(: <i>Grad</i> : <i>Member</i>) SubClassOf(: <i>Lecturer</i> : <i>Member</i>) SubClassOf(: <i>UnderGrad</i> : <i>Member</i>)
LIB-CON-01	<i>DisjointClasses</i> ()	DisjointClasses(: <i>Book</i> : <i>CD</i>) DisjointClasses(: <i>Book</i> : <i>DVD</i>) DisjointClasses(: <i>CD</i> : <i>DVD</i>)
LIB-CON-02	<i>DisjointClasses</i> ()	DisjointClasses(: <i>AdminStaff</i> : <i>Grad</i>) DisjointClasses(: <i>AdminStaff</i> : <i>Lecturer</i>) DisjointClasses(: <i>AdminStaff</i> : <i>UnderGrad</i>) DisjointClasses(: <i>Grad</i> : <i>Lecturer</i>) DisjointClasses(: <i>Grad</i> : <i>UnderGrad</i>) DisjointClasses(: <i>Lecturer</i> : <i>UnderGrad</i>)
LIB-CON-03	<i>borrowDaysR1</i> is a <i>maxDaysBorrow</i>	Declaration(NameIndividual(: <i>borrowDaysR1</i>)) ClassAssertion(: <i>AdminStaff</i> : <i>borrowDaysR1</i>) DataPropertyAssertion(: <i>maxDaysBorrow</i> : <i>borrowDaysR1</i> "7"^^xsd:integer)
LIB-CON-04	And, configure data property assertion directly through GUI in the tool.	
LIB-FUN-03	<i>hasReturn</i> is a relationship Every <i>Member</i> <i>hasReturn</i> <i>Item</i>	Declaration(ObjectProperty(: <i>hasReturn</i>)) ObjectPropertyDomain(: <i>hasReturn</i> : <i>Member</i>) ObjectPropertyRange(: <i>hasReturn</i> : <i>Item</i>)
LIB-FUN-04	<i>DataProperty</i> () <i>DataPropertyDomain</i> () <i>ObjectSomeValuesFrom</i> () <i>DataPropertyRange</i> ()	Declaration(DataProperty(: <i>fine</i>)) DataPropertyDomain(: <i>fine</i> : <i>Member</i>) ObjectAllValuesFrom(: <i>hasReturn</i> : <i>Member</i>) DataPropertyRange(: <i>fine</i> :xsd:integer)

Fig. 6. The ontology syntax of LMS.

Fig. 7 shows the ontology structure of LMS generated by ROO tool. It consists of two classes that are related to each other. The *Member* class is a member of the library including *AdminStaff*, *Grad*, *Lecturer*, and *UnderGrad*. The *Item* class is a library resource that can be borrowed including *Book*, *CD*, and *DVD*. The *ObjectProperty* between the *Member* and *Item* classes represents the relationship in which members can borrow (*hasBorrow*) library resources. Another relationship, *hasReturn* is a relationship where members can return library resources after they have been borrowed. Furthermore, the *DataProperty* is also an entity of data, the domain is a

class, and the data type is a range of data properties. For example, *borrowDate* has class *Member* to be a domain and *xsd:dateTime* to be a range. Moreover, an individual or instance of value such as *borrowDayR1* "7" is the condition for the maximum of days to borrow the *Book* of *UnderGrad* member type.

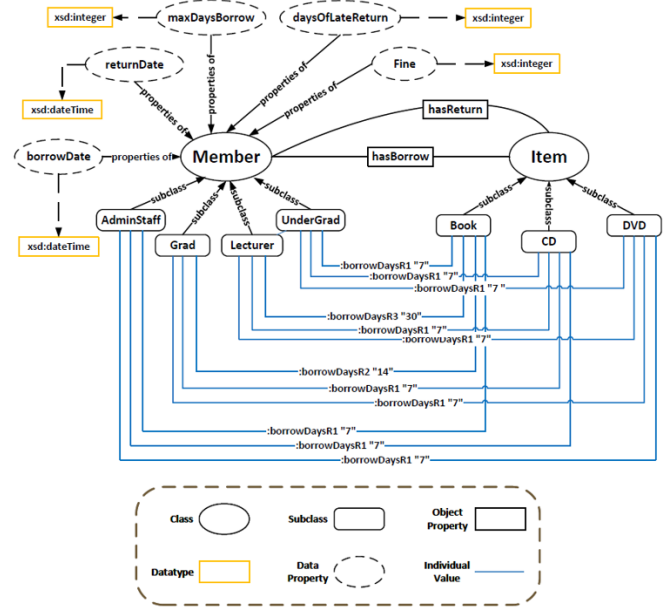

Fig. 7. The ontology structure of LMS.

Test Case Generation: Fig. 8 demonstrates the classification tree resulted from CTM technique. In the tree, *Library Management System* as a system name is considered to be a root node, before the subsystem *Return Item* is defined as a terminal classification in the next level. Variables *Member*, *Item*, *borrowDate*, *returnDate*, *maxDaysBorrow*, *daysOfLateReturn*, and *fine* related to this function are defined in the below level in the tree. These variables are considered to generate test cases by using ECP in the later step. The terminal class of each terminal classification defining the possible range of value is used to be a partition for generating test cases and test data in ECP.

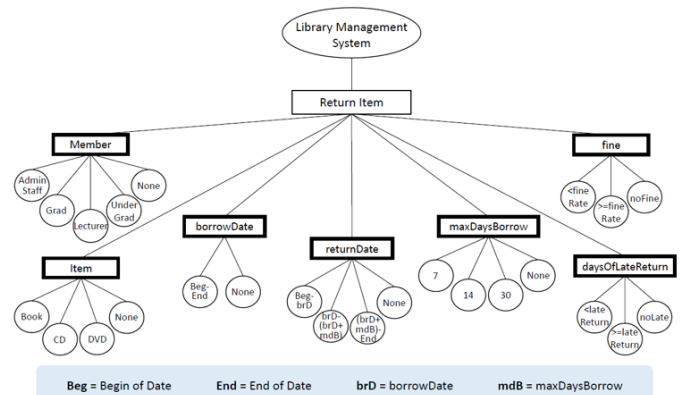

Fig. 8. The classification tree of LMS.

Test cases are generated from the Cartesian product of all

equivalence classes defined in four input variables (*Member*, *Item*, *borrowDate*, *returnDate*). There are a total of 160 (5*4*2*4) test cases to be generated. An example of test cases and test data is shown in Table III.

TABLE III. EXAMPLE OF TEST CASES AND TEST DATA FOR TESTING RETURN OPERATION

TC#	Member	Item	borrow Date	return Date	maxDays Borrow	daysOf LateReturn	fine	Comments
1	AdminStaff	Book	1/7/2019	2/7/2019	7	0	0	Valid
2	AdminStaff	Book	5/7/2019	15/7/2019	7	3	9	Valid
...
67	Lecturer	Book	10/7/2019	9/6/2019	30	-1	-3	Invalid
68	Lecturer	Book	10/7/2019	None	30	None	None	Invalid
...
160	None	None	None	None	None	None	None	Invalid

Table III is the test case generation result for testing return operation. Consider test case #1, it is a normal test case in which there is no late return for *AdminStaff*. This test case is different from test case #2. This results in the fine of 9 (3*3) to be calculated. Furthermore, the generated test cases cover in the case of invalid. In invalid test case #67, for example, it defines the return date before the borrowing date.

2) *Kidney Failure Diagnosis (KFD) Subsystem*: The KFD subsystem is a system for recommending the treatment appropriately to physicians for patients that have kidney dysfunction. It is calculated from the *Glomerular Filtration Rate (GFR)* result, consisting of *sex*, *age*, and *creatinine result (SCr)*. The *GFR* and *Urine Creatinine (UO)* results are paired to interpret the stage of kidney failure. This case study is based on [15]. It is an open-source system and is part of the Hospital Information System called HospitalOS³. It is a system that is installed and used in community hospitals and more than 100 clinics in Thailand.

Requirements: The functional requirements of KFD that design and develop an ontology comprise a total of four requirements as shown in Table IV.

TABLE IV. THE FUNCTIONAL REQUIREMENTS OF KFD

Req. ID	Requirements
KFD-FUN-01	Stage is paired with GFR and UO.
KFD-FUN-02	Stage of GFR includes ESRD, Loss, Failure, Injury and Risk.
KFD-CON-01	ESRD, Loss, Failure, Injury, Risk must be disjointed.
KFD-CON-02	GFR is calculated with sex, age, height and SCr.

Ontology Engineering: From the functional requirements of KFD in Table IV, it can be used to design and develop an ontology which consists of classes, relationships, and data properties. The ontology syntax of KFD is shown in Fig. 9.

Fig. 10 shows the ontology structure of KFD resulted from ROO tool. It consists of three classes: *Stage*, *GFR*, and *UO*. The stage of kidney failure includes *ESRD*, *Loss*, *Failure*, *Injury*, and *Risk*. The *ObjectProperty* is the relationship between classes. For example, *hasPair* is a relationship between *GFR* and *UO* class to represent a pair to interpret the stage of kidney failure. Furthermore, the *DataProperty* is also an entity of data. As *GFR* contains *Scr*, *Height*, *Age* and *Sex*, they are defined as a data property. In the data property, the domain is a class and the data type is a range. For example, *Height* has class *GFR*

Req. ID	Roo-CNL Structure	OWL2 Functional Syntax
KID-FUN-01	Stage is a concept GFR is a concept UO is a concept hasGFR is a relationship Every Stage hasGFR GFR	Declaration(Class(:Stage)) Declaration(Class(:GFR)) Declaration(Class(:UO)) Declaration(ObjectProperty(:hasGFR)) ObjectPropertyDomain(:hasGFR :Stage) ObjectPropertyRange(:hasGFR :GFR)
KID-FUN-02	Every ESRD is a kind of Stage Every Loss is a kind of Stage Every Failure is a kind of Stage Every Injury is a kind of Stage Every Risk is a kind of Stage	SubClassOf(:ESRD :Stage) SubClassOf(:Loss :Stage) SubClassOf(:Failure :Stage) SubClassOf(:Injury :Stage) SubClassOf(:Risk :Stage)
KID-CON-01	DisjointClasses()	DisjointClasses(:ESRD :Loss) DisjointClasses(:ESRD :Failure) DisjointClasses(:ESRD :Injury) DisjointClasses(:ESRD :Risk) DisjointClasses(:Loss :Failure) DisjointClasses(:Loss :Injury) DisjointClasses(:Loss :Risk) DisjointClasses(:Failure :Injury) DisjointClasses(:Failure :Risk) DisjointClasses(:Injury :Risk)
KID-FUN-03	DataProperty() DataPropertyDomain() DataPropertyRange() sex1 is a Sex And. configure data property assertion directly through GUI in the tool.	Declaration(DataProperty(:Sex)) DataPropertyDomain(:Sex :GFR) DataPropertyRange(:Sex xsd:integer) Declaration(NameIndividual(:sex1)) DataPropertyAssertion(:Sex :sex1 "Female"^^xsd:string)

Fig. 9. The ontology syntax of KFD.

to be a domain and *xsd:integer* to be a class range including the restriction of data property is 0-300 (0-300^^xsd:integer). Another example is *Sex* which has a domain to be class *GFR* and a range to be *xsd:string*. For this property, two individuals or instances are defined *Female* and *Male* to represent the gender of the patient.

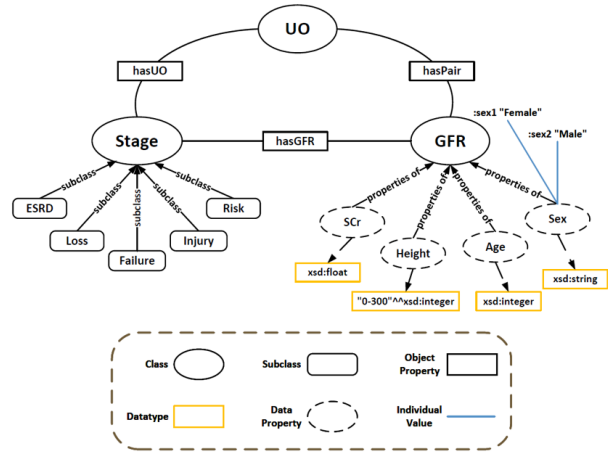

Fig. 10. The ontology structure of KFD.

Test Case Generation: Fig. 11 demonstrates the classification tree resulted from CTM technique. In the tree, *GFR Module* as a system name is considered to be a root node, before the subsystem *GFR Interpreted* is defined as a terminal classification in the next level. Variables *Sex*, *Age*, *Height*, *Scr*, *GFR*, *UO*, and *Stage* related to this function are defined in the below level in the tree. These variables are considered to generate test cases by using ECP in the later step. The terminal class of each terminal classification defining the possible range of value is used to be a partition for generating test cases and test data in ECP.

Table V is the test case generation result for testing *GFR interpreted* operation. Consider test case #1, it is a valid test case for *GFR* calculation of a female patient less than 18 years old. This result of the stage of kidney failure interpreted as the *Injury*. Furthermore, the generated test cases cover in the case

³http://www.opensource-technology.com

Fig. 11. The classification tree of KFD.

of invalid. In test case #144, it is an invalid test case because the data value is out of the range of interest.

TABLE V. EXAMPLE OF TEST CASES AND TEST DATA FOR TESTING RETURN OPERATION

IV. PROOF OF CONCEPT

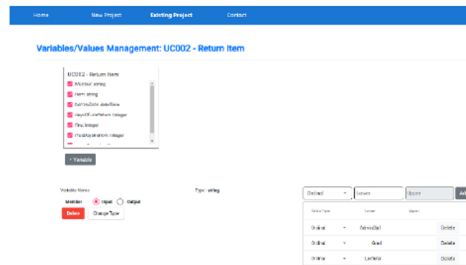

A. Tool Development

To demonstrate the effectiveness of *ReqOntoTesGen* approach, a prototype tool was developed. The developed tool is a Java based web application using Node.js 16.14.0⁴ JavaScript runtime environment that is well known and widely used.

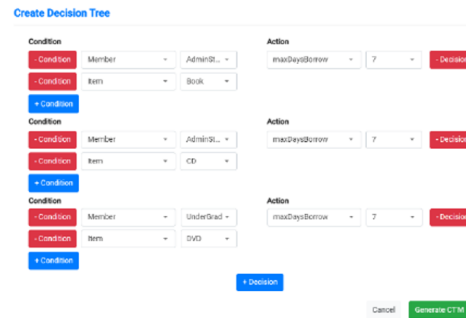

Fig. 12 demonstrates an example of our developed tool. Fig. 12a shows the screen for importing the necessary XML file. Two types of XML files are imported into the tool (1) the XML file of use cases indicating functionality from SRS documents and (2) the OWL file of requirement specifications created by the ROO tool. Then, the XML file of data dictionary is automatically generated from the OWL file. All extracted variables and their range value from the XML file of data dictionary are analysed. This includes variable name, variable type and variable range value as shown in Fig. 12b. The next step is the decision tree creation in the case that the system uses the condition for decision making on the operation process. The condition and decision of the decision tree can be adjusted as necessary as demonstrated in Fig. 12c. This decision tree is considered with the transformed data dictionary to generate test cases by the CCTM technique in the tool. The classification tree and equivalence partition of related variables resulted from CCTM are shown on the screen as demonstrated in Fig. 4 and 5 respectively. Test cases are automatically generated from this classification tree and equivalence partition. The result of test case generation is shown on the screen as in Fig. 12d.

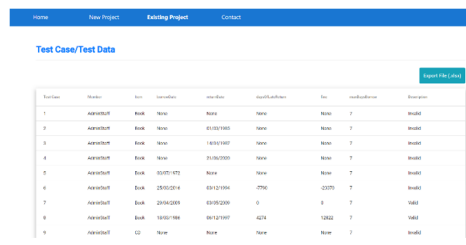

(a) The import file management screen

(b) The variables and values management screen

(c) The screen for adding decision tree

(d) The test case / test data generation screen

Fig. 12. Example of the tool screens.

B. Tool Validation

To validate the developed tool whether all functionalities of the tool perform correctly according to the *ReqOntoTestGen* framework proposed in Section III. Three test scenarios corresponding to three steps of the framework were conducted as shown in Table VI. This includes 1) *TS-01 Validate OWL transformation to XML function* with 13 relevant designed transformation rules. 2) *TS-02 Validate variable and decision tree management function* to validate the correctness of extracted variables from the XML file of use case and data dictionary together with the decision tree information. 3) *TS-03 Validate test case generation function* that validates the correctness of test case generation with CCTM techniques.

⁴<https://nodejs.org/en/about/>

TABLE VI. THE RESULT OF TOOL TESTING

Test Scenario	Result	Revision
TS-01 Validate OWL transformation to XML function	Fail	Pass
TS-02 Validate variable and decision tree management function	Pass	-
TS-03 Validate test case generation function	Pass	-

Table VI demonstrates the validation result. This led us to reveal an error that occurred in *TS-01*. The validation result of *TS-01* was *Fail* because the individual value transformation rule generated the wrong order in the XML element as shown in Fig. 13a This resulted in the data property element e.g., *maxDaysBorrow* to be generated outside the class element. This violated our designed transformation rules in which the data property needs to be inside the class. This led us to restructure the rule according to the design. Fig. 13b shows the corrected version of this error that resulted in this testing scenario to be *Pass*.

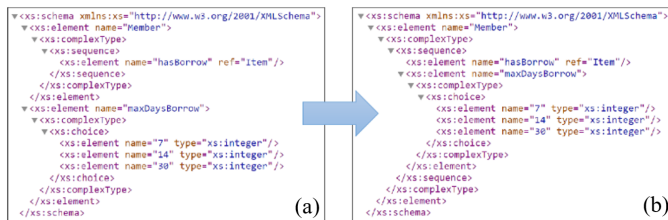

Fig. 13. The error of *TS-01*.

C. Tool Evaluation

We evaluated the effectiveness of our proposed approach with two real case studies, Library Management System (LMS) and Kidney Failure Diagnosis (KFD) subsystem. This evaluation is divided into two parts that are 1) effectiveness evaluation and 2) satisfaction evaluation.

1) *Effectiveness evaluation*: The precision, recall and F-measure computation were calculated by comparing the result produced by the manual operation and automated tool. The computation metrics were adapted from [35] as follows.

$$Precision = \frac{|\{Expert\ Identified\} \cap \{Tool\ Identified\}|}{|\{Tool\ Identified\}|} \times 100 \quad (1)$$

$$Recall = \frac{|\{Expert\ Identified\} \cap \{Tool\ Identified\}|}{|\{Expert\ Identified\}|} \times 100 \quad (2)$$

$$F - measure = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (3)$$

TABLE VII. THE RESULT OF IMPACT ANALYSIS

System	# Test cases		Precision	Recall	F-measure
	identified by an expert	identified by the tool			
LMS	300	160	100%	53.33%	69.56%
KFD	144	144	100%	100%	100%

Table VII demonstrates the comparison results between the expected test case manually created by experts and the actual test case automatically generated by the tool. Considering the calculated F-measure with precision and recall of KFD case study, the accuracy of the automatic tool performing with this

case study is very high. This is because KFD case study is not a complex case study compared to LMS case study. However, considering the calculated F-measure, with precision and recall of LMS, they are quite low. We have found that in the manual design of test cases by experts, the out of range of variable *borrowDate* and *returnDate* was identified as invalid partition. This led to 300 (5*4*3*5) test cases to be created. However, after we revealed this case, we discovered that this type of *dateTime* variable has the range of time from “*Begin of Date*” to “*End of Date*” that can be selected at any time for testing. Therefore, it is impossible to be “*Out of Range*”. This led us to recalculate the number of created test case after cutting these “*Out of Range*” partition (partitions 12 and 13 in Fig. 14) and resulted in this recalculation to be the same as calculated by the tool.

Partition	Num of Partition	Valid Data	Invalid Data
Member (input)	5	AdminStaff ⁽¹³⁾ , Grad ⁽¹⁴⁾ , Lecturer ⁽¹⁵⁾ , UnderGrad ⁽¹⁶⁾	None ⁽⁵⁾
Item (input)	4	Book ⁽¹⁶⁾ , CD ⁽¹⁷⁾ , DVD ⁽¹⁸⁾	None ⁽⁹⁾
borrowDate (input)	3	Begin of Date – End of Date ⁽¹⁹⁾	None ⁽¹¹⁾ , Out of Range ⁽¹²⁾
returnDate (input)	5	hasBorrowDate – ⁽¹³⁾ (hasBorrowDate + hasMaxDaysBook) – End of Date ⁽¹⁴⁾	Begin of Date – ⁽¹⁵⁾ (hasBorrowDate + hasBorrowDate) – End of Date ⁽¹⁶⁾ , None ⁽¹⁶⁾ , Out of Range ⁽¹⁷⁾
maxDaysBorrow (fix rate)	4	7 ⁽¹⁸⁾ , 14 ⁽¹⁹⁾ , 30 ⁽²⁰⁾	None ⁽²¹⁾
daysOfLateReturn (output)	3	1 – Late Return ⁽²²⁾ , None ⁽²³⁾	Smallest Number – 1 ⁽²⁴⁾
fine (output)	3	1 x Fine Rate – ⁽²⁵⁾ daysOfLateReturn x Fine Rate	None ⁽²⁶⁾ , Smallest number – Fine Rate ⁽²⁷⁾

Fig. 14. The partition of variable change.

2) *Satisfaction evaluation*: The satisfaction of our proposed approach and tool was evaluated with a wide range of experts that have at least five years in software engineering and software testing. This included two programmers and three testers. We designed questions for satisfactory evaluation, *Q1) Functionality*, *Q2) Efficiency and reliability*, *Q3) Usability*, and *Q4) Ability and applicability* that is shown in Table VIII.

TABLE VIII. SATISFACTION QUESTIONS

Questions	Average
Q1. Functionality	
Q1.1 The function can operate accurately and appropriately.	Likert scale (Mandatory)
Q1.2 The function can operate with each other.	Likert scale (Mandatory)
Q1.3 The function can operate according to the users' requirements.	Likert scale (Mandatory)
Q2. Efficiency and reliability	
Q2.1 The prototype can appropriately process the test cases.	Likert scale (Mandatory)
Q2.2 The prototype can increase the structure of functional requirements.	Likert scale (Mandatory)
Q2.3 The prototype can reduce errors caused by functional requirements.	Likert scale (Mandatory)
Q2.4 The prototype can work completely.	Likert scale (Mandatory)
Q3. Usability	
Q3.1 The prototype is easy to learn and understand.	Likert scale (Mandatory)
Q3.2 The prototype is easy to use, and the function is not complicated.	Likert scale (Mandatory)
Q4. Ability and applicability	
Q4.1 The prototype can be applied in the system or other case studies.	Likert scale (Mandatory)
Q4.2 The prototype can be easily installed and used.	Likert scale (Mandatory)

The Likert scale was used to design the levels of satisfactory for each question including Strongly Agree (5), Agree (4),

Neutral (3), Disagree (2), and Strong Disagree (1) respectively. The evaluation result of the satisfactory is shown in Fig. 15.

Fig. 15. Results of the four Likert scale questions.

As can be seen in Fig. 15, most of the specialists strongly agreed that our developed tool provides an accurate and appropriate functionality and interoperability (with an average of Q1.1-1.3, 86.66% of them strongly agree). They also strongly agreed that the tool is efficient and reliable (with an average of Q2.1-2.4, 75% of them strongly agree). Considering the usability (Q3), 60% of specialists strongly agreed that the functions provided by the tool are not complicated and easy to use and understand. Furthermore, the specialists satisfied the prototype in terms of its ability and applicability (Q4) from the agree level (with half of them satisfied at the strongly agree level). Overall, we can conclude that the specialists were mostly satisfied our *ReqOntoTestGen* approach and its corresponding tool.

V. LESSON LEARNED AND DISCUSSION

In this section, we discuss the benefits of the proposed *ReqOntoTestGen* approach for generating test cases with the software requirement ontology. This section also shares lessons learned achieved from our implications of practical implementation and experiment. The approach influences the benefits according to our research questions as follows.

- It provides a systematic mechanism and framework to generate test cases from a very clear structure of functional requirements encoded in the form of ontology. The application of ROO tool in the framework enables the unstructured requirement to be transformed into more structured and clearer requirements before generating ontology. This results in the complexity of requirement structure to be reduced and the ambiguity of the terminology used in the ontology to be eliminated as discussed in [8][11][16][36][37]. This also guarantees that the main causes of errors in software testing that are mainly from requirements to be eliminated and the correct test cases that satisfied user requirements to be generated.
- CCTM test case generation technique implemented in the framework to construct test cases influences benefits that the number of test cases is reduced with maximizing testing coverage. As claimed in [14][15] we have discovered from our implemented experiences

that CTM technique in CCTM enables the redundant test cases to be eliminated, On the other hand, ECP technique in CCTM expands the possible range value both valid and invalid cases. This led to the testing coverage to be increased.

- *ReqOntoTestGen* approach provides a semi-automatic prototype tool that implemented the algorithm to generate test cases from well-defined ontology. The results of the experiment by comparing the manual test case generation and automatic test case generation by the tool with two case studies: LMS and KFD can guarantee the correctness, effectiveness, and accuracy of the proposed approach and tool. Furthermore, the efficiency and potential use in the future are confirmed by the evaluation result from experts.

However, as suggested by the practical specialists from the satisfaction evaluation, there are limitations of the approach. Firstly, the proposed approach provides the semi-automated prototype tool in which the conceptual ontologies from the requirement specification resulted from the ROO tool need to be input manually into the prototype for test case generation. Furthermore, the experiment for the prototype validation and evaluation is based on two real case studies. It needs to be evaluated with other different domain of case studies.

VI. CONCLUSION AND FUTURE WORK

This paper presents a novel approach, *ReqOntoTestGen*, to enhance the efficiency of traditional testing techniques. It provides a semi-automatic framework that integrates ontology engineering with software testing for test case generation. The effectiveness and efficiency of our *ReqOntoTestGen* approach and framework is demonstrated by the developed prototype tool. The experiment results with the implementation of two case studies have shown that the Control Natural Language (CNL) from the ROO tool used in our tool enables the unstructured functional requirements that may lead the generated test cases to be inconsistent to the users' needs to be more structured and clearer, before transforming them into the OWL conceptual ontology. This OWL file is, then, transformed automatically into the XML file of data dictionary. CCTM technique implemented in the tool creates the automatic test case generation environment in which test cases are generated automatically from the transformed XML file of data dictionary with the decision tree. This influences the benefits that the redundant test cases to be eliminated and the coverage of the test case generation to be increased. Furthermore, the evaluation result has shown that our developed tool has a high degree of validity, accuracy and satisfaction level from the practical specialist perspective. As a result of this, it can be confirmed that our proposed approach contributes a hybrid test case generation technique with a software requirement ontology engineering that both meets the users' need and covers all possible testing scenarios.

For the future work, to increase the capability and reliability of the developed prototype, it needs to link with the ROO tool which can automatically input the conceptual ontology resulted from the ROO to the prototype. Furthermore, the evaluation of the prototype with different domain of case studies is still open as another research issue.

DEPLOYMENT AND AVAILABILITY

The developed tool with the user guide document and source of example case studies is available at <https://sites.google.com/phuket.psu.ac.th/reqontotestgen/>.

Eligible Personal Loan Applicant Selection using Federated Machine Learning Algorithm

Mehrin Anannya, Most. Shahera Khatun, Md. Biplob Hosen, Sabbir Ahmed,
Md. Farhad Hossain, M. Shamim Kaiser
Institute of Information Technology, Jahangirnagar University, Bangladesh

Abstract—Loan sanctioning develops a paramount financial dependency amongst banks and customers. Banks assess bundles of documents from individuals or business entities seeking loans depending on different loan types since only reliable candidates are chosen for the loan. This reliability materializes after assessing the previous transaction history, financial stability, and other diverse kinds of criteria to justify the reliance of the bank on an applicant. To reduce the workload of this laborious assessment, in this research, a machine learning (ML) based web application has been initiated to predict eligible candidates considering multiple criteria that banks generally use in their calculation, in short which can be briefed as loan eligibility prediction. Data from prior customers, who are authorized for loans based on a set of criteria, are used in this research. As ML techniques, Random Forest, K-Nearest Neighbour, Adaboost, Extreme Gradient Boost Classifier, and Artificial Neural Network algorithms are utilized for training and testing the dataset. A federated learning approach is employed to ensure the privacy of loan applicants. Performance analysis reveals that Random Forest classifier has provided the best output with an accuracy of 91%. Based on the mentioned prediction, the web application can decide whether the customers' requested loan should be accepted or rejected. The application was developed using NodeJs, ReactJS, Rest API, HTML, and CSS. Furthermore, parameter tuning can improve the performance of the web application in the future along with a usable user interface ensuring global accessibility for various types of users.

Keywords—*Loan eligibility prediction; machine learning; random forest; K-Nearest Neighbour; Adaboost; extreme gradient boost; artificial neural network; federated learning*

I. INTRODUCTION

People all over the world reckon on banks to gain various kinds of financial support depending on their needs. Besides, depositing individual money it provides loans to its customers assessing different conditions and criteria. In general, banks variably provide sixteen types of loan applications [1]. In recent years, the lend-leasing industry has created significant growth increasing number of individuals seeking personal loans for various purposes. This increase in demand has led to a need for more efficient and accurate methods of loan applicant selection. Loan approval criteria defer from bank to bank. Forbes refers to the top five banks in the world providing different personal loan applications and sanctioning criteria with some common attributes [2]. Assessing those top five [3][4][5][6][7] banks, it is seen that some attributes like - credit score, social security number, loan amount, loan type, mortgage information, employment, etc. are common. Depending on these criteria, traditional loan application processing carries forwards with manual reviews and human judgment which can be subjective and biased, leading to inefficient loan processing

and higher default rates consuming a huge time in taking a decision which is a cumbersome task of the banking system. Due to human error, sometimes loans are sanctioned mistakenly to some people who cannot repay banks' money with interest in proper time. Moreover, banking sectors more or less face challenges with huge data management and security issues during data processing. But the use of FL in processing all the eligible loan applicants at a time is left behind. The primary motivation behind this research is to tackle the aforementioned challenges progressively, aiming to alleviate the burden on bankers in identifying loan defaulters and streamline the loan sanction process efficiently. By providing swift decisions, this research aims to support loan applicants in making informed choices that depend on the approval of their loans. Additionally, the research aims to expedite the loan sanctioning process, reducing the waiting time for loan applicants. The research introduces a web application developed using ML and DL algorithms for selecting eligible personal loan applicants in an FL approach to ensure security and a better data management process. Since, today's modern world increasingly depends on ML for any type of big data analysis and prediction because of having different statistical models, and banks need more accurate predictive systems, in this research ML models are used for personal loan prediction. In a study [8], loan prediction has been done with a random forest algorithm providing better performance than a decision tree. Thereupon, in this research, the best accuracy-giving algorithm is selected among four ML and one DL algorithms for achieving better performance of data in checking the eligible personal loan applicants among all the submitted applications. The app uses data-driven approaches for analyzing vast amounts of data and making predictions about the candidates who are likely to be selected for the loan sanction. This leads to a more objective assessment of loan applicants and a reduced risk of loan defaults. And another lesson that has been found from analyzing different research on the loan prediction arena is, very few concrete systems have been developed for predicting eligible personal loan applicants ensuring the privacy of loan applicants. The key contributions of the research are:

- To train and test a loan prediction dataset with four ML and one DL algorithm that has been found after the literature review.
- To choose the best-performing ML algorithm among those five for loan prediction.
- To ensure the privacy, security, and robustness of data processing, an FL approach will be utilized with different loan applicant selection datasets.

- Lastly, to develop a web application for checking eligible loan applicants when customers request a loan with an online application to the bank.

The rest of the paper includes a literature review in Section II, methodology in Section III, result analysis and discussion in Section IV, and a conclusion in Section V wraps up the overall research.

II. BACKGROUND STUDY

In this section, the research background has been categorized into three subsections: ML-based loan prediction, FL-based loan prediction, and web applications using ML for loan prediction.

A. ML-based Loan Prediction

Authors in [9] used the ML approach to predict eligible candidates to receive loan amounts by collecting previous banks' data who are accredited before. For predicting loans, a simple comparative study was made in [10] based on six machine-learning classification models in R to find out whether allocating a loan to a certain person is risky or not without recommending any specific algorithm. In 2021, a comparison of seven different classifiers was performed in [11], which also showed a method for combining results from multiple classifiers. In [12], authors suggested a better method for performing the identical function in banking procedures. In terms of accuracy, it is shown in a study [13] that the Decision Tree ML algorithm outperformed rather than Logistic Regression and Random Forest ML techniques, according to the results of the trial. In [14], authors made a comparative analysis comprising Random Forest and Decision Trees, declaring the latter to have the highest accuracy when evaluated on the same dataset. To forecast an outcome on loan prediction, a Decision Tree ML algorithm was employed in [15]. In [16], Big Data mining was utilized to collect approved clients' previous data and for training and testing the ML models. Among the four ML models, the Decision tree algorithm gave the best accuracy result. In [17], three ML models are utilized to train the past data to decide whether the loan request will be accepted or not, and among them, the Decision tree algorithm outperformed than Random Forest and Logistic Regression ML approaches. An understandable artificial intelligence (AI) decision-support system was researched to automate the loan underwriting process with a belief-rule-base (BRB) and was capable of learning from and incorporating human knowledge through supervised learning, and historical data [18]. In recent times, authors of [19] made a comparative study in predicting eligible customer loan receivers using five ML algorithms recommending a Decision tree with AdaBoost ML to have the highest accuracy rate where the data cleansing mechanism played an important role. In [20], a logistic regression model was utilized for predicting the problem of forecasting loan defaulters fetching the Kaggle dataset, depending on sensitivity and specificity as the two parameters to compare the performance of the ML model. Authors of [21] used the Logistic regression model to estimate various performance metrics providing a wide range of outcomes disregarding two important variables, such as gender and marital status. A technique was utilized in [22] for developing a model using the information and outcomes of loan applicants who had already submitted applications which

discovered that the logistic regression model performs better than other models. Under the assumption that loan quality has a direct impact on a bank's profitability, in [23], a combined logistic regression method and artificial neural network (ANN) was utilized to improve the predictive performance based on real data from a rural commercial bank. In [24], a research project was made intending to create a cutting-edge algorithm to predict events for different financial institutions to protect them from fraudsters while also streamlining the pre-approval procedure for loan applications and the associated verification process. For performing data categorization with good accuracy, K-nearest neighbor (K-NN), decision tree, support vector machine, and logistic regression models are taken into account to measure their performance. A loan default dataset was used in [25], which is taken from the lending club. To address the dataset's class imbalance issue, the ADASYN (Adaptive Synthetic Sampling Approach) method was used in increasing the prediction accuracy. Following an experimental comparison, it was discovered that the fusion model proposed in this paper outperformed using three other models—Logistic Regression, Random Forest, and CatBoost—in terms of its ability to predict the likelihood of customer loan default which was trained with the dataset lowering the external risk posed by customer loan default for the online loan platform. To classify a Kaggle dataset with the best degree of feasible accuracy, it is found that the random forest classification approach provided better performance in loan candidate classification [26]. The authors of the paper [27], researched that the loan grants were given to people in previous years after mining them in their recommended model using random forest ML to predict the loan grants to develop a better risk prediction system for the network loan platform reducing its risks. In [8] also showed that Random Forest Classification outperformed better than the Decision Tree algorithm with a mean accuracy of 89.94% in finding eligible loan applicants after their loan application in a bank. Data Mining Techniques are used in [28], to assess the manual way of loan sanctions made by banks, and following that deep learning models are used to perform the task for prediction. In [29], a proprietary dataset from an agency was utilized to compare the efficacy of a variety of regression models and ML algorithms for forecasting the probability of paying the loan discovering rule-based algorithms to outperform other approaches. A model is created by Debnath et al. in [30], to forecast whether to approve credit for or deny credit utilization for clients using loan application data from consumers. The proposed model took into account the factors that affect a person's loan status and produces precise results for approving or rejecting the customer's request for credit after carefully assessing all available possibilities. To entrench the convolutional neural network (CNN) and the integration model of stacking, a loan risk prediction model called Stacking+CNN was proposed by Li et al. [31]. The prediction model created in this work was superior to the single model and other integrated models in terms of forecasting accuracy and recall rate, according to empirical results. A mechanism for foretelling loan failure was developed by Muslim et al. [32]. For the prediction analysis procedure, an enhanced light gradient boosting machine via features selection using swarm methods such as ant colony optimization and bee colony optimization was applied having a 95% success rate. Authors in [33], utilized an ML method to anticipate loan defaults recommending the Naive Bayes model to perform better than

other models. Arutjothi et al. in [34] build a credit rating model using loan status. Credit rating models are used to distinguish defaulters and legitimate consumers. This research used credit data to develop a rating model and presented an ML-based data analysis methodology with K-NN and Min-Max normalization. The proposed approach was 75.8% accurate.

B. FL-based Loan Prediction

In a recent study by [35], Yang et al., an overall description of FL with its use in different sectors like health and communication had been made. Then it found its drawback in security issues and finally discussed its future and its use in the application layer. In [36], an FL approach was utilized by Gu et al. in processing the trained model data and updating the parameters on the centralized server ensuring accuracy, privacy, and model fairness. FL approach had been remarked on by Kawa et al. in [37] for assessing credit risks by learning shared prediction models from different banks collaboratively to update their data in the central repository. Authors in [38] proposed an FL model to predict the loan requester's financial situation using the clients' banking information concluding that the F1-score metric gave identical results in both the centralized and decentralized environment. In [39], federated learning (FL) is used in finding the loan applications that have less possibility to repay the loans in due time, and a Synthetic Minority oversampling Technique (SMOTE) is used in solving the imbalanced data.

C. Web Application using ML for Loan Prediction

Sujatha et al. in [40] referred to the deployment of a web application project that utilizes an ML algorithm named logistic regression for loan prediction with a high accuracy rate. In another study by Thomas et al. [41], a similar type of suggestion has been given to achieve eligible loan applicants. But, comparisons have been made among XGBoost, K-NN, and support vector machine, recommending XGBoost to have the highest accuracy rate of about 91.6%. In a study by Shukla et al. [42], research on loan prediction-based web applications using logistic regression, random forest classification, and XGB ML algorithms has been made using Stream the lit library. The application shows either "Loan denied" or "Loan approved" status to the loan applicant customer after prediction using ML algorithms. The app can be modified to increase its accuracy in the future.

Along with the above three categories, the paper of Divate et al. [43], also predicted the outcome by mining the data of previously accepted clients. The system was developed using an AI model that delivered the most accurate result in this research. Authors in [44], employed LightGBM in predicting categorization outcomes using observational datasets as the most successful algorithm after multi-observation and multi-dimensional data cleaning. In [45], Blaszczyszynski et al. used an upgraded dataset for pre-programmed loan applications to test a tool for financial fraud prediction named DRSA-BRE and found that it performed better than existing methods. Robisco et al. Authors of [46] presented a new framework to compare ML approaches and model risk adjustments. To solve this issue, they first identified up to 13 risk variables using internal ratings-based methods, then grouped them into three primary categories: statistics, technology, and market conduct. Using

natural language processing and risk terminology based on expert knowledge, they calculated the weight of each type based on the frequency of its mentions.

The above discussion on background works assisted that myriad works prevail in the selection of eligible loan applicants using ML algorithms with good prediction providing impressive accuracy rate. But still, most of the paper indicates to increase in this accuracy rate. Moreover, web applications based on loan applicants' prediction process couldn't reach huge popularity in research sectors ensuring data security. Therefore, to develop a comprehensive web application that utilizes ML algorithms in predicting eligible loan applicants in an FL environment, further research is needed to address these challenges and ensure the fairness and transparency of the system.

III. METHODOLOGY

A. Overview

In this article, an end-to-end solution for loan prediction using ML algorithms with a series of features related to scalability, and security with a distributed federated transfer learning model has been proposed. To ensure client-side rendering with data protection, the aim is to provide a microsystem structure with exchangeable FL capabilities and client-side rendering. Elaborately, the research is working combining three parts namely - ML prediction using loan data, FL for client-side rendering, and Web application development for sanctioning loans.

B. Working Procedure

1) Web application development for sanctioning loan:

This is the main software system with whom the bankers (Admin or Bank Employees) will interact. It will work with all online loan applications from customers. The workflow of the proposed system is shown in Fig. 1. Here, a web app is developed commencing with individual access to the system. There are three types of users, namely- Admin, Customer, and Employee. The user Authentication Section will give the required roles according to the logged-in user. If the user type is Admin, then it will be redirected to the "Controls and Operates the whole system". If the user type is Customer, then the individual customers can request a loan from the bank. the system provides the loan sanctioning form to the customer. Customers fill up the form and submit it to the system. Then, the customer has to wait for its approval or rejection. If the user type is Employee, then it can view all the loan requests of the customers. When the bank employee hits the Submit button, the ML prediction analysis starts working with all the loan requests to sort the eligible loan applicants using the best ML algorithm. The process to find the best ML algorithm is shown in Fig. 2. Based on this ML prediction result, the Employee can view the customers who are accepted and rejected for the loan request. The following tools and techniques are used for its development:

- NodeJs is used for backend coding and calling the REST API using a GitHub link.
- Tensorflow javascript library is used to load and run those data.

Fig. 1. Workflow diagram of the proposed system.

- After that, the generated result is uploaded to GitHub.
- Using javascript, reactjs, HTML, and CSS, the front end is developed.

2) *ML Prediction using loan data:* In the literature review section, the use of different ML algorithms has been observed, among which the ML algorithms, which are least popular, performed badly, and worked with similar datasets are chosen. Comprising all the ML and DL algorithms found to be used in similar research, four ML algorithms, namely - Random Forest Classifier, K-NN Classifier, AdaBoost Classifier, XGB Classifier, and one DL algorithm, namely - ANN have been used in this research. These five algorithms are then used to find the best one for developing the web application to predict the customers to whom the loan can be sanctioned or declined. The working procedure to find the best ML algorithm for the system is shown in Fig. 2.

At first, the data is collected from a popular dataset available on Kaggle [47]. It contains genuine 10,001 records of a bank. Then the data pre-processing has been done maintaining the following steps: *i) Null value elimination:* There are some cells in the dataset which has no values. These cells can result in improper results when tested. These null values are filled by the statistical estimation method. *ii) Label Encoding:* Some values are string-type in nature which are converted into numeric values. *iii) Correlation:* Since some attributes (LoanID, CustomerID, and Tax Liens) are not relevant to the model, this process automatically chooses useful features while removing redundant or unnecessary characteristics. Discarding a feature results in an O coefficient value. The data has 19 attributes of customers. Among these 15 attributes are used as independent attributes and 1 attribute as a dependent attribute. The attributes are given in Table I. The whole Dataset is then split into two parts: The Training Dataset and Test Dataset. All five ML models are trained with 8000 data and then tested with the rest. Then an analysis among the models has been done to select the best-performing one with the highest accuracy level. Noticeably, since ANN is a DL algorithm it is trained in the FL environment. A comparative analysis is made among ML and

Fig. 2. Workflow diagram to find the best ML algorithm.

TABLE I. ATTRIBUTES

Dependent Attributes	Independent Attributes	
Loan Status	Current Loan Amount	Home Ownership
	Number of Open Accounts	Term

	Current Credit Balance	Credit Score
	Years of Credit History	Monthly Debt
	Maximum Open Credit	Annual Income
	Years in current job	Bankruptcies
	Months since last delinquent	

DL algorithms to choose the best one. Using the best ML or DL model, eligible customers for loan sanction are predicted and utilized in the proposed system's Utilize the best ML or DL Algorithm to predict the eligible loan applicants in the FL environment as mentioned in Fig. 1.

3) *FL for client-side rendering:* A federated learning approach is adopted to train the loan property detection model. This approach involves multiple clients, each possessing its local dataset. During each training round, the clients independently perform local training using their respective datasets. This process allows the clients to learn from their data, capturing the specific characteristics and patterns of their datasets. After the local training phase, the clients generate model updates based on their trained models. These updates typically consist of either the updated model parameters or gradients, which represent the direction and magnitude of the parameter updates. The clients then transmit their model

updates to the aggregator, a central entity responsible for coordinating the federated learning process. The federated transfer learning approach of ANN consists of several clients, where n number of client nodes $N_1, N_2, N_3 \dots \in N_n$ can participate in processing, assuming each device has at least P computational power. The local batch size B and iteration C are adaptive, depending on the user end of the generated data. Each N_i can train on private data PD and a central server-based classification model is shared between all of the nodes with a synchronized upload and download time T_u and T_d respectively. The objective function is to minimize binary cross entropy loss (BCE) over all models referring to equation 1, where y is the ground truth and ε is the prediction with optimization of all of the weight and biases denoted by w_i and b_i respectively as mentioned by Zhang et al. in [48]. This BCE loss is calculated individually for each ANN model on the client side.

$$BCE = -(y \log(\varepsilon) + (1 - y) \log(1 - \varepsilon)) \quad (1)$$

Upon receiving the model updates (BCE) from all participating clients, the aggregator computes their mean, where $\partial BCE(X_t)$ of equation 2 denotes the gradient descent and η_t is the learning rate of each node, N_i which also denotes the local update of i-th nodes with a learning convergence assumption. Again, X_t refers to the current instance of input in the i-th nodes, which can be calculated from previous instances. A large number of local models are aggregated (e.g., averaged) on the client side to create the global model. As local models are developed utilizing client-specific training data on devices, local and global models often differ. This aggregation step consolidates the model updates into a single global update, representing the collective knowledge from all the clients. By computing the mean of the model updates, the aggregator ensures a fair combination of local knowledge while preventing the dominance of any particular client. By averaging the model updates, the aggregation process balances the contributions of individual clients and facilitates the convergence towards an accurate and generalized eligible loan applicant's prediction model.

$$X_t = X_{t-1} - \sum_{i=1}^N \eta_t \partial BCE_i(X_t) \quad (2)$$

On deployment, the ML model is trained on the user side and only the prediction and updated model are sent over the network. Thus, any practical or private information needed for the ML model to operate will be separated from the central cloud storage, resulting in a more secure and reliable application system. It also solves critical issues like data security, privacy, and authorized access. This is also a more decentralized approach where edge devices actively participate in computation, reducing the computation complexity on a central server. Therefore, this process also enables reducing the unnecessary model parametric complexity.

IV. RESULT ANALYSIS AND DISCUSSION

This research can determine the eligibility of a customer to get a loan. After getting all the related information about customers, the system checks that using the best ML algorithm, the system can approve or reject the loan applicants.

Fig. 3. Performance comparison of random forest classifier.

Fig. 4. Performance comparison of Adaboost classifier.

A. ML Prediction Result

To determine the best-performing ML algorithm for the dataset [47], accuracy, CV Mean, Precision, Recall, and F1-score metrics of the confusion matrix are used since most of the research papers referred to in the literature review section used them. The graphs for each of the five algorithms using the above-mentioned metrics are analyzed here:

1) *Random forest classifier for loan prediction:* Fig. 3 describes that the test data performed better than the training data generating a value near 1 for each of the attributes except for the CV mean. CV means calculated a significant degradation in value compared to all the train and test data. All the metrics of the train data are generating a value near 0.9 except for recall which is slightly below compared to the other metrics.

2) *Adaboost classifier for loan prediction:* From Fig. 4, it is observed that the training data performed better than the test data for all metrics and are near 0.65 which is poor than the Random Forest Classifier in Fig. 3.

3) *K-NN classifier for loan prediction:* Fig. 5, Fig. 6, Fig. 7, and Fig. 8 describe graphs for four different values of k. Here, K=7, 11, 13 and, 17 were used to of K-NN identify any significant change in its pattern. When the value of K in Fig. 5 was 7, it was observed that for all the metrics of confusion matrix, the probability was above 0.75 except for CV-mean. But, when the value of K in Fig. 6 was bit increased to 11, it was observed that for all the metrics of confusion matrix,

Fig. 5. Performance comparison of K-NN classifier (n=7).

Fig. 7. Performance comparison of K-NN classifier (n=13).

Fig. 6. Performance comparison of K-NN classifier (n=11).

Fig. 8. Performance comparison of K-NN classifier (n=17).

the probability was 0.75 except for CV-mean. Similarly, when the value of K in Fig. 7 was a bit increased from 11 to 13, it was observed that for all the metrics of confusion matrix, the probability was 0.75 except for CV-mean. However, when the value of K in Fig. 8 was searched covering wide range to 17, it was observed that for all the metrics of confusion matrix, the probability was near to 0.75 except for CV-mean. Furthermore, no significant differences were observed in it. For all the four values of k, the training data performed better than test data similar to Adaboost Classifier in Fig. 4 calculating a value around 0.75 for each of the metrics with a significant decrease in the value of CV Mean metrics. But the values are less than the Random Forest Classifier in Fig. 3.

4) *Extreme gradient boosting classifier*: Fig. 9 describes that the training data performed slightly better than the test data calculating a value near 0.60 for each of the metrics similar to the Adaboost Classifier in 4 and K-NN in Fig. 5 to 8. But couldn't outrange the Random Forest Classifier in Fig. 3.

5) *ANN*: This section generates Fig. 10 and Fig. 11 using the equation 2 and 1 respectively. Since it uses a neural network to perform the calculation, with the increase in the number of epochs [49] i.e. the learning rate, observing the Fig. 10 and Fig. 11, it is seen that accuracy of FL-based ANN is also increasing for both the training and the testing data with a corresponding decrease in loss value. But since the measurement is made on a scale of 1, the peak value of it is around 0.8 which is less than the Random Forest Classifier in Fig. 3. Considering all the values of each confusion matrix for

all the ML and DL algorithms, a comparative graph is created in Fig. 12. In this graph, for the overall analysis, only the accuracy and F1-score metrics are selected for both training and test data since they gave excellent results for all the ML algorithms. However, the FL-based ANN couldn't beat the ML algorithm even after having multiple iterations. Hence, it is concluded that Random Forest Classifier's performance is the best in comparing all the other ML and DL algorithms. This Random Forest Classifier is then used in the FL environment for data analysis of the web application.

B. User Interface (UI) of Web Application

In this section, some salient figures of the developed web application have been highlighted using which the customer and bank employee will interact for loan processing. Here, ABC Bank is considered an exemplary name of a bank.

- **User-Customer:** Fig. 13 shows a customer named Sam has been sanctioned with his requested loan and Fig. 14 shows a loan decline UI for a customer named Bob. However, the customer's application form's UI is skipped from inclusion.
- **User-Employee:** Fig. 15 shows the employee dashboard UI which comes after processing the customers' loan application using ML prediction techniques. In Fig. 15, it is seen that the customer with LoanID: 1 is declined from getting the loan, LoanID: 2 has been approved for loan sanction, and LoanID: 3 and 4's loan requests are still on review status. Employees can review loan requests using ML algorithms. If the

V. CONCLUSION

Sanctioning a loan is a challenging task for bankers since there occur some phenomena when the borrowers cannot return their debts in due time. Sometimes, debt cannot be collected too due to some misjudgment. Various types of loans are provided by the banks. In this research, an ML-based web application has been used to check the eligibility of personal loan applicants. To conduct the task, data is used for prediction using four ML and one DL algorithm. The prediction has been performed depending on some attributes in which the most crucial factors that are considered in taking decisions are - loan amount, loan length, loan term, and age. Among those five ML algorithms, Random Forest Classifier has been suggested to be used by the banks since it has given the best result for all the metrics of the confusion matrix. Moreover, another remarkable component of the research is the implementation of a decentralization technique in local PC for data processing using the FL approach to ensure its data security and robustness.

However, the research lacks working with more real and relevant data that can effect the accuracy augmentation of the ml algorithms. It could have worked with more latest ml algorithms which have not been used in this type of research. The back-end architecture of the web application have been developed with modern programming tools.

In future, the research could have work with more real data integrating more empirical attributes that the banks follow and use during their assessment so that the accuracy of prediction can be enhanced. Furthermore, the user interface of the web application can also be enhanced in the future using modern tools and techniques.

A Low-Cost Wireless Sensor System for Power Quality Management in Single-Phase Domestic Networks

Cristian A. Aldana B, Edison F. Montenegro A
Universidad Distrital, Francisco José de Caldas, Bogotá D.C., Colombia

Abstract—This article presents a novel low-cost hardware and software tool for monitoring power quality in single-phase domestic networks using an ESP32 microcontroller. The proposed embedded system allows remote evaluation and monitoring of electrical energy consumption behavior through non-invasive current measurement parameters. Based on these measurements, power, power factor, total harmonic distortion, and energy consumption are calculated. The collected data is then published and visualized on a free and open IoT application in the cloud. The tool was designed to be both cost-effective and high-quality. During laboratory testing, the equipment demonstrated a high level of precision, as compared to a network analyzer. Additionally, the design utilized the smallest number of components possible, while still maintaining quality performance. The ESP32 microcontroller enables wireless data transmission, making remote monitoring and management of energy consumption more accessible and efficient. Moreover, the non-invasive measurement method makes the tool safer and more user-friendly, as it does not require any interruption of power supply. The proposed tool can help identify and address power quality issues that arise in domestic networks, which can have a significant impact on energy consumption and costs. The IoT application enables users to access their power consumption data remotely, facilitating better energy management and reducing wastage.

Keywords—Cost-effective; current measurement; energy consumption; ESP32 microcontroller; non-invasive; power quality; remote monitoring

I. INTRODUCTION

As the world population continues to grow, so does the demand for energy. Unfortunately, this increase in demand is accompanied by a decline in natural resources and an increase in environmental pollution, leading to climate change. It is crucial to raise awareness among people about the importance of energy usage and to bridge the gaps in accessibility and culture [1], to create a better environment for all.

However, the current home energy measurement technology falls short of achieving this goal. The technology is primarily used to charge users for the service provided, without giving them the means to measure, verify, or control the amount charged. Furthermore, most users do not understand or have access to information provided by their energy meter [2], as it typically displays only a set of numbers on a counter located outside their homes.

Modern and innovative technologies such as embedded systems with high-capacity microcontrollers and IoT information technologies can provide more efficient, compact, and cost-effective solutions for domestic energy measurement [3].

These technologies have the potential to optimize energy measurement, enabling more precise remote monitoring and control from anywhere in the world, and providing the user with easily accessible and understandable information [4]. By creating a more precise and accessible energy measurement tool, users can plan their energy consumption more intelligently and responsibly. This can help mitigate the effects of global warming and promote energy efficiency [5], thus contributing to the conservation of the environment.

The aim of this research is to design and implement a robust IoT meter prototype capable of measuring electrical energy consumption and providing the average user with accurate real-time information about their energy usage at home. This information will enable the user to manage their energy consumption with an innovative and cost-effective solution, contributing to energy efficiency and promoting sustainability [6].

The proposed tool provides a high-quality and efficient solution for domestic networks, enabling users to be more aware of their energy consumption and manage it more intelligently and responsibly. By creating a robust and user-friendly IoT meter, this research aims to address the issues of accessibility and awareness in the use of energy. The use of innovative technologies such as embedded systems and microcontrollers has the potential to revolutionize the field of power quality monitoring and management [7], contributing to the sustainable development of modern society.

A. Issues in Existing Work

In recent years, power quality management in single-phase domestic networks has witnessed significant advancements. However, there remain certain inherent challenges. The majority of existing systems fall into one of the following categories:

- 1) Systems that prioritize advanced functionalities but, as a result, become too complex and expensive for regular household users [8], [9].
- 2) Systems that are affordable but compromise on the depth of data and the quality of measurements they provide. This often leads to a lack of complete understanding of energy usage patterns, reducing the efficacy of management efforts [10].
- 3) Devices that focus solely on energy consumption, overlooking the broader aspect of power quality which is crucial given the increased presence of non-linear loads in contemporary households [11].

- 4) Systems that although being technologically advanced, aren't user-friendly or accessible for an average user. Such systems, despite their potential, have limited real-world application due to the steep learning curve they present [12].

These issues represent significant barriers for users who wish to adopt sustainable energy consumption practices in their homes.

In addition to its simplicity and cost-effectiveness, the prototype was designed to maintain quality in both hardware and software, while keeping in mind the experience and prices of the market. The hardware and software were designed to ensure flexibility and openness to the public. In fact, there is no need for subscription to IoT platform Adafruit.io, which allows data to be uploaded at a rate of one data per second and stored at no cost.

The ESP32 Dev Kit v1 microcontroller [13] serves as the brain of the circuit and has an integrated Wi-Fi capability, which is a significant advantage for sending data directly to the cloud without additional devices. Wi-Fi enables the data to be sent in real-time to the internet or a local network if required. In this case, it is connected to the cloud platform dashboard Adafruit.io. The SCT 013030 [14] current sensor is used for signal conditioning, which has a ratio of 30A/1Vac, is ideal for its low cost and suitability for many households that do not exceed a power consumption value of 7200 W. One of its main features is its non-invasive type, which allows the installation to be safer by avoiding the need to cut parts of the wiring. The current conditioning is carried out through a precision full-wave rectification circuit to obtain a reliable signal at the ADC input and with minimal voltage loss in the diodes. An operational amplifier, the LM324, is used for this purpose. With these materials, the prototype can be constructed. The rest of the design is software-based and is programmed in the Arduino IDE environment, which is widely known and easily programmable using the C++ language.

Upon analyzing various studies related to energy meters, it was observed that the technologies used do not meet the characteristics of simplicity in their design. This means that more than one board must be used to fulfill the same functions that can be provided by an ESP32 microcontroller, which has greater processing capabilities and is more integrated and cheaper than an Arduino solution with an additional IoT communication card. Additionally, many of the designs do not consider the price, which can be a significant barrier to the acquisition of an energy meter by the user. Although some functions, such as bidirectional measurement, may seem important, most people currently do not have access to this type of technology due to their low-income status, so it would not make sense to include this function [15]. Other technologies are based on conditioning additional circuits to the energy meter. However, if the energy meter makes a mistake in the measurement, the additional device will also be incorrect, which does not provide reliability to the readings. Many designs also include functions of an incorporated power analyzer, which seems relevant given the increase of non-linear loads in homes and which can shed light on their impact on the distribution network. However, the contemplated design is not compact, and the solution is not cheap.

B. Overcoming the Challenges with the Proposed Approach

Our research aims to bridge the aforementioned gaps in power quality management for single-phase domestic networks. The proposed wireless sensor system addresses the need for a balance between advanced functionalities and user accessibility. Leveraging the capabilities of the ESP32 microcontroller, the system offers a comprehensive suite of measurements, from active power to total harmonic distortion, while ensuring that the data is readily accessible through an intuitive IoT interface [16]. Furthermore, our commitment to a cost-effective design ensures that our solution remains affordable, promoting widespread adoption and contributing substantially to the global energy efficiency movement.

Over recent years, the significance of monitoring energy consumption has grown considerably, especially in the wake of rising energy demands and the increased focus on sustainable living. As a response to these trends, this work introduces a comprehensive IoT-based current meter, designed to provide real-time insights into energy consumption patterns, thus facilitating better energy management. Our endeavor is rooted in the following main contributions:

- Development of an IoT-based current meter firmware that harnesses the power of the Fast Fourier Transform (FFT) for precise and efficient current monitoring.
- Configuration of the Analog-to-Digital Converter (ADC) tailored to ensure a detailed representation of the current waveform, enhancing energy monitoring capabilities.
- Adoption of Robin Scheibler's FFT library for high fidelity signal decomposition.
- Empirical derivation of an amplitude correction factor, thereby refining energy consumption measurements.
- Comprehensive power and energy calculations, offering real-time energy consumption insights.
- Incorporation of Total Harmonic Distortion of Current (THDi) calculations, revealing the system's performance metrics and potential energy consumption anomalies.
- Rigorous prototype testing and validation against industry-standard measurement tools, ensuring the reliability and accuracy of the developed system.

The ensuing sections detail the methods employed, the design considerations, and the empirical findings that validate the contributions outlined above.

II. RELATED WORKS

The efficient use of electrical energy is becoming increasingly important in the face of rising demand and limited resources [17]. Energy providers charge customers for the energy delivered to their homes or businesses, but not all of this energy is utilized efficiently; a portion is wasted. The energy demand of a system is known as the *apparent power* or *absorbed power*, which can be further broken down into the *active power* that is actually used and the *reactive power* that is wasted. In practice, active power should be as close

as possible to apparent power, but this is not always the case. The difference between the two can be measured by the power factor [18]. With the growing number of electronic devices in homes, the situation is different, as loads have increased their nonlinear components, increasing the harmonic content and the power factor, which can significantly affect the network and loads [11]. Therefore, it is essential to begin measuring these variables in homes to facilitate future studies on the impact of harmonics in the distribution network. The proposed tool can help identify and address power quality issues that arise in domestic networks, which can have a significant impact on energy consumption and costs.

In recent years, several studies and devices have been developed to measure power consumption and other parameters in order to determine the quality of energy in homes. Trujillo and Lorenzo [8] proposed an electric power consumption analyzer using Arduino and MATLAB to study various household loads. Benalcazar et al. [9] analyzed the generation and correction of the main sources of harmonic distortion commonly found in household and some industrial electrical networks, using LabVIEW and the National Instruments DAQ 6008 acquisition card. Garcia-Granados et al. [19] designed and implemented a single-phase power analyzer for domestic use using voltage, current, and power waveforms.

In the same vein, Mathew [10] aimed to optimize energy consumption by implementing intelligent control of household appliances using a smart meter and IoT. The system analyzed usage patterns, collected physical variables through an Arduino Uno, and featured a switching mechanism. Furthermore, the system was parametrized based on peak demand hours to reduce the electricity bill.

The disadvantages of the prototypes compared to the one proposed are mainly related to their limitations in terms of functionality, precision, and cost-effectiveness. For instance, the prototype developed in [8] only measures the active power consumption, whereas the proposed system using an ESP32 can measure not only the active power but also other parameters such as power factor, total harmonic distortion, and energy consumption. Similarly, the prototype presented in [9] focuses on the analysis of harmonic distortion in household and industrial networks but lacks the capability to provide real-time energy consumption information to users. The system presented in [19] is a single-phase power analyzer that can measure voltage, current, and power, but it does not have wireless data transmission capabilities and requires additional hardware for data visualization. Additionally, the prototypes mentioned in the paragraph do not take advantage of modern and innovative technologies such as IoT, which can facilitate remote monitoring and management of energy consumption in a cost-effective and user-friendly way.

Several prototypes and devices have been developed to monitor and control energy consumption in households using IoT technology. Ramani et al. [12] propose a prototype that combines IoT with solar energy monitoring and household energy consumption control using an Arduino and an ESP8266. The aim of the prototype is to improve energy efficiency by controlling the use of generated and consumed energy in parallel. However, the use of an ESP8266 may limit the range of the system due to its lower wireless transmission capability compared to the ESP32.

Another prototype proposed by Sheeba et al. [20] improves the conventional digital energy meter by converting it into an IoT-enabled device using an optocoupler circuit to capture LED pulses and a system that sends data to a cloud-based platform called Firebase. This design reduces the number of components required and improves the efficiency of the existing infrastructure.

Although several commercial energy meters are available in the market, they have limitations. For example, eMon energy [21] is an energy monitoring system in Indonesia that can measure up to 14 circuits accurately, store and upload real-time information to cloud services such as InfluxDB & Grafana, Emon CMS, or Mango Automation. However, it may not be suitable for all households as it may not measure voltage in all phases or may not be configurable for both residential and industrial sectors.

The use of intelligent meters for measuring energy consumption has gained significant attention in recent years. One such example is the Engage smart meter [22], which can measure instantaneous values with power factor in four quadrants. It operates as a bidirectional energy meter for both consumption and generation, with a cost of approximately 141.99 Euros. Another example is the Wibeec Box [23], a WiFi-enabled electricity meter that monitors data on electricity consumption and allows users to view it from their smartphones, tablets, or computers. This device has a cost of 181.75 Euros. These devices provide valuable information on energy consumption and can help users make informed decisions about their energy usage, leading to energy savings and a reduction in greenhouse gas emissions. However, they often come with a high price tag, which can be a barrier to their widespread adoption.

To address this issue, we propose a novel low-cost hardware and software tool for monitoring power quality in single-phase domestic networks using an ESP32 microcontroller [16]. Our embedded system enables remote evaluation and monitoring of electrical energy consumption behavior through non-invasive current measurement parameters. Based on these measurements, power, power factor, total harmonic distortion, and energy consumption are calculated. The collected data is then published and visualized on a free and open IoT application in the cloud.

Our tool was designed to be both cost-effective and high-quality, utilizing the smallest number of components possible while still maintaining quality performance. The ESP32 microcontroller enables wireless data transmission, making remote monitoring and management of energy consumption more accessible and efficient. Moreover, the non-invasive measurement method makes the tool safer and more user-friendly, as it does not require any interruption of power supply. Our proposed tool can help identify and address power quality issues that arise in domestic networks, which can have a significant impact on energy consumption and costs. The IoT application enables users to access their power consumption data remotely, facilitating better energy management and reducing wastage.

III. METHODS

In this section, we outline the materials utilized for the hardware design, as well as the software employed in the

development and implementation of the prototype. Our goal is to provide a step-by-step account of the prototype's creation, emphasizing IoT technology and energy savings as the focus of our innovation.

The main components in our prototype's development were an SCT013-030 current sensor and an ESP32 dev kit V1 module. For the programming of the module, the Arduino IDE development environment was used, in which we configured the relevant libraries for the ESP32 module and Adafruit platform libraries (Adafruit MQTT Library) to facilitate the web publication of the results.

A. Material Description

- 1) **ESP32:** The ESP32 module from Espressif Systems is a System on Chip (SoC) that incorporates a dual-core 32-bit Tensilica Xtensa LX6 microprocessor (Fig. 1). This microprocessor typically operates at 160 MHz, but it is capable of achieving a clock speed of up to 240 MHz. The module integrates both a Wi-Fi communication stack and a Bluetooth Low Energy (BLE 4.1) communication stack, underlining its capacity for seamless integration into IoT applications.

Fig. 1. Development board Dev kit V1 ESP32.

The programming of the ESP32 is achieved using the Arduino IDE and the C language, reinforcing its accessibility to developers across varying skill levels. The module employs a Reduced Instruction Set Computer (RISC) architecture, making it optimal for executing instructions at a high speed, thereby supporting more efficient energy use.

Featuring 30 pins, the module is flexible and adaptable for various inputs and outputs. The power supply voltage is 5 Vdc via the micro USB port or the Vin port, while all input and output pins operate at 3.3 Vdc. With 25 digital pins, the board can connect with a range of devices including sensors, LEDs, buttons, and other peripherals.

In addition, the ESP32 module includes two 12-bit ADC converters with 18 channels, expanding its interfacing capabilities. At an approximate cost of \$8 USD, the ESP32 provides a cost-effective solution for developing IoT devices with an emphasis on energy efficiency.

- 2) **SCT013-030 Current Sensor:** The SCT013-030 is a split-core current transformer typically used to measure alternating current (Fig. 2). One of the major advantages of this sensor is that it does not require cutting of wires for operation, thereby enhancing the

safety of its usage. The sensor is relatively affordable, with a market price of approximately \$9 USD.

Fig. 2. SCT013-030 current sensor.

Key features of the SCT013-030 current sensor are outlined below:

- **Input current:** The sensor can accurately measure AC in the range of 0-30A with a 1Vac output. This broad range accommodates a variety of applications, underscoring the sensor's versatility.
- **Non-linearity:** It exhibits a non-linearity of $\pm 1\%$, implying that the output is a highly accurate representation of the input. This characteristic is crucial for precise control and measurement tasks.
- **Bandwidth:** With a bandwidth of 1000Hz, the sensor is capable of handling fast-changing current levels, making it suitable for monitoring harmonic distortion.
- **Resistance grade:** The sensor has a B-grade resistance level, indicating its ability to withstand moderate current flows without performance degradation.
- **Working temperature:** The sensor can operate efficiently in a wide temperature range, from -25°C to 70°C , which ensures its performance under diverse environmental conditions.
- **Dielectric strength:** The sensor exhibits a dielectric strength of 1000Vac/1 min 5mA between its shell and output. This feature implies a high level of insulation, reducing the risk of electric shock.
- **Cable length and Size:** The sensor comes with a 1-meter long cable and has a compact size of 13mm x 13mm. This makes it convenient to integrate the sensor into various system configurations.

B. Signal Conditioning for the SCT013 Sensor

- 1) **Voltage signal conditioning:** At the outset of this project, the operating parameters of the current sensor were duly

identified, verifying its ability to measure up to the 11th harmonic, courtesy of its 1 kHz bandwidth. The signal fed into the current sensor or current transformer is an AC signal ranging from 0 to 30 A ac. The sensor then transforms this into a voltage level between 0-1 V_{rms} due to the presence of an internal burden resistor.

If the incoming current signal is in a sinusoidal mode, the output of the current transformer is a sinusoidal signal with an amplitude between 0 and 1 V_{rms}. Consequently, the maximum peak-to-peak voltage this signal can achieve is given by Eq. (1):

$$V_{pp} = V_{rms} \times 2\sqrt{2} = 2.82842 \quad (1)$$

Considering that the Analog to Digital Converter (ADC) of the ESP32 module only receives positive values between 0 and the reference voltage (in this case 3.3 VDC), it is necessary to condition the signal from the current sensor to fit within this operational window (Fig. 3). To achieve this, we decided to add a DC voltage of 1.56 V to the sensor's input signal. Therefore, the maximum and minimum peak voltages at the ADC input will be Eq. (2) and (3):

$$V_{pmax} = 1.56V_{dc} + \sqrt{2} = 2.97V_p \quad (2)$$

and

$$V_{pmin} = 1.56V_{dc} - \sqrt{2} = 0.1458V_p \quad (3)$$

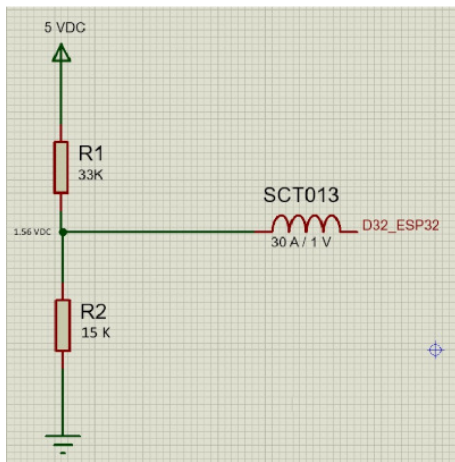

Fig. 3. Voltage divider on the analog input of the ESP32.

Through this voltage signal conditioning process, we ensure that the ADC of the ESP32 module operates within its specified range, optimizing the accuracy of our current measurements and contributing to the overall energy efficiency of the prototype.

C. Characterization Test for the SCT 013-030 Sensor Curve

To validate if the SCT013-030 sensor aligns with the manufacturer's linearity specifications, a characterization test was conducted. A resistive load was used alongside a stepwise variable voltage source that incremented by 0.5 V until an output current of 27A was achieved. This test's purpose was

twofold: firstly, to ensure the performance of the sensor under various operating conditions, and secondly, to formulate an associated equation reflecting the sensor's response, which would be instrumental in the prototype's implementation.

The test's resultant curve depicting the sensor's behavior is presented in the Fig. 4. It should be noted that this characterization is crucial not only for validation against the manufacturer's specifications but also as an input to the development of the control algorithm that drives the IoT device's energy savings.

The equation that describes the sensor's behavior, derived from the curve, is crucial in determining the precise measurements of current. This data is used to calibrate the signal conditioning process and to feed accurate current values into the system's control algorithm, ensuring the IoT device operates at optimal energy efficiency.

D. Software Development

The development of the firmware for the current meter encompassed several stages, each contributing to the comprehensive functionality of the IoT device. The process began with the generation of a vector comprised of 1024 twelve-bit values, corresponding to the samples of the current signal emanating from the sensor. This data acquisition is essential in capturing the intricate details of the current waveform and provides a robust base for the subsequent Fast Fourier Transform (FFT) algorithm implementation Eq. (4).

$$\text{Vectorcurrent} = [I_1, I_2, \dots, I_{1024}] \quad (4)$$

where I_i are the twelve-bit samples of the current signal.

After data collection, the selection and testing of the FFT algorithm were carried out. FFT is a powerful computational tool used to transform the acquired time-domain current samples into the frequency domain. The frequency domain representation of the current signal provides a more detailed understanding of the signal components, which aids in accurate and efficient current monitoring Eq. (5).

$$\text{FFT}(\text{Vector}_{\text{current}}) = [\text{Amp}_1, \text{Amp}_2, \dots, \text{Amp}_{1024}] \quad (5)$$

Subsequent to the FFT process, the final stage involved integrating the firmware with the Adafruit.io platform for data publication. This stage is of paramount importance in the IoT application, as it provides a way to share, visualize, and analyze the data generated by the IoT device in a user-friendly manner. This step bridges the gap between raw data collection and actionable insights, contributing significantly to the overall energy savings facilitated by the IoT device.

E. ADC Configuration and Sampling Time

The Analog-to-Digital Converter (ADC) was configured with a resolution of 12 bits and an internal reference voltage of 3.3 VDC, the default setting. This provided an operating voltage window from 0 to 3.3 VDC, corresponding to output values ranging from 0 to 4096. For ease of operation, a mapping function, `mapf()`, was implemented to convert the ADC output values to input values expressed in millivolts. The

Fig. 4. Experimental characterization curve sensor SCT 013-030.

`mapf()` function accepts the maximum and minimum values of the ADC as parameters and returns a floating-point value between 0 and 3300 mV Eq. (6).

$$\begin{aligned} \text{Mapped Value (mV)} = \\ \text{mapf}(\text{ADC Value, ADC Minimum,} \\ \text{ADC Maximum, 0, 3300}) \quad (6) \end{aligned}$$

To sample the current waveform accurately, it was determined that data should be collected over ten periods of the fundamental grid frequency. Given that the grid frequency for Colombia is 60 Hz, this corresponds to a sampling period of approximately 166.66 ms. The sampling time and frequency can therefore be calculated as Eq. (7) and (8):

$$t_s = \frac{0.166666}{1024} = 0.00016275 \text{ s} \quad (7)$$

and

$$f_s = \frac{1}{t_s} = \frac{1}{0.00016275} = 6144 \text{ Hz} \quad (8)$$

This sampling frequency is more than sufficient for measuring up to the 15th harmonic (900 Hz), ensuring that the device captures a detailed picture of the current waveform for efficient energy monitoring and control.

F. Implementation of Fast Fourier Transform Algorithm

We utilized the Fast Fourier Transform (FFT) computation library authored by Robin Scheibler, which offers a comprehensive description on [FFT On The ESP32](#). This particular library algorithmically decomposes a discrete signal into its spectral constituents through a Radix-2 Decimation

in Frequency method. It employs the Bit-reversal technique to reorder the output vector, starting from the DC component (zero frequency at position zero of the output array) up to the sampling frequency divided by two for a unilateral transform or up to the sampling frequency for a bilateral transform.

The output vector of the algorithm contains complex values corresponding to each frequency in the measurement range. Hence, post-FFT, the amplitude calculations for each frequency are performed on the input vector. The fundamental frequency and its corresponding amplitude are identified as the maximum of the computed magnitudes Eq. (9).

$$A_f = \sqrt{\text{Real}^2 + \text{Imag}^2} \quad (9)$$

Here, A_f denotes the magnitude at a specific frequency, and this value should coincide with the amplitude at that frequency. Based on our practical observations, we found a need to correct these values. Thus, we introduced a correction factor for the amplitude of each frequency component, which we denoted as $I_{error} = 0.662946429$. This value was derived empirically using laboratory measurements and curve fitting techniques Eq. (10).

$$A_f = 0.662946429 \sqrt{\text{Real}^2 + \text{Imag}^2} \quad (10)$$

These corrective steps ensured the precision of the signal decomposition, thereby enabling more accurate energy consumption measurements and contributing to the broader goal of enhancing energy efficiency through IoT technologies.

G. Calculation of Power and Energy

The SCT013 sensor's current measurement range (0 to 30A) is mapped once the amplitude of the fundamental frequency is obtained. This mapping is accomplished through the function `Calculate_Irms()`. Assuming a sinusoidal input

voltage regime of 120 Vrms amplitude, the instantaneous power P_0 in kilowatts is defined as follows Eq. (11):

$$P_0 = \frac{V_{rms} \times I_{rms}}{1000} \quad (11)$$

The energy calculation used a base time of 1.04 seconds, the time it takes for the program to complete all computations, from sampling to THDi calculation, six times over. Hence, energy, E , is calculated as Eq. (12):

$$E = P(W) \times T_{(1040)ms}[h] = P(W) \times 1040[ms] \times \frac{1h}{3600 \times 10^3ms} \quad (12)$$

Given that energy accumulation should not exceed 24 hours, the accumulation timer and energy counter reset every 24 hours (86400 seconds).

H. Calculation of Current Harmonic Distortion

Once the FFT of the current signal and the corresponding harmonic amplitudes are obtained, the Total Harmonic Distortion of Current (THDi), caused by the presence of nonlinear loads in the system, is determined Eq. (13):

$$THD_i = \frac{\sqrt{\sum_{n=2}^{n_{max}} I_n^2}}{I_1} = \frac{I_H}{I_1} \quad (13)$$

Here, I_H denotes the root mean square (rms) value of the harmonic current, and I_1 represents the rms value of the fundamental current. This calculation offers an important insight into the system's performance, specifically concerning the influence of nonlinear loads, which directly impacts energy consumption and system stability. Thus, it provides a key factor for implementing energy-saving solutions in IoT environments (Fig. 5).

I. Prototype Testing

In order to comprehensively evaluate the performance of the prototype, a specialized testing setup was designed and implemented. This process required a current source capable of supplying current to a biphasic load. In this instance, the load was represented by four infrared lamps, typically used in automotive paint-drying ovens. This testbed, under normal operation, is capable of delivering 380V line-to-line (VLL). However, the load can withstand up to 220VLL.

The testing process started from a zero-baseline voltage, which was progressively increased. Simultaneously, the current values were measured using the SCT013 current sensor, an Extech clamp meter, and an AEMC 8220 power quality analyzer. This procedure was done to cross-verify and confirm the accuracy of the measurements taken by the developed prototype. The Fig. 6 illustrates the high voltage laboratory setup, which was utilized for performing these tests on the prototype.

Fig. 7 provides a comprehensive illustration of the intricate connection or measurement schema adopted in this study. At the core of this configuration are the three principal devices, which are pivotal to the research:

Fig. 5. Flowchart of the processing algorithm.

- **SCT013 Current Sensor:** This sensor is designed to measure the current flowing through a conductor without the need to interrupt the circuit. It uses a magnetic core to detect changes in current and convert it into a voltage, which can then be read by our prototype. Its non-invasive nature allows for safer and more convenient monitoring, especially in scenarios where continuous power supply is paramount.
- **Extech Clamp Meter:** Acting as a supplementary tool, the Extech clamp meter aids in the measurement process by clamping onto the conductor to determine current values. Its utility is evident when one wishes to validate readings quickly without delving into intricate circuit connections, providing a quick yet reliable snapshot of the current scenario.
- **AEMC 8220 Power Quality Analyzer:** This device is considered the gold standard in our research. The AEMC 8220 is a versatile tool capable of measuring multiple parameters, including voltage, current, and power quality attributes. In our schema, it serves the dual purpose of providing reference measurements and validating the accuracy of our prototype's readings. By comparing results from the IoT-based energy sav-

Fig. 6. Test bench.

ing prototype with the AEMC 8220, we ensure the credibility and reliability of our device.

The strategic arrangement of these devices is essential to achieve two key objectives: firstly, to enable accurate and consistent data acquisition by our IoT-based energy saving prototype; and secondly, to ensure that the measurements from the prototype can be cross-verified against established and well-regarded instruments in the industry, thereby reinforcing the validity and reliability of our findings.

A comprehensive view of the entire setup employed for prototype testing with the infrared lamps is depicted in Fig. 8. This illustration provides a clear visual of the prototype, connected and functioning within the wider measurement system.

Moreover, as shown in Fig. 7, the infrared lamps can be seen reaching incandescence during the testing phase. This phenomenon is a result of the power supplied to the lamps, showcasing the operational flow of the overall system. The lamps glowing red-hot emphasize the real-time nature of the prototype testing, hinting at the authenticity and practical applicability of this IoT-focused energy-saving system.

During the initial phase of testing, depicted in Fig. 9, the

Fig. 7. Connection and operation of load and measuring instruments.

prototype exhibited behavior that deviated from the anticipated performance due to a confluence of factors. These variables are inherent in any experimental setup and include the accuracy of resistors, the measurement error introduced by the SCT013 current sensor, and the intrinsic variations in data acquired over time.

To account for these factors and to validate our prototype's performance, we compared the measurements obtained from our IoT-based energy-saving system with those acquired from two robust measurement tools: the Extech clamp meter and the AEMC 8220 power quality analyzer. This comparative approach allowed us to understand the performance nuances of the prototype and adjust the system to minimize the influence of external variables on the overall performance.

Following the preliminary testing phase and the insight gleaned from it, we made software adjustments to correct the discrepancies detected in the prototype's behavior. Our goal was to reduce the measurement error and improve the accuracy of the energy metrics provided by our IoT-based system.

During the subsequent testing phase, illustrated comprehensively in Fig. 10, we observed marked enhancements in the performance of our prototype. This phase of testing was crucial, as it allowed us to evaluate the modifications made after our initial tests.

- **Data Points Alignment:** The data points captured from our system were strikingly more aligned with those obtained from our reference measurement tools. Instead of a broad scatter or deviation, the points clustered around the readings from the AEMC 8220 and the Extech clamp meter. This closer alignment served as an early indication of the success of our recent tweaks and calibrations.

Fig. 8. Measurement and capture instruments during testing.

- **Reference Measurement Tools:** The choice of AEMC 8220 and Extech clamp meter as our reference tools was strategic. The AEMC 8220, being a renowned power quality analyzer, provided us with accurate and industry-accepted measurements. On the other hand, the Extech clamp meter gave us rapid and reliable snapshots of the current, serving as an essential tool for instant validation. Our prototype's readings moving closer to these reference tools' measurements was a significant achievement.
- **Software Adjustments:** The software adjustments we incorporated after the initial test phase were pivotal. These adjustments, a combination of algorithm tweaks and calibration methods, aimed at refining the measurement accuracy and eliminating any observed anomalies. The data from the subsequent testing phase strongly suggested that these software interventions played a major role in enhancing the prototype's performance.

Conclusively, the dataset from this testing phase clearly indicated that our prototype's behavior was now in tight congruence with the expected outcomes, grounded on the reference tools' readings. This not only solidified our confidence in the software changes we had implemented but also underscored the prototype's potential for reliable energy measurements in real-world applications.

IV. RESULTS

Examining the response portrayed in the various figure plots, it is evident that the devised energy meter's performance measures favorably with existing industry standard devices. Despite the intricate characteristics inherent in this prototype, it not only fulfils the capabilities of measuring active power and Total Harmonic Distortion of current (THDi) but accomplishes these tasks with significant cost advantages.

These characteristics are particularly vital for efficient energy management, and by having a solution that can provide such capabilities at a much lower cost, we are propelling ourselves towards improved energy savings. The insight from the experimental results suggest that integrating IoT technology with traditional electronics and control engineering principles can indeed form a basis for a high-performing, yet cost-effective solution for power and THDi measurement.

The overall performance of our device, as suggested by the curves depicted in the figures, confirms the robustness of the design and the success of our software adjustments in refining the meter's precision. These results provide substantial evidence that our approach to a more economical and compact energy meter can be invaluable in power quality and energy management systems where budget and space constraints are of importance.

While the prototype exhibited excellent performance with a precision rate of 91% compared to the AEMC 8220, it's worth noting that in scenarios with fluctuating loads, the device consistently measured active power within a margin of 2%. Moreover, the THDi measurements provided insights into the harmonics present, showcasing its capability to be a tool not just for energy measurement but also for preliminary power quality analysis in households. The low cost of approximately \$24 USD makes this device particularly attractive for residential settings, especially in developing regions where budget constraints are paramount.

A. Limitations

Despite the evident success and promise of our IoT energy meter, it is crucial to acknowledge certain limitations of our study:

- **Scope of Testing:** The comparative testing was primarily performed against the AEMC 8220 energy meter. While it provides a benchmark, the results might differ when compared with a broader range of energy meters available in the market.
- **Prototype Stage:** The device is still in its prototype stage. Real-world application and longevity tests are required to ensure its robustness and durability over extended periods.

Fig. 9. Initial prototype testing.

Fig. 10. Software-adjusted prototype testing.

- **Potential Interferences:** The prototype was tested in controlled environments. External factors like electromagnetic interferences or extreme environmental conditions, which can potentially affect the performance, were not extensively studied in this research.
- **Software Limitations:** While open-source software offers cost advantages and customizability, it might not be as optimized or stable as proprietary software solutions in certain scenarios. This might lead to performance or stability issues in some edge cases.

V. CONCLUSION

Throughout this study, we focused on the design and development of a cost-effective, user-friendly, and feature-rich IoT energy meter as an alternative to other market offerings. Our goal was to enable mass production of the meter to aid in critical global endeavors, including energy efficiency and optimization, especially considering the growing prevalence of nonlinear loads in residential settings.

The successful development of a prototype has been achieved using accessible and cost-effective materials, in con-

junction with open-source software, costing approximately \$24 USD. Comparative testing against a well-regarded AEMC 8220 energy meter yielded a precision of 91% in relation to key parameters such as active power and Total Harmonic Distortion of current (THDi).

The developed prototype's low cost and high quality offer substantial benefits to the realm of energy efficiency. It equips end-users with a simple, attainable tool for monitoring and managing their household energy consumption, thereby advancing residential energy optimization.

As we look to the future, it is feasible to extend the functionality of the device to include bidirectional energy measurement capabilities. This would enable the support of alternative energy sources for low-income users. Furthermore, the inclusion of THD measurements can assist in calculating the impact of harmonics on the distribution network, leading to improved power quality management at a residential level.

VI. FUTURE RESEARCH DIRECTIONS

While the current research and development have proven successful in designing an economical and precise IoT energy meter, there are several promising avenues for future research and enhancement of the device:

- **Integration with Renewable Energy Sources:** As the global shift towards green energy continues, integrating the energy meter with renewable energy sources such as solar and wind can be invaluable. It would be insightful to research how our meter could be enhanced to support not just traditional power sources but also renewable ones, offering users a comprehensive view of their energy consumption and generation.
- **Advanced Harmonics Analysis:** With the increasing use of nonlinear devices in homes, harmonics play a crucial role in power quality. Future research can delve deeper into advanced harmonic analysis techniques and provide users with detailed reports and insights into their energy consumption patterns, enabling them to make informed decisions on managing and reducing their harmonic footprint.
- **Machine Learning and Predictive Analysis:** By incorporating machine learning algorithms, the energy meter can offer predictive analytics on energy consumption, allowing users to anticipate their energy needs and adjust accordingly. This research could lead to the development of an intelligent system that not only monitors but also predicts and optimizes energy consumption based on historical data and user behavior.

Abstract—Monitoring the pollen foraging behavior of honeybees is an important task that is beneficial to beekeepers, allowing them to understand the health status of their honeybee colonies. To perform this task, monitoring systems should have the ability to automatically recognize images of pollen-bearing honeybees extracted from videos recorded at the beehive entrance. In this paper, a novel convolutional neural network architecture is proposed for recognizing pollen-bearing and non-pollen-bearing honeybees from their images. The performance of the proposed model is illustrated based on a real dataset and the obtained results show that it performs better than some other state-of-the-art deep learning architectures like VGG16, VGG19, or Resnet50 in terms of both accuracy and execution time. Thus, the proposed model can be considered an effective algorithm for designing automatic honeybee colony monitoring systems.

Keywords—Pollen-bearing honeybee; image classification; convolutional neural network; honeybee monitoring system; pollen dataset

I. INTRODUCTION

Honeybees bring great benefits to human life. Products from honeybees such as honey, propolis, and pollen bring high economic efficiency. They are both popular components for daily consumption and an important source of raw materials in the production of medicines and beauty care. The global honey market was valued at 8.9 billion dollars by the year 2022, and it is predicted to reach 12.6 billion dollars in the year 2030, according to a report in VANTAGEMarketResearch¹. In addition, honeybees are known as the most common and effective pollinators [1]. A large-scale survey in [2] has shown that honeybee pollination has contributed to increased yields and improved quality for many crops worldwide. For example, in the US, honeybees have increased fruit setting by 60% and seed yield by 20% for almonds; in Argentina, honeybees simultaneously increase fruit setting (by 15%) and the content of fruit sugar for apples, thereby increasing profits by 70%; and in Brazil, honeybees increased soybean yield by 18.9%. Besides that, the pollination of honeybees also contributes to the preservation of the diversity of plant ecosystems.

To take care of honeybee colonies, beekeepers must monitor the health of the colonies regularly. This task requires gathering information about the activities, status, and behaviors of honeybees in the colony, including pollen foraging behavior. In fact, pollen is the leading food of honeybees. It

provides proteins, lipids, vitamins, and minerals necessary for the growth and reproduction of honeybees [3]. Information about the foraging behavior of honeybees can bring valuable understanding about the pollen source status in the habitat, the need for food, the increase of individuals, and the health of the whole honeybee colony. As a result, it allows beekeepers to understand the status of their honeybee colonies and detect unusual problems in the colonies for timely intervention. Recognizing honeybees bringing pollen back to the hive is then an effective solution for monitoring the beehives.

In recent years, thanks to the application of IoT (Internet of Things) technologies, several automatic honeybee monitoring systems have been deployed. These systems use surveillance cameras to record the activities of honeybees at the beehive entrance, then use different techniques to extract and analyze information from the recorded images [4]. Due to its powerful ability in image data processing, the Convolutional Neural Network (CNN) is perhaps the most widely used technique in these systems. In the context of recognizing pollen-bearing honeybee images, many CNN-based models have been designed. For example, several well-known CNN-based models like VGG16, VGG19, Resnet50, and DarkNet53 have been applied in [5] towards precise recognition of pollen-bearing honeybees. Rodriguez et al. [6] tested with several types of CNN architectures and showed that shallow-CNN architecture gives higher recognition accuracy than machine learning methods such as SVM (Support Vector Machine), Naive Bayes, or K-nearest neighbors. The authors also provided a real dataset of pollen-bearing and non-pollen-bearing honeybee images. However, we have found that there are a few mislabeled samples in this dataset where some images of non-pollen-bearing honeybees were assigned as pollen-bearing honeybees and vice versa. In addition, the use of complex structures for these CNN-based models requires a large number of samples for training and testing, leading to a significant cost of calculation and resources for the execution. To provide an effective model for designing automatic beehive monitoring systems, in this study, we propose a novel CNN architecture for recognizing pollen-bearing honeybee images. Here, we aim to find a model that is better than existing models in terms of both efficiency and execution cost. The performance of the proposed model is validated by comparing it with several other complex models like VGG16, VGG19 [7], and Resnet50 [8] architectures using the same dataset.

In summary, the main contributions of the study are as follows:

¹<https://www.vantagemarketresearch.com/industry-report/honey-market-2138>

- We adjust a dataset published in a previous study by assigning correct labels to some previously mislabeled samples.
- We propose a novel structure for a CNN-based model to classify the images of pollen-bearing and non-pollen-bearing honeybees. We also suggest a data augmentation technique to handle the cases where there are few observed samples.
- We verify the efficacy and cost of the proposed method by extensive experiments, achieving an absolute accuracy for pollen-bearing honeybee recognition on the testing set.

The rest of the paper is organized as follows. Section II is to present the recent related works in the literature. In Section III, we describe the dataset considered in the study and the proposed CNN architecture. The experiments and the obtained results are presented in Section IV. Finally, Section V is for some concluding remarks.

II. RELATED WORK

In this section, we briefly discuss recent studies related to the classification models of pollen-bearing and non-pollen-bearing honeybees.

For pollen-bearing honeybee image recognition, many studies relied on image processing techniques and conventional machine learning algorithms [9]. Babic et al. [10] applied background subtraction using a Mixture of Gaussian for the segmentation of honeybees. Then, based on the difference in color variance and eccentricity features between pollen-bearing and non-pollen-bearing honeybees, the authors used the Nearest Mean Classifier to classify them. The accuracy achieved by the classifier is 88.7%. However, the classification accuracy depends on the results of background subtraction and the light source in the video recording area. Yang and Collins [11] used color thresholding and the Mixture of Gaussian to detect and extract images of individual honeybees in frames captured from video recorded at the beehive entrance and track them using Kalman filter and Hungarian algorithm. The bee blob analysis method from the binary image of each frame was applied to remove the main body of the honeybee and retain only the pollen blobs. The two main features of the pollen blobs, including the area of the pollen blobs and the location of them relative to the bee's body, will be used to remove noise blobs. Finally, the pollen sacs detection results are combined with the previous honeybee detection and tracking model to identify if a honeybee bears pollen sacs. The test results with several videos show that the pollen measurement model has the highest sensitivity of 76%. In [12], the authors conducted experiments using two methods to segment honeybee images: the k-means algorithm and the algorithm that only considers the b component of the CIE LAB color space. Then, the SVM classifier with Gaussian kernel was used to classify the pollen-bearing and non-pollen-bearing honeybee images based on the Dense SIFT (Dense Scale Invariant Feature Transform) descriptors and the VLAD (Vector of Locally Aggregated Descriptors) encoder. The test results show that the method that combines the k-means segmentation algorithm and the classifier based on the descriptors on the decorrelated channels

gives the highest value of the area under the ROC curve (AUC-ROC) at 0.915. In [6], authors performed the classification of pollen-bearing and non-pollen-bearing honeybees with three traditional methods: K-Nearest Neighbor algorithm, Naive Bayes statistical algorithm, and Support Vector Machines with linear and non-linear kernel functions. The results show that the SVM RBF method (Support Vector Machine with Radial Basis Function) with PCA (Principal Component Analysis) preprocessing technique and using the Gaussian feature map gives the highest accuracy at 91.16%.

In machine learning models, the important features were often selected from the inputs manually and subjectively. This can greatly affect the performance of the model once the key elements are not considered. To overcome this disadvantage, recent research suggest using models based on deep learning, more specifically, different CNN architectures. Rodriguez et al. [6] conducted experiments with 1-layer and 2-layer Shallow-CNN models, VGG16, VGG19, and Resnet50. The results show that all these models achieve high accuracy in which Shallow-CNN with small step size gives the highest accuracy of 96.4%, followed by VGG19, VGG16, and Resnet50 with an accuracy of 90.2%, 87.2%, 61.7%, respectively. Sledevič [13] investigated different CNN architectures with different numbers of hidden layers. After several experiments, the author stated that the architecture consisting of three hidden layers 7-7, 5-5, and 3-3 is the most suitable for classifying pollen-bearing and non-pollen-bearing honeybees, achieving a 94% accuracy. In [14], a pollen sac detection model on an individual honeybee image is used to classify a honeybee image as a pollen-bearing or non-pollen-bearing honeybee. This detection model uses Faster R-CNN architecture with the core for classification as VGG16. When a pollen sac is detected on an individual honeybee image, it is marked by a bounding box labeled "pollen" and a numerical value that is the confidence score of the detection. When the confidence score is greater than or equal to a predefined threshold, it is counted as a pollen sac, and the individual honeybee image is counted as a pollen-bearing honeybee image. This model has a pollen detection accuracy of 81.5%. Ngo et al. [15] relied on the YOLOv3-tiny model to detect and classify objects. Since YOLO-v3 treats the object classification problem as a regression problem, whereby an input image is divided into grid cells, each grid cell is responsible for detecting a target honeybee. This model allows the simultaneous detection of multiple objects on a frame belonging to one of two classes of pollen-bearing and non-pollen-bearing honeybees. The obtained results from this study showed that the proposed model gives a classification accuracy of 94%. In another research, nine different pre-trained CNN models, including VGG16, VGG19, Resnet50, ResNet101, Inception V2, Inception V3, Xception, DenseNet201, and DarkNet53 have been explored [5]. The authors also considered the influence of color by applying some image preprocessing techniques to the input dataset. The experimental results showed that the DarkNet53 and VGG16 architectures attained higher recognition accuracy than the others. In [16], the authors first tested the image classification using the transfer learning method with seven pre-trained Deep Neural Networks (DNNs) including AlexNet, DenseNet201, GoogLeNet, ResNet101, ResNet18, VGG16, and VGG19. After that, the authors continued to experiment with the SVM classifier using shallow features, deep features,

and shallow+deep features extracted from the DNNs. Three different standard datasets were used for the training and evaluation of models. The experimental results showed no significant difference in performance between them. For the pollen-bearing honeybee image dataset, the transfer learning method with pre-trained DNN yielded the highest accuracy of 99.07%.

III. MATERIALS AND METHODS

A. Data Description

In this study, the Pollen dataset published in [6] has been considered. The dataset is available and can be accessed publicly at GitHub². The authors stated that at the beginning, there were 810 honeybee images extracted and manually annotated from videos taken at the beehive entrance under natural light conditions. However, after being curated, many have been removed due to misclassification. Thus, the final data downloaded from the source above contains only 714 images. The photo was built by fixing the size of the cropping rectangle to 180×300 pixels, containing a fully visible image of a single honeybee. The images are also adjusted to make sure that the honeybees are facing upward in all images. Each photo was then labeled with pollen or non-pollen. Out of 714 images, 369 are labeled as pollen (P) and the rest 345 are non-pollen (NP). Fig. 1 presents some images of pollen-bearing and non-pollen-bearing honeybees in this dataset.

Fig. 1. Images of pollen-bearing honeybees (a) and non-pollen-bearing honeybees (b).

Based on this dataset, we have conducted several experiments to investigate the performance of the proposed model. The obtained results have shown that our model has misidentified some images from pollen-bearing honeybees to non-pollen-bearing ones and vice versa. We then carried out a thorough analysis of these misidentified images and found that some of them were mislabeled. According to our knowledge, images *NP24865-145r* and *NP27452-203r* are images of honeybees that bear pollen but are annotated as non-pollen-bearing ones (NP). Meanwhile, images *P7660-97r*, *P7776-99r*, *P11440-32r*, and *P11762-35r* in the dataset are images of honeybees that do not bear pollen but are annotated as pollen-bearing honeybees (P). Fig. 2 shows these mislabeled images.

TABLE I. THE STRUCTURE OF THE POLLEN DATASET

Dataset	Class label	Number of images
Original	Pollen	369
	Non-pollen	345
Corrected	Pollen	367
	Non-pollen	347

We have relabeled these images and used the corrected dataset to train and test the performance of the proposed model (as well as control models). The structure of the original Pollen dataset and the relabeled one is summarized in Table I.

Fig. 2. Mislabeled images in the Pollen dataset, from Pollen to Non-Pollen (a) and vice versa (b).

B. Proposed Method

1) *Convolutional neural networks*: Convolutional Neural Networks (CNNs) refer to a well-known deep learning algorithm specialized in handling image data. The basic architecture of a CNN model consists of three main types of layers, as displayed in Fig. 3.

The functions of each type of layer are as follows:

- The first type of layer of a basic CNN architecture is Convolution, the core of a CNN model used to extract various features from the input. The mathematical convolutional operation is performed in this layer, between the input and a filter. The dot product is taken between the filter and the parts of the input by sliding the filter over the image. The output from each layer containing information about the image like corners and edges is then fed to the next layer to learn other input features.
- Following the convolutional layers are the Pooling layers. These layers summarize the features extracted from the previous convolution layers, aiming to decrease the size of the obtained feature map and reduce computational costs. Several types of pooling operations can be used in a CNN model depending on the specific situation, such as Max Pooling and Average Pooling.
- The last Fully connected layers perform the classification task based on the features extracted from previous layers, mapping the representation between the input and the output. They generate scores for each class, then use them for the final classification.

In general, there is no universal optimal model for all datasets. For different problems, one should design different models with different structures to achieve the best performance. Choosing the right model is the key to solving many

²<https://github.com/piperod/PollenDataset>

Fig. 3. Architecture of a basic CNN model.

problems in practice. More introduction and discussion about the architectures of CNN-based deep learning model can be seen in [17] and [18].

2) *The proposed CNN model:* As discussed above, the CNN architectures have been widely applied to the problem of recognizing pollen-bearing honeybees, some of them achieved up to about 99% accuracy. Several transfer learning models whereby different CNN architectures such as VGG16, VGG19, Resnet50, and Resnet101, etc. are pre-trained and some SVM classification models are based on features extracted from CNN architectures, were presented in [5] and [16]. However, the use of these models requires significant costs due to their complex architectures. To overcome this problem and aim for simplicity and efficiency in use, we thought about using a basic CNN model. This idea can be verified by investigating the basic CNN structures with different hyperparameters. In particular, using the Grid search method, we have figured out an optimal architecture for the CNN model in classifying pollen-bearing and non-pollen-bearing honeybees. The proposed architecture comprises:

- 4 convolutional layers equipped with a ReLU (Rectified Linear Unit) activation function,
- 5 max-pooling layers,
- 1 flatten layer, a dense layer with a ReLU activation function, and a dense layer with a Sigmoid activation function.

The use of this simple architecture obviously makes the model lighter than other pre-trained deep-learning models like VGG16, VGG19, and Resnet50 which contain more layers and parameters. In addition, in this study, we use some data augmentation techniques such as image rescaling, random rotating, shifting (horizontally and vertically), shearing, random zooming, random flipping, and nearest filling. These techniques enrich the data by generating different variations from the original images which will be used in different epochs of the model training process, thereby improving the performance of the classification model. Fig. 4 shows a visualization of several images obtained after applying data augmentation techniques to a honeybee image.

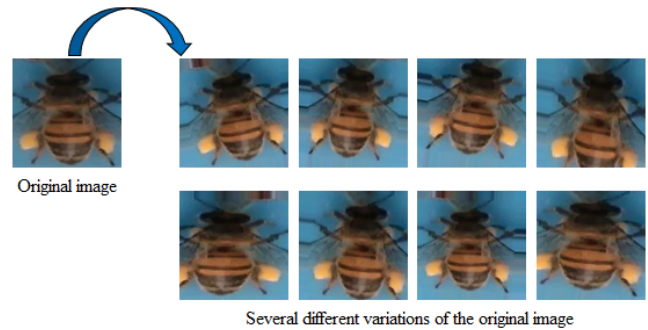

Fig. 4. An example of data augmentation.

The architecture of the proposed model is illustrated in Fig. 5. Each input is a 224×224 RGB image containing the image of an individual honeybee. After passing through the convolutional layers and the max-pooling layers to extract the important features, it is fed to fully connected layers. A predefined threshold is used to classify whether the honeybee image is a pollen-bearing honeybee or not. The performance of the proposed method will be discussed in the sequel.

IV. EXPERIMENTS AND RESULTS

A. Experimental Setup

In this study, two schemes of splitting the Pollen dataset are considered. By the first scheme, as in several previous studies, we randomly divide the corrected Pollen dataset into three subsets, i.e., the training set, the validation set, and the testing set at a ratio of 6:1:3. Accordingly, 60% of the samples corresponding to 428 images (which include 221 images of pollen-bearing honeybees and 207 images of non-pollen-bearing honeybees) are for model training, 10% of the samples corresponding to 70 images (which include 36 images of pollen-bearing honeybees and 34 images of non-pollen-bearing honeybees) are for model validation, while the remaining 60% of the samples corresponding to 216 images (which include 110 images of pollen-bearing honeybees and 106 images of non-pollen-bearing honeybees) are for model testing. Moreover, to investigate the effect of partitioning data

Fig. 5. The proposed CNN architecture.

TABLE II. TWO SCHEMES OF SPLITTING THE POLLEN DATASET

Scheme	Class label	Training set	Validation set	Testing set
1	Pollen	221	36	110
	Non-pollen	207	34	106
2	Pollen	183	36	148
	Non-pollen	173	34	140

into training, validation, and testing sets on the model performance, we design the second scheme where the Pollen dataset is split into the three subsets at a ratio of 5:1:4, namely fewer samples for training and more samples for testing compared to the first scheme. The details of the number of images in each subset of each scheme are presented in Table II.

The experiments were performed on Google Colab, using Python 3 Google Compute Engine backend (GPU) with a system RAM of 83.5 GB, GPU RAM of 40 GB, and Disk of 166.8 GB.

After hyperparameters tuning, hyperparameters are set up for model training as follows: batch size is 4, the number of epochs is 25, the initial learning rate is 0.001, and the optimizer is Adam.

B. Evaluation Metrics

To evaluate the performance of the proposed pollen-bearing honeybee recognizing model comprehensively, in this study,

Precision, Recall, F1-score, Accuracy, Loss, and AUC-ROC metrics have been utilized. These are widely used metrics to assess the performance of the classification models.

- Precision, Recall, F1-score, and Accuracy are computed as follows:

$$\text{Precision} = \frac{TP}{TP + FP} \quad (1)$$

$$\text{Recall} = \frac{TP}{TP + FN} \quad (2)$$

$$\text{F1-score} = \frac{2 * \text{Recall} * \text{Precision}}{\text{Recall} + \text{Precision}} \quad (3)$$

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \quad (4)$$

where

- TP: number of pollen-bearing honeybees images that are properly classified as pollen-bearing honeybees images;
- FP: number of non-pollen-bearing honeybees images that are misclassified as pollen-bearing honeybees images;
- FN: number of pollen-bearing honeybees images that are misclassified as non-pollen-bearing honeybees images;
- TN: number of non-pollen-bearing honeybees images that are properly classified as non-pollen-bearing honeybees images.

- Loss (Binary Cross Entropy) is calculated as follows:

$$\text{Loss} = \frac{-1}{N} \sum_{i=1}^N (y_i \log_e p_i + (1 - y_i) \log_e (1 - p_i)) \quad (5)$$

where

- N is the number of images;
- y_i is the real label of the i th image ($y_i = 1$ if the i -th image is a pollen-bearing honeybee image; $y_i = 0$ if the i -th image is a non-pollen-bearing honeybee image);
- p_i is the probability of the event predicting the i -th image as a pollen-bearing honeybee image ($1 - p_i$ is the probability of the event predicting the i -th image as a non-pollen-bearing honeybee image).

- AUC-ROC: one of the most important evaluation metrics for checking any classification model's performance is calculated as the area under the ROC (Receiver Operating Characteristics) curve.

From the above definitions, the larger the values of Precision, Recall, F1-score, Accuracy, and AUC-ROC, and the smaller the value of Loss, the better the model is at classifying classes in a dataset.

TABLE III. THE PERFORMANCE OF CNN-BASED MODELS ON THE FIRST SCHEME OF SPLITTING THE POLLEN DATASET

Method	Precision	Recall	F1-score	Accuracy	Loss	AUC-ROC
VGG16 ([6])	-	-	-	87.20	-	-
VGG16 ([5])	-	-	-	94.80	-	-

Proposed CNN	100.00	100.00	100.00	100.00	1.32	1.0000

TABLE IV. THE EXECUTION TIME OF CNN-BASED MODELS ON THE FIRST SCHEME OF SPLITTING THE POLLEN DATASET

Method	Training time (s)	Testing time (s)
VGG16	272.830	133
VGG19	265.359	167
Resnet50	7471.634	39
Proposed CNN	150.543	6

C. Experimental Results and Discussion

The performance of the proposed method and the corresponding execution time on the first scheme of splitting the Pollen dataset is presented in Table III and Table IV. For the purpose of comparison, we also show the performance and the execution time of other CNN-based transfer learning methods using the same dataset in the literature.

Several important remarks can be drawn from these tables as follows.

- The proposed CNN model provides the best performance in terms of all the metrics. Although the use of other CNN-based models results in quite an impressive efficiency (for instance, an accuracy of 99.54% with Resnet50, and 98.61% with VGG16), our proposed method can still achieve higher performance, with an absolute efficiency of 100% for the metrics of Precision, Recall, F1-score, and Accuracy, and the maximum value is 1 for the metric of AUC-ROC. It also leads to the smallest value of the Loss of 1.32. This means the proposed model can accurately recognize all pollen-bearing and non-pollen-bearing honeybee images in the Pollen dataset.
- After correcting the mislabeled images, the accuracy of other CNN-based models is generally improved. For example, based on the original Pollen dataset, the Resnet50 model in [6] and [5] provided an accuracy of 61.70% and 86.60%, respectively. Meanwhile, on the corrected dataset, it can reach an accuracy of 99.54%.
- Thanks to its simple architecture with fewer layers than some other CNN architectures such as VGG16, VGG19, and Resnet50, the proposed model also reduces significantly the execution time for both training and testing processes. Indeed, it took only 150.543 seconds for training and 6 seconds for testing. Meanwhile, the second-fastest models asked for about 265.359 seconds for training (VGG19) and 39 seconds for testing (Resnet50), which are significantly slower than the proposed model, as can be seen in Table IV. This finding has a practical meaning as it allows the

designing of efficient real-time recognition systems of pollen-bearing honeybees.

Fig. 6 and Fig. 7 show the curves of the training and validation accuracy, and the training and validation loss of the models compared. As can be seen from these figures, the proposed CNN model gives a higher performance than the other models. This is accordant with the results discussed above.

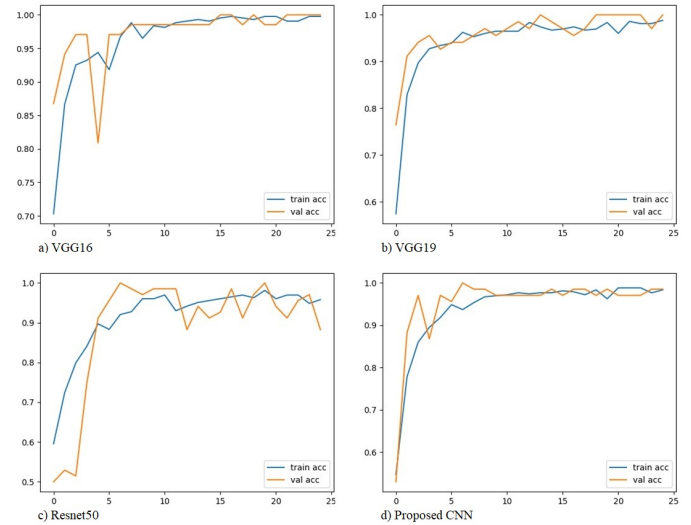

Fig. 6. Training and validation accuracy curve.

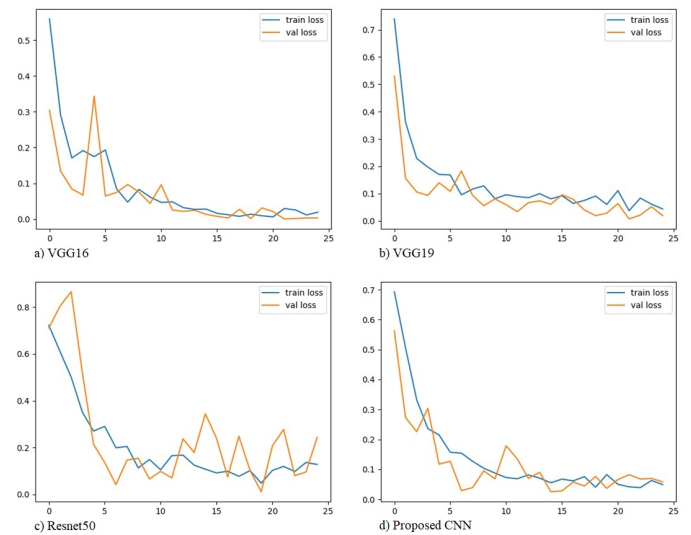

Fig. 7. Training and validation loss curve.

In Tables V and VI, we present the experimental results obtained from using the second scheme of splitting the Pollen dataset at the ratio 5:1:4. Since the scheme has not been considered in previous studies, we present the performance of our experiments only. The same result as the first scheme can also be witnessed in these two tables where our proposed method still brings the best Precision, Recall, F1-score, Accuracy, and Loss in the fastest processing time. However, the performance of all models, in this case, has been reduced a bit compared

TABLE V. THE PERFORMANCE OF CNN-BASED MODELS ON THE SECOND SCHEME OF SPLITTING THE POLLEN DATASET

Method	Precision	Recall	F1-score	Accuracy	Loss	AUC-ROC
VGG16	98.27	98.25	98.26	98.26	9.24	0.9961
VGG19	97.61	97.54	97.57	97.57	13.03	0.9941
Resnet50	95.73	95.40	95.47	95.49	9.58	0.9966
Proposed CNN	98.95	98.99	98.96	98.96	8.02	0.9921

TABLE VI. THE EXECUTION TIME OF CNN-BASED MODELS ON THE SECOND SCHEME OF SPLITTING THE POLLEN DATASET

Method	Training time (s)	Testing time (s)
VGG16	217.666	179
VGG19	241.568	223
Resnet50	6295.647	49
Proposed CNN	123.874	10

to the first scheme. For example, the proposed model does not achieve an absolute accuracy as in the first scheme, instead, it decreases to 98.96%. This result can be explained by the reduced number of samples in the training set. As a result, the model learns less from the training set, resulting in reduced classification performance.

V. CONCLUSION

In this paper, we have proposed a novel convolutional neural network model for classifying pollen-bearing and non-pollen-bearing honeybee images. Rather than using complex and pre-trained CNN models, we design a basic CNN architecture with a few layers, leading to a lighter and also more efficient model. We have also corrected some mislabeled samples from a widely used dataset in the literature. The performance of the proposed CNN model has been investigated and compared with other models based on this corrected dataset. The obtained results have shown that our method leads to the best performance in terms of both accuracy and execution time. In particular, it could identify correctly 100% all the pollen-bearing and non-pollen-bearing honeybee images from the testing set in the shortest time.

There are still several limitations that should be considered before deploying the use of the proposed model in designing automated systems to recognize pollen-bearing honeybees in practice. For example, the efficiency of the model was verified based on a small dataset that contains 714 images only. Its performance should be validated on other datasets with larger sizes. In addition, the choice of hyperparameters of the proposed architecture is suitable for the current dataset, but may not be for other datasets. Therefore, it would be better to have another method to find hyperparameters that are optimal for each dataset. From this point of view, some optimization algorithms such as Random search or Bayesian optimization could be applied for future work. In addition, the model can be applied to process honeybee images for some other related tasks, like counting the number of pollen-bearing honeybees (for the purpose of measuring the amount of pollen carried by honeybees to the hive), classifying pollen, or recognizing disease-carrying honeybees. However, its performance needs to be verified for each specific situation.

ACKNOWLEDGMENT

The authors would like to thank the Vietnam National University of Agriculture for sponsoring this research through the University-level science and technology project with the title "Research on deep learning algorithms of convolutional neural network and their applications in recognizing pollen-bearing honeybee images" and number "T2022-10-39".

Tomato Disease Recognition: Advancing Accuracy Through Xception and Bilinear Pooling Fusion

Hoang-Tu Vo, Nhon Nguyen Thien, Kheo Chau Mui
Software Engineering Department, FPT University, Cantho City, Vietnam

Abstract—Accurate detection and classification of tomato diseases are essential for effective disease management and maintaining agricultural productivity. This paper presents a novel approach to tomato disease recognition that combines Xception, a pre-trained convolutional neural network (CNN), with bilinear pooling to advance accuracy. The proposed model consists of two parallel Xception-based CNNs that independently process input tomato images. Bilinear pooling is applied to combine the feature maps generated by the two CNNs, capturing intricate interactions between different image regions. This fusion of Xception and bilinear pooling results in a comprehensive representation of tomato diseases, leading to improved recognition performance. Extensive experiments were conducted on a diverse dataset of annotated tomato disease images to evaluate the effectiveness of the suggested approach. The model achieved a remarkable test accuracy of 98.7%, surpassing conventional CNN approaches. This high accuracy demonstrates the efficacy of the integrated Xception and bilinear pooling model in accurately identifying and classifying tomato diseases. The implications of this research are significant for automated tomato disease recognition systems, enabling timely and precise disease diagnosis. The model's exceptional accuracy empowers farmers and agricultural practitioners to implement targeted disease management strategies, minimizing crop losses and optimizing yields.

Keywords—Tomato disease recognition; Xception; Bilinear pooling; convolutional neural networks; disease management

I. INTRODUCTION

Tomato plants are a vital crop worldwide, serving as a staple in numerous cuisines and contributing to global food security. Besides, regular consumption of tomatoes can contribute to improved health and a decreased susceptibility to various ailments, including cancer, osteoporosis, and cardiovascular disease. Those who incorporate tomatoes into their diet on a consistent basis are found to have a lower likelihood of developing cancer, encompassing lung, prostate, stomach, cervical, breast, oral, colorectal, esophageal, pancreatic, and several other forms of cancer [1]. However, tomato harvests are at risk of a variety of diseases that can cause significant yield losses and quality deterioration. Early and reliable identification of such diseases is necessary for implementing timely disease management strategies and minimizing agricultural losses. Tomato diseases are a significant concern for tomato growers worldwide, including Vietnam [2], [3], [4].

Techniques derived from Machine Learning (ML) and Deep Learning (DL) have been extensively utilized in image recognition across diverse domains, including agriculture [5], [6], medicine [7], [8], self-driving cars [9], [10], etc. Numerous studies have explored the application of these technologies to achieve accurate image recognition in these respective fields.

The purpose of this paper is to address the crucial need for accurate classification of tomato diseases in order to effectively manage them and maintain agricultural productivity. The study presents a novel approach to tomato disease recognition by combining Xception, a pre-trained convolutional neural network (CNN), with bilinear pooling to enhance accuracy. Extensive experiments were conducted on a diverse dataset of annotated tomato disease images to evaluate the effectiveness of the suggested approach. The model obtained an impressive test accuracy of 98.7%.

The paper is structured as follows: Section II offers an extensive literature review, presenting pertinent background information. Section III details the methodology utilized for Tomato Disease Recognition, including the Data Set, Data Preparation, and Model Evaluation Metrics. Section IV describes the experimental system and final results. Lastly, Section V concludes the study by summarizing the findings and providing concluding remarks. Section VI gives future directions of research.

II. RELATED WORKS

In recent years, improvements in DL techniques, particularly convolutional neural networks (CNNs) and transfer learning models (TL), have shown promising results in automating disease recognition tasks in agriculture. Zahid Ullah et al. [11] presents a hybrid deep learning approach, EffiMobNet, combining EfficientNetB3 and MobileNet models with techniques to handle overfitting, achieving a 99.92% accuracy in accurately detecting tomato leaf diseases. This study [12] utilizes pre-trained CNNs, specifically Inception V3 and Inception ResNet V2, to classify healthy and unhealthy tomato leaf images, achieving high accuracy (99.22%) and low loss (0.03%) with dropout rates of 50% and 15%, respectively. Sachin Kumar et al. [13] utilized a dataset of 6,594 tomato leaves, including six disease classes and one healthy class, from Plant Village, and achieved a significant accuracy of 96.35% using the ResNet-50 model. The authors in [14] suggest a method for classifying tomato leaf diseases employing transfer learning and feature concatenation by leveraging pre-trained kernel from MobileNetV2 and NASNetMobile models. They extract features from these models, concatenate them, and then reduce the dimensionality using kernel principal component analysis. The effectiveness of the concatenated features is confirmed through experimental results, with multinomial logistic regression achieving the best performance among the evaluated traditional machine learning classifiers, achieving an average accuracy of 97%.

The authors in the article [15] focus on developing a combined model for identifying tomato diseases utilizing image

data. Seven architectures, including VGG16, ResNet50, and various EfficientNet models, are evaluated for performance using transfer learning. The best-performing models are then combined using a weighted average ensemble, resulting in a suggested model with an accuracy of 98.1%. Nagamani H S et al. in the study [16] explores the identification of diseases affecting tomato leaves using ML techniques, including Fuzzy-SVM, CNN, and Region-based Convolutional Neural Network (R-CNN). Various image processing and feature extraction methods are employed, and R-CNN achieves the greatest accuracy of 96.735% in classifying different disease types. In this study [17], a DL model combining CNN and SVM is deployed to recognize and categorize tomato leaf images into 8 classes, including 7 prevalent diseases and a healthy class. The model is trained on a dataset of 8,000 photos and achieves an accuracy of 92.6% by utilizing CNN for feature extraction and SVM for classification.

Sanjeela Sagar et al. in this paper [18] presents an experimental study comparing traditional ML algorithms (RF, SVM, NB) with a deep learning CNN algorithm in order to classify tomato leaf disease. The results show that the CNN approach outperforms traditional methods, achieving over 95% accuracy in detection and classification. The authors in the article in this study [19] focus on using CNN methods, specifically the VGG model, for the detection of Multi-Crops Leaf Disease (MCLD). The trained model successfully classifies disease-affected leaves with high accuracy, achieving 98.40% accuracy for grapes and 95.71% accuracy for tomatoes. In this paper [20], the authors conduct a thorough evaluation of deep-learning approaches utilizing pre-trained CNN models and the PyTorch framework for classifying instances of diseases affecting tomato plants. Several models, including EfficientNet-B0, ResNext-50-32x4d, and MobileNet-V2, were tested, and ResNext-50-32x4d achieved the highest accuracy of 90.14%.

The paper in [21] presents an approach for classifying seven different types of tomato illnesses using DL models trained on a dataset of 10,448 images. The trained models demonstrated high accuracy, with the best testing precision reaching 95.71%. Sakkarvarthi, Gnanavel, et al in the article [22] proposes a deep-learning-based agricultural disease detection technique, employing a CNN approach in order to detect and classify diseases. The model, consisting of a pair of convolutional and pooling layers, exceeded the performance of the pre-trained InceptionV3, ResNet 152, and VGG19 models, achieving 98% training accuracy and 88.17% testing accuracy. In this paper [23], Singh, Rahul, et al. utilizes transfer learning with the EfficientNetB3 model for leaf classification, using a dataset of 11 different leaf types collected from an internet database. With a batch size of 32, the model is trained for 15 iterations and evaluated using the Adam optimizer, achieving an accuracy of 0.94. Sultana, Irene, et al. [24] present a dataset of 14,529 tomato leaf images containing ten different infections. InceptionV3 and ResNet-50 serve as employed learning algorithms, leveraging transfer learning techniques to train a classifier. The proposed deep learning model achieves promising results with an 85.52% accuracy rate for InceptionV3 and 95.41% for ResNet-50. The study in [25] aims for the purpose of identifying the presence of early blight infestation affecting tomato plants using a CNN approach. Various image processing techniques are applied to refine the dataset, and the CNN model is trained and evaluated

using different performance metrics, achieving a high accuracy of 98.10% with specific hyperparameters. The article [26] presents a CNN model that combines elements of different approaches for classifying diseases in tomato leaf images, utilizing well-known CNN architectures and feature transfer techniques. The suggested approach obtains high accuracy rates of 98.3% and 96.3% for both the dataset specifically designed for detecting tomato leaf diseases and the dataset collected in Taiwan, respectively.

The purpose of this study is to introduce an innovative method for tomato disease recognition by combining Xception, a pre-trained CNN, with bilinear pooling to enhance accuracy. The proposed model incorporates two parallel Xception-based CNNs that independently process tomato images and utilizes bilinear pooling to capture complex interactions between image regions. This fusion of Xception and bilinear pooling yields a comprehensive representation of tomato diseases, resulting in improved recognition performance.

III. METHODOLOGY

A. Data Collection and Preparation

In this research, a dataset comprising 32,535 images was used, obtained from the PlantVillage dataset [27] and Kaggle. The Tomato Disease dataset consists of 10 diseases and 1 healthy class, including Late blight (Class1), healthy (Class2), Early blight (Class3), Septoria leaf spot (Class4), Tomato Yellow Leaf Curl Virus (Class5), Bacterial spot (Class6), Target Spot (Class7), Tomato mosaic virus (Class8), Leaf Mold (Class9), Spider mites Two-spotted spider mite (Class10), and Powdery Mildew (Class11).

The examples of tomato disease pictures from the dataset are displayed in Fig. 1, and Fig. 2 illustrates the distribution of the dataset. Before training and evaluating the model, the images are preprocessed by resizing them to 224x224 and applying an image preprocessing function. The dataset is then split into 25,851 photos for the training dataset, 4,010 photos for the validation dataset, and 2,674 photos for the test dataset.

B. Proposed Model

This paper introduces a novel approach for accurate classification of tomato diseases using a model that combines Xception [28], a pre-trained CNN, with bilinear pooling. The proposed model consists of two parallel Xception-based CNNs that independently process tomato images, with bilinear pooling capturing intricate interactions between different regions of the images. The model aims to accurately classify images into 11 different classes.

The proposed model is based on the Xception architecture. It takes an input image of size 224x224x3. The model consists of two parallel Xception layers that process the input image independently, resulting in two sets of feature maps with dimensions 7x7x2048. These feature maps are then combined by the so-called bilinear pooling layer (by taking their outer product). An average pooling layer is applied to reduce the spatial dimensions to 1x1 while preserving the depth of 2048. The output is flattened to a 1D vector of size 2048.

Next, a batch normalization layer is used, followed by a 256-unit dense layer. A dropout layer is introduced to prevent

Fig. 1. Sample tomato disease in tomato disease dataset.

Fig. 2. A dataset distribution.

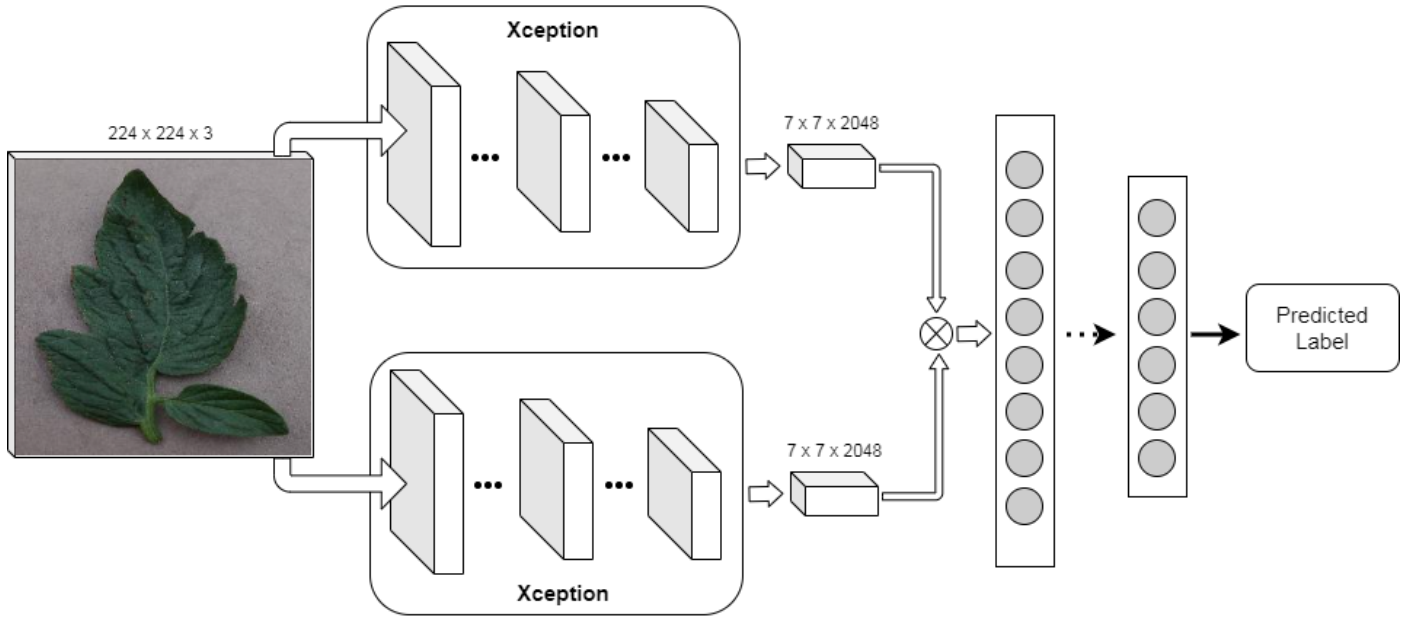

Fig. 3. The model proposed for classifying tomato diseases.

overfitting, and another dense layer with 11 units (matching the number of classes) is added as the final output layer. Fig. 3 shows the suggested model.

In the suggested model, a learning rate (LR) scheduling strategy [29] is integrated into the training phase. LR scheduling is a dynamic technique that adapts the LR, determining the size of the steps taken in the gradient descent optimization algorithm, during the model's training process. The objective of this approach is to improve the model's convergence by gradually decreasing the LR as training progresses.

In this specific model, the LR is reduced by a factor of 0.5 after two epochs, allowing for adjustments if training accuracy does not show improvement. To mitigate the risk of overfitting, the architecture of the model utilizes regularization techniques, which aid in avoiding overfitting and improving the overall performance of the model. These measures are crucial for real-world applications where optimal performance is of utmost importance.

The proposed model exhibits a substantial parameter count, with a total of 42,258,523 parameters. Among these, 42,145,371 parameters are trainable, meaning they are optimized and adjusted during the training process to enhance the model's performance. Additionally, there are 113,152 non-trainable parameters, which consist of fixed or pre-defined values that remain unchanged during training.

The suggested model and its underlying architecture can be visualized in Fig. 4, while Fig. 5 provides a comprehensive representation of important details. This includes information about the model's layers, the output shape, the trainable parameter count, and the overall number of trainable parameters that are examined for each layer in the model.

Fig. 4. The suggested model architecture proposed in this study.

C. Performance Evaluation Measures

The performance of the proposed integrated Xception and bilinear pooling model was comprehensively evaluated using a range of essential metrics. Precision, which quantifies the ratio of correctly predicted positive instances to the total

Layer (type)	Output Shape	Param #	Connected to
input_layer (InputLayer)	[(None, 224, 224, 3 0)]	0	[]
xception_layer_2 (XceptionLayer)	(None, 7, 7, 2048)	20861480	['input_layer[0][0]']
xception_layer_3 (XceptionLayer)	(None, 7, 7, 2048)	20861480	['input_layer[0][0]']
tf.einsum_5 (TFOPLambda)	(None, 7, 7, 2048)	0	['xception_layer_2[0][0]', 'xception_layer_3[0][0]']
average_pooling2d_5 (AveragePooling2D)	(None, 1, 1, 2048)	0	['tf.einsum_5[0][0]']
flatten_5 (Flatten)	(None, 2048)	0	['average_pooling2d_5[0][0]']
batch_normalization_53 (BatchNormalization)	(None, 2048)	8192	['flatten_5[0][0]']
dense_10 (Dense)	(None, 256)	524544	['batch_normalization_53[0][0]']
dropout_5 (Dropout)	(None, 256)	0	['dense_10[0][0]']
dense_11 (Dense)	(None, 11)	2827	['dropout_5[0][0]']

Total params: 42,258,523
Trainable params: 42,145,371
Non-trainable params: 113,152

Fig. 5. The layers of suggested model.

predicted positive instances, reflected the model’s ability to minimize false positives in classifying tomato diseases. Recall, capturing the ratio of correctly predicted positive instances to the actual total positive instances, demonstrated the model’s proficiency in identifying all relevant disease cases. The F1-score, a harmonic mean of precision and recall, provided a balanced assessment of the model’s precision-recall trade-off. Accuracy, a fundamental measure in classification tasks, gauges the proportion of correctly predicted instances out of the total instances in the dataset. In the context of tomato disease recognition, accuracy indicates the model’s overall correctness in identifying and classifying different disease types from input tomato images.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F_1 - Score = \frac{Precision * Recall}{Precision + Recall} \quad (4)$$

In which, TP represents True Positive, TN signifies True Negative, FP represents False Positive, and FN stands for False Negative.

IV. RESULTS

A. Environmental Settings

The experimental results were obtained by conducting the experiments on the Kaggle platform. The system used for the experiments had 13GB of RAM and a GPU Tesla P100-PCIE with 16GB of memory. The training of the model spanned across 30 epochs, and a batch size of 32 was used during the training process.

B. Evaluation Overall

The confusion matrix, showcasing the results of the proposed model, is presented in Fig. 6 and Fig. 7. Additionally, Fig. 8 and Fig. 9 illustrate the performance metrics, such as loss and accuracy, that were evaluated during both the model’s training and validation stages. The model achieves its highest accuracy at the 17th epoch and exhibits the lowest loss at the 28th epoch.

Fig. 6. Proposed model for tomato disease classification.

Fig. 7. Proposed model for tomato disease classification (%).

The classification report Table I provides a detailed analysis of the evaluation metrics for each tomato disease class. It includes various metrics like precision, recall, and F1-score, which assess the model’s accuracy in identifying specific diseases.

Table II provides a comprehensive analysis of the suggested model in comparison to other state-of-the-art methods tackling similar problems. The results indicate that the proposed model

TABLE I. CLASSIFICATION REPORT

Class	Precision	Recall	F1-Score	Support
Bacterial_spot	0.99	0.99	0.99	293
Early_blight	0.97	0.95	0.96	257
Late_blight	0.99	0.98	0.99	317
Leaf_Mold	0.99	0.99	0.99	296
Septoria_leaf_spot	0.97	0.99	0.98	298
Spider_mites_Two-spotted_spider_mite	1.00	0.99	1.00	174

Tomato_mosaic_virus	0.99	0.98	0.98	234
healthy	0.98	1.00	0.99	322
powdery_mildew	1.00	0.99	1.00	101

TABLE II. A COMPARISON OF OUR PROPOSED MODEL WITH CONTEMPORARY APPROACHES ON SIMILAR PROBLEMS

The study	Dataset	Method of Use	Accuracy
[21]	Plantvillage dataset	CNN model	95.71%
[14]	PlantVillage dataset	MobileNetV2 and NASNetMobile	97%
[13]	PlantVillage dataset	ResNet-50	96.35%
[15]	Plantvillage dataset	Wavelet-like Auto-Encoder (WAE)	98.1%
[19]	Plantvillage dataset	VGG16	95.71%
[18]	Plantvillage dataset	Inception v3	95%
[22]	Plantvillage dataset	CNN model	88.17%
This study	Plantvillage dataset	Xception and Bilinear Pooling	98.7%

achieved superior performance surpassing all other techniques mentioned in the table.

Fig. 8. Training and validation accuracy plot of the suggested model.

V. CONCLUSION

In conclusion, the proposed approach combining Xception-based CNNs and bilinear pooling demonstrates significant advancements in accurately detecting and classifying tomato diseases. With a remarkable test accuracy of 98.7%, surpassing conventional CNN approaches.

In Table I, the precision values indicate the accuracy of positive predictions for each class, ranging from 0.97 to 1.00. A higher precision value suggests a lower rate of false positive predictions.

Fig. 9. Training and validation loss plot of the suggested model.

The recall values reflect the ability of the model to correctly identify positive instances for each class. The range of recall values varies from 0.95 to 1.00, indicating a high level of accuracy in capturing true positive instances.

The F1-scores, which represent the precision-recall harmonic mean, provide an overall measure of the model's performance for each class. The F1-scores range from 0.96 to 1.00, indicating a strong balance between precision and recall.

This comparison data demonstrates that the suggested model performs well across multiple classes, with consistently high precision, recall, and F1-scores. These metrics indicate the model's effectiveness in accurately identifying and classifying the different classes in the dataset.

This integrated model empowers farmers and agricultural practitioners with timely and precise disease diagnosis, enabling them to implement targeted disease management strategies and optimize yields. The successful integration of these techniques showcases the potential of advanced deep learning methods in automated tomato disease recognition, contributing to the advancement of agricultural systems.

VI. FUTURE WORKS

Building upon the innovative approach presented in this paper, future research directions in the field of agricultural disease recognition can explore several promising avenues. Firstly, investigating the generalizability of the proposed Xception and bilinear pooling model to other crops and diseases holds great potential. Additionally, refining the model's interpretability and explainability could enhance its usability by providing insights into the features and regions contributing to disease classification. Exploring techniques like attention mechanisms or saliency maps could shed light on the decision-making process of the model, enabling users to trust and fine-tune its predictions.

Abstract—This research aims to improve the process of finding alternative drugs by utilizing artificial intelligence algorithms. It is not an easy task for human beings to classify the drugs manually, as this requires much longer time and more effort than doing it using classifiers. The study focuses on predicting high-quality medical drug data by considering ingredients, dosage forms, and strengths as features. Two datasets were generated from the original drug dataset, and four machine learning classifiers were applied to these datasets: Random Forest, Support Vector Machine, Naive Bayes, and Decision Tree. The classification performance was evaluated under three different scenarios, which varied the ratio of the training and test data for both datasets, as follows: (i) 80% (training) and 20% (test dataset), (ii) 70% (training) and 30% (test dataset), and (iii) 50% (training) and 50% (test dataset). The results indicated that the Decision Tree, Naive Bayes, and Random Forest classifiers showed superior performance in terms of classification accuracy, with over 90% accuracy achieved in all scenarios. The results also showed that there was no significant difference between the results of the two datasets. The findings of this study have implications for streamlining the process of identifying alternative drugs.

Keywords—classification; alternative drugs; medical; decision tree; Support Vector Machine; Naive Bayes; Random Forest

I. INTRODUCTION

Computers have brought significant technical improvements that have resulted in the creation of huge amounts of data, particularly in pharmaceutical and healthcare systems. The availability of huge amounts of data has increased the need for data mining techniques to produce useful knowledge [1]. Accurate analyses of medical drug data are required to discover appropriate alternative medication for a patient, which is gaining with increasing data in the health care and biomedical communities [2][7].

Raw drugs data requires a clear description and interpretation for analysis purposes, this is to find the similarities between drugs that have the same properties and then to find the alternative drugs [2]. The drugs data has many different attributes collected from different sources. The heterogeneity of drug sources, and the variation of their types, made it an uneasy task for human beings to classify the drugs manually as this needs much longer time and more effort than doing it using classifiers. One of the biggest problems is that big data processing and analysis are challenging to acquire meaningful data to support an accurate medical drug practice [10]. As a result, automated medicines classifiers can assist pharmacists and clinicians in prescribing an acceptable replacement

prescription if the desired drug is unavailable, as long as the alternative drug has the same constituent name [1][29].

Quality medical drug data refers to accurate and reliable information about medications, including their uses, dosage, side effects, interactions, and other important details. This information is used by healthcare professionals, researchers, and patients to make decisions about the use and prescribing of drugs. Quality drug data is essential for ensuring safe and effective medication use and is typically obtained from reputable sources such as the FDA, the WHO, and medical literature [1].

Artificial intelligence (AI) can play a role in the collection, analysis, and dissemination of quality medical drug data. For example, AI algorithms can be exploited to mine large amounts of data from various sources, such as clinical trials, and electronic health records, to identify patterns and generate new insights about drugs [14]. AI can also be used to support drug discovery and development by identifying potential new drug candidates, predicting their efficacy and safety, and optimizing their formulation and delivery. AI models can also be used in drug safety monitoring by analyzing electronic health records, clinical trial data, and spontaneous reports to detect safety signals and identify potential risks associated with drugs [24]. Moreover, AI-based chatbots can be used to provide patients with personalized information about their medications, including dosage instructions, potential side effects, and interactions with other drugs. Overall, AI can help to improve the quality of medical drug data by enabling faster, more accurate, and more complete data analysis, and by providing new ways to access and use this information. Many ongoing AI research projects aim to improve the quality of medical drug data, such as Insilico [28], Medicine [27], Exscientia [25], DeepChem [17], and Numerate [26] all of these focused on drug discovery and development.

Pharmacies and other medical professionals can benefit from using an alternative drugs model by assisting them in classifying drugs based on their chemical properties. Such a proposed model would remarkably shorten the time to identify alternative medicines if the original is not found [1]. It also helps people who are looking for a drug with a lower price and cannot afford to purchase the original drug. So, the proposed model can help them to identify other drugs alternatives that are more affordable to them at the same time, and such options have similar chemical properties to the original option [2]. This research aims to predict alternative medical drug using AI algorithms. The alternative drug has the same chemical

characteristics as the original drugs using several features such as Ingredients, Dose Forms, and Strengths. This goal can be accomplished by proposing a conceptual approach for classifying structured medical data using Machine Learning (ML) algorithms: Random Forest (RF), Naive Bayes (NB), Decision Tree (DT), and Support Vector Machine (SVM). This aim can be accomplished by considering the following objectives: (i) to investigate the performance of the different classifiers mentioned above. (ii) to investigate the quality of raw data in terms of data amount, diversity, and minimization. (iii) to propose a conceptual approach for classifying structured medical data using machine learning.

The main contribution that can be provided by the proposed method is in the following: (i) propose an efficient method that is used to deal with semi-structured data and transform it into a structured format, which is a meaningful format used with the classifiers. (ii) provide a new way that is used to label the input drugs according to their properties based on two rules. Each labeling rule takes into account a specific combination of attributes. (iii) investigate the use of different classifiers, study their effect on the accuracy of predicting the correct drugs as well as compare their performances.

The remainder of this paper is structured as follows: Section II presents different machine learning algorithms and discusses their importance in such a study. The third Section III illustrates the related previous work. In Section IV, the proposed approach, four main steps used to build the prediction model is presented and explained. The experimental results and discussion is discussed in Section V. Lastly, Section VII presents our work's conclusion and future work.

II. BACKGROUND

Predictions from AI refer to forecasts or estimates made by an artificial intelligence (AI) system. These predictions can be made using a variety of techniques, such as machine learning, deep learning, or natural language processing [7]. The accuracy of these predictions will depend on the quality of the data used to train the AI model, as well as the complexity of the model itself. Some examples of predictions made by AI include stock market forecasting, weather forecasting, image or speech recognition, and many more [11][16]. Furthermore, the quality of the data that has been processed and analyzed by a machine learning model to make predictions or forecasts. The quality of the predictions will depend on the accuracy of the model, as well as the quality of the input data used to train the model [24].

Predicting the efficacy and safety of a medical drug is an important task in the drug development process. Artificial intelligence can be used to help predict the effectiveness of a drug by analyzing large amounts of data from preclinical and clinical trials. This includes things such as genetic data, demographics of the patient, and laboratory results [14]. In addition, artificial intelligence can be used to identify potential side effects and interactions with other drugs. One of the popular methods is using machine learning (ML) models to analyze data from drug trials and electronic health records (EHRs) to identify patterns that may indicate a drug's efficacy or potential side effects. Another approach is to use deep learning models to analyze the chemical structure of the drug and predict its

potential interactions with other molecules in the body. It is worth noting that AI-based predictions for medical drugs are still in the early stage, and many pharmaceutical companies are actively researching and developing new methods for using AI in drug development. Under the umbrella of AI in drug scope encompass, two branches of drugs are drug discovery and predicted drug.

Drug discovery is a process for identifying and developing new medications while predicting drug efficacy and safety refers to using artificial intelligence techniques to analyze data to make predictions about how a drug will perform in preclinical and clinical trials [29]. Drug discovery involves identifying potential drug targets, synthesizing and testing new compounds, and conducting preclinical and clinical trials to determine a drug's efficacy and safety. This process can take many years and involve a significant investment of time and resources [5]. On the other hand, using AI to predict drug efficacy and safety involves analyzing data from various sources, such as preclinical trial results, electronic health records, and genetic data, to identify patterns that may indicate a drug's effectiveness or potential side effects. This can be done more quickly and efficiently than traditional methods and can help reduce the cost and time associated with drug development [1] [2]. In summary, drug discovery is the process of identifying and developing new drugs from scratch, while using AI to predict drug efficacy and safety is a way to analyze existing data and make predictions about how a drug will perform in preclinical and clinical trials.

Also, this section provides the necessary background to understand how the following classifiers work: Random Forest (RF), Naive Bayes (NB), Decision Tree (DT), and Support Vector Machine (SVM).

Random Forest. Random forest is a learning algorithm for classification and regression tasks. It works by building multiple decision trees at training time, which is the cornerstone for the classification or discrimination regression processes. These multiple decision trees use RF to ensure accurate and reliable prediction [21].

Naive Bayes. Naive Bayes is one of the most famous machine learning algorithms, data analysis, and classification. Specifically, it can be characterized by rapid processing and efficiency in forecasting processes. This classifier is based on the statistical concept, Bayes' theorem. It computes the probability of a given result by verifying what is available and known as Naive because it adheres to the independence assumptions principle. As a result, the relationships between all attributes and features are thought to be independent of one another [18]. So that the Naive Bayes model is trained with the data and its characteristics available in the databases. The model then determines the type of new records and classifies them based on the data and statistics available to it. The formula for Naive Bayes is [18]:

$$P(C|X) = \frac{(P(X|C)P(C))}{(P(X))} \quad (1)$$

Decision Tree. A decision tree is a supervised learning algorithm that continuously divides data according to a specific parameter. As it is a tree that looks like a flow chart that

contains a node called the root and has no edges, while all other nodes have edges and are called leaves (also known as decision nodes) [22][3].

Support Vector Machine. Finding a hyperplane that categorizes the data points in N-dimensional space (N: the number of features) is the goal of the support vector machine algorithm (SVM) [9]. After constructing the hyperplanes, the SVM determines the boundaries between the input classes and the input elements [6].

III. RELATED WORK

There is ongoing research in using AI to predict drug efficacy and safety. Here are the most recent and relevant related works in this field.

One approach is using machine learning (ML) models to analyze data from drug trials and electronic health records (EHR) to identify patterns that may indicate the efficacy or potential side effects of a drug. Nature Medicine used an ML model to analyze data from a clinical trial of a drug to treat Alzheimer's disease and was able to predict which patients would respond well to the drug with high precision [5][20].

Another approach is to use deep learning models to analyze the chemical structure of a drug and predict its potential interactions with other molecules in the body [31]. These models can be trained on large datasets of chemical compounds and their known interactions with proteins, enzymes, and other molecules, to predict potential interactions of new compounds. A deep learning model called a graph convolutional neural network (GCNN) was trained on a dataset of known drug-protein interactions and then used to predict potential interactions of new compounds with a protein called cytochrome P450 3A4 (CYP3A4). The results showed that the model was able to predict potential interactions with high accuracy [19]. Similar research purposes are in [32], a deep learning model called a graph attention network (GAT) was trained on a dataset of known drug-protein interactions and then used to predict potential drug-protein interactions. The results showed that the model was able to predict potential interactions with high accuracy and outperformed traditional machine learning methods.

In [2], Alzyadat et al. proposed an approach to predict a targeted drug for the variety of large data structures measured by a stability scale in the preprocessing phase. Their approach performs quality data analysis using correlation methods to identify feature choices related to mapping data, which concerns the basic methods for predicting data based on the K-mean cluster and decision tree. The result of the prediction of the target drug was used as a principal component analysis (PCA) by distance value.

In [1], Al-Hgaish et al. proposed an approach based on the K-Mean algorithm to maintain the quality of medical drug data toward meaningful data in the data lake by clustering big data scope. The K-Mean clustering is used to form different clusters. Each cluster that was produced represents an alternative drug that is compatible with data lake components. The results show that the approach presented in their paper has achieved 92.7% accuracy.

In [12], Huang et al. proposed an approach to classify unknown drugs and provide assistance for drug screening during the development process. They collected a drug dataset using a web crawler. Based on this dataset, the authors derived an equation to calculate the similarity between drugs and defined similarity calculation equation parameters from a subset of the data. Drug data was categorized using the KNN (K closest neighbor) classifier based on drug similarities. The findings demonstrated that the suggested drug classification model can achieve a 77.7% accuracy value.

In [13], using the DrugBank dataset, Ibrahim et al. suggested a similarity-based machine learning system named "SMDIP". To describe the sparse feature space, they computed drug-drug similarities using an evaluation metric for the available biological and structural information on DrugBank. The chosen DDI (Drug-Drug Interaction) key features are subjected to the deployment of six different ML model types. With the following results: Precision 82%, Recall 62%, F-measure 78%, and Accuracy 79%, SMDIP has demonstrated favorable prediction performance when compared to relevant studies.

In [8], Dang et al. used data consisting of approved drugs of histamine antagonists that are connected to 26,344 Drug-Drug Interactions (DDI) pairs from the DrugBank database. Several classifiers such as Random Forest, Naive Bayes, Logistic Regression, Decision Tree, and XGBoost were used with five-fold cross-validation to approach a large-scale DDIs prediction among histamine antagonist drugs. According to the prediction performance, their model performed better than previously published works on DDI prediction with the best Precision of 78.8%, Recall of 92.1%, and F1-score of 83.8% among 19 given DDIs types.

The differences between our work with other studies are as follows:

- 1- A new methodology not used before in the previous studies to achieve the aim of this study by using the two datasets produced from the original dataset.
- 2- To the best of our knowledge, we have not come across any study conducted by using the four classifiers that are used in this study, especially, on this dataset (i.e. FDA) in order to achieve the aim.

IV. THE PROPOSED APPROACH: BUILDING PREDICTION MODEL

The proposed approach is presented in this section. In the beginning, we give a holistic view of the approach. The approach's steps are then detailed in subsequent subsections.

A. Overview

The essential steps of the proposed medicine categorization approach are explained in this section. Fig. 1 shows the four steps for the suggested model after importing the dataset to obtain an alternative drug. These steps are as follows: 1) pre-processing, 2) feature extraction, 3) applying heuristic-based rules, and 4) applying different classifiers with different scenarios. The following is an explanation of the proposed approach, which consists of the following steps:

Fig. 1. An overview of the proposed approach (F: Feature, L: Label).

TABLE I. SELECTED FEATURES FOR TRAINING

Features	Type	Description
Ingredients	textual	The active ingredients of the medicine
Strengths	numerical	Active component effect
Dose Forms	numerical	The medicine dose route or form

B. Step 1: Pre-processing

This is the first step in the proposed approach, as shown in Fig. 1. Pre-processing is the step-in machine learning and natural language processing where raw data is cleaned, transformed, and organized in a format that is suitable for the model to train. This can include tasks such as tokenization, stemming, and removing stop words, as well as more complex tasks such as creating new features or dealing with missing data. Pre-processing is a crucial step in building a successful machine learning model, as the quality and structure of the input data can have a big impact on the performance of the model. In this step, you consider the content of the data (indexing) through two aspects. The first aspect performs a vertical process that indexes each attribute with missing data, incomplete data, outliers, or empty data (anything that is zero or none). The second aspect of data pre-processing is horizontal, where duplication of all rows is considered. The importance of this step is to avoid ambiguity and to increase the meaningful data set. On the other hand, the relationship between these attributes, which are best derived by feature selection will be clear [2].

C. Step 2: Features Selection

The important attributes were extracted in this step based on the previous studies and opinions of specialists of pharmacists and doctors. The database features that were picked for the investigation are displayed in Table I.

D. Step 3: Applying Heuristic-based Rules

Heuristic-based rules are a type of rule-based method used in artificial intelligence and natural language processing. These rules are based on heuristics, which are general problem-solving strategies or “rules of thumb” that are used to make decisions or solve problems. Heuristic-based rules use these rules of thumb to make decisions about how to process or understand natural language input. Heuristic-based rules are generally simple and easy to understand, but they can be prone to errors and biases. They are useful in situations where the data is well understood, and the rules can be defined to cover most cases. However, they may not be able to handle more complex or ambiguous input. An example of using heuristic-based rules in medical drug data would be to identify drug interactions based on a set of predefined rules. For example, a rule may state that if a patient is taking drug A and drug B, there is a high risk of interaction and the dosage of one or both drugs should be adjusted. Another example is extracting information from electronic medical records (EMR) using heuristic-based rules. The rules can be defined to identify specific patterns in the text, such as identifying the name of a drug, the dosage, the frequency of administration, and the duration of treatment. Once these patterns are identified, the information can be extracted and organized into a structured format for analysis. Heuristic-based rules are also used to classify clinical notes from EMR, for example, a rule can be defined that states if a patient is complaining of chest pain and shortness of breath, then it is likely a case of Angina [15]. In summary, heuristic-based rules are an efficient and cost-effective way to extract and analyze medical drug data. They are particularly useful when the data is well-defined, and the rules can be easily formulated to cover most cases. However, they may not be as robust as other methods in handling complex or ambiguous input.

In this study, two heuristic-based rules (rule 1 and rule 2) were used in the proposed approach to produce two datasets, as follows.

1) *Rule 1: Two Similar Features:* Dataset 1 was produced from the original dataset after applying rule 1, which is explained in (Equation 2 below). The content of this rule suggests that all drugs having similar ingredients, and strength values would have the same label number.

$$L1 = sim(D_i(x_1, x_2), D_j(x_1, x_2)) \quad (2)$$

From Equation 2, suppose that there are two drugs, D_i , D_j each drug has two attributes, i.e. the ingredient, and strength represented by the variables x_1 , x_2 . As rule 1 suggests that if these two drugs have the same or similar values of x_1 , x_2 , it can be said that both drugs have the same category or label (L).

2) *Rule 2: Three Similar Features:* Dataset 2 was produced using the same idea that was used to produce dataset 1. However, the content of this rule suggests that all drugs having similar ingredient, strength, and dose values would have the same label number, as stated in Equation 3.

$$L2 = sim(D_i(x_1, x_2, x_3), D_j(x_1, x_2, x_3)) \quad (3)$$

The equation can be read as follows. x_1 , x_2 , x_3 are ingredient, dose form, and strength, respectively. D_i , D_j are two drug items. Sim is similarity measurement, and L represents the label ID.

E. Step 4: Applying Different Classifiers with Different Scenarios

In this final step, the following classifiers are applied in this study: Decision Tree, Random Forest, Support Vector Machine, and Naive Bayes. These classifiers are applied individually to the datasets, which are obtained in the previous step, according to their description in the background section. The application of these classifiers on each dataset (dataset 1 and dataset 2) is done according to different scenarios. In each scenario, a percentage of the dataset's records is considered to train the prediction model while other records are used to test the prediction model.

V. EXPERIMENTS AND EVALUATION

In this section, the dataset used to evaluate the proposed approach is described, and the evaluation procedure and metrics are listed.

A. Dataset Description

The dataset utilized in this investigation is from the Food and Drug Administration (FDA) and may be found in the following link (<https://www.fda.gov/drugs/drug-approvals-and-databases/drugsfda-data-files>). This dataset consists of 14 features and 37,071 records. The selected features and the description for each feature of the dataset are based on the specialists' viewpoints as shown in Table I. The dataset was approved by FDA and this took several years and involved multiple stages, including preclinical testing, phases of clinical trials, and a review of the drug's safety and efficacy by an advisory committee [1].

The reliability of a dataset refers to the consistency and accuracy of the data it contains. In the case of datasets such as *clinicaltrials.gov* and the FDA's drug approval dataset, the

data is typically considered to be reliable as it is collected and compiled by reputable government agencies with strict oversight and regulations in place. The features and properties of drug approval datasets such as *clinicaltrials.gov* and the FDA's drug approval dataset include [1][2]:

- 1- Drug Information: these datasets contain information on drugs that are currently in development, have been approved, or have been withdrawn from the approval process. This information includes the drug's name, active ingredients, intended use, and the company developing the drug.
- 2- Study Information: these datasets also contain information on the clinical trials that have been conducted to evaluate the safety and efficacy of the drugs. This includes the study design, the number of participants, the inclusion and exclusion criteria, and the primary and secondary outcome measures.
- 3- Status Information: these datasets provide information on the current status of the drug's development and approval. This includes whether the drug is currently in preclinical testing, phase 1, 2, or 3 clinical trials, or has been approved or withdrawn by the FDA.
- 4- Search and Filter Capabilities: these datasets are searchable and can be filtered by various criteria such as drug name, condition, company, and study status.
- 5- Publicly Available: these databases are publicly available and can be accessed by anyone with an internet connection.
- 6- Regularly Updated: the data in these datasets is updated regularly as new information becomes available.

B. Research Questions and Evaluation Metrics

In this study, two research questions are answered. These questions are in the following:

- **RQ1:** To what extent the proposed approach is accurate to suggest alternative drugs? This research question aims to show the ability of the proposed approach to suggest the most suitable alternative drugs.
- **RQ2:** To what extent the proposed approach is comparable to the most recent works in the subject? This research question aims to measure the efficiency of the proposed approach when it is compared to the research works in the literature.

To address the first research question (RQ1), The obtained results are evaluated using well-known measures in this subject [4][23]. These measures are as follows: Precision, Recall, F-measure, and Accuracy. The values of these measures take a range of [0-1]. We looking to have values near to the one in all considered measures. The equations of these measures are as follows:

$$Precision = \frac{TP}{TP + FP} \quad (4)$$

$$Recall = \frac{TP}{TP + FN} \quad (5)$$

TABLE II. CLASSIFIERS RESULTS OF SCENARIO 1.

Classifier	Evaluation Measure	Dataset 1	Dataset 2
RF	F1-measure	92.34%	89.73%
	Recall	93.61%	91.62%
	Precision	91.79%	88.64%
	Accuracy	93.61%	90.27%
NB	F1-measure	97.10%	98.48%
	Recall	96.88%	98.73%
	Precision	97.59%	98.36%
	Accuracy	96.88%	98.58%
DT	F1-measure	97.95%	98.47%
	Recall	98.27%	98.73%
	Precision	97.85%	98.34%
	Accuracy	98.27%	98.73%
SVM	F1-measure	2.85%	3.44%
	Recall	9.53%	10.48%
	Precision	1.16%	2.28%
	Accuracy	8.98%	10.48%

TABLE III. CLASSIFIERS RESULTS OF SCENARIO 2.

Classifier	Evaluation Measure	Dataset 1	Dataset 2
RF	F1-measure	91.28%	87.58%
	Recall	92.83%	90.19%
	Precision	90.65%	86.09%
	Accuracy	92.83%	90.19%
NB	F1-measure	95.04%	96.94%
	Recall	95.83%	97.52%
	Precision	94.92%	96.64%
	Accuracy	95.83%	97.52%
DT	F1-measure	96.47%	96.88%
	Recall	97.10%	97.52%
	Precision	96.25%	96.54%
	Accuracy	97.10%	97.52%
SVM	F1-measure	1.45%	2.44%
	Recall	8.56%	9.24%
	Precision	0.16%	1.75%
	Accuracy	7.97%	9.49%

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (6)$$

$$F - measure = \frac{2 * Precision * Recall}{Precision + Recall} \quad (7)$$

where TP, TN, FP, and FN indicate to true positive class, true negative class, false positive, and false negative class, respectively.

The classifiers used in this study(i.e. Random Forest (RF), Decision Tree (DT), Naive Bayesian (NV), and the Support Vector Machine (SVM)) were applied to each dataset separately; dataset 1 and dataset 2. However, in the training and test dataset of each classifier, three scenarios were used in the study, as follows:

- 1- **Scenario 1:** 80% of the dataset's records are used for training while 20% of dataset's records are used for testing.
- 2- **Scenario 2:** 70% of the dataset's records are used for training while 30% of dataset's records are used for testing.
- 3- **Scenario 3:** 50% of the dataset's records are used for training while 50% of dataset's records are used for testing.

To address the second research question (RQ2), a comparison was made between the proposed approach in this study with other recent and relevant works in terms of Precision, Recall, F-measure, and Accuracy metrics.

VI. RESULTS AND DISCUSSION

This section explains the experimental results from testing the model in different scenarios. As this study was designed for three scenarios, each has two datasets based on the two rules. The results of classifiers are represented by several evaluation criteria: classification Accuracy, F-measure, Recall, and Precision.

A. Research Question (RQ1)

1) *The Results of Scenario 1:* this subsection presents the results of Scenario 1. This scenario was built based on the percentage of the samples of the dataset used in the experiment. 80% of the records were used to train the dataset while 20% of the records were used to test the dataset. This scenario applied to two datasets; the four classifiers were conducted on each dataset. Table II shows the results of Scenario 1. The results show that DT has achieved high classification accuracy for dataset 1 (98.27%), and dataset 2 (98.73%) compared to other classifiers used in the study. The high accuracy of the Decision Tree over the other classifiers can be attributed to the fact that these kinds of algorithms, i.e., the tree-based classifiers, are less prone to overfitting. At the same time, training makes them robust and rigid against outliers and misclassification [30]. Both the RF and the DT outperformed the SVM, as can be seen. Also, we can see that there was no big difference between the results of dataset 1 and dataset 2. This demonstrates that using two attributes can achieve the study's goal of finding an alternative drug with the strongest effect by using two attributes.

2) *The Results of Scenario 2:* this subsection presents the results of Scenario 2. This scenario was built based on the percentage of the samples of the dataset used in the experiment. 70% of the records were used to train the dataset, while 30% of the records were used to test the dataset. As can be seen from Table III, it can be derived the same observations noticed for scenario 1. The average performance of each one of the NB, DT, and RF was also higher than 90% which indicates that these three classifiers are good enough to handle the input data. As an observation, the SVM classifier still has minor performance outcomes compared to the other classifiers involved in the study. This is for the same interpretation mentioned in Scenario 1. Also, we can see that there was no big difference between the results of dataset 1 and dataset 2. This proves that using two attributes can achieve the aim of this study and find an alternative drug for the strongest effect of choosing the two attributes.

3) *The Results of Scenario 3:* this subsection presents the results of Scenario 3, As can be seen from Table IV. This

TABLE IV. CLASSIFIERS RESULTS OF SCENARIO 3.

Classifier	Evaluation Measure	Dataset 1	Dataset 2
RF	F1-measure	89.31%	85.60%
	Recall	91.46%	88.77%
	Precision	88.27%	83.84%
	Accuracy	91.46%	88.77%
NB	F-measure	91.64%	92.81%
	Recall	93.26%	94.41%
	Precision	91.00%	91.92%
	Accuracy	93.26%	94.41%
DT	F1-measure	93.29%	92.78%
	Recall	94.77%	94.41%
	Precision	92.54%	91.87%
	Accuracy	94.77%	94.41%
SVM	F1-measure	6.15%	5.59%
	Recall	7.18%	6.99%
	Precision	5.57%	4.86%
	Accuracy	7.18%	6.99%

scenario was built based on the percentage of the records of the dataset used in the experiment. 50% of the records were used to train the dataset while 50% of the records were used to test the dataset. Not far from the results in both Scenario 1 and 2, it can be realized that the experimental results in Scenario 3 for the tested classifiers have almost similar experimental results for the same reasons mentioned in both Scenario 1 and Scenario 2. Also, we can see that there was no big difference between the results of dataset 1 and dataset 2. This proves that using two attributes can achieve the aim of this study and find an alternative drug for the strongest effect of choosing the two attributes.

As a summary, we can note that the DT classifier outperforms other studied classifiers (RF, NV, and SVM) in terms of Precision, Recall, F-measure, and Accuracy. Also, it is noted that SVM always produced unsatisfactory results. This is based on the experimental results shown in Table II, III, and IV.

B. Research Question 2 (RQ2)

The most recent and relevant work in the literature is the work proposed by Dang et al.[8]. They conducted their study on drug data. Also, various classification algorithms were applied in their studies such as Naive Bayes, Decision Tree, Random Forest, Logistic Regression, and XGBoost. They used the Precision, Recall, F-measure to evaluate the obtained results, but we used the Accuracy measure in addition to Precision, Recall, and F-measure to evaluate our proposed model. Al-Hgaish et al.[1] conducted their study on the same as our dataset but using clustering algorithms. Their study is to maintain the quality of medical drug data toward meaningful data in the data lake by clustering big-data scope using K-Mean Algorithm. They were focused only on analyzing the dataset. Huange et al.[12] conducted their study to classify unknown drugs and provide assistance for drug screening during the development process. They collected the drug dataset using a Web crawler and applied the accuracy as a metric using the k-nearest neighbor classifier. In our study, four classifiers were used (Random Forest, Naive Bayes, Decision Tree, and Support Vector Machine). Also, two datasets were analyzed based on applying two heuristic-based rules. In addition,

three different scenarios were applied for each dataset using the following metrics in the analysis: Precision, Recall, F1-measure, and Accuracy.

Table V shows the comparison results among the most recent and relevant works (mentioned above) in this subject. It has been noted that from Table V that the proposed model has outperformed three modern methods published in the past few years in terms of accuracy Dang et al.[8], Al-Hgaish et al.[1], and Huange et al.[12]. This is because of the use of a new methodology as well as applying classifiers that have not been used before in previous studies of the dataset (i.e., the Food and Drug Administration).

VII. CONCLUSIONS AND FUTURE WORK

The goal of this study is to predict quality medical drug data toward meaningful data from an input drug dataset. The alternative drug has the same chemical characteristics as the original drugs have several features: ingredients, dose forms, and strengths. This aim can be accomplished by considering the following objectives: (i) to investigate the performance of different classifiers (i.e., Decision Tree, Random Forest, Support Vector Machine, and the Naive Bayesian) on the drugs dataset. (ii) to investigate the quality of raw data in terms of data amount, diversity, and minimization. (iii) to propose a conceptual approach for classifying structured medical data using machine learning. The experiments were conducted on three scenarios for the following classifiers: Decision Trees, Random Forest, Support Vector Machine, and Naive Bayesian. The obtained results indicated that the Decision Tree, Naive Bayes, and Random Forest classifiers showed superior performance in terms of classification accuracy, with over 90% accuracy achieved in all scenarios. The results also showed that there was no significant difference between the results of the two generated datasets. The findings of this study have implications for streamlining the process of identifying alternative drugs. When it comes to the performance of the Support Vector Machine, it can be realized that it has a major degradation in performance.

Future work involves exploring the use of more advanced machine-learning techniques to improve the accuracy and performance of the classifiers. Another avenue for further research would be to include more features and variables in the analysis to provide a more comprehensive evaluation of the drugs. Additionally, it would be beneficial to compare the results of this study with other existing drug classification systems to identify any areas for improvement. Finally, conducting user studies and gathering feedback from medical professionals could provide valuable insights into the real-world applicability of the proposed approach and identify any potential limitations.

Incorporating Learned Depth Perception Into Monocular Visual Odometry to Improve Scale Recovery

Hamza Mailka, Mohamed Abouzahir, Mustapha Ramzi

High School of Technology of Salé Laboratory of Systems Analysis-Information Processing
and Industrial Management (LASTIMI),
Mohammed V University in Rabat, Morocco

Abstract—A growing interest in autonomous driving has led to a comprehensive study of visual odometry (VO). It has been well studied how VO can estimate the pose of moving objects by examining the images taken from onboard cameras. In the last decade, it has been proposed that deep learning under supervision can be employed to estimate depth maps and visual odometry (VO). In this paper, we propose a DPT (Dense Prediction Transformer)-based monocular visual odometry method for scale estimation. Scale-drift problems are common in traditional monocular systems and in recent deep learning studies. In order to recover the scale, it is imperative that depth estimation to be accurate. A framework for dense prediction challenges that bases its computation on vision transformers instead of convolutional networks is characterized as an accurate model that is utilized to estimate depth maps. Scale recovery and depth refinement are accomplished iteratively. This allows our approach to simultaneously increase the depth estimate while eradicating scale drift. The depth map estimated using the DPT model is accurate enough for the purpose of achieving the best efficiency possible on a VO benchmark, eliminating the scaling drift issue.

Keywords—Visual odometry; scale recovery; depth estimation; DPT model

I. INTRODUCTION

The greatest anticipated technological advancement in the near future is autonomous ground vehicles (AGV), which operate entirely automatically. A vehicle operating autonomously requires precise and reliable information regarding its position for a successful navigation [1], [2], [3], [4]. There are currently many popular methods of providing comparatively reliable positioning information, such as the Global Navigation Satellite System (GNSS), Visual Odometry, and the Inertial Navigation System (INS) [5], [6], [7], [8], [9], [10], [11].

A growing interest in autonomous vehicles has led to well-developed novel approaches based on VO. Different approaches have been well studied since they estimate the position and orientation of moving objects based on the analysis of image sequences [12], [13], [14], [15]. A precise VO system is one of the most crucial techniques in the area of mobile robots. [16], [17], [18], [19]. The way conventional monocular VO systems operate is by assuming that the scale is one or by using ground truth for an approximation of the scale. Due to significant drift, monocular VO systems cannot operate on image sequences without ground truth or estimate the pose with significant drift [20], [21], [22], [23].

Despite the fact that several traditional monocular VO systems have been developed, they have still performed poorly or are unable to work in some conditions, like monotonous scenes that lack visible texture information or large-scale camera movements. When it comes to learning-based VO systems, they are developed by training neural networks in supervised or unsupervised manners through end-to-end pose estimation [24], [25], [26], [27]. Moreover, the efficiency of networks completely determines how accurate pose estimation is. Even with numerous training datasets and a network structure optimized, it is unavoidable for a network to encounter issues such as insufficient accuracy when estimating rotational pose.

Over the years, a lot of work has gone into developing a reliable and precise VO system. In terms of traditional VO algorithms, two main types exist: feature-based [13], [28] and direct methods [29], [30]. Calibration of the camera, identifying and matching features, rejecting outliers (using RANSAC), estimating motion, and estimating scale are typical components of feature-based techniques (e.g., Bundle Adjustment). However, finding the right features to reconstruct certain motions is still difficult. The motion of the pixel is tracked, and pose predictions are obtained by minimizing photometric error, so it is highly sensitive to light variations. Additionally, the classic monocular VO's absolute scale estimation requires the use of additional data or knowledge (such as the camera's height). In monocular systems, obtaining scale information is complicated and typically depends on an earlier, predefined absolute reference. A reference scale can be provided by integrating with some other sensors, like an inertial measurement unit. Scale drift [31] is often addressed by local optimization techniques like bundle adjustment and loop closure detection. In addition, researchers employ the depth estimation [32] from images to approximate the scale and adjust the calculated translation in addition to other approaches, like a ground plane estimation using the camera height, which is assumed to remain stable during motion.

The vast amount of training data (ground truth) required by supervised deep learning methods is usually collected with RGB-D cameras indoors and 3D laser scanners. Nevertheless, since ground truth is required, the supervised technique has a number of drawbacks. At first, the sensors' own inaccuracy and noise may have an impact on the network. Second, these sensors cannot record high-resolution information as well as images since their measurements are often sparser. Lastly, those sensors may not be able to obtain ground truth in some

locations. Because of this, researchers have begun to pay greater attention to unsupervised approaches that only need training data. In this context, the goal of our contribution is to propose a reliable localization that just requires images from a monocular camera in order to obtain an estimation of motion. The suggested strategy deals with the problem of scale estimation by using a dense prediction transformer model to estimate the depth map of the environment. As shown in this work, according to KITTI odometry benchmarks, the system's scale estimation performs in a manner comparable to that of the state-of-the-art.

The remainder of this paper is organized as follows: Section II represents a brief summary of related work. The DPT model utilized in our paper is summarized in Section III. In Section IV, we provide details on our end-to-end approach. Section V shows experimental results on the KITTI. In Section VI, the paper's contributions are summarized, as well as it concludes with some recommendations for future work.

II. RELATED WORK

Numerous studies have investigated how depth can be estimated from images employing stereo and monocular images, or multi-view images. By using conventional and traditional techniques in a single-view image, it is difficult to recognize the structure of the scene. Luckily, since the innovative research of [33], deep learning has progressed greatly in the computer vision field. Most CNN-based depth-map prediction approaches are supervised. To learn parameters, these techniques require more than one labeled dataset. We will look at how to solve the scale estimation problem in the following parts: In this section, we provide a brief summary of the most closely related work that is needed to assess the scene depth estimation and camera motion prediction.

A. Recovering Camera Poses and Depth using Conventional Techniques

Researchers in computer vision have long been interested in recovering depth-maps and camera poses. A learning depth approach based on 2D to 3D image conversion using examples is proposed by Konrad et al. [34]. They create an efficient and simplified version of the current 2D to 3D frame conversion algorithms. A feasible depth generation method from sequences of images was described in [35] employing auxiliary data from non-parametric depth sampling. The performance of this method was superior to all current standard depth methods. Camera posture research another important topic of study in the discipline of computer vision, has a great success using conventional methods. The most well-known conventional approach that is used to estimate camera pose using images is called ORB-SLAM [36]. It uses the feature matching approach for mapping and localization combined with a single monocular image. The process of this method has four stages: loop closure, tracking, mapping, and re-localization. But each stage needs to be carefully planned. Gao et al. [37] expanded this knowledge to build reconstructions of 3D objects from 2D images based on motion techniques. A method for predicting 3D structures and camera projections was put out in [38]. The strategy is in the area of estimating 3D symmetric objects from 2D symmetric perspectives and forms using numerous intra-class objects as an input model. It was

suggested by Ma et al. [39] that in remote sensing imagery, rigid and non-rigid structures can be matched using a locally linear transformation model. To determine scene depth, all of the approaches mentioned above either rebuild 3D geometry or establish pixel-by-pixel correspondences between input views. Nevertheless, the input data for these methods is multi-view images.

B. A Supervised Learning Approaches using Monocular Images

Since we can't obtain the structural properties from a single view image, determining a depth-map using a monocular camera is a difficult issue. Depth estimation has recently been viewed by some academics as a supervised learning approach. A network with two factors was proposed by Eigen et al. [40], the first of which assesses the scene's overall structure and the second of which refines it using local information. As one of the few papers using deep CNN to estimate scene depth using monocular images. Three separate computer vision issues were handled simultaneously via a framework that Eigen et al. [41] created (prediction of surface normals, depth estimates, and semantic identification) based on prior research. A completely convolutional architecture was suggested by Laina et al. [42] to describe the uncertain mapping between depth maps and monocular pictures. Li et al. [43] introduced a multi-streamed CNN architecture for depth estimation that is quick to train. Yan et al. [44] used a reference as the surface normal to aid in the monocular depth estimation problem. Up to this point, some studies on monocular depth prediction have combined CNNs and Random Forests. In certain studies on monocular depth prediction, CNNs and random forests were merged. Regression based on deep CNN characteristics was used by Li et al. [45] to overcome this issue, together with conditional random fields for post-processing refinement. Using only one image as a source of depth prediction, Roy et al. [46] introduced a deep regression forest approach that blends CNNs with random forests. As a result of depth data being continuous, Liu's formulation of depth prediction as the "random field learning with continuous conditions" problem [47] was developed. Although the aforementioned techniques have shown precise monocular-depth prediction, the ground truth is used as a basis for training, which limits the model's capacity for generalization.

C. An Unsupervised Learning Approaches using Monocular Images

Several unsupervised learning techniques that address the monocular depth estimation issue have recently been introduced to get over the ground-truth issue. Garg et al. [48] built a CNN to approximate the complex non-linear transformation that turns stereo images into depth maps using input camera motions. The proposed method of [49], [50] constructed a model based on Garg's work to incorporate a spatial smoothness loss into the unsupervised optical flow total loss function. Their efforts and outcomes are comparable. When training, Godard et al. [51] approached the difficulty of predicting depth as an issue with image reconstruction using epipolar geometry constraints. To determine the relationship between the rectified stereo images, a loss function is developed. In a semi-supervised manner, Kuznetsov et al. [52] employed

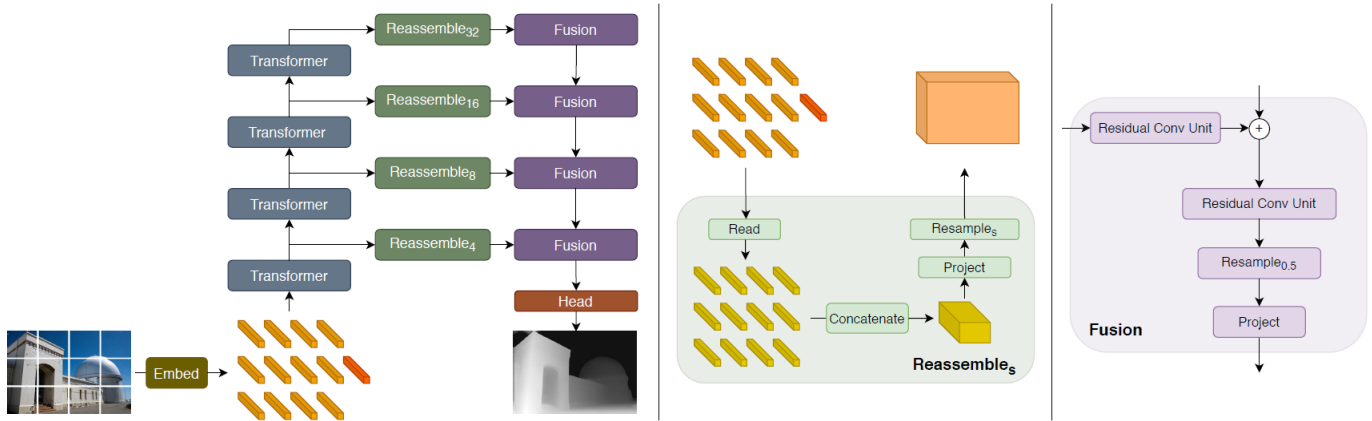

Fig. 1. The architecture of dense prediction transformer model that we used in our approach to estimate disparity maps from monocular cameras. This enables the recovery of precise metric estimates [61].

projected inverse and sparse ground truth depth data. Their models depend on a 3D laser sensor and camera that are precisely calibrated externally. A learning approach called CCRFN (Convolutional Conditional Random Field Network) was proposed by Yan Hua and Hu Tian [53] For estimating depth and identifying features by using the learning approach. It offers two benefits: first, it doesn't require manually created features, and second, it uses the relationship between individual features to estimate depth. Based on the research of Zhou[54], Yin et al. [55] introduced the GeoNet architecture for unsupervised learning, which jointly predicts optical flow, monocular depth, and dynamic object detection. Luo et al. [56] from SenseTime Research suggested stereo matching as the first sub-issue to address after the monocular depth estimation method. The above unsupervised learning approaches were trained on mono-image sequences or using stereo images with precise calibration. Temporal information cannot be fully utilized by stereo pictures. Due to depth ambiguity, which can occur in monocular images, different depths may correlate to objects that appear to be similar in the image. Although these unsupervised models succeeded in their objective of estimating scene depth without the need for ground truth, they have received little attention for their joint use of stereo and monocular sequences for depth prediction.

III. DPT MODEL

Due to the quick advancement of computer technology and digital imaging sensors. The camera sensor is progressively becoming more advantageous, and as a result, navigation using visual assistance and its related combined system have emerged as a significant component of the integrated navigation system. Since Transformer was so successful in natural language processing (NLP) [57], the computer vision community has given it a lot of attention. It has recently demonstrated exceptional performance on a variety of computer vision tasks, including semantic segmentation, object identification, imaging classification, and depth estimation. The standard architecture for dense prediction is fully-convolutional networks [58], [59]. Although many variations of this fundamental pattern have been presented throughout time, all current architectures use convolution and subsampling as their core components to learn

multi-scale models that can make use of a sufficiently wide context. When trained on enormous datasets and deployed as high-capacity architectures, transformer models have proven particularly effective. Attention processes have been adapted to image analysis in a number of publications. In particular, it has recently been shown that a direct application of effective token-based transformer designs in NLP may produce competitive performance on image categorization [60]. This work's most important finding was that, similar to transformer models in NLP, visual transformers require a substantial quantity of training data to reach their full potential.

In contrast to the state-of-the-art CNN-based method, Ranftl et al. [61] reported improved relative performance using the dense prediction transformer (DPT) model for monocular depth estimation. This is why we decided to estimate the depth map using the DPT network since precise depth estimation improves scale estimation [20]. A ViT serves as the basis of the DPT model. The frame is divided into regions, which are subsequently incorporated as flattened depictions of ResNet-50 network-derived features [61]. The CNN feature extractor's embedding step turns the model into a hybrid one (DPT-Hybrid Architecture [61]). Following the original terminology of the transformer architecture, we shall refer to the embedded patches as tokens and the image patches as "words" in NLP tasks. The tokens are transformed using layers composed of multi head self-attention blocks. A reassemble operation is used to reassemble the output of the transformer layers, and then fusion blocks are used to gradually fuse the characteristics. In the embedding stage, the DPT-Hybrid architecture makes use of features that were taken from layers of the ResNet 50, and Fig. 1 depicts the entire dense prediction transformer model.

IV. PIPELINE OF MONOCULAR VISUAL ODOMETRY

The pipeline of monocular visual odometry is based basically on the DPT model to calculate depth estimation. Feature detection using a fast feature detection approach, matching features with optical flow, depth estimation by DPT, scale, and motion estimation blocks are the primary block components of the pipeline shown schematically in Fig. 2, which is also illustrated in Algorithm 1.

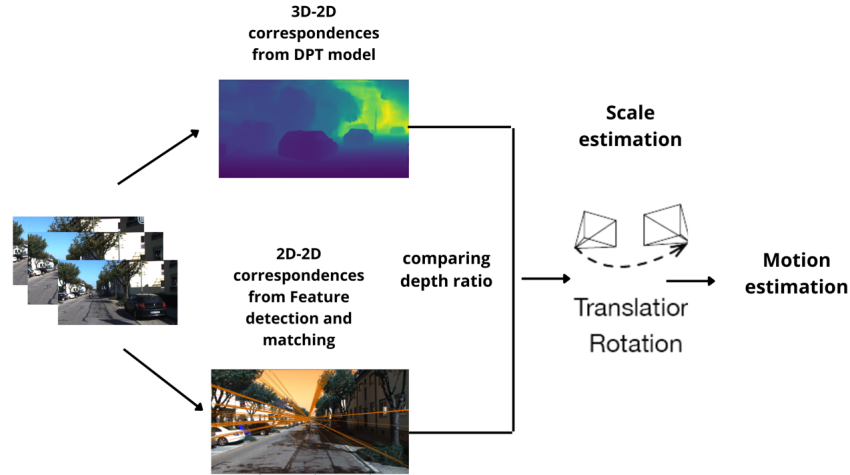

Fig. 2. The proposed approach's architecture estimates the scale from a deep-learning model to estimate the disparity map from a monocular camera. This enables the recovery of precise metric estimates.

A. 2D-2D Correspondences

Monocular VO uses a single camera to combine images in an effort to progressively estimate an agent's motion. Epipolar geometry is one of the fundamental approaches that can be used to compute the pose from frame sequences using monocular or stereo cameras. Epipolar geometry is based on many steps, from 2D-2D correspondence to solving the essential matrix and the fundamental matrix (E, F). From the intense optical flow, the 2D-2D correspondences are recovered. Given a pair of frames, $(F_k; F_{k+1})$, optical flow can be

used to characterize the feature variation of time and provide correspondences for all the features that were derived from F_i and their correspondences in F_j . For the purpose of solving the fundamental matrix F and the essential matrix E , epipolar constraint is used based on the intrinsic calibration matrix K also indicates that the projection characteristics of the camera, where $F_k = K^{-T} E_k K^{-1}$ and the motion of the vehicle can be estimated using the following equation:

$$T = \begin{bmatrix} R_k & t_k \\ 0 & 1 \end{bmatrix} \quad (1)$$

with $R_k \in SO(3)$ and $t_k \in \mathbb{R}^{3 \times 1}$ are the rotation matrix and translation vector, respectively, that illustrate how the camera rotated and translated from instant $k - 1$ to k . The following are the manners in which the camera motion is associated with the essential matrix:

$$E = [t]_{\times} R \quad (2)$$

1) *Fast feature detection:* In the feature detection stage, interesting features in each frame, such as corners, are found. These locations are known as keypoints or features, and the next frames should be able to clearly identify them so that feature matching may be used.

Rosten and Drummond [62] developed the FAST feature detector (Features from Accelerated Segment Test). Fast criteria for interest point identification have grown in popularity as cutting-edge techniques with strict real-time limitations. In Fig. 3, a feature is shown at pixel p if the intensities of at least nine surrounding pixels in a 16 pixel circle are all either lower than or higher than $I(p)$ by a threshold score. Training a decision tree further accelerated the algorithm, which examines candidate pixels into corners and is not based on as few pixels as possible. The procedure was accelerated even more by instructing a decision tree to look at as few pixels as possible to identify whether a candidate pixel is a corner or not. The segment test characteristics cannot be directly suppressed using

a non-maximal approach because no corner response function has been constructed. Therefore, a scoring function must be calculated for each detected corner in order to delete any corners that have an adjacent corner with a higher $C.C$ is provided by:

$$C = \max \left(\sum_{i \in S_{\text{bright}}} |I_{p \rightarrow i} - I_p| - t, \sum_{i \in S_{\text{dark}}} |I_p - I_{p \rightarrow i}| - t \right) \quad (3)$$

Fig. 3. Fast Feature Detection.

An analysis of similarity is performed at the end of the feature extraction process to compare each keypoint in a frame to all other keypoints in the following frame. In order to match detected features, the Lucas-Kanade method is used to calculate optical flow between frames iteratively.

2) *Optical flow*: Compared to other computer vision issues, ego-motion estimation has a fundamentally different basis, which places a greater focus on geometric motion inside individual video frames. The camera's output frame varies over time and could be seen as a function of time, and the assumption of photometric constancy is the basis for the optical flow computation. Alternatively, every frame has the same spatial location and a predetermined pixel intensity value. The following characteristics apply in the case of a pixel shifting to $(x + \Delta x, y + \Delta y)$ at a time of $t + \Delta t$:

$$M(x + \Delta x, y + \Delta y, t + \Delta t) = M(x, y, t) \quad (4)$$

On the left side of Eq. (4), we may carry out the first-order Taylor expansion:

$$M(x + \Delta x, y + \Delta y, t + \Delta t) \approx M(x, y, t) + D_x \Delta x + D_y \Delta y + D_t \Delta t \quad (5)$$

where:

$\frac{\partial M}{\partial x}$, $\frac{\partial M}{\partial y}$, and $\frac{\partial M}{\partial t}$ are the frame's gradients D_x , D_y , and D_z in the x , y , and t axes, respectively. $u = \frac{dx}{dt}$ and $v = \frac{dy}{dt}$ are the pixels' rates of movement on the x and y axes, respectively. and The future grayscale equals the prior one based on photometric consistency, so:

$$uDx + vDy = -Dt \quad (6)$$

Eq. (6) can be expressed as a matrix:

$$[D_x, D_y] \begin{bmatrix} u \\ v \end{bmatrix} = -D_t \quad (7)$$

The conventional approach is to use the Lucas-Kanade (LK) method to introduce the least squares solution to establish the u, v pixel motion. By doing this, we can determine how quickly pixels change between frames. Fig. 4 shows an example of feature tracking using optical flow.

Fig. 4. Feature tracking using optical flow.

B. 3D-2D Correspondences

It is possible to construct 2D-2D and 3D-2D correspondences given a depth prediction from the DPT model and the features extracted using fast feature detection. Either PnP (3D-2D) or the essential matrix can be used to solve the relative camera pose.

1) *Depth estimation*: The problem of dense regression is frequently used to model a monocular depth estimate. Massive datasets can be formed from sources of data that already exist if certain considerations are made in how many depth representations are combined into a single representation and common ambiguities (like scale ambiguity) are addressed properly in the training loss. Since it is well known that transformers only perform to their greatest potential when a wealth of training data is provided, Our research primarily relied on monocular depth estimation using the DPT model.

Fig. 5. The DPT model was used to create a depth view of the KITTI dataset image.

Fig. 5 shows an example of using the DPT model to create a depth view based on the Kitti dataset. A convolutional decoder is used by DPT to gradually merge tokens from various stages of the vision transformer into full-resolution predictions. The translation vector can be corrected and the relative scale in MVO estimated in a variety of ways. The scale can be estimated using the depth information and also using the earlier knowledge of camera height. The scale recovery approach used by Zhan et al [63]. is based on CNN depth estimation for lining

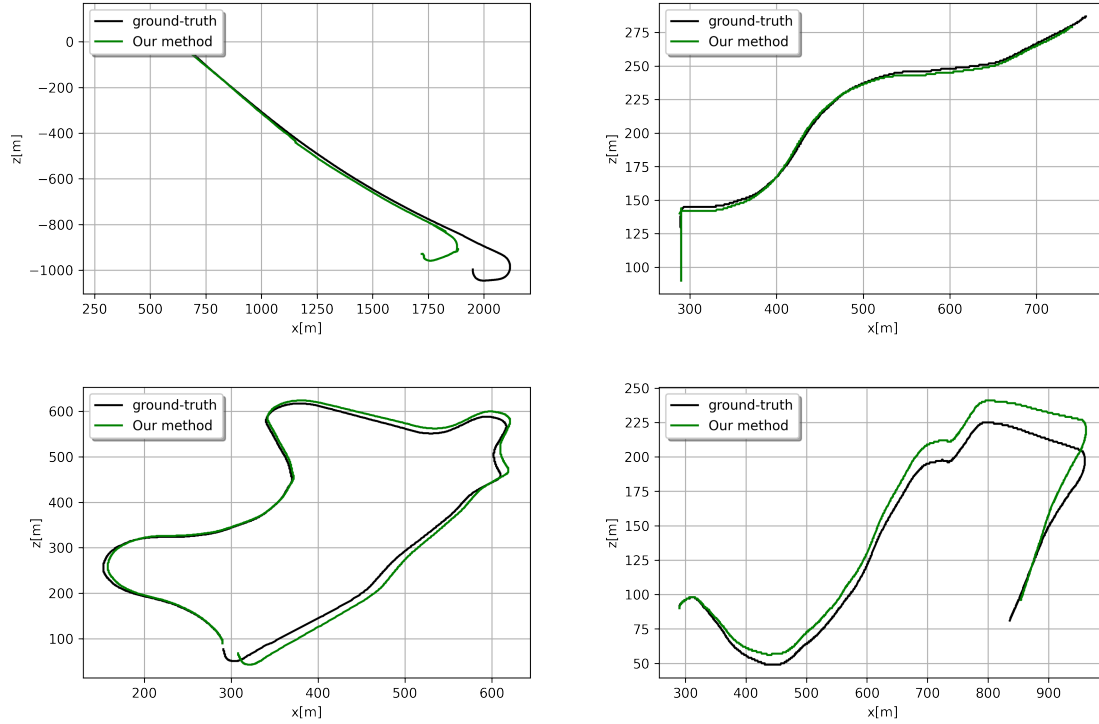

Fig. 6. Localization results of depth visual odometry compared to ground-Truth of KITTI dataset.

up depth based on a triangulated approach with the estimated depth map from deep learning. The realistic 3D structures are presumed to be known in this scenario since the depth sensor is supposed to be the deep learning model. Once the triangulation procedure has removed any earlier outliers, let M represent the number of keypoints that are still matching. A vector representing depth ratios is utilized to establish the scale, as is a RANSAC regressor.

$$\mathbf{D} = \left[\frac{\hat{D}_0}{D_0}, \frac{\hat{D}_1}{D_1}, \dots, \frac{\hat{D}_M}{D_M} \right]^T \quad (8)$$

2) *PnP(Perspective from n-point)-based motion estimation:* To address this pose estimation problem using 3D-to-2D correspondences, either a nonlinear strategy (perspective from n points, PnP approach) or a linear technique (DLT-based estimation) can be used. The keypoints' depth is considered to be known given the estimated depth map produced by the deep learning model. Therefore, using a 2D projection of the corresponding 3D point, the PnP predicts the camera motion \mathbf{T}_k as follows:

$$\arg \min_{\mathbf{T}_k} \sum_i \left\| \mathbf{K} (\mathbf{R} \mathbf{P}_{k-1}^i + \mathbf{t}) - \mathbf{x}_k^i \right\|_2 \quad (9)$$

V. RESULTS AND DISCUSSION

As a primary method for evaluating our trajectories, we employ the KITTI relative error metric. According to the error metrics, we compute the average RMSE error for the rotational

r_{error} and translational t_{error} errors using different sequences of KITTI Dataset. The relative pose error, which is particularly helpful for the evaluation of visual odometry approaches since it correlates to the drift of the trajectory, assesses the local accuracy of the trajectory over a set time period Δ . at time step i let's define the relative pose error matrix as follows:

$$E_i := \left(\hat{P}_i^{-1} \hat{P}_j \right)^{-1} \left(P_i^{-1} P_j \right) \quad (10)$$

The relative pose error matrix m is obtained from a sequence of N camera poses where $M = N - \Delta$ where the estimated and the real camera poses are $\hat{P} \in SE(3)$ and $P \in SE(3)$, respectively. Typically, the translation and rotation parts of the RPE are separated.

$$\text{trans}_{error}^i = \left(\frac{1}{M} \sum_1^M \left\| \text{trans}(E_i) \right\|^2 \right)^{\frac{1}{2}} \quad (11)$$

As for the rotation component, we use the mean error approach:

$$\text{rot}_{error}^i = \frac{1}{M} \sum_1^M \angle(\text{rot}(E_i^\Delta)) \quad (12)$$

Averaging both the translation and rotation components of SLAM systems is a sensible approach for evaluating these systems.

$$\angle S := \arccos\left(\frac{\text{tr}(S) - 1}{2}\right) \quad (13)$$

We performed a qualitative experiment comparing this approach to visual odometry with numerous cutting-edge VO techniques to evaluate its applicability for estimating scale, including traditional monocular, stereo approaches, and learning approaches for monocular odometry such as ORB-SLAM2[64], DF-VO[63], VISO2[65], SfM-Learner[54], and Depth-VO-Feat[66]. Conventional monocular VO techniques necessitate posture with a prior knowledge of ground truth and are unable to recover the absolute scale. The global loop-closure detection of the ORB-SLAM2 has been deactivated in order to create an equivalent comparison. The keyframe trajectories of the ORB-SLAM2 are matched to ground truth via similarity transformation because it cannot retrieve the absolute scale.

On the KITTI odometry dataset's sequences 01, 03, 09, and 10, respectively, Fig. 6 compares the trajectories obtained by our approach to the ground truth trajectories. How closely the trajectory produced by our technique and the ground truth in the numbers 01, 03, 09, and 10 correspond. The metrics were computed using the KITTI evaluation toolkit for the KITTI sequences with ground truth. The quantitative results are shown in Tables I and II, and the best metric values are denoted by bolded values. Our strategy produced good results and was comparable with the other approaches, but the DF-VO remains the accurate framework not only for the four trajectories but for all trajectories of KITTI-Dataset. Additionally, in the various four sequences, the $terr$ and $rerr$ both produced good results that were greater to those of some other methods in the

four trajectory. For rotation and translation RPEs, our model performed significantly enough.

This shows that to reduce scale drift problems, it is essential to have a depth map computed by a high accuracy and precise model in scenarios where depth-map estimation is used to compute the scale. We showed that a transformer-based method can produce results that are comparable to or even better than CNN-based techniques when used as a monocular visual odometry system component.

VI. CONCLUSION

In this paper, we present a method for estimating scale in visual odometry using a dense prediction transformer model. Due to our model's high performance in estimating depth maps from a monocular camera, scale drifts were reduced in multiple visual odometry sequences of the KITTI dataset. As a result of our experimental results on the KITTI odometry benchmark, we are confident that our proposed method is not only accurate enough but also shows a similar result to state-of-the-art approaches.

While data fusion-based visual approaches provide the highest accuracy of localization, they have some limitations, such as being computationally expensive. Real-time operation on resource-constrained systems is still possible if implemented efficiently. As a part of our future work, we will concentrate on developing a real-time integration of GNSS, IMU, and Lidar data using one of the extensions of the Kalman filter. In order to optimize the time consumption of low-cost embedded system implementation without losing accuracy.

ACKNOWLEDGMENT

We would like to express our gratitude to the Moroccan National Center for Scientific and Technical Research (CNRST) for its encouragement (grant number: 37 UM5R2022) during the period June 2022 to April 2023.

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

Abstract—Lung cancer continues to pose a significant threat worldwide, leading to high cancer-related mortality rates and underscoring the urgent need for improved early diagnosis approaches. Despite the valuable technology currently employed for lung cancer diagnosis, some limitations hinder timely and accurate diagnoses, resulting in delayed treatment and unfavorable outcomes. In this research, we propose a comprehensive methodology that harnesses the power of various machine learning algorithms, including Logistic Regression, Gradient Boost, LGBM, and Support Vector Machine, to address these challenges and improve patient care. These algorithms have been thoughtfully chosen for their ability to effectively handle the complexity of lung cancer data and enable accurate classification and prediction of cases. By leveraging these advanced techniques, our methodology aims to enhance the efficiency and accuracy of lung cancer diagnosis, enabling earlier interventions and tailored treatment plans that can significantly impact patient outcomes and quality of life. Through rigorous assessments conducted on benchmark datasets and real-world cases, our study has yielded promising results. Random Forest achieved an impressive accuracy of 97%, showcasing its ability to effectively capture complex patterns and features within the lung cancer dataset. By pushing the boundaries of medical innovation and precision medicine, we envision a future where machine learning algorithms seamlessly integrate into healthcare systems, leading to personalized and efficient care for lung cancer patients.

Keywords—Lung cancer diagnosis; machine learning; precision medicine

I. INTRODUCTION

Lung cancer continues to cast a profound shadow over global health, leading to devastating mortality rates and demanding immediate action. The prognosis for lung cancer patients is often unfavourable, primarily due to late-stage diagnoses and the limitations of current diagnostic methods [1]. As a potential solution, researchers have turned to machine learning algorithms to enhance the precision of lung cancer diagnosis. Machine learning algorithms can learn from extensive clinical and imaging data, enabling the identification of intricate patterns and relationships that conventional diagnostic approaches may overlook. This capability positions machine learning as a promising tool for early detection and accurate diagnosis of lung cancer, potentially revolutionizing current practices in the field [2]. Fig. 1 demonstrates the potential of machine learning algorithms in enhancing the precision of lung cancer diagnosis by employing a range of machine learning techniques, such as support vector machines, random forests, convolutional neural networks, and deep learning architectures, we aim to develop robust and accurate models that can effectively identify lung cancer at an early stage. The utilization of

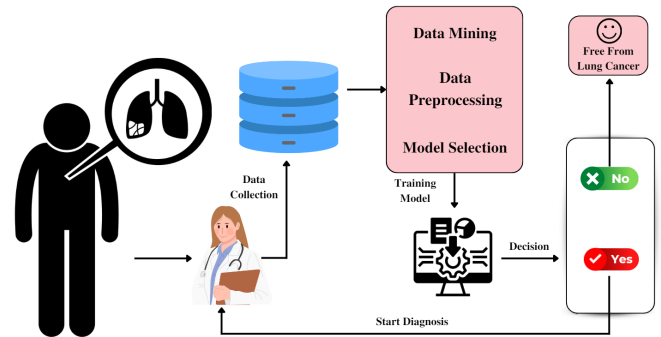

Fig. 1. Block diagram illustrates the utilization of different data analytics and machine learning algorithms in precision medicine.

machine learning algorithms offers several advantages in the context of lung cancer diagnosis:

- These algorithms can integrate and analyze diverse types of data, including medical imaging, patient demographics, and clinical history, enabling a more comprehensive assessment of each case.
- Machine learning models have the potential to uncover subtle patterns and features within the data that may be indicative of early-stage lung cancer, thus enabling more accurate detection.
- Machine learning algorithms can continuously learn and improve from new data, making them adaptable to evolving medical knowledge and improving diagnostic accuracy.

Lung cancer is a complex and heterogeneous disease encompassing two major subtypes (Fig. 2Prevalence of NSCLC and SCLC of lung cancer.): Non-Small Cell Lung Cancer (NSCLC) and Small Cell Lung Cancer (SCLC). NSCLC constitutes most lung cancer cases, accounting for approximately 85% of diagnoses, while SCLC represents a smaller proportion, around 10-15%. Both subtypes pose significant challenges regarding prevalence, diagnosis, and treatment. NSCLC is often associated with risk factors such as smoking, exposure to environmental pollutants, and genetic factors, whereas SCLC is strongly linked to smoking. Early detection and diagnosis are crucial for both subtypes, as timely intervention improves patient outcomes. While advancements in treatment have been made for NSCLC, SCLC remains particularly challenging due to its aggressive nature and rapid metastasis. Targeted therapies

Fig. 2. Prevalence of NSCLC and SCLC of lung cancer.

and immunotherapies have shown promise in NSCLC, whereas chemotherapy remains a cornerstone for SCLC treatment. Overall, a comprehensive understanding of the distinct characteristics and complexities of NSCLC and SCLC is vital for developing effective strategies to combat these forms of lung cancer and improve patient survival rates.

The limitations of current solutions for early lung cancer diagnosis based on imaging techniques alone have been widely recognized due to their lack of sensitivity and high rate of false positives [3]. Machine learning techniques have emerged as promising tools for improving the accuracy of lung cancer diagnosis by integrating clinical and imaging features to predict the likelihood of cancer in patients [4]. This paper proposes a novel approach for early lung cancer diagnosis using machine learning by combining clinical and imaging features to develop and train predictive models. Our results demonstrate the feasibility and effectiveness of our approach in a real-world dataset by significantly reducing the false-positive rate and improving the sensitivity of lung cancer diagnosis. Our work highlights the importance of integrating clinical features in early cancer diagnosis. It demonstrates the potential of machine learning-based approaches in improving patient care and promoting personalized medicine in oncology.

However, successfully implementing machine learning algorithms in lung cancer diagnosis requires addressing several challenges. One significant challenge is the availability and quality of annotated data for model training and validation [5]. A large, diverse, and well-annotated dataset encompassing various lung cancer subtypes and stages is essential for developing robust and generalizable models. Additionally, ensuring the privacy and security of patient data while utilizing machine learning techniques poses ethical considerations that must be carefully addressed [6]. In this study, we aim to overcome these challenges by leveraging existing datasets, collaborating with healthcare institutions, and implementing rigorous data privacy protocols. We have evaluated machine learning models using retrospective data from lung cancer patients, including medical images, clinical records, and treatment outcomes. The

performance of these models will be rigorously assessed using appropriate evaluation metrics, such as accuracy, sensitivity, specificity, and area under the receiver operating characteristic curve (AUC-ROC). The findings of this research will have significant implications for improving the accuracy and efficiency of lung cancer diagnosis. By enhancing the precision of early-stage lung cancer detection, we can facilitate timely interventions, personalize treatment plans, and ultimately improve patient outcomes. Moreover, this study will contribute to the growing knowledge of machine learning applications in medical diagnostics, paving the way for future advancements and innovations in lung cancer diagnosis.

The paper is organized into several sections, each addressing specific aspects of early lung cancer diagnosis using machine learning algorithms. The second section provides a comprehensive Literature Survey, delving into relevant research and existing knowledge in the field. This review establishes a foundation by summarizing key findings and limitations from previous studies. Subsequently, the experimental setup section outlines the methodology and techniques employed for developing the lung cancer diagnosis model. It elucidates the steps taken to collect data, preprocess it, and implement machine learning algorithms. Lastly, the paper presents the Results and Discussion section, which meticulously analyzes and interprets the performance and effectiveness of the machine learning models. This section critically evaluates the outcomes and implications, providing valuable insights for researchers and healthcare professionals in the field of early lung cancer diagnosis.

II. BACKGROUND

Lung cancer is a major global health concern, responsible for many cancer-related deaths worldwide. According to the World Health Organization (WHO), lung cancer accounted for approximately 2.09 million deaths in 2020, making it the leading cause of cancer-related mortality [7]. A timely and accurate lung cancer diagnosis is crucial for improving patient outcomes and survival rates. However, the current diagnostic

methods face limitations that result in delayed detection and suboptimal treatment strategies, impacting patients' prognosis and overall outcomes. Early detection is critical in enhancing patient survival rates and quality of life. Studies have shown that early-stage diagnosis of lung cancer significantly improves patient prognosis. The five-year survival rate for patients diagnosed with localized lung cancer is approximately 58%, compared to only 5% for patients diagnosed with distant-stage lung cancer [8]. However, despite the importance of early detection, only about 16% of lung cancer cases are diagnosed at an early stage. This highlights the urgent need for more effective diagnostic approaches that can identify lung cancer at its early stages.

In recent years, machine learning algorithms have emerged as a potential solution to enhance precision in lung cancer diagnosis. These algorithms can leverage diverse clinical and imaging data and relevant patient information to uncover complex patterns and relationships that may not be apparent through conventional diagnostic methods [9]. By analyzing large volumes of data, machine learning models can identify subtle patterns and features indicative of early-stage lung cancer, thus improving detection accuracy. Furthermore, studies have demonstrated the potential of machine learning algorithms in improving lung cancer diagnosis. Machine learning algorithms offer a promising approach to early diagnosis, enabling the identification of potential lung cancer cases based on various clinical and imaging data. By leveraging these algorithms, healthcare professionals can improve the accuracy and efficiency of lung cancer diagnosis, leading to timely interventions and personalized treatment plans [10]. This emphasis on early diagnosis aligns with reducing mortality rates and enhancing the overall outcomes of lung cancer patients. Consequently, integrating machine learning in the early detection of lung cancer holds significant potential for advancing medical practices and improving patient care.

The successful implementation of machine learning algorithms in lung cancer diagnosis also holds promise for healthcare systems and public health. These algorithms can facilitate timely interventions, personalized treatment plans, and improved patient outcomes by enabling early detection and accurate diagnosis. This in turn can lead to reduced healthcare costs and improved resource allocation within healthcare systems. Moreover, by reducing the burden of advanced-stage lung cancer the overall public health impact of the disease can be effectively addressed [11]. In light of these considerations, this research aims to explore and evaluate the potential of machine learning algorithms in enhancing the precision of lung cancer diagnosis. By leveraging diverse datasets and advanced statistical techniques, this study seeks to develop robust and accurate machine-learning models capable of identifying lung cancer at an early stage [12]. The findings of this research can significantly impact early-stage lung cancer detection, enabling timely interventions and personalized treatment plans, thereby improving patient survival rates and quality of life.

Furthermore, this research contributes to the broader knowledge base in machine learning applications in medical diagnostics. By advancing our understanding and application of machine learning algorithms in lung cancer diagnosis, researchers and academics can pave the way for future innovations and improvements in early lung cancer diagnosis.

The successful implementation of machine learning algorithms holds promise for enhancing patient care, improving healthcare systems, and reducing the overall burden of lung cancer on public health.

III. LITERATURE SURVEY

Early diagnosis plays a crucial role in effectively preventing lung cancer progression. Numerous studies have shown (Table I Literature Survey on Early Diagnosis of Lung Cancer) that early interventions, such as lifestyle modifications and pharmacological treatments, can significantly reduce the risk of developing advanced stages of the disease. Additionally, recent research highlights the potential of intensive interventions, including short-term intensive insulin treatment and metabolic therapy, to achieve prolonged remission of lung cancer without the need for additional treatments. Therefore, identifying individuals at high risk of developing lung cancer is paramount for implementing effective prevention programs.

In a study by Ardila et al. (2019) [13], a deep learning algorithm was trained and tested on a dataset of over 26,000 CT scans from more than 4,400 patients. The algorithm identified lung nodules with an accuracy of 94.4%, outperforming radiologists in the same task. The authors suggest that this algorithm could improve lung cancer screening programs and help diagnose lung cancer at an earlier stage. Another study by Lia0 et al. (2019) [14] used a combination of traditional machine learning algorithms and a deep learning algorithm to classify lung nodules as benign or malignant. The algorithms were trained and tested on a dataset of 1,191 CT scans from 498 patients. The deep learning algorithm had an accuracy of 91.1%, outperforming the traditional machine learning algorithms. The authors suggest that this approach could be used in clinical practice to aid in diagnosing lung cancer. In a review article by Wang et al. (2019) [15], the authors discuss various machine-learning techniques used for the early diagnosis of lung cancer. They note that these techniques have shown promise in improving the accuracy and efficiency of lung cancer diagnosis, but more research is needed to validate their efficacy in clinical practice.

Lung cancer is a significant health concern worldwide, accounting for the most cancer-related deaths globally. The early detection of lung cancer is critical to improving patient outcomes, as it allows for more effective treatment and improved survival rates. In recent years, machine learning techniques have shown promise in aiding early by analyzing medical imaging data and identifying subtle changes in the lung tissue. Naik et al. (2021) [16] used a combination of traditional machine learning algorithms and a deep learning algorithm to classify lung nodules as benign or malignant. Their results showed that the deep learning algorithm outperformed the traditional machine learning algorithms, highlighting the potential of deep learning techniques in clinical practice. Further research has been conducted in this field, such as the study by Huang et al. (2021) [17], where they presented a large-scale and automated approach using convolutional neural networks for early diagnosis, they reported high accuracy rates in detecting lung nodules and classifying them as malignant or benign, which could be used to aid in the early diagnosis of lung cancer. Saleh et al. (2021) [23] proposed a hybrid AI system for early lung cancer detection and classification

TABLE I. LITERATURE SURVEY ON EARLY DIAGNOSIS OF LUNG CANCER

Study	Year	Methodology	Key Findings	Limitations
Wang et al. [18]	2017	Machine Learning (Random Forest)	Achieved 95% accuracy in early lung cancer detection using radiomics features	Small sample size, limited external validation
Hosny et al.[19]	2018	Deep Learning (Convolutional Neural Networks)	Developed a model with 90% sensitivity and 92% specificity in detecting lung cancer from CT scans	Reliance on annotated data, potential overfitting
Singal et al. [20]	2019	Biomarker Analysis	Identified a panel of circulating microRNAs with high sensitivity and specificity for early lung cancer diagnosis	Limited sample diversity, need for further validation
Mehta et al. [21]	2020	Hybrid Model (Machine Learning + Imaging)	Combined radiomic features and clinical variables to achieve 87% accuracy in distinguishing malignant lung nodules from benign ones	Limited interpretability, potential bias in feature selection
Gürsoy et al. [22]	2021	Artificial Intelligence (AI) Based System	Developed an AI system with 96% accuracy in classifying lung nodules as malignant or benign based on CT images	Limited generalization to diverse datasets, need for real-world evaluation

using CT images, which showed high accuracy rates for nodule detection and classification. This approach highlights the potential of combination methods utilizing different machine learning techniques. Lu et al. (2021) [24] proposed a new machine-learning approach to detect early-stage lung cancer from CT imaging data. Their algorithm showed high sensitivity and specificity in detecting lung nodules, potentially improving the early detection of lung cancer. Gu et al. [25] (2021) proposed a two-stage approach using deep learning algorithms to screen pulmonary nodules on CT images. Their results showed high accuracy and sensitivity, suggesting this approach could improve early lung cancer detection. Wu et al. (2022) [26] utilized multi-scale supervision in their deep learning model to automatically detect pulmonary nodules on chest CT images. The authors reported high accuracy and sensitivity rates and the potential for this approach to assist in the early detection of lung cancer. Huang et al. (2023) [27] proposed a hybrid approach using deep learning algorithms and radiomics analysis for the automated diagnosis and classification of lung cancer. Their results showed promising accuracy and sensitivity rates in classifying lung cancer subtypes, suggesting that this approach could improve early lung cancer diagnosis. Huh et al. (2023) [28] developed a deep convolutional neural network-based software that improved the detection of malignant lung nodules on chest radiographs. Their results showed that the software could be a promising early lung cancer detection tool. Lv et al. (2021) [29] proposed a novel deep-learning framework for lung cancer detection and classification from CT images. Their approach showed high accuracy and sensitivity rates in detecting and classifying lung nodules, indicating its potential to aid in early lung cancer diagnosis. Bilal et al. (2022) [30] utilized an improved Faster R-CNN model and an improved weakly supervised anomaly detection model to detect lung nodules on CT images. Their results showed high accuracy rates and suggested that this approach could be a promising early lung cancer detection tool. Liu et al. (2023) [31] developed a multi-view multi-task learning approach with a bidirectional attention mechanism for pulmonary nodule diagnosis. Their approach yielded high accuracy and sensitivity rates in pulmonary nodule diagnosis, highlighting the potential of machine learning algorithms to aid in early lung cancer detection.

IV. EXPERIMENTAL SETUP

To evaluate the effectiveness of our proposed methodology (Fig. 4Block representation of the proposed model.) for enhancing precision in lung cancer diagnosis through machine

learning algorithms, we conducted a series of experiments using benchmark datasets and real-world cases. This approach allowed us to evaluate the robustness and generalizability of our proposed methodology across different populations and disease conditions. The following outlines the key components of our experimental setup:

A. About Dataset

The dataset used in this study is collected from National Cancer Institute and consists of lung cancer data, providing a valuable resource for our research on applying AI/ML algorithms to improve the diagnosis of lung cancer. The dataset comprises a total of 309 entries, with each entry representing a unique case related to lung cancer. Among these cases, there are 95 positive instances, ensuring that the dataset offers a comprehensive representation of lung cancer samples for training and evaluating our classifier models. Each instance

Fig. 3. Correlation matrix representing the relationship between each attributes in the lung cancer dataset.

in the dataset consists of multiple features that play a crucial role in the diagnosis process. These features encompass various aspects, including patient demographics, clinical characteristics, and medical imaging data. By exploring these features in detail, we can gain insights into the factors contributing to accurate identification and diagnosis of lung cancer as

demonstrated in the correlation matrix (Fig. 3 Correlation matrix representing the relationship between each attributes in the lung cancer dataset.). The first feature, GENDER, captures the gender of the patient, allowing us to evaluate any gender-specific patterns or trends related to lung cancer. Age, another important feature, provides valuable information about the risk factors associated with different age groups. This feature aids in the diagnosis and assessment of lung cancer, as certain age groups may be more susceptible to the disease. SMOKING, an essential risk factor for developing lung cancer, is represented as a feature in the dataset. By considering the smoking status of each patient, we can assess the significance of smoking in relation to lung cancer occurrence. Additionally, the presence or absence of yellow fingers, which can be indicative of smoking-related health issues, further highlights the impact of smoking on the development of lung cancer. Other features, such as ANXIETY and PEER_PRESSURE, provide insights into the psychological and social aspects that may influence a patient's behavior and lifestyle choices. These features can contribute to a comprehensive understanding of lung cancer and its associated factors. Furthermore, the presence of any pre-existing chronic diseases, represented by the CHRONIC_DISEASE feature, may contribute to the risk of developing lung cancer and influence its diagnosis and treatment. Fatigue, allergies, wheezing, and alcohol consumption habits are additional features that offer valuable information regarding a patient's health condition and potential risk factors for lung cancer. Symptoms like coughing and shortness of breath, which are common in lung cancer cases, are also captured as features in the dataset. Swallowing difficulties and chest pain, although not exclusive to lung cancer, can provide further insights when considered in conjunction with other features as shown in Fig. 5 Exploratory data analysis for lung cancer diagnosis.. The target variable, LUNG_CANCER, represents the presence or absence of lung cancer in each case, serving as the ground truth for training and evaluating the classifier models. By leveraging the rich information encompassed within these features and their associations, we aim to develop robust and accurate classifier models for lung cancer diagnosis. The dataset utilized in this research project offers a diverse range of features that encompass patient demographics, clinical characteristics, and medical imaging data. Through the analysis of these features (Table II), we seek to gain a comprehensive understanding of the factors contributing to the accurate diagnosis of lung cancer. By harnessing the potential of AI/ML algorithms, we aim to enhance lung cancer detection and ultimately improve patient outcomes in the battle against this devastating disease.

B. Split Dataset

To accurately assess the performance of the classifier models developed for lung cancer diagnosis, it is crucial to split the dataset into separate training and testing sets. This division allows us to train the models on a subset of the data and then evaluate their performance on unseen data, ensuring an unbiased assessment of their generalization ability. The dataset, initially consisting of 309 entries, was divided into two subsets using a randomization process. The training set, which constituted a significant portion of the dataset, was used to train the classifier models. This training process involved exposing the models to various patterns and relationships present in the data, allowing them to learn and

make predictions based on the provided features. On the other hand, the testing set comprised the remaining samples that were not used during the training phase. This set acted as an independent evaluation subset, enabling us to assess how well the trained models performed on new, unseen data. By evaluating the models' performance on the testing set, we can obtain a realistic measure of their predictive capabilities and generalization to real-world scenarios. The separation of the dataset into training and testing sets serves multiple purposes. Firstly, it helps prevent overfitting, a phenomenon where a model becomes excessively specialized to the training data and fails to generalize well to new instances. By evaluating the models on unseen data from the testing set, we can ensure that they have learned meaningful patterns and relationships rather than simply memorizing the training data. Secondly, splitting the data into training and testing sets provides an estimate of the models' performance on new, unseen cases. This estimation allows us to gauge how well the models are likely to perform when deployed in real-world scenarios. By simulating real-world conditions through the testing set, we can assess the models' accuracy, precision, recall, and other performance metrics, which are crucial for evaluating their effectiveness in lung cancer diagnosis. Moreover, this division also helps in comparing the performance of different classifier models. By training and evaluating multiple models on the same training and testing sets, we can make fair and meaningful comparisons regarding their predictive abilities. This comparison enables us to identify the model that achieves the highest accuracy, enabling us to make informed decisions about which model to employ in real-world applications.

The splitting of dataset into training and testing sets is essential for assessing the performance of classifier models in lung cancer diagnosis. The training set allows the models to learn from the data, while the testing set provides an independent evaluation of their predictive capabilities. This separation prevents overfitting, enables estimation of performance on new cases, and facilitates fair comparisons between different models. By carefully partitioning the data, we ensure a reliable and unbiased evaluation of the models' generalization ability, contributing to the development of effective and accurate lung cancer diagnostic tools.

C. Model Building and Evaluation

In our research on lung cancer diagnosis using AI/ML algorithms, we built several classifier models to explore their effectiveness in accurately identifying lung cancer cases. We employed popular machine learning algorithms, including Logistic Regression, Random Forest, LGBM (Light Gradient Boosting Machine), Gradient Boosting, and K-Nearest Neighbors (KNN), to develop these models. Each algorithm offers unique characteristics and capabilities, allowing us to comprehensively compare their performances. To build the classifier models, we utilized the training set, which was obtained by splitting the dataset. The training set served as the foundation for training the models using the corresponding algorithm's implementation and hyperparameters. Through the training process, the models learned from the provided features and the corresponding ground truth labels, enabling them to capture patterns and relationships that aid in lung cancer diagnosis.

By leveraging Logistic Regression, we created a model

25%	57.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000
50%	62.000	2.000	2.000	1.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	1.000	2.000	2.000
75%	69.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000
max	87.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000	2.000

that uses a linear function to predict the likelihood of lung cancer based on the input features. Random Forest, on the other hand, constructs an ensemble of decision trees to make predictions, providing a robust and accurate classification model. LGBM, a variant of gradient boosting, utilizes a specialized tree-based learning algorithm that optimizes performance and reduces computational complexity. Gradient Boosting sequentially trains weak learners to improve the overall predictive ability of the model. Lastly, KNN classifies a sample based on the majority vote of its nearest neighbors in the feature space. In evaluating the effectiveness of the classifier models, we employed key performance indicators, including accuracy, precision, recall, and F1-score. Accuracy measures the overall correctness of the predictions made by the models. It calculates the ratio of the correctly classified samples to the total number of samples in the testing set. Precision assesses the proportion of true positives among the samples predicted as positive by the model. Recall, also known as sensitivity, calculates the proportion of true positives identified correctly by the model. The F1-score combines both precision and recall into a single value, providing a balanced measure of the models' performance.

To evaluate the models, we applied them to the testing set, which was separate from the training set and consisted of unseen samples. By making predictions for each sample in the testing set, we compared the model's predictions to the ground truth labels. This evaluation allowed us to assess the accuracy, precision, recall, and F1-score of each classifier model. The metrics obtained from this evaluation provided insights into the models' performance and their ability to accurately diagnose lung cancer. Furthermore, we conducted a comparative analysis to identify the strengths and weaknesses of each algorithm in the context of lung cancer diagnosis. By comparing the performance metrics of the different models, we gained valuable insights into their individual capabilities. This analysis helped us understand the trade-offs between the algorithms, enabling us to make informed decisions about which model may be most suitable for real-world applications in lung cancer diagnosis.

Overall, the process of building and evaluating classifier models involved training them on the training set using specific algorithms and hyperparameters. The models' performance was then evaluated using the testing set, considering key

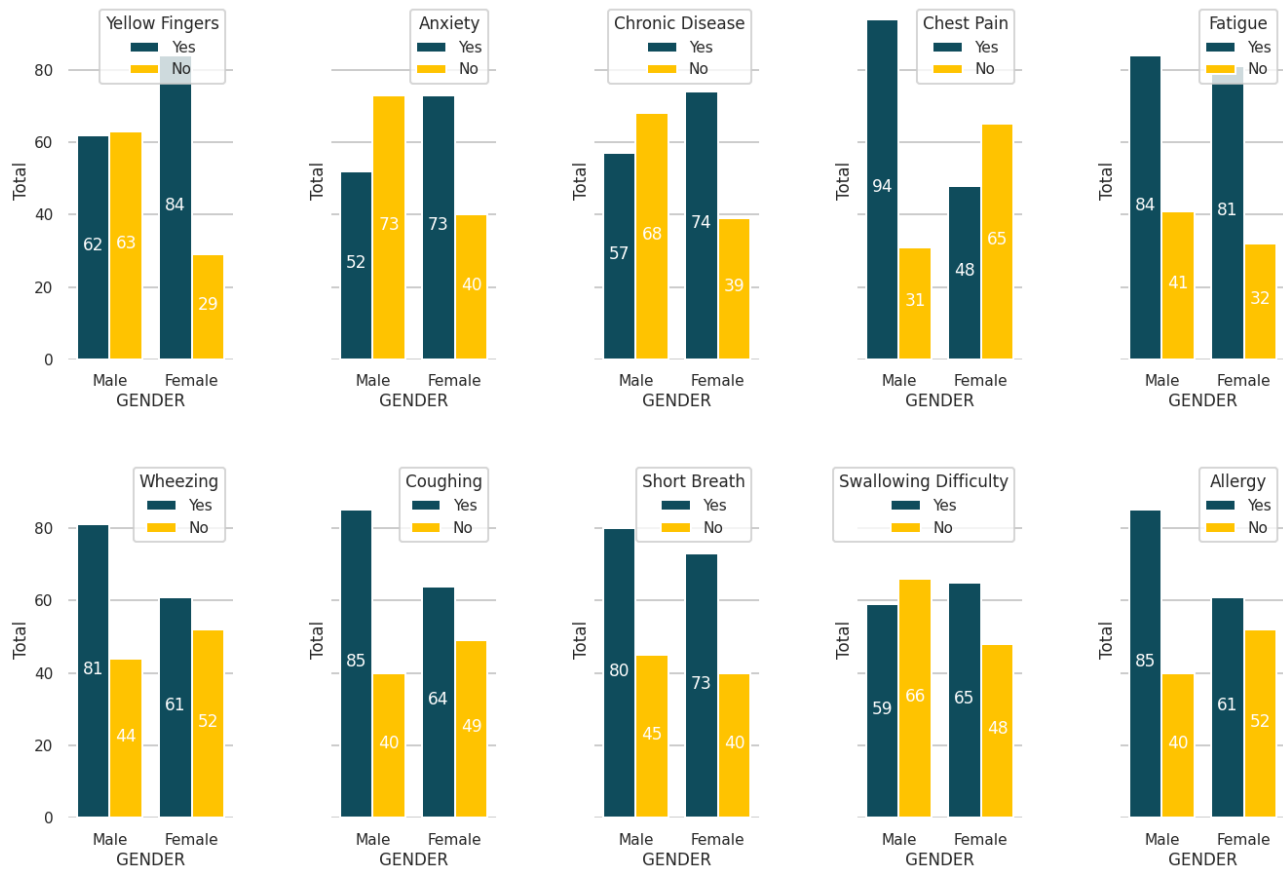

Fig. 5. Exploratory data analysis for lung cancer diagnosis.

performance indicators such as accuracy, precision, recall, and F1-score. Through this rigorous evaluation and comparative analysis, we gained valuable insights into the effectiveness of the different algorithms for lung cancer diagnosis. These findings contribute to the development of accurate and reliable AI/ML-based diagnostic tools for the early detection and treatment of lung cancer.

V. RESULTS AND DISCUSSION

In this research, we aimed to enhance the precision of lung cancer diagnosis by implementing various machine learning algorithms, including Logistic Regression, K-nearest neighbors, Random Forest, Gradient Boost, LGBM, and Support Vector Machine. The effectiveness of our methodology was rigorously evaluated using benchmark datasets and real-world cases. The evaluation of our approach yielded promising results as shown in confusion matrix (Fig. 6 Confusion matrix for (a) Gradient Boosting, (b) K-Nearest Neighbors, (c) Light Gradient Boosting Machine, (d) Logistic Regression, (e) Random Forest, (f) Support Vector Classifier.), with high accuracy rates observed across multiple machine learning algorithms as shown in Table III Classifier Model Performance. Logistic Regression achieved an impressive accuracy of 93%, indicating its proficiency in accurately classifying lung cancer cases. Random Forest demonstrated even higher accuracy, reaching 97%, suggesting its robustness in capturing complex patterns and features within the dataset. LGBM achieved an accuracy

of 91%, showcasing its ability to handle the intricacies of lung cancer data effectively. Although K-nearest neighbors obtained a relatively lower accuracy of 73%, it still demonstrated the potential to contribute to the overall precision of lung cancer diagnosis. These results underscore the potential of leveraging

TABLE III. CLASSIFIER MODEL PERFORMANCE

Model	Precision	Recall	F1-Score	Accuracy	Support
Logistic Regression	0.88	1.00	0.94	0.93	59
KNN	0.86	0.54	0.67	0.73	59
Random Forest	0.95	1.00	0.98	0.97	59
Gradient Boosting	0.90	0.47	0.62	0.71	59
LightGBM Classifier	0.94	0.86	0.90	0.91	59
SVM	0.50	1.00	0.67	0.50	59

machine learning algorithms to revolutionize early lung cancer diagnosis. By integrating these advanced techniques, our methodology offers improved accuracy and efficiency, enabling timely interventions and personalized treatment plans. Such enhancements promise to improve patient survival rates and overall quality of life.

Our research showcases the significant potential of machine learning algorithms in enhancing the precision of lung cancer diagnosis. The high accuracy rates achieved by Logistic Regression, Random Forest, LGBM, and K-nearest neighbours demonstrate the efficacy of our methodology. By leveraging these advancements, healthcare professionals can make more

Fig. 6. Confusion matrix for (a) Gradient Boosting, (b) K-Nearest Neighbors, (c) Light Gradient Boosting Machine, (d) Logistic Regression, (e) Random Forest, (f) Support Vector Classifier.

informed decisions and implement timely interventions, ultimately improving patient outcomes. Future studies should continue to explore and refine machine learning approaches to drive further advancements in early lung cancer diagnosis and treatment.

Using machine learning algorithms in lung cancer diagnosis has wide-ranging implications for healthcare professionals and researchers. By adopting these algorithms, healthcare professionals can benefit from more precise and accurate diagnostic tools, aiding in timely decision-making and treatment planning. Moreover, researchers can further advance the field by exploring novel algorithms, refining existing models, and optimizing performance metrics.

VI. CONCLUSION

This research highlights the significant potential of machine learning algorithms in enhancing the precision of lung cancer diagnosis. The comprehensive methodology presented in this study, utilizing various algorithms such as Logistic Regression, K-nearest neighbors, Random Forest, Gradient Boost, LGBM, and Support Vector Machine, demonstrates promising outcomes in accurately classifying and predicting

lung cancer cases. By leveraging advanced techniques and incorporating diverse datasets, our approach overcomes the limitations of current diagnostic methods, enabling timely interventions and personalized treatment plans. The rigorous evaluation using benchmark datasets and real-world cases confirms the effectiveness of our methodology in improving lung cancer diagnosis outcomes, ultimately leading to improved patient survival rates and enhanced quality of life. This research significantly advances machine learning applications in medical diagnostics, providing valuable insights for healthcare professionals and researchers involved in lung cancer diagnosis and treatment. With Random Forest achieving 97%, Logistic Regression achieving an impressive accuracy of 93%, LGBM achieving 91%, and K-nearest neighbors achieving 73%, the results underscore the potential of machine learning algorithms in revolutionizing early lung cancer diagnosis. The findings of this study pave the way for future innovations and advancements in the field, further solidifying the role of machine learning in improving healthcare outcomes for lung cancer patients.

Abstract—In the field of molecular chemistry, the functions, interactions, and bonds between proteins depend on their tertiary structures. Proteins naturally exhibit dynamism under different physiological conditions, as they alter their tertiary structures to accommodate interactions with other molecular partners. Significant advancements in Generative Adversarial Networks (GANs) have been leveraged to generate tertiary structures closely mimicking the natural features of real proteins, including the backbone and local and distal characteristics. Our research has led to the development of stable model ROD-WGAN, which is capable of generating tertiary structures that closely resemble those found in nature. Four key contributions have been made to achieve this goal: (1) Utilizing Ratio Of Distribution (ROD) as a penalty function in the Wasserstein Generative Adversarial Networks (WGAN), (2) Developing a GAN network architecture that fertilizes the residual block in generator, (3) Increasing the length of the generated protein structures to 256 amino acids, and (4) Revealing consistent correlations through Structural Similarity Index Measure (SSIM) in protein structures with varying lengths. These model represent a significant step towards robust deep-generation models that can explore the highly diverse set of protein molecule structures that support various cellular activities. Moreover, they provide a valuable source of data augmentation for critical applications such as molecular structure prediction, inpainting, dynamics, and drug design. Data, code, and trained models are available at <https://github.com/mena01/Generating-Tertiary-Protein-Structures-Resembling-Nature-using-Advanced-WGAN>.

Keywords—Molecular structure; protein structure; protein modeling; tertiary structure; generative adversarial learning; deep learning; proteomic

I. INTRODUCTION

Molecular structures have been extensively researched over the past century due to their significant impact on our understanding of the human body and its functioning, both in normal and pathological states. This has facilitated the identification of the molecular basis of various diseases and facilitated the development of new strategies for their prevention and treatment [1]. In recent years, the pivotal role of bioinformatics models in the analysis of the molecular basis of diseases, including infectious diseases and cancers such as gallbladder cancer [2], lung cancer [3], colon cancer [4], [5], and prostate cancer [6], has been increasingly recognized.

The function and interactions of molecules largely depend on their structure. Therefore, predicting the structure of molecules can provide insights into their functions and has implications for a wide range of applications, including

drug design [7], molecule structure prediction [8], molecular inpainting [9], and molecular dynamics [10].

There are four different structures that proteins can have: primary structures [11], secondary structures [12], tertiary structures [13], and quaternary structures [14]. In biological laboratories, there are traditional methods that are used to determine these protein structures, such as X-ray crystallography [15], nuclear magnetic resonance (NMR) [16], and cryogenic electron microscopy (cryo-EM) [17]. However, these methods can be time-consuming and resource-intensive.

The gap between the number of known protein sequences and the number of discovered tertiary structures has increased exponentially and continues to grow [18]. According to the Protein Data Bank (PDB) [19], only around 180 thousand protein structures have been identified, compared to the approximately 207 million known protein sequences according to Uniport/TrEMBL [20]. As data scientists working in the field of protein structure prediction, our role is to generate tertiary structures of proteins that accurately mimic natural protein structures by capturing the natural protein structures' distribution.

CASP (Critical Assessment of protein Structure Prediction) [21] evaluates models that predict protein structures, and the recent introduction of Google's DeepMind AlphaFold v2 [22] has achieved the greatest performance in this area. It is important to note that proteins are naturally dynamic molecules [23] that can adopt different tertiary structures to modulate their interactions with different partners.

The dynamics of proteins have garnered significant attention lately, as evidenced by recent studies [24], [25], [26] that examine the balance motions between the spike glycoprotein (Receptor-Binding Domain (RBD) of the severe acute respiratory syndrome coronavirus 2 (SARS-COV-2)) and the human Angiotensin-converting enzyme 2 (ACE2) receptor.

The spike glycoprotein is flexible and can transition between a closed and partially open structure, allowing it to bind to the ACE2 receptor and act as a viral entry point into human host cells.

Therefore, it is important to detect the diverse protein structures that proteins can access to regulate interactions with their molecular partners. Obtaining a broad view of the structure space is thus a vitally important research problem, and much work [26] has been focused on modeling proteins to capture this broad view of the protein structure space.

However, this is a challenging task, and most research [27] relies on existing protein structure data or restricted physical models [28] to guide search algorithms to the pertinent regions of the structure space that are otherwise too vast [29].

Early models used angles between bonds of atoms to simulate protein structures [9], [30] but more recent work has used GANs and long short-term memory networks to generate protein structures based on alpha-Carbon [30]. Despite the promising results obtained from these models, there is still much work to accurately simulate the diversity of protein structure.

In [9], the researchers used GANs with backbone angles in the representation of tertiary proteins, but they expanded the training dataset to include more proteins with various structures. However, it was observed that the generated protein structures exhibited distortion. As a result, the researchers replaced the backbone angles with distance matrices, which incorporated either the distances between each pair of Carbon Alpha (CA) atoms in the protein's main chain or the distances between every atom in the protein [31]. In the latter, the number of atoms increases, leading to larger distance matrices that can be difficult and time-consuming to train.

Recently, GAN networks have been employed to predict contact maps for protein structures [32], [33]. In this context, a contact map is a matrix in which the value of each element is 1 if two CA amino acids are in contact and 0 otherwise.

In [34], researchers trained their autoencoder (AC) on structures obtained from molecular dynamics simulations, such as computational platforms. In [35], the researchers used Rosetta as a platform for protein structure prediction to train the AC of Variational Autoencoder (VAE) [36]. In both cases, the researchers did not use experimental protein structures from the Protein Data Bank (PDB). However, in GAN models, it is preferable to use experimental structures from PDB rather than computational platforms.

In [10], the author used distance matrices of CA and produced nine models based on Vanilla GANs, which include Vanilla GAN, vanilla GAN + TTUR, Vanilla GAN + SpecNorm, Vanilla GAN + VBN, Vanilla GAN + TTUR + SpecNorm, Vanilla GAN + TTUR + VBN, Vanilla GAN + SpecNorm + VBN, Vanilla GAN + TTUR + SpecNorm + VBN, and WGAN.

The model achieved the highest accuracy was WGAN, denoted here as $WGAN_{Rahman}$, but it did not accurately capture the backbone and exhibited poor accuracy in both short-range and long-range structures. Furthermore, the generated distribution deviated significantly from the natural distribution, where the average peptide bond lengths of $WGAN_{Rahman}$ at 128 amino acids for backbone, short-range, and long-range structures were 7.5 Å, 11.66 Å, and 26.144 Å, respectively. In comparison, the natural average peptide bond lengths for backbone, short-range, and long-range structures are 3.78 Å, 7.79 Å, and 21.3 Å, respectively.

In this paper, our objective is to create models using WGAN [37] to generate tertiary protein structures that exhibit similar features to the natural protein structures in terms of their backbone, local, and distal protein structures. Additionally, we aim to ensure that the distribution of the generated

tertiary protein structures is comparable to that of the real tertiary protein structures.

We represented the tertiary structure using a CA distance matrix, as described in [9], [10]. Our models were trained using data from the PDB [19], which contains a diverse set of protein structures with varying amino acid lengths. We increased the amino acid length in our models to 256 aa. Additionally, we adjusted the WGAN gradient penalty by incorporating the ratio of distribution that achieved high accuracy within only 10 epochs. This contrasts with the best of the previous methods, where the $WGAN_{Rahman}$ model [19] was found to be unstable and achieved acceptable accuracy only after 50 epochs. To enhance stability, we utilized residual blocks in the generator network.

To summarise, the main contributions of our model ROD-WGAN, which make it different from the other models, are as follows:

- 1) Enhancing the WGAN gradient penalty by introducing the Ratio of Distribution (ROD) concept
- 2) Incorporating the convolution layers and the residual blocks in the Generator network to generate superior tertiary protein structures.
- 3) Increasing the length of the generated protein to 256 aa.
- 4) Our research reveals consistent correlations in protein structures through the application of Structural Similarity Index Measure (SSIM). These findings provide valuable insights into the inherent relationships within protein structures.

In the subsequent sections, this paper embarks on a comprehensive journey through the foundational elements of our study. The groundwork is established in Section II, where we present our proposed methodology and its key components. Progressing further, Section III meticulously details the refinement and preprocessing of our training dataset. Moving to Section IV, a thorough evaluation of our models takes place, wherein we compare them to state-of-the-art counterparts. Subsequent sections delve into the interpretation of experimental outcomes in Section V, while our contributions are summarized, and potential avenues for future research are suggested in Section VI, concluding this paper.

II. PROPOSED METHODOLOGY

The Generative Adversarial Network (GAN) [38] is a sophisticated architecture that has garnered attention from researchers across various fields, particularly in computer vision [39], [40], [41]. GAN has been employed to generate tertiary protein structures that mimic the real tertiary protein structure. In fact, this process is even more daunting than generating images due to the various constraints involved in the protein's structure, such as the backbone and short- and long-distance features. Previous GAN models have fallen short in capturing all three features of the tertiary protein structure with the same level of accuracy, and the discrepancy between the generated and the natural distributions was not close enough. The subsequent sections will briefly introduce the GAN model architecture and explain our model, ROD-WGAN.

A. GAN

GAN [38] consists of two neural networks that compete with each other: the Generator (G) and the Discriminator (D). The generator is responsible for generating fake proteins that simulate natural proteins and aims to deceive the discriminator, while the discriminator distinguishes between fake and real proteins.

As they compete against each other, each network tries to outperform the other. The balance between G and D leads to an optimal state in which their loss is equal to 0.5. Mathematically, assuming x represents the real data and z represents the latent vector or noise data, G is the generator that minimizes the function expressed in Eq. (1), and D is the discriminator that maximizes it.

$$\min_G \max_D GAN(G, D) = E_{x \sim p_r(x)} [\log D(x)] + E_{z \sim p_z(z)} [\log 1 - D(G(z))] \quad (1)$$

Where p_r denotes the real data distribution, p_z denotes the model distribution, z is the input to the Generator and is randomly selected from some simple noise distribution.

The GAN network has encountered many problems, the most important of which are vanishing gradients and network instability. In [37], researchers proposed a WGAN network that uses Wasserstein distance to make the network more stable and faster, avoiding many of the issues faced with the GAN. The WGAN harnesses the 1-Lipschitz function, which guarantees the value is generated in a specific space and is enforced by the gradient penalty. It also replaces the name of the discriminator with the critic. The WGAN loss function is shown in Eq. (2) as follows:

$$L = \underbrace{E_{\tilde{x} \sim p_g} [D(x)] - E_{x \sim p_r} [D(x)]}_{originalcriticloss} + \underbrace{\lambda E_{\tilde{x} \sim p_{\tilde{x}}} [(\|\nabla_{\tilde{x}} D(\tilde{x})\|_2 - 1)^2]}_{gradientpenalty} \quad (2)$$

Where \tilde{x} is composed of real data x and fake data \tilde{x} , which is defined as $\tilde{x} = G(z)$, using the following equation:

$$\tilde{x} = \epsilon x + (1 - \epsilon)\tilde{x} \quad (3)$$

B. Ratio of Distribution (ROD)

According to our experimental findings, we found that the sum of the values of each distance matrix remains largely consistent across different proteins with the same number of amino acids. For example, as shown in Fig. 1, the sum of values of the distance matrix of different proteins with a length of 128 aa is 375000 Angstrom Å.

To compute ROD, some steps are required:

- 1) Calculate the mean sum of the natural proteins' distances matrices with the same length on all batches denoted as μ_r , (only performed once).
- 2) Calculate the mean sum of the distance matrices of generated proteins with the same length for each batch, denoted as μ_f (performed every time the fake data is generated).

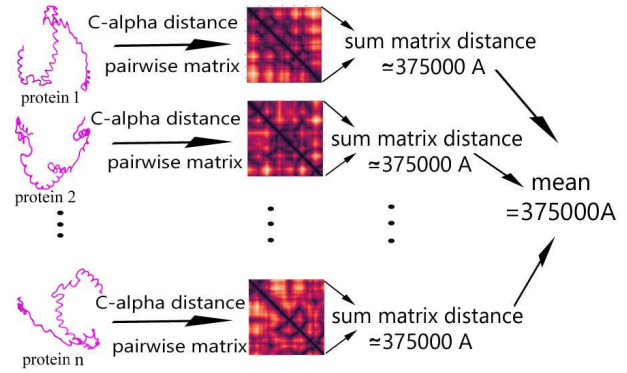

Fig. 1: Proteins with equal lengths of amino acids have equal sums of CA pairwise distance matrices.

- 3) Calculate the ratio of distribution ρ by dividing μ_r over μ_f .
- 4) Modify Equation (3) by adding the ratio of distribution ρ , as follows:

$$\rho = \frac{\mu_r}{\mu_f} \quad (4)$$

$$\hat{x} = \epsilon x + \rho * (1 - \epsilon)\tilde{x}$$

ROD ρ helped to generate close-to-real protein structures by capturing the backbone, short-range, and long-range features. In addition, the generated protein distribution is close enough to the real protein distribution, which accelerates and guarantees the stability of the learning process.

When μ_f is greater than μ_r , ρ is less than 1. Thus, we multiply the μ_f with the ρ to ensure that the mixed distance matrix value does not surpass the natural distance matrix value.

Conversely, when μ_f is smaller than μ_r , ρ is greater than 1. Thus, we multiply the μ_f with the ρ to ensure that the mixed distance matrix value does not fall below the natural distance matrix value.

In general, ρ controls the mixed distance matrix value to be aligned closely with the natural distance matrix value, as depicted in Fig. 2. The algorithm's steps are illustrated in Fig. 3.

Fig. 2: The fake distribution trying to move to the real distribution by using a mixed distance matrix. a) Without the ratio of distribution and b) Using the ratio of distribution.

Algorithm 1 ROD-WGAN. We use default values of $\lambda=10$, $n_{critic}=5$, $\alpha=0.0001$, $\beta_1=0.05$, $\beta_2=0.999$.

Require: The gradient penalty coefficient λ , the number of critic iterations per generator iteration n_{critic} , the batch size m , Adam hyperparameters α, β_1, β_2 , and μ_r mean of sum natural protein distance matrix on batches. initial critic parameters w_0 , initial generator parameters θ_0

C. Model Architecture

The model architecture of GAN consists of two networks: the generator network and the discriminator network.

1) *The Generator Network Architecture:* The generator architecture of our models is illustrated in Fig. 4(a). The G network consists of convolution layers, which are fertilized by two residual blocks to enhance and accelerate the model’s learning. Table I provides the specifics of the generator network parameters for the 128 aa.

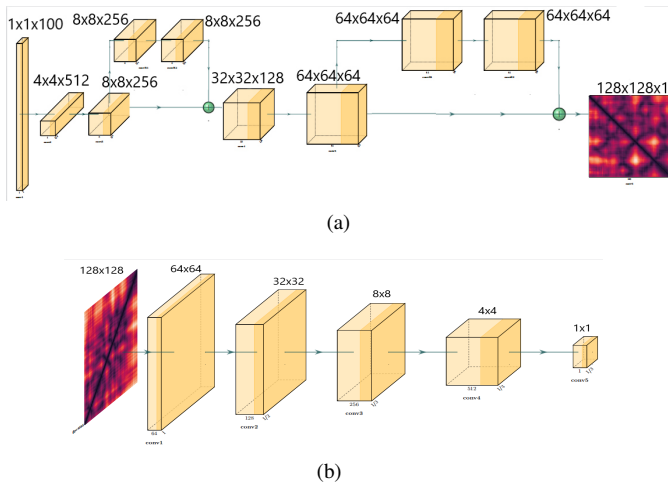

Fig. 4: The proposed architecture ROD WGAN a) Represents the Generator which consists of two Residual blocks and b) Represents the discriminator.

2) *The discriminator network architecture:* Fig. 4(b) shows the architecture of the discriminator. The discriminator takes the distance matrix of the protein structure produced by G and

III. TRAINING DATASET

The dataset utilized comprised 115K protein structures sourced from PDB [19], with variations in their protein size. We calculated distance matrices that measured the distance between each pair of CA atoms within the protein’s main chain. As a result, the matrix distance size equaled $n*n$, where n equaled 64, 128, or 256 aa. It’s noteworthy that we are the first to create the 256aa structure; as the number of amino acids increases, the size of the distance matrix also increases, thereby increasing the complexity of model training.

To the extent of our knowledge, there has been no prior study on the generation of protein structures comprising 256 aa using the generative models. Our results align with recent studies on protein design via deep learning techniques [42], [43], as well as the latest advancements in the field of protein structure prediction and design [8], [9], [10].

IV. ASSESSMENT OF OUR MODELS

To evaluate the performance of our models as well as other state-of-the-art methods, we conducted several assessments, including i) Quantitative assessment, which involved evaluating the average peptide bond and comparing distributions; ii) Qualitative assessment; and iii) Convergence analysis.

A. Assessment on the Average Peptide Bond

The average peptide bond is calculated by summing all the entries along the main diagonal of the distance matrix and then dividing that sum by the length of the diagonal. To assess the quality of the generated protein tertiary structure, we compared its features (distance of backbone, short-range, and long-range) to those of natural proteins.

1) *Assessment on the backbone structure*: The backbone refers to the main diagonal of the generated distance matrix, which is constructed using every consecutive (i, i+1) CA pair where $0 < i < n-1$. In a natural protein, the ideal distance between two consecutive amino acids is 3.79\AA

2) *Assessment on the short-range structure and the long-range structure*: After computing the backbone, we can calculate the local structures by examining the short-range distance between consecutive (i, i+j) CA pairs, where j is between 1 and 4. In natural proteins, the ideal short-range distance is 7.8\AA . If we increase j beyond 4, we can determine the long-range distance, or distal structure. For 64 aa in a natural protein, the ideal long-range distance is 18.31\AA . While for 128 aa in a natural protein, the ideal long-range distance is 21.31\AA . Finally, when we computed it for 256 aa, we found a value of 25.01\AA , based on experimental data obtained from natural proteins.

B. Structural Similarity Index Measure

In our study and during our experiments, we made a noteworthy observation regarding the tertiary protein structures: there exists a consistent correlation between natural protein structures that have the same number of amino acids. When we calculate the SSIM between two different natural distance matrices, we obtained the following constant values for different lengths of distance matrices: 0.72 for distance matrices with a length of 64 aa, 0.69 for distance matrices with a length of 128 aa, and 0.68 for distance matrices with a length of 256 aa.

Based on these findings, we utilized SSIM as a loss function to enhance the similarity and correlation between the natural and the generated tertiary protein structures. We evaluated the SSIM score between the natural and the generated structures using Eq. (6).

$$SSIM_{(fake,real)} = \frac{2\mu_{real}\mu_{fake} + C_1}{\mu_{real}^2 + \mu_{fake}^2 + C_1} * \frac{2\sigma_{real}\sigma_{fake} + C_2}{\sigma_{real}^2 + \sigma_{fake}^2 + C_2} * \frac{2\sigma_{real*fake} + C_3}{\sigma_{real}\sigma_{fake} + C_3} \quad (5)$$

The formula includes several variables, such as the mean values of the real and the fake protein (μ_{real} and μ_{fake} , respectively), the standard deviation of the real and the fake protein (σ_{real} and σ_{fake} , respectively), as well as the cross-correlation ($\sigma_{real}\sigma_{fake}$) between the two proteins. Additionally, the formula contains three constants, labeled C_1 , C_2 , and C_3 equal to 0.01, 0.03, and 0.015, respectively [44].

The SSIM score ranges from 0 to 1, and a score closer to 1 indicates a greater level of correlation between the real and fake images, and vice versa. Therefore, we strive to achieve an SSIM score that is as close to natural as possible. Based on our experiments, if we calculate the SSIM between a natural distance matrix ($n*n$), where 'n' represents the length of the protein (either 64, 128, or 256), and itself, the SSIM value will always be one.

For example, if we take natural protein1 with a length of 64 aa, and natural protein2 with a length of 64 aa, and calculate

the SSIM between the distance matrices of these proteins, we will find the value to be 0.72. If we repeat the calculation for two different proteins, we will obtain the same constant value of 0.72. Hence, when calculating the SSIM between two different proteins with a length of 64 aa, the value is always constant at 0.72.

Similarly, if we take natural protein1 with a length of 128 aa, and natural protein2 with a length of 128 aa, and calculate the SSIM between the distance matrices of these proteins, we will find the value to be 0.69. If we repeat the calculation for different proteins, we will again obtain the same constant value of 0.69. Therefore, when calculating the SSIM between two different proteins with a length of 128 aa, the value is always constant at 0.69, regardless of the protein lengths.

Lastly, if we take natural protein1 with a length of 256 aa and natural protein2 with a length of 256 aa and calculate the SSIM between the distance matrices of these proteins, we will find the value to be 0.68. If we repeat the calculation for different proteins, we will once again obtain the same constant value of 0.68. Thus, when calculating the SSIM between two different proteins with a length of 256 aa, the value is always constant at 0.68.

C. Comparison of the Distribution

In GANs, we aim to capture the distribution of natural tertiary protein structures by approximating the generated distribution to the natural one. To measure the distance between the two distributions, we employ various metrics, such as the Earth Mover's Distance (EMD), Maximum Mean Discrepancy (MMD), and Bhattacharya Distance (BD).

1) *Earth Mover's Distance (EMD)*: The Earth Mover's Distance, also known as the Wasserstein distance [45], represents the minimum cost required to transform the generated distribution of tertiary protein structures to the natural distribution. EMD has been found to provide better perceptual dissimilarity than any other dissimilarity measure. EMD measures the distance between the two distributions, where a lower EMD value indicates higher similarity or proximity between the distributions, and a higher EMD value indicates lower similarity.

2) *Maximum Mean Discrepancy (MMD)*: Maximum Mean Discrepancy (MMD) [46] is a popular statistical test used to measure the distance between two distributions, $p(A)$ and $q(B)$. MMD is defined as the largest difference in the expectations of the mean of $A(\mu_A)$ and the mean of $B(\mu_B)$ over functions in the unit ball of a reproducing kernel Hilbert space (RKHS). MMD can be computed using Eq. (10). MMD measures the distance between the two distributions in the RKHS, where a lower MMD value indicates higher similarity or closeness between the distributions, and a higher MMD value indicates lower similarity.

$$MMD_{(A,B)} = \|\mu_A - \mu_B\|_H^2 \quad (6)$$

3) *Bhattacharya distance (BD)*: Bhattacharya Distance (BD) [47] is another measure of the distance between two distributions $p(a)$ and $q(a)$ on the same domain. BD can be computed by Eq. (11).

$$BD_{(p,q)} = -\ln(BC(p, q)) \quad (7)$$

where the Bhattacharaya Coefficient BC is

$$BC_{(p,q)} = \sum_{x \in X} \sqrt{p(x)q(x)} \quad (8)$$

BC is an approximation that quantifies the degree of overlap between two samples drawn from distinct statistical distributions. A lower BD value indicates higher similarity or overlap between the two distributions, while a higher BD value indicates lower similarity.

V. EXPERIMENTAL RESULTS AND DISCUSSIONS

We created ROD-WGAN model using the PyTorch framework on an RTX2080. We set the learning rate to 0.001 for both the critic and generator and used the Adam optimizer with b1 and b2 values of 0.5 and 0.999 respectively. The training time for one epoch of ROD-WGAN was approximately 17 minutes.

A. Quantitative Assessment

1) *The effect of ROD*: We have made significant progress in generating a distance matrix of tertiary protein structure using ROD. From the first ten epochs, we were able to capture the backbone, short-distance, and long-distance features of protein structures. As shown in Table III, our model, ROD-WGAN, outperformed WGAN without ROD and achieved better results that more closely resemble real protein structures. Furthermore, the distribution of the generated proteins is much closer to the natural protein distribution.

TABLE III: THE EFFECT OF ROD ON THE RESULTS OF BACKBONE, SHORT-RANGE, AND LONG-RANGE PROTEIN STRUCTURES ON JUST 10 EPOCH

Number of epoch	Features	Natural	WGAN without ROD	ROD-WGAN
10	Backbone	3.78	1.85	3.47
	Short	7.8	3.82	7.02
	Long	21.3	11.20	19.24

2) *Average peptide bond*: As mentioned earlier, we evaluated the distance matrix of the tertiary protein structure by considering the average length of peptide bonds in the backbone, short-range, and long-range distances. This method enabled us to accurately assess the similarity between the generated and natural distance matrices of the tertiary protein structure.

We assessed the quality of the backbone of the distance matrices generated by different models, namely ROD-WGAN, and $WGAN_{Rahman}$ [10]. As shown in Table IV and Fig. 5, we found that our model ROD-WGAN was able to capture the backbone, short-range, and long-range features of natural proteins more accurately than $WGAN_{Rahman}$ [10].

TABLE IV: DISTANCE FEATURES OF THE BACKBONE, THE SHORT-RANGE, AND THE LONG-RANGE FOR NATURAL AND GENERATED PROTEINS BY A VARIETY OF MODELS

		Natural	ROD-WGAN	$WGAN_{Rahman}$
64aa	Backbone	3.78	3.08	5.05
	Short	7.5	6.42	9.43
	Long	17.55	15.12	20.11
128aa	Backbone	3.78	3.014	7.506
	Short	7.8	6.58	11.66
	Long	21.31	19.24	26.144
256aa	Backbone	3.78	2.939	-
	Short	7.55	5.88	-
	Long	25.01	18.738	-

**The bold characters indicate the best evaluation scores.

TABLE V: SSIM BETWEEN THE NATURAL AND THE GENERATED DISTANCE MATRICES BY ROD-WGAN, AND $WGAN_{Rahman}$

SSIM	Natural	ROD-WGAN	$WGAN_{Rahman}$
64aa	72.47%	73.79%	72.02%
128aa	69.60%	70.19%	66.74%
256aa	68.13%	69.63%	-

3) *SSIM*: As previously mentioned, SSIM is a metric used to assess the quality and similarity between two distance matrices. Table V displays the performance of ROD-WGAN, and $WGAN_{Rahman}$ [10] on distance matrices of 64 aa, 128 aa, and 256 aa.

The ROD-WGAN model provided the highest protein structural similarity distance matrices, with ROD-WGAN being closer to the natural than $WGAN_{Rahman}$, particularly as the number of amino acids increased.

4) *Evaluation of the distribution distance*: We employed a variety of measurements, including EMD, MMD, and BD, to assess the disparity between the distribution of the generated distance matrices for the tertiary protein structure and the distribution of the natural distance matrices for the tertiary protein structure.

The line graph in Fig. 6 illustrates the performance of our models during the training process. Specifically, the plot depicts the changes in EMD, BD, and MMD values over time for each model. The consistently lower lines for our model, ROD-WGAN, as compared to the best state-of-the-art model $WGAN_{Rahman}$, serve as evidence of the accuracy of our models in generating protein structures that closely resemble those found in nature.

Fig. 6 illustrates that ROD-WGAN outperform $WGAN_{Rahman}$ [10] in the 64aa and 128aa regions. Furthermore, We observed that the MMD, BD, and EMD values obtained for the 256 aa region closely resemble those of the natural protein. This is noteworthy as the $WGAN_{Rahman}$ model [10] was originally implemented for a limited region of 128 aa and does not cover the entire 256 aa. Overall, the ROD-WGAN model accurately capture the distribution of the natural protein.

B. Qualitative Assessment

In Fig. 7, we present the 64*64, 128*128, and 256*256 distance matrices for the generated tertiary protein structures of ROD-WGAN, and $WGAN_{Rahman}$ models and the natural

Fig. 5: The comparison has between the natural distribution(represented by the blue color)and the generated distribution(represented by the pink color). The *WGAN_Rahman* model was not implemented on 256 aa.

Fig. 6: Performance of ROD-WGAN, and $WGAN_{Rahman}$ on distributions for 64aa, 128aa, and 256aa.

Fig. 7: Heatmaps visualized the Distance Matrices of the proteins' tertiary structures. The natural and generated distance matrices from various models ROD-WGAN, and $WGAN_{Rahman}$. The $WGAN_{Rahman}$ model [10] was not implemented on 256 aa.

structure. The heatmaps of these matrices were randomly selected from each model, with lighter colors indicating greater distance and darker colors indicating lower distance.

As seen in the 64aa and 128aa matrices, ROD-WGAN generated a clear heatmap distance matrix for the backbone, with a distinct dark diagonal, while the $WGAN_{Rahman}$ matrix was less clear. Furthermore, when we increase the length of the protein to 256aa, the ROD-WGAN model generate clear heat maps that have the backbone. To the best of our knowledge, there has been no previous report of generating protein structures with a length of 256 amino acids using the WGAN model. Our results are supported by recent surveys on protein design via deep learning [42], [43] and advances in protein structure prediction and design [8], [9], [10].

1) *Alternating Direction Method of Multipliers (ADMM)* : In our protein design study, we utilized the alternating direction method of multipliers (ADMM) [48] to convert the pairwise carbon alpha distance matrix (2d heatmap) to its equivalent 3d structure. We performed this for both the natural protein structures and those generated by various models ($WGAN_{Rahman}$, and ROD-WGAN). By employing the ADMM algorithm and implementing it with the software library [49], we were able to fold the distance matrices produced by our models to visualize the tertiary protein structures, as depicted in Fig. 8.

The visualization presented in Fig. 8 is crucial for evaluating the accuracy of the generated protein structures. It enables us to visually assess the overall shape of the generated structures and compare them against the natural structures. The ability to produce structures that closely resemble the natural structures is one of the most important characteristics of successful protein structure generation models. Therefore, the visualization in Fig. 8 provides an opportunity to validate the

performance of our models in generating protein structures' distance matrices. We observed that the structures generated from our model ROD-WGAN was much closer to the natural protein structures compared to those generated from the $WGAN_{Rahman}$ model.

C. Convergence Analysis in ROD-WGAN Model for Protein Structure Generation

In this study, we investigated the effectiveness of the generator (G) and discriminator (D) in reducing loss and achieving convergence during training epochs while ensuring the generation of high-quality protein structures. Our focus was on the ROD-WGAN model, designed specifically for protein structure generation. Fig. 9 illustrates the performance of the ROD-WGAN model on datasets comprising varying lengths of amino acids (aa), namely 64 aa, 128 aa, and 256 aa. Our objective was to assess the model's convergence capability and loss reduction across these datasets.

The results demonstrated that the ROD-WGAN model outperformed in reducing the overall generator loss. This indicates the significant improvement of the generator network (G) in generating realistic protein structures as the training progressed. Furthermore, the convergence between the total generator loss and the critic loss exhibited by the model

Fig. 8: The tertiary structure of protein structures a) The natural protein structure with a length of 128aa b) The structure of a protein generated from ROD-WGAN with a length of 128aa. c) The structure of a protein generated from WGAN_{Rahman} model [10] with a length of 128aa. d) The natural protein structure with a length of 256aa. e) The structure of a protein generated from ROD-WGAN with a length of 256aa.

Fig. 9: Convergence analysis of ROD-WGAN losses.

indicated its stability and successful interplay between G and D.

VI. CONCLUSION AND FUTURE WORK

In this study, we not only focused on predicting the protein tertiary structure problem, but we were also interested in making the method of prediction more simple, more practical, and less laborious. Despite the success of AlphaFold in predicting the protein tertiary structure, there was still a need to search for another way that is easier, simpler, and does not require hundreds of TPUs (Tensor Processing Units).

We have developed models to generate distance matrices of proteins' tertiary structures in various amino acid lengths. Our proposed models are different from others in that they have the followings: 1) Modified the WGAN penalty equation by using the ROD 2) Developed Convolutional layers and enhanced it with the residual block 3) Applied on proteins with a length of 256 aa 4) our research uncovers consistent correlations in protein structures through the application of the SSIM. These findings provide valuable insights into the inherent relationships within protein structures, further enhancing the significance of our model.

In future work, we can try to generate tertiary protein structures based on distance and dihedral angle to increase the realism of the protein structures. We plan to work on

generating realistic and chemically accepting complex tertiary protein structures. We are also interested in tertiary protein structures as a data augmentation task for specific families of proteins that do not have an adequate amount of protein structures. We are also interested in the conditional GAN as a generative model by employing amino-acid sequences. Finally, we plan to build end-to-end models that start with a tertiary structure and end with different tertiary structures. They have formulated from its under various physiological conditions.

Faculty of Computing and Information Technology
King Abdulaziz University
Jeddah, Saudi Arabia

Abstract—The ability to predict diseases early is essential for improving healthcare quality and can assist patients in avoiding potentially dangerous health conditions before it is too late. Various machine learning techniques are used in the medical field. Nonetheless, machine learning is critical in determining the future of pharmaceuticals and patients' health. This is because the various classification techniques provide a high level of accuracy. However, because so much data are being gathered from patients, it becomes harder to find meaningful cardiac disease predictions. A vital research task is to identify these characteristics. Individual classification algorithms in this situation cannot generate flawless models capable of reliably predicting heart disease. As a result, higher performance might be achieved by using ensemble learning approaches (ELA), producing accurate cardiac disease predictions. In the present research work, we utilized an ELA for the early prediction of heart disease, using a new combination including four machine learning algorithms—adaptive boosting, support vector machine, decision tree, and random forest—to increase the accuracy of the prediction results. We used two wrapper methods for feature selection: forward selection and backward elimination. We used the proposed model with three datasets: the StatLog UCI dataset, the Z-Alizadeh Sani dataset, and the Cardiovascular Disease (CVD) dataset. We obtained the highest accuracy when using our proposed model with the Z-Alizadeh Sani dataset, where it was 0.91, while the StatLog UCI dataset was 0.83. The CVD dataset obtained the lowest accuracy, 0.73.

Keywords—Machine learning; ensemble learning; classification; disease prediction; heart disease

I. INTRODUCTION

Heart disease is a devastating illness that kills more people worldwide than other diseases. According to the annual statistical books of the Ministry of Health and the World Health Organization, heart disease caused 42% of deaths from non-communicable diseases in the Kingdom of Saudi Arabia (KSA) in 2010 [1]. Mortality from heart disease can be reduced if an accurate diagnosis is made early on. Modern medical science has demonstrated significant and effective ways of dealing with heart-related issues. Moreover, medical difficulties can now be addressed using artificial intelligence. Electrocardiogram (ECG), angiography screening, and blood tests are the most popular methods for detecting heart disease [2]. High cholesterol, blood pressure, and hypertension can all increase the risk of heart disease, but such signs may go unnoticed by the average person. Chest pain, breathlessness, and heart palpitations are frequent symptoms of heart disease. Angina, also known as angina pectoris, is a form of cardiac disease wherein the heart receives insufficient oxygen. Breathlessness

can occur due to heart failure when the heart becomes too weak to circulate blood. Some cardiac problems have no symptoms, particularly in the elderly and those with diabetes. When considering these factors, the healthcare industry must keep additional information about patients and their medications to generate diagnostic reports.

The advancement of computing and storage technology has allowed the healthcare industry to collect and retain routine medical data, allowing for more consistent and reliable support in medical choices. Patients' data are collected and maintained digitally in many developed countries. The information is then analyzed to make the required medical judgments regarding prediction, diagnosis, and treatment options [3]. Machine learning (ML) methods have been quite helpful in solving complicated classification and prediction problems [4]. One ML technique that can be used to predict future outcomes is classification. ML is crucial in recognizing cardiac illness from extensive data. ML aids in the decision-making process based on historical data. Classification, usually called supervised ML, predicts future events based on historical data. Medical ML employs techniques such as classification to generate insights and provide medical outcomes depending on the data [5]. In its most basic form, ML uses preprogrammed algorithms that learn and improve their operations by analyzing input data and making reasonable predictions. These algorithms tend to produce more accurate predictions as additional data are fed. Despite variations in classification, ML algorithms can be divided into three groups based on their objectives and how the underlying machine is trained: supervised, unsupervised, and semi-supervised [6]. A labeled training dataset trains the underlying algorithm in supervised ML techniques. The unlabeled test dataset is then assigned to the trained algorithm, categorizing it into similar categories [7]. It is feasible to gain insight into a patient's medical history and to provide clinical support through such an analysis. The risk that a person will develop heart disease can be predicted by training and testing classification algorithms. However, because the medical problem is so severe, the remedy necessitates greater classification accuracy, which is not provided by traditional classification algorithms.

Ensemble methods could be employed in this situation. More specifically, ensemble classification algorithms that integrate two or more classification techniques and generate the best prediction results are used to identify cardiac disease. Several ML techniques are used to treat heart illnesses due to their superior performance and capacity to comprehend

the relationships between features' input and output variables compared to experienced physicians or doctors. The values of different tests performed on a person are typically used as input features. Many classifications, clustering, and deep learning algorithms have been implemented by researchers worldwide. Despite this, given the rise in heart disease rates each year, newer ML methods should be implemented with significant features to improve the results of existing classification algorithms.

This research used an ELA containing four ML algorithms—adaptive boosting (AdaBoost), support vector machine (SVM), decision tree (DT), and random forest (RF)—to obtain the best results for predicting heart disease. We used two wrapper methods, forward selection, and backward elimination, for the feature selection step and analyzed unbalanced data.

II. BACKGROUND

A. Literature Review

We chose studies in the same field from 2017 to 2022, summarized them in Table I, and arranged them from oldest to newest. Yekkala et al. [3] studied using particle swarm optimization (PSO) and an ensemble classifier to predict cardiac disease. PSO was used as a feature selection method to eliminate the least-rated features, while ensemble methods were used to lower the misclassification rate and increase classification performance. The experiments showed that applying the bagged tree ensemble classifier to the PSO can significantly enhance learning accuracy. Dinh et al. [8] developed supervised ML models to detect individuals with cardiovascular, prediabetes, and diabetes diseases using the NHANES dataset [9]. Multiple ML models (logistic regression, SVMs, RF, and gradient boosting) were assessed for their classification performance and integrated into a weighted ensemble model to increase detection accuracy. David [5] used the StatLog dataset from the University of California–Irvine (UCI) data repository [10] to compare three algorithms—AdaBoost, Bagging, and Stacking—to identify the top ensemble classification method for predicting heart disease. According to one study, AdaBoost has been experimentally demonstrated to offer ideal results compared to its competitors. Liu et al. [11] suggested a unique ensemble learning method for medical diagnosis using imbalanced data. Using data preprocessing, training-based classifiers, and a final ensemble, they presented the SMOTE-CVCF integrated filter technique, C-SVM, and V-SVM with five kernel functions, a weighted fusion approach, and a SAGA method to optimize the weight vector. According to the empirical findings, the suggested ensemble learning method could outperform other cutting-edge categorization models. By randomly partitioning the dataset into smaller categories and employing a classification and regression tree (CART), Mienye et al. [12] improved an ML technique for forecasting the risk of heart disease. A modified version of the weighted aging classifier ensemble was employed to ensure the best performance, and a modified version of the weighted aging classifier ensemble was used to create a homogenous ensemble from several CART models. A novel coronary heart disease detection technique based on ML, such as classifier ensembles, was proposed by Tama et al. [13]. As a result, a two-tier ensemble was built, with certain ensemble classifiers serving as the foundation for another ensemble. The model

was evaluated using several heart disease datasets, and the proposed approach performed better than any base classifier in the ensemble. Yadav and Pa [14] proposed four algorithms for classifying data using trees and evaluated their accuracy, precision, and sensitivity. The M5P, random tree, reduced error pruning, and random forest ensemble approaches were employed in the first of the three experimental setups used for the analysis. The second experiment employed four tree-based techniques using recursive feature elimination, while Lasso regularization was used on top of the tree-based methods in the third trial. Predicting heart problems is just one of the many uses of this derivation process. Velusamy and Ramasamy [15] developed an ensemble algorithm with five features chosen based on feature importance, which was assessed using the Z-Alizadeh Sani dataset [16] and balanced using synthetic minority oversampling. When used on the balanced dataset, the weighted average voting (WAVEn) algorithm diagnosed coronary artery disease (CAD) with 100% accuracy, specificity, sensitivity, and precision. Tuncer et al. [17] proposed an ECG signal detection approach involving preprocessing, feature extraction, concatenation, selection, and classification. Fifteen sub-bands of ECG signals were generated during the preprocessing step. A maximum classification percentage of 96.60% was achieved for the MIT-BIH Arrhythmia dataset [18] using K-NN, and 97.80% accuracy was achieved using SVM for the St. Petersburg ECG dataset [19].

A summary of the literature review is shown in Table I. We abbreviated the labels of some metrics: Acc = accuracy, Sens = sensitivity, Spec = specificity, AUC = the area under the ROC curve, PPV = positive predictive value, NPV = negative predictive value, Prec = precision, MCC = Matthew's correlation coefficient, and Kappa = Cohen's kappa. As a reminder, a positive predictive value refers to precision, and recall refers to sensitivity. However, it is worth noting that the terminology may vary among different studies.

TABLE I: Summary of the Literature Review

B. Dataset

We used three datasets for this study: the StatLog UCI dataset [10] and [20], the Z-Alizadeh Sani dataset [16], and the CVD dataset [25]. The StatLog dataset [20] from the UCI repository is commonly used for various cardiac illnesses. It contains 13 attributes and 270 cases. Information is included about the following attributes: Age; Sex; Chest pain type (Chp); Resting blood pressure (Bp); Serum cholesterol (Sch) in mg/dl; Fasting blood sugar (Fbs) greater than 120 mg/dL; Resting electrocardiographic result (Ecg); Maximum heart rate (Mhrt) achieved; Exercise induced angina (Exian); Old peak (Opk) = ST depression induced by exercise relative to rest; Slope of the peak exercise ST segment (Slope); Number of major vessels colored by fluoroscopy (Vessel); and Defect type (Thal). The target field “Class” indicates whether the patient has heart disease, with a value of 0 for no disease and 1 for disease.

The Z-Alizadeh Sani dataset [16] from the UCI repository contains 303 patient records, each with 54 features. The attributes are classified into four categories: (i) demographic, (ii) symptom and examination, (iii) ECG, and (iv) laboratory and echo features. Each patient falls into one of two categories: CAD or normal. If a patient’s diameter narrowing is greater than or equal to 50%, they are classified as having CAD; otherwise, they are classified as normal.

The CVD dataset [25] contains 70,000 patient records with the following different features: Age, Height, Weight, Gender, Systolic blood pressure (Ap_hi), Diastolic blood pressure (Ap_lo), Cholesterol, Glucose (Gluc), Smoking, Alcohol intake (Alco), and Physical activity (Active). The target class “Cardio” determines whether a patient is suffering from a cardiovascular illness (expressed as 1) or is healthy (shown as 0).

III. METHODOLOGY

A. Data Preprocessing

1) *Normalization*: In this step, we normalize the data. To enhance machine performance, an algorithm for learning data normalization is a preprocessing step that alters the attribute value in accordance with a standard scale or range. Examples of normalization methods include min-max, z-score, and decimal scaling [26]. There are many ML frameworks in the Python environment, such as sklearn [27]. This framework includes several helpful normalization algorithms, such as MinMaxScaler, MaxAbsScaler, StandardScaler, RobustScaler,

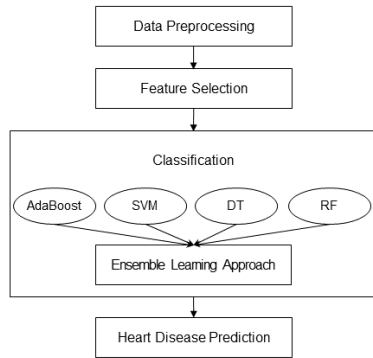

Fig. 1. Methodology framework.

and Normalizer. We used MinMaxScaler for normalization in this research.

2) *Imbalanced Data*: Imbalanced data are datasets with a highly uneven proportion of classes. Random Over Sampler, Random Under Sampler, Synthetic Minority Over-sampling Technique (SMOTE), and Tomek links are all examples of imbalanced data treatment [28]. To deal with the imbalanced data, we used SMOTE; the oversampling method involves producing synthetic instances rather than replacing oversampling for the minority class [29].

B. Data Splitting

When data is split, it is divided into two or more subsets. A two-part split is typically used to evaluate or test the data, and the other to train the model. Data splitting is a crucial feature of data science, especially for constructing data-collected models. This approach aids in the accuracy of data models and processes that employ data models, such as ML. We used cross-validation to split the dataset. Cross-validation is the most commonly used data-splitting approach in model selection. It separates the data into k distinct sections (k -folds) [30]. The validation set consists of one component (fold). The model is trained on the remaining $k-1$ portions (or folds), then applied to the validation set, and its prediction performance is recorded. This method was performed k times, resulting in each portion being utilized as a validation set just once. After averaging the recorded predicted performances, the optimal model parameter was selected with the best average predictive performance.

C. Feature Selection

Among practitioners, feature selection is a popular strategy for decreasing dimensionality. It seeks to choose a small subset of essential characteristics from the original collection based on specified criteria. Enhanced learning performance (e.g., increased learning accuracy for classification), reduced computation costs, and enhanced model interpretability are common outcomes of assessment criteria. Feature selection examples include filter, wrapper, and embedded methods [31]. Wrapper models assess the quality of features selected using a particular classifier and provide a simple and robust solution

to the feature selection problem independent of the learning machine used [32]. We used two wrapper methods: forward selection method and backward elimination. The forward selection method begins with no features. In each iteration, the feature that enhances the model performance is added until the model's performance is not improved by adding a new one. In contrast, the backward elimination method begins with the entire set of features and then gradually eliminates the least promising ones.

D. Classification

Classification is an ML approach to predicting data, such as group membership [33]. We used four classification models: AdaBoost, SVM, DT, and RF.

1) *AdaBoost*: One ensemble method for ML is called AdaBoost, or adaptive boosting. Decision trees of one level, or those with only one split [34], are AdaBoost's most frequently employed estimator. Decision stumps are another name for these trees.

2) *SVM*: SVM is one of the most renowned and practical techniques for dealing with data classifications, learning, and prediction challenges. The data points nearest the decision surface are support vectors [35]. It uses a hyperplane to classify data vectors in infinite dimensional space. The simplest type of SVM is the maximal margin classifier, which aids in determining the most basic classification problem of linearly separable training data with binary classification [36]. The maximal margin classifier determines the hyperplane with the most significant margin in real-world complexities. SVMs employ a variety of kernel methods. In this work, we used a linear kernel.

3) *DT*: The categorization process was improved by the straightforward DT modeling approach. All decision tree algorithms are typically built in two stages: (i) tree growth, where the training set is divided repeatedly based on local optimal criteria until the majority of the records in the partition have the same class label, and (ii) tree pruning, where the size of the tree is reduced to make it more comprehensible [35].

4) *RF*: A classification system using several decision trees is called the random forest approach. It uses bagging and feature randomization to create each tree, resulting in an uncorrelated forest of trees whose forecast by the committee is more accurate than any one tree [37].

E. Ensemble Learning Approach

Combining data fusion, data modeling, and data mining into a unified framework is the aim of ensemble learning. A set of features is first extracted from the ensemble learning data using various transformations [38]. Based on these learned attributes, a few learning algorithms produce mediocre predictions. Finally, utilizing voting systems, ensemble learning combines the valuable data from the quick findings to provide knowledge discovery and enhanced prediction performance.

F. Evaluations

One of the best ways to evaluate how well the proposed model performs is to examine its accuracy, PPV, NPV, sensitivity, specificity, AUC, MCC, and Kappa. Accuracy evaluates

how often the classifier guesses accurately [39]. The accuracy of a forecast can be defined as the ratio of correct predictions to total predictions, and is defined as

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN}$$

The PPV reveals how many of the accurately anticipated cases were positive. Precision is functional when False positives are more of a worry than false negatives. The proportions of true positive and true negative results in diagnostic tests and statistics are PPV and NPV [40]. PPV and NPV describe the effectiveness of a diagnostic test or a similar statistical metric. A high result indicates that the statistic is accurate and can be determined, and is defined as

$$PPV(Precision) = \frac{TP}{TP+FP}$$

$$NPV = \frac{TN}{FN+TN}$$

According to Miao and Miao [41], sensitivity is the probability of successfully diagnosing the presence of cardiac disease in individuals, and is defined as

$$Sensitivity = Recall = \frac{TP}{TP+FN}$$

The probability of successfully identifying patients without cardiac disease is known as specificity, and is defined as

$$Specificity = \frac{TN}{FP+TN}$$

F1 provides a synthesis of the PPV and sensitivity measurements. It reaches its optimum when PPV and sensitivity are equal, and is defined as

$$F1 = \frac{2*Precision*Recall}{Precision+Recall} = \frac{2*TP}{2*TP+FP+FN}$$

The measure of a classifier’s ability to discriminate across classes is called the area under the curve (AUC) [40], and is defined as

$$AUC = Sensitivity - (1 - Specificity)$$

$$AUC = TPR - FPR$$

A statistical tool for assessing models is the MCC. It is accountable for determining the difference between anticipated and actual values, and is defined as

$$MCC = \frac{TP*TN-FP*FN}{\sqrt{(TP+FP)(TP+FN)(TN+FP)(TN+FN)}}$$

Kappa statistic is an excellent tool for handling difficulties involving multiple and unbalanced classes [42], and is defined as

$$Kappa = \frac{Po-Pe}{1-Pe}$$

IV. EXPERIMENTS AND RESULTS

A. Experiment 1

In this experiment, we used three datasets without applying the selection features. First, our proposed approach used the Statlog dataset. Using the Python environment AdaBoost classifier (with random state = 50), RF classifier (with n estimators = 600), SVM classifier (with linear kernel), and DT classifier (with random state = 500), we obtained the results mentioned in Table II.

In addition, we used the Z-Alizadeh Sani dataset with our proposed approach using the Python environment AdaBoost

TABLE II. EXPERIMENT 1 - RESULTS OF STATLOG UCI DATASET WITHOUT SELECTION

Model	Acc	Sens	Spec	PPV	NPV	AUC	F1	Kappa	MCC
AdaBoost	0.80	0.8	0.8	0.82	0.81	0.89	0.80	0.62	0.62
RF	0.84	0.82	0.82	0.87	0.83	0.92	0.84	0.69	0.70

ELA	0.89	0.92	0.90	0.87	0.88	0.96	0.89	0.77	0.77

classifier (with random state = 400), RF classifier (with n estimators = 100), SVM classifier (with linear kernel), and DT classifier (with random state = 22); we obtained the results mentioned in Table III.

Furthermore, we used the CVD dataset without applying any selection feature methods using the Python environment AdaBoost classifier (with random state = 50), RF classifier (with n estimators = 500), SVM classifier (with linear kernel), and DT classifier (with random state = 200); we obtained the results mentioned in Table IV.

B. Experiment 2

In this experiment, we used the features obtained from three studies: Yekkala et al. [3], Velusamy and Ramasamy [15], and Chintan et al. [43]. The feature selection step was carried out by the three studies. In the first study, Yekkala et al. [3] used a PSO feature selection method to extract features from the Statlog dataset and extract seven features: Chp, Ecg, Mhrt, Exian, Opk, Vessel, and Thal. We took the same seven features they obtained and used them with the proposed model: the AdaBoost classifier (with random state = 1), RF classifier (with n estimators = 10), SVM classifier (with linear kernel), and DT classifier (with random state = 2), and obtained the results mentioned in Table V.

In the second study, Velusamy and Ramasamy [15] used feature selection from the Z-Alizadeh Sani dataset based on SVM. It is based on model information in which the model is trained to integrate the relationship between predictors for computing variable importance. They chose the top 12 features, namely: Atypical, Typical Chest pain, Age, Region with Regional wall motion abnormality (Region RWMA), Ejection Fraction (EF-TTE), Nonanginal Chest Pain (Nonanginal), Hypertension (HTN), FBS, Tinversion, BP, Diabetes Mellitus (DM), and TG. Then chose the following top five significant features: Typical Chest pain, Atypical, Age, Region RWMA, and EF-TTE. We used these features with the proposed model:

the AdaBoost classifier (with random state = 1), RF classifier (with n estimators = 10), SVM classifier (with linear kernel), and DT classifier (with random state = 2). We obtained the results mentioned in Table VI and Table VII.

In the third study, Chintan et al. [43] used feature selection from the CVD dataset and estimated the mean arterial pressure (MAP) from the diastolic blood pressure (Ap_lo) and systolic blood pressure (Ap_hi) values for each instance. Patients' ages were initially given in days. Nonetheless, it was changed to years by dividing it by 365 to improve the analysis and prediction. They transformed the attributes of height and weight into body mass index (BMI), which may increase the performance of the heart disease prediction model. The nine features they obtained from the selection were Age, Gender, BMI, MAP, Cholesterol, Gluc, Smoke, Alco, and Active. We used these features with the proposed model: the AdaBoost classifier (with random state = 50), RF classifier (with n estimators = 500), SVM classifier (with linear kernel), and DT classifier (with random state = 200). We obtained the results mentioned in Table VIII.

C. Experiment 3

In this experiment, we used two wrapper methods for selecting features: forward selection and backward elimination. An iterative process called forward selection starts with the model having no features. The feature that best enhances our model is added in each iteration until the model's performance is not improved by adding a new variable. Backward elimination helps the model perform better by starting with

TABLE VIII. EXPERIMENT 2 - RESULTS WITH 9 FEATURES FROM CVD DATASET

Model	Acc	Sens	Spec	PPV	NPV	AUC	F1	Kappa	MCC
AdaBoost	0.72	0.64	0.64	0.76	0.69	0.78	0.69	0.44	0.44
RF	0.70	0.74	0.66	0.70	0.66	0.78	0.71	0.32	0.32
SVM	0.71	0.59	0.59	0.78	0.67	0.77	0.67	0.43	0.44
DT	0.63	0.60	0.60	0.63	0.62	0.63	0.62	0.26	0.26
ELA	0.66	0.65	0.67	0.67	0.66	0.74	0.66	0.33	0.33

all the features and removing the least important aspects one at a time. We keep doing this until we see no improvement when we remove features. We used four algorithms: AdaBoost, SVM, DT, and RF. We used R-squared as a measure of the performance of the feature-selection models. We applied it to the Statlog UCI, the Z-Alizadeh Sani, and the CVD datasets.

The result of feature selection with the Statlog UCI dataset is shown in Table IX, and it had the highest impact when using SVM with forward and backward methods. With the Statlog UCI dataset, we obtained the same result using both methods, but we chose the SVM with the forward method, as the number of significant features is less than 10. The results of the proposed model with the Statlog UCI dataset after using the SVM with the forward selection method are shown in Table XII. With the Z-Alizadeh Sani dataset, the highest R-squared result of the feature selection method was the SVM with the backward method using 26 features, as shown in Table X. The results of the proposed model with the Z-Alizadeh Sani dataset after using the SVM with the backward elimination method are shown in Table XIII.

With the CVD dataset, the result of feature selection is shown in Table XI, and it had the highest impact when using DT with backward, RF with forward, AdaBoost with forward, and AdaBoost with backward. We chose AdaBoost with the forward method. The results of the proposed model with the CVD dataset after using AdaBoost with the forward selection technique are shown in Table XIV.

We compared the results of the proposed model with previous studies that used one of the three datasets. When comparing the results of the proposed model with David's model [5], which used the Statlog UCI dataset, we found that the results of the proposed model outperformed their obtained results. In contrast, we obtained PPV = 0.83, which is higher than the [5] model (PPV = 0.812), and the proposed model got a higher sensitivity = 0.83, whereas the [5] model got a lower result (0.806 sensitivity). In addition, the [5] model had a lower F1 (F1 = 0.802) compared to the F1 of the developed model (F1 = 0.83). Unfortunately, David [5] was content with only three matrices to evaluate their results. It would have been better if they had used more matrices to comprehensively view the results. While Yekkala et al. [3] got 100% accuracy, sensitivity, specificity, PPV, and NPV. Some previous studies [13] and [15], which used the Z-Alizadeh Sani dataset obtained better results than the proposed model. Tama et al. [13] got an accuracy = 98.31%, F1 = 96.60% and AUC = 98.70%, while the proposed model obtained an accuracy = 91%, F1 = 89%, and AUC = 97%. Velusamy and Ramasamy [15] got 100% in accuracy, sensitivity, specificity, Kappa, PPV, F1, and MCC. However, this does not necessarily mean that their results are as good as in ML when 100% accuracy is achieved, which may indicate data overfitting.

V. CONCLUSION

The main goal of this study was to predict cardiac disease utilizing ELA, which included four ML algorithms: AdaBoost, SVM, DT, and RF. We applied it to three datasets: the StatLog UCI dataset, the Z-Alizadeh Sani dataset, and the CVD dataset.

TABLE XII. EXPERIMENT 3 - RESULTS OF PROPOSED METHOD WITH WRAPPER SELECTION USING STATLOG UCI DATASET

Table with 10 columns: Model, Acc, Sens, Spec, PPV, NPV, AUC, F1, Kappa, MCC. Rows include AdaBoost, RF, SVM, DT, ELA.

TABLE XIII. EXPERIMENT 3 - RESULTS OF PROPOSED METHOD WITH WRAPPER SELECTION USING Z-ALIZADEH SANI DATASET

Table with 10 columns: Model, Acc, Sens, Spec, PPV, NPV, AUC, F1, Kappa, MCC. Rows include AdaBoost, RF, SVM, DT, ELA.

We used two wrapper methods for the feature selection step, forward selection and backward elimination, and we dealt with the data imbalance using SMOTE. When using the proposed model with the StatLog UCI dataset, we obtained accuracy = 0.83, sensitivity = 0.83, specificity = 0.82, AUC = 0.90, PPV = 0.85, NPV = 0.83, F1 = 0.83, Kappa = 0.67, MCC = 0.68. When we used the Z-Alizadeh Sani dataset, we obtained accuracy = 0.91, sensitivity = 0.92, specificity = 0.90, AUC = 0.97, PPV = 0.93, NPV = 0.92, F1 = 0.89, Kappa = 0.81, MCC = 0.84. When using the CVD dataset, we obtained accuracy = 0.73, sensitivity = 0.63, specificity = 0.82, AUC = 0.77, PPV = 0.78, NPV = 0.69, F1 = 0.70, Kappa = 0.45, MCC = 0.46. In future work, we aim to collect a local dataset from King Abdullah Hospital - Bisha in the KSA, apply the proposed model to it, and improve the accuracy of the model. We will also use PSO and Gray Wolf Optimizer feature selection techniques that have shown promising results in disease prediction to further improve the model's performance.

TABLE XIV. EXPERIMENT 3 - RESULTS OF PROPOSED METHOD WITH WRAPPER SELECTION USING CVD DATASET

Table with 10 columns: Model, Acc, Sens, Spec, PPV, NPV, AUC, F1, Kappa, MCC. Rows include AdaBoost, RF, SVM, DT, ELA.

A Framework for Agriculture Plant Disease Prediction using Deep Learning Classifier

Mohammela Baljon*

Department of Computer Engineering,
College of Computer and Information Sciences,
Majmaah University, Majmaah, Saudi Arabia, 11952

Abstract—The agricultural industry in Saudi Arabia suffers from the effects of vegetable diseases in the Central Province. The primary causes of death documented in this analysis were 32 fungal diseases, two viral diseases, two physiological diseases, and one parasitic disease. Because early diagnosis of plant diseases may boost the productivity and quality of agricultural operations, tomatoes, Pepper and Onion were selected for the experiment. The primary goal is to fine-tune the hyperparameters of common Machine Learning classifiers and Deep Learning architectures in order to make precise diagnoses of plant diseases. The first stage makes use of common image processing methods using ml classifiers; the input picture is median filtered, contrast increased, and the background is removed using HSV color space segmentation. After shape, texture, and color features have been extracted using feature descriptors, hyperparameter-tuned machine learning (ML) classifiers such as k-nearest neighbor, logistic regression, support vector machine, and random forest are used to determine an outcome. Finally, the proposed Deep Learning Plant Disease Detection System (DLPDS) makes use of Tuned ML models. In the second stage, potential Convolutional Neural Network (CNN) designs were evaluated using the supplied input dataset and the SGD (Stochastic Gradient Descent) optimizer. In order to increase classification accuracy, the best Convolutional Neural Network (CNN) model is fine-tuned using several optimizers. It is concluded that MCNN (Modified Convolutional Neural Network) achieved 99.5% classification accuracy and an F1 score of 1.00 for Pepper disease in the first phase module. Enhanced GoogleNet using the Adam optimizer achieved a classification accuracy of 99.5% and an F1 score of 0.997 for Pepper illnesses, which is much higher than previous models. Thus, proposed work may adapt this suggested strategy to different crops to identify and diagnose illnesses more effectively.

Keywords—Suggested agricultural plant disease prediction system; tuned ML models; machine learning classifiers; plant disease detection; deep learning architectures

I. INTRODUCTION

The vast boundaries of the Kingdom of Saudi Arabia include an area of over two million square kilometres, or more than 80% of the whole landmass of the Arabian Peninsula. The country's position helps to explain its mild winters and hot, dry summers. It is between 15.2 and 32.6degrees north latitude and 34.1 and 55.5degrees [1] east longitude. Outside of the south-western highlands, where it rains more often in the summer, air receives less than 100 millimetres of precipitation annually. The natural springs in the Hue region provide the vast bulk of the water utilised in local farms in order to sustain water supply

and replenish aquifers, dams have been built at various locations around the country.

The agriculture industry in Saudi Arabia has received significant attention as part of the country's five-year growth goals. These initiatives aim to diversify the economy away from oil exports so that more people can eat and the quality of life can be kept high despite the population boom. The full potential of the country's agriculture sector is now being tapped upon. The quantity of land under cultivation is skyrocketed from around 435 thousand ha in 1980 to more than 1.5 million ha in 1990, [2] and a large part of that increase may be attributed to government encouragement and support. Two further agricultural academies emerged at the same time as new plant varieties were developed, the greenhouse business was launched, and massive agricultural undertakings were undertaken. In addition to meeting domestic need, the country currently exports food products such as wheat, dates, melons, poultry, fresh eggs, and milk [3]. Fig. 1 shows Saudi Arabia's market production.

Wheat, sorghum, barley, and millet are examples of important cereal crops; tomatoes and watermelons are examples of important vegetable crops; date palms, citrus trees, and grapevines are examples of important fruit crop species. The importance of fodder crops like lucerne is also significant. More over 1,100,000 acres, or around 81% of the total cultivated land area, is devoted to these crops. In 1990, wheat was grown on an estimated total of around 744 422 acres [4], or almost 55% of the total cultivated area. About 3.5 million metric tonnes were harvested from the crop.

Saudi Arabia Fruits and Vegetables Market: Export Volume in Metric Ton, Dates, 2017-2021

"Smart farming," often known as "precision agriculture," refers to the practise of using computer-based intelligent technologies in agriculture. Research in its infancy includes, but is not limited to, studies of intelligent irrigation systems, automated pesticide management, and the detection of plant diseases. Systematic methods of disease detection are crucial for the early diagnosis and prevention of certain conditions. Horticulturalists have an 88% success rate [5] in diagnosing plant diseases using standard diagnostic approaches. Despite this, it's a complicated procedure that calls for experience in the field. It may be difficult to undertake an inquiry of this sort in certain cases due to the crop's location. Several studies have proposed using Deep Learning Architectures (VGG 16, VGG 19, ResNet 50) or conventional Image Processing methods (Image filtering, contest stretching, segmentation, feature extraction, and disease classification) to classify various plant diseases. Traditional image processing techniques excel in situations when a large number of training data is unavailable. This means that several, fine-grained techniques, all fine-tuned to a high degree of precision, are required for correct sickness classification.

The structure of the paper is as follows; Section II includes study of existing methodology, Section III includes proposed methodology, Section IV includes Experimental analysis, Section V includes conclusion and future work.

II. LITERATURE SURVEY

A farmer's first priority should be the detection and eradication of plant diseases. The leaves are the first part of the plant to show damage from an approaching attack, and the changes that occur in the leaves are readily apparent. However, if you try to segment a picture of a sick leaf, you'll probably wind up with a jumbled, poorly lit composite. Because of this, we'll be taking a look at and ranking the latest classification algorithms for identifying problems with tomato leaves.

Effective convolutional neural network (CNN) was the name given to the deep CNN model developed by the team working on this project [2]. After the model was built and trained, it was put to the test by identifying images of healthy and diseased tomato leaves. The U-net model and a modified U-net model were put to the test and compared with regards to how effectively they segmented leaves. Experiments using six- and ten-class classification models were also undertaken in addition to the binary-classification ones. When it comes to segmenting images of leaves, only the U-net model was able to achieve an accuracy of 98.66 per cent. In contrast, EfficientNet-B7 showed stable performance across a range of classification tasks, from binary to six-class classifications. Using segmented pictures, the average accuracy of binary classification is 99.95%, while the average accuracy of six-class classification is 99.12%.

Using an image segmentation approach optimised for super pixels, the authors of [3] created a system for automatically recognizing and classifying tomato illnesses. A color-balance technique was employed during preproduction so that the optimal threshold for each kind of image collection could be identified. To further distinguish the leaves from the background, a ground-breaking method based on a histogram of gradients and color changes was used. A pyramid of the

histogram of gradients, a shape descriptor, and a grey level co-occurrence matrix (GLCM) are all components of a feature extraction approach that has been shown to be effective in distinguishing various medical presentations that are otherwise identical. The use of classifiers is pervasive in this investigation. Still, the best results towards the goal of the suggested framework were achieved by the random forest classifier, trained on a dataset of one hundred trees. When comparing the results of this study with those of many others that are quite similar to it [4,5,6,7], it was found that comparative analysis based on estimate parameters was the most accurate technique.

To classify potential tomato leaf diseases, the authors of [8] proposed a multi-class feature extraction strategy. The system is based on a deep CNN model that makes use of the attention method and the residual block. The findings show that the model is effective at picking up commonalities across diseases. Moreover, it uses the widely-used Plant Village dataset to get better results than a substantial body of prior deep learning literature. The overall positive identification percentage for this inquiry was 99.24%.

In [9], the feasibility of separating apart the various tomato diseases is examined. To boost model performance with little computational overhead, a lightweight CNN approach was developed and shown. The computational complexity, performance, and network architecture are only few of the areas that were explored for this essay. The used dataset consists of information from one healthy person and nine patients with various diseases. According to the results, if a model that is easy to understand and computationally efficient is created, the classification accuracy might be improved. Many different CNN architectures were developed for the tomato leaf disease detection study presented in [10]. LeNet, VGGNet, ResNet50, and Xception are only few of these designs. Scientists used 14,903 images of tomato plant leaves from the Plant Village dataset to build a deep Convolutional Neural Network (CNN). Both healthy and diseased plant leaves were shown in these photographs. The data showed that among all the tested designs, the fine-tuned VGGNet de-sign provides the best classification (99.25% accuracy) and achieves the lowest loss. This is true despite the fact that there is a significant time commitment associated with training and substantial financial outlay for the necessary technology

Grape plant leaf diseases are no match for the deep transfer learning-based model developed by the authors of [11]. In order to separate out the most crucial features, the authors built a fully connected layer. After that, redundant data was removed from the feature extractor vector using the variance method. With the use of images from the Plant Village dataset, the Efficient Net B7 deep architecture was retrained in this case. Then, logistic regression was utilized to further refine the collected data. By using this method, we were able to improve our categorization accuracy to 99.7%.

Using a dataset of 3,000 images of tomato leaves using the Google Collaborative Net-work (CN) model, the authors of [12] were able to accurately identify and classify nine different diseases and one healthy leaf class. Images are first preprocessed, then regions are separated, and finally the

findings are presented in this novel approach. The images are then processed further, which entails tuning the CNN model's hyper-parameters. The input picture is then analysed by the CNN, which pulls out features like as colors, borders, and textures. Prediction accuracy for the built categorization model is 98.49%.

According to the study published in [13], a CNN model with three convolutional layers, one max-pooling layer, and a filter count that can be adjusted between one and ten was developed. The authors of the Plant Village dataset used augmentation techniques to rectify the imbalance they discovered between the number of photos in each class. This model has an average accuracy of 91.2% and needs nearly 1.5 MB of storage space, whereas the pretrained model needs 100 MB.

The authors of [14] employed a transfer learning technique to construct a deep learning model that needed less training data, less computational resources, and less time to train. The scientists employed five different deep network topologies—MobileNet, Resnet50, Xception, Densenet121 Xception, and Shuffle Net—to extract characteristics. The authors experimented with many educational methods and tempos. With a classification accuracy of 97.10%, the DenseNet Xception easily triumphed over the competition.

According to [15], a deep residual network is built to identify tomato leaf diseases. To improve the remaining thick network, the authors chose to alter its structure. The model might be easily modified into a classification model with a 95% accuracy rate. The authors of [16] provide a system that can automatically detect and classify leaf diseases. To lessen the load on the computer's resources, the input photographs must be downscaled before the background can be removed and the photos separated. In order to extract features, the researchers in this work used two distinct deep learning models: VGG19 and Alex Net. Then, an ECOC-based SVM classifier was used to determine the identities of these characteristics. The results showed that VGG19 and Alex Net both achieved 98.8% and 98.9% classification accuracy, respectively.

In order to categorize the wide variety of diseases that might afflict soybean plants, the authors of [17] use multilayer perceptron deep learning and support vector machine techniques. In all, 19 diseases were correctly classified by the SVM. There were 683 examples in the dataset used; 643 were correctly classified while the remaining 40 had incorrect labels, for a classification accuracy rate of 94.14 per cent.

As was seen in the prior section of this article, the classification accuracies of various deep learning and machine learning algorithms created and contested for the detection of tomato leaf diseases vary widely. In addition, a few techniques have been created. In Table I, we can see a comparison of the algorithms utilized the diseases that may be identified, and the accuracy of the various classification systems that have been covered thus far.

TABLE I. A COMPARISON BETWEEN THE RECENTLY DEVELOPED CROP CLASSIFICATION SYSTEM

[2]	CNN model	3 disease classes	RF: 97%
[3]	Segmentation-based CNN	8 disease classes	99.23%
[4]	Light weight CNN	8 disease classes	99.25%
[5]	VGGNet- CNN	8 disease classes	VGGNet: 99.25%
[6]	Hybrid CNN (Hy-CNN)		
[7]	RNN Model	8 disease classes	97%
[8]	SVM model	8 disease classes	98.39%
[9]	ResNet-50 + SeNet	8 disease classes	97.8%
[15]	Restructured residual dense network	8 disease classes	95%
[16]	VGG19, Alex Net		91.2%
[17]	Deep learning, SVM		Densenet121 Xception

III. PROPOSED MATERIALS AND METHODS

A. Proposed First Phase DLPDS

The sequential method is used for the first phase of layer creation. This is due to the fact that building the model in layers is easiest using the sequential approach. To implement Softmax's input shape of (28, 28, 1), we utilise the add () function with the parameters conv2D, kernel _size, activation 'Elu,' and model layers. These are the fundamental building blocks of a convolutional neural network.

This procedure, which starts with the input picture and continues through the Conv2D layers and the flatten layers [18] connects the convolution and the other dense layers. Machine learning (ML) algorithms have become widely employed as artificial intelligence (AI) has advanced because ML succeeded in achieving emerges and cost-effective solutions to exploration of harvest yield [19]. The best result, which might be any of the values 0 through nine, is selected by setting the node in output to ten.

Each value is given a probability according to the Softmax activation, and the highest probability value is used as the forecast to determine whether the model needs more training to improve.

The agriculture sector makes use of validity measures to assess the performance of the disease segmentation technique for leaf blight. Blight, which affects tomatoes, is caused by the proteobacterium Xanthomonas Axonopodisis [20]. There are few illnesses as damaging as this one. Similarly, if a pepper plant is infected with blight, its yield might drop by 27.57.36 per cent. Fig. 2 depict a tomato leaf that has been infected with the blight disease.

Fig. 2. Tomato leaf image.

Fig. 3. Pepper leaf images.

Fig. 3 shows the pepper leaf images of the proposed work. Pepper leaf pictures, as well as unaffected input tomato, are taken into consideration for the input image, which is indicated by the letter I, and the impacted area of interest (ROI) is written as follows,

$$I = \sum_{x=1}^n S_x \quad (1)$$

In Eq. (1), n is represented as number of regions in input image, n number of regions are represented in terms of $S_1 + S_2 + \dots + S_n$.

Let us take two different regions then S_i not equal to S_j for $i \neq j$. The name for this kind of property is a disjoint property. A method for segmenting the intensity of histograms based on indices has been developed as a means of enhancing the segmentation and classification results produced by the aforementioned technique. Fig. 4 shows the proposed work block diagram.

1) *Denoising in input image:* This section explains the process of noise removal, since the provided input may have a possibility of having undesirable signals, which are referred to as noise. Denoising is a method that removes undesired signals from a picture while still preserving important information. Denoising is an essential step in the preprocessing of the picture, as it helps increase the accuracy of the final product. The median filter was used to eliminate

the sounds. The following is a representation of the three-by-three matrix that serves as the input to the median filter procedure. Fig. 5 shows the pixel selection and analysis of proposed work.

Let M be the input matrix, and then apply the sorting procedure to M in order to sort all of its values, and finally, get the median of M. In the previous illustration, the picture was smoothed down when the values of the surrounding neighborhoods were replaced with the median value of 214. After that, an adjustment was made to the image's contrast. The procedure described above is used in the process of pixel representation for the input picture in order to remove noise from the image and get the specific area of the leaf image that was damaged.

It can be seen in Fig. 6, that the noise has been reduced from the leaf photos. The median filter is applied to the photos of the three distinct illnesses, including foiled, rot, and rust, that have impacted the leaves.

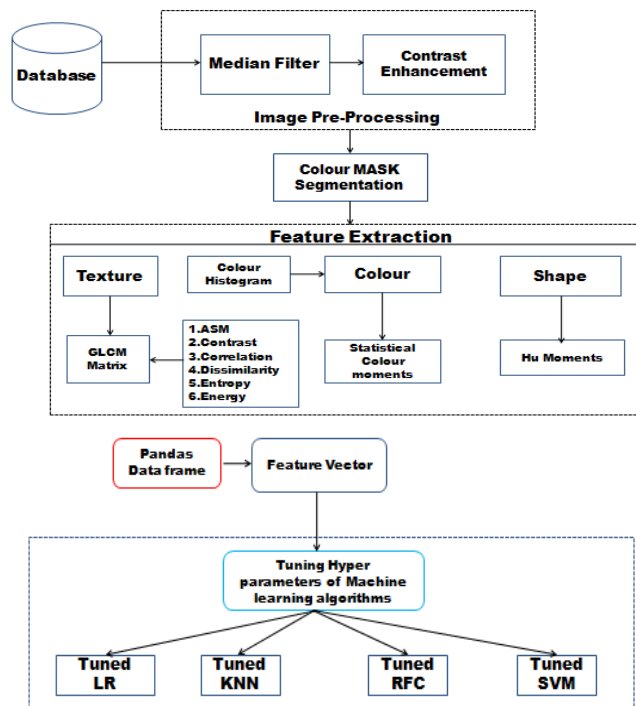

Fig. 4. Proposed first phase DLPD.

Fig. 5. Pixel selection.

Fig. 6. Pre-processed leaf images.

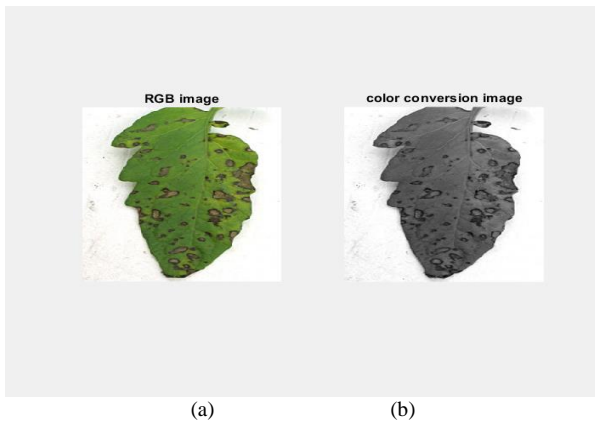

Fig. 7. (a). The original version, (b) Color conversion image.

Fig. 7 shows the original and color conversion results of provided dataset.

B. HSV Color Space Segmentation

The use of the Thresholding approach, the ROI may be extracted from the picture. Determine a value for the threshold, denoted by "T," depending on the highest and lowest points of the histogram. It is possible to employ the local threshold

method, the global threshold technique, or the optimum threshold technique depending on the application. The area that is of interest is known as the ROI, and it may either be a portion of the picture or the whole image. It depends on the application, but often it involves combining the OTSU threshold approach with the canny edge detection operator and dividing the jujube leaf into a number of regions. The function f is used to depict the picture of a Pepper leaf after it has been translated into a digital format using MATLAB (x, y) . By selecting the picture's threshold value, which is symbolized by the letter T, you can see that the image has been segmented. If the pixel intensity value is more than T, then it assigns value as 1; else, it takes the value as 0 for the pixel.

The formula for thresholding the leaf disease on Pepper is represented as follows, as in

$$\text{Threshold} = \begin{cases} 1 & \text{if } f(x, y) > T \\ 0 & \text{if } f(x, y) < T \end{cases} \quad (2)$$

Choose the T value but the result varies based on the selected domain. Same T value could not give accurate ROI for all kinds of input image. Implementation of the image segmentation technique used to separate the disease affected part from the background image. In this scenario first choose the seed point from the image. By using the seed point separate the diseased part. Choosing seed point is one of the biggest challenges in region growing method and wrong selection of seed point may lead to over segmentation. The study [21] implemented region growing method in cucumber downy mildew disease and get more accurate segmentation result compared with Otsu and K-means algorithm. Foliar disease of the leaf can be detected by using proposed region growing method and produced better result compared with existing algorithms. In this paper new algorithm is introduced based on the indices of histogram. During the analyze process, Pepper leaf images taken as input with the size of 256×256 as shown in Fig. 8.

Table II shows the feature metrics of the images and their values.

Fig. 8. (a) Graph cut algorithm (b) The original version, (c) Otsu thresholding, (d) HSV Color space segmentation.

TABLE II. COLOR MASKS FOR TOMATO, ONION, PEPPER LEAVES

S.no	Crop	Upper Green	Lower Green	Upper Brown	Lower Brown	Upper Yellow	Lower Yellow
1	Tomato	[86,255,255]	[36, 0, 0]	[30, 255, 200]	[8, 60, 20]	[40, 255, 255]	[21, 39, 64]
2	Onion	[86,255,255]	[36,0,0]	[30, 255, 200]	[8, 60, 20]	[255, 255, 255]	[3,3,3]
3	Pepper	[86,255,255]	[36,0,0]	[30, 255, 200]	[8, 60, 20]	[255, 255, 255]	[21,30,5]

C. Feature Extraction

1) *Color*: Extracting in all plant disease detection systems, color characteristics are essential since ill regions have different colors than healthy leaf photos; in this work, color features are recovered by measuring the color histogram and statistical color moments. The features of the HSV color histogram are extracted in the following stages: To begin, the cv2.COLOR_RGB2HSV function converts the input image from the RGB color space model to the HSV color space model. Quantizing the HSV color model has the effect of lowering both the cost of computation and the size of the feature. At this part of the process, each channel's H, S, and V components are quantized using eight different bins. The frequency distribution of quantized HSV values for each pixel in an image is shown by a histogram, which is created for each quantized picture. This histogram is specific to the image in question. In addition, statistical color moments are generated by first isolating the R, G, and B components of the input image, then computing the mean and standard deviation for each channel separately. This process is repeated for all three channels. In conclusion, color moments provide a feature vector that is six-dimensional.

2) *Shape*: An essential component of the quantification process for image objects is the extraction of shape information. In this work, form attributes are determined by calculating shape moments and locating shape edges. For the purpose of computing Hu moments, the function Hu moments found inside the Open – CV Python module is utilized. Converting the RGB image to grayscale is the first step that must be taken before attempting to calculate the Hu moments, which need just a single channel. Calculating the first 124 moments of the original picture is the responsibility of the CV2.moment module. After that, the real moments are input into the CV2 method, and the first six Hu moments are generated using the results of that. In order to get a shape feature vector, the Hu moments method and the array flattening method are used.

3) *Texture*: There are four distinct varieties of texture measurements that may be used in image processing, and they are structural, statistical, model-based, and transform-based. Statistical approaches may be used in this situation since the size of the texture is about equivalent to the size of the pixels. For instance, GLCM is an example of a statistical method that may be used to measure the textural features of an image, which can then result in various shades of grey. In order to generate the grey level co-occurrence matrix, fourteen Haralick texture characteristics, such as ASM, Correlation, Contrast, Entropy, Homogeneity, and Dissimilarity, in addition to eight additional features, were extracted. This process was carried out. This results in a thirteen-dimensional feature vector, with the fourteenth feature being omitted due to the substantial increase in the amount of processing it requires. Using manually chosen feature descriptors, the shape, color, and texture characteristics of the panda's data frame are

concatenated together to generate a 532-dimensional feature vector.

D. ML Classifier Tuning

The numerous layers that make up the CNN are capable of performing a wide variety of tasks, some of which include convolution, max pooling, activation, and a fully connected network (Fig. 9). Every CNN input image that is sent on to the Convolution layers includes filters, receptive fields, stride, padding, pooling, and ReLu stacks in some form or another. The receptive field of a CNN is the part of the network that monitors the activity of any filter that responds to each individual pixel. As further stack layers are added to the convolutional layers, it behaves in a linear manner throughout the process.

Fig. 9. Architecture of CNN.

When there is a negative number, the activation level that follows after it clips off to zero. This happens because negative numbers are less than zero. While the ReLu activation function converges more rapidly than the sigmoid activation function, it is also saturated in the negative region, which causes the gradient to be zero. This is because the ReLu activation function is a Convolutional Neural Network.

The very next pooling layer happens in between the convolutional layers, and as a consequence, it reduces the amount of data sampled by the network and gets rid of the other value data that is not relevant. After passing through the pooling layer, the dataset is shrunk down to a more manageable size, and the process of sending the dataset through the pooling layer is repeated until the desired output is produced. The matrix size will be decreased from 4x4 to 3x3 as a direct consequence of the maximum pooling layer, and then it will be decreased even more from there. The next layer is likewise fully connected, and it comprises neurons that have a full connection to all of the activations that were produced using a matrix multiplication. This layer is referred to as "totally linked."

Inside of a CNN network with several layers, the image is first warped and then converted into pixels. Following that, an activation of a neuron is performed for each location, and the results are compiled inside of the feature map. If the receptive field is moved one pixel further away from the activation layer, then the field plane will overlap with the previous activation by an amount that is equal to the field plane width minus one input value. This will occur if the receptive field is moved. After this, the fully connected layers will proceed to categories the many classes that have been instructed as binary values.

The supervised machine learning algorithms L.R., KNN, SVM, and R.F. are used in the initial step of the DLPDS process. In most cases, machine learning models are made up of two parameters: the default Model Parameter, and the hyperparameter.

Algorithm 1: Training and Testing phase

Step 1: Initialize the bias and weights to a random value.
Step 2: Input the training input vector and its targets.
Step 3: Compute the output of the hidden layer. The net input of the hidden layer is computed as follows,

$$y_k = \sum w_{ik}x_i + b_k$$

where b_k is the bias of the hidden layer, w_{ik} is the weights between the input and the hidden node and x_i is the input vector.

The output of the hidden layer is given by,

$$P_k = f(y_k)$$

where $f(0)$ is the activation function of the neuron.

Step 4: Compute the output of the output layer. The net input of the output layer is computed as follows.

$$z_1 = \sum w_{jk}p_k + b_i$$

where b_1 is the bias of the output layer, w_{jk} is the weights between the hidden and the output node and p_k is the output vector from the hidden neuron. The output of the output layer is given by.

$$y_1 = f(z_1)$$

where $f(0)$ is the activation function of the neuron.
Step 5: Compute the error at the output layer and at the hidden layer.

The error at the output layer is given by,

$$E_j = (t_j - y_j)f'(z_j)$$

The error at the hidden layer is given by.

$$E_k = \sum \delta_j w_{jk} f'(y_k)$$

Step 6: Update and renew the weights and bias with the learning rate α for output layer which is given by,

$$\Delta w_{jk} = \alpha E_j x_i$$

$$\Delta b_k = -\alpha E_k$$

$$w_k(\text{new}) = w_{ik} + \Delta w_{ik}$$

$$b_k(\text{new}) = b_j + \Delta b_k$$

Update and renew the weights and bias with the learning rate α for hidden which is given by,

$$\Delta w_{ik} = \alpha E_k y_k$$

$$\Delta b_{kk} = -\alpha E_j$$

$$\Delta w_{jk}(\text{new}) = w_{jk} + \Delta w_{jk}$$

$$b_j(\text{new}) = b_j + \Delta b_j$$

Step 7: Repeat step 2 to step 6 until the stopping criteria is reached.

5.2.2 Testing Process

Step 1: Feed the unknown data vector X
Step 2: Compute the output of the hidden layer. The net input of the hidden layer is computed as follows,

$$y_k = \sum w_{ik}x_i + b_k$$

The output of the hidden layer is given by,

$$P_k = f(y_k)$$

Step 3: Compute the output of the output layer. The net input of the output layer is computed as follows.

$$Z_1 = \sum w_{jk}P_k + b_i$$

The output of the output layer is given by.

$$y_j = f(Z_j)$$

where $f(0)$ is the activation function of the neuron.

Step 4: Obtain the classification result from the output neuron in the output layer.

The practitioner may modify the hyperparameters to improve the classification results. Grid search and Manual search are used in this study for the Tomato, Tomato, and Pepper datasets because they provide results more quickly than other techniques. Fig. 10 shows the proposed methodology block diagram stage 2.

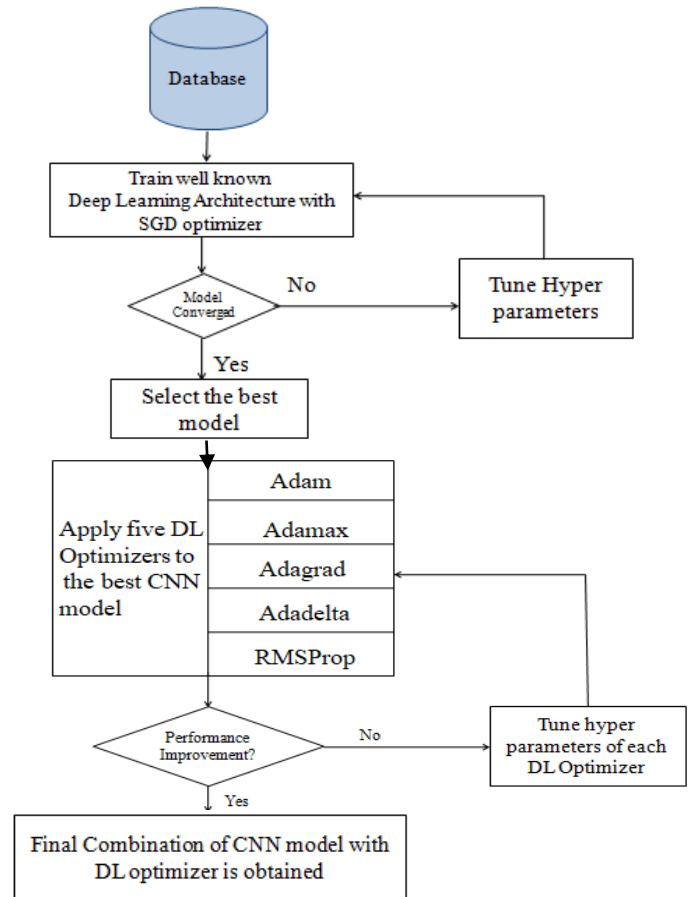

Fig. 10. Proposed second phase DLPDS.

E. Deep Learning Optimizers

First, the SGD optimizer is put to use in order to train the previously stated well-known architectures on the basis of validation accuracy, after which the best CNN model is selected. In conclusion, the Six DL Optimizers, whose features are outlined in Table III, are fine-tuned in order to improve the classification accuracy.

TABLE III. PARAMETERS OF DEEP LEARNING

IV. EXPERIMENTAL ANALYSIS

For the purpose of this study, ten thousand photographs spanning fourteen distinct categories were taken in the area of agriculture and sourced from the EPPO Global Database, both of which are open to the public. In addition, there are eight other categories that make up the Classification of Tomato plant diseases. In this study, we utilize datasets including both pepper and tomato. In both the pepper and tomato, onion datasets, the pictures are divided into training and testing sets in an 80:20 arrangements. There are a total of 5932 photos in the pepper and tomato collection shown in Table IV.

A. Tuning ML Classifiers

1) *LR Tuning*: C value [100, 10, 1.0, and 0.1], solver ['newton-cg,' 'lbfgs,' and 'liblinear,'] and penalty [12] are the most important parameters that are extracted from the default Python specification to tailor the performance of LR. The settings shown above have been applied to these parameters in order to modify the Tomato, Pepper, and Tomato characteristics shown in Table IV.

TABLE IV. LR-TUNING RESULTS

Sigma Value	Penalty	Solver	Accuracy %		
			Tomato	Pepper	Onion
100	elasticnet	saga	0.936333	0.937667	0.938667
		sag	0.936333	0.939000	0.937333
		liblinear	0.945333	0.929000	0.974667
10		lbfgs	0.874561	0.894561	0.925333
		newton-cg	0.861234	0.929000	0.925333
		lbfgs	0.797531	0.974333	0.895333
1.0		liblinear	0.971667	0.945333	0.970667
		sag	0.974000	0.974333	0.974000

2) *SVM Tuning*: The kernels- ['linear', 'poly', and 'rbf'] parameter, the C value- [10, 1.0, and 0.1] parameter, and the gamma-scale parameter are the ones that were chosen from the default Python SVM classifier specification. Table V demonstrates that an SVM with a C value of 1.0 and a kernel of poly achieves an accuracy of 88.13% for tomato features, 97.12% for Pepper features, and 87.13% for onion leaf features.

Table V shows the existing tuning values of the SVM classifier.

TABLE V. SVM-TUNING RESULTS

ML classifier	Para meters	Tomato								Accuracy %
		Healthy	Early blight	Leaf mold	Septoria leaf spot	Target spot	Bacterial blight	Late blight	Spider millets	
TLR	P	0.96	0.79	0.84	0.80	0.81	0.94	0.81	0.89	85.50
	R	0.95	0.81	0.91	0.75	0.88	0.91	0.75	0.88	
	F1	0.96	0.80	0.88	0.77	0.84	0.93	0.78	0.88	
TSVM	P	0.92	0.82	0.88	0.81	0.79	0.93	0.82	0.87	85.62
	R	0.92	0.81	0.94	0.76	0.86	0.92	0.81	0.83	
	F1	0.92	0.81	0.91	0.79	0.82	0.93	0.82	0.85	
TKNN	P	0.92	0.80	0.82	0.84	0.72	0.93	0.90	0.73	82.87
	R	0.86	0.74	0.95	0.74	0.79	0.84	0.63	0.82	
	F1	0.85	0.75	0.85	0.76	0.74	0.88	0.72	0.80	
MCNN	P	0.97	0.85	0.94	0.92	0.77	0.97	0.87	0.92	90.12
	R	0.98	0.88	0.96	0.88	0.90	0.93	0.80	0.88	
	F1	0.98	0.86	0.95	0.90	0.82	0.94	0.84	0.90	

3) *KNN Tuning*: The parameters n neighbors [3, 4], metric ['Euclidean', 'Manhattan'], and weights ['uniform', 'distance'] were chosen from the KNN default python specification. According to Table VI, using n neighbors =4 with metric = Manhattan, weights = Distance results in an accuracy of 82.75% for tomato, 90.12% for tomato, while using n neighbors =3 with Euclidean metric and distance as weight results in an accuracy of 99.21% for Pepper leaf characteristics.

4) *RF Tuning*: When it comes to tuning, the parameters max features ['sqrt', 'log2'], and n estimators [10, 100, and 1000] were chosen from the RF default Python specification. According to Table VII, using max features = sqrt and n estimators =1000 results in an accuracy of 95% for tomato and 99.50% for Pepper. Yet, using the same max features and the same number of estimators results in an accuracy of 90.12%.

TABLE VI. KNN-TUNING RESULTS

Max-Features	metric	weights	Accuracy %		
			Tomato	Pepper	Onion
10	sqrt	estimators	0.7975	0.9	0.9862
		estimators	0.81	0.891	0.9921
	log2	estimators	0.8062	0.9051	0.9752
		estimators	0.82	0.8937	0.9923
100	sqrt	estimators	0.7762	0.8811	0.9775
		estimators	0.8087	0.8957	0.9921
	log2	estimators	0.8025	0.8912	0.9712
		estimators	0.8275	0.9012	0.9923

B. First Phase DLPDS with Tuned Models

1) *Tomato diseases*: For the purpose of categorization, a total of 4000 different photos of tomato leaves are taken, 500 of which are healthy and 3500 of which display one of seven different disorders. For the objectives of experimentation, the 50:50 technique has been selected. The training and testing photos consist of 250 healthy and 1750 sick images.

TABLE VII. RF-TUNING RESULTS

max-features	estimators	Accuracy %		
		Tomato	Pepper	Onion
sqrt	10	82.50	91.00	99.12
	100	90.12	93.00	99.21
	1000	89.50	95.00	99.50
log2	10	82.00	91.00	98.96
	100	88.00	92.23	99.34
	1000	88.62	93.50	99.37

SHAPE and TEXTURE are put to use for the purpose of distinguishing sick samples and healthy samples using 10-fold cross-validation (a). According to Table VIII, the Tuned Random Forest Classifier has an overall accuracy of 90.12%. Higher values of performance measures include Precision

equal to 0.97 for both healthy tomatoes and tomatoes with bacterial blight, recall equal to 0.98 and 0.96, and F1 score equal to 0.98 and 0.95 for both healthy tomatoes and healthy tomatoes with leaf mold shown in Table VIII.

TABLE VIII. PERFORMANCE METRICS BASED ON ACCURACY

Sigma Value	Penalty	Solver	Accuracy %		
			Tomato	Pepper	Onion
100	elasticnet	saga	0.936333	0.937667	0.938667
		sag	0.936333	0.939000	0.937333
		liblinear	0.945333	0.929000	0.974667
10		lbfgs	0.874561	0.894561	0.925333
		newton-cg	0.861234	0.929000	0.925333
		lbfgs	0.797531	0.974333	0.895333
1.0		liblinear	0.971667	0.945333	0.970667
		sag	0.974000	0.974333	0.974000

Moreover, there are two classifications that are used for categorizing tomato leaf diseases, and each class has a selection of one thousand photos. The majority of the illnesses that might affect tomato seem to be bacterial infections, according to the visual examination. Hence, any and all photographs of a sick tomato plant are saved under the heading "tomato diseases," whereas any and all images of a healthy tomato plant are saved under the heading "healthy tomato" shown in Table IX.

The tomato train and the test dataset are both developed by the use of the 50:50 approach. Validation of the tomato test picture dataset was accomplished with the help of the tuned four ML models. MCNN delivers 95% overall accuracy with Precision= 0.96, F1 score= 0.95 for bacterial illness characteristics, and Recall =0.96 for Healthy leaf features. The experimental findings are produced by ten-fold cross-validation, as shown in Fig. 11(b), and from Table IX, MCNN gives 95% overall accuracy.

TABLE IX. PERFORMANCE METRICS OF TOMATO LEAVES

ML classifier	Parameters	Tomato		
		Bacterial Disease	Healthy	Accuracy %
TLR	P	0.90	0.87	88.50
	R	0.86	0.91	
	F1	0.88	0.89	
TSVM	P	0.95	0.91	92.50
	R	0.90	0.95	
	F1	0.92	0.93	
TKNN	P	0.94	0.87	90.50
	R	0.86	0.95	
	F1	0.90	0.91	
TRF	P	0.96	0.94	95
	R	0.94	0.96	
	F1	0.95	0.95	

2) *Pepper diseases*: There are four categories that make up the Pepper leaf disease categorization system, and each category has a thousand pictures. A total of four thousand photographs are amassed, and then, applying the 50:50 technique, the picture datasets for the train and test are partitioned into healthy images, class 500 images, and test images, respectively. There are 1500 photos that fall under the heading of the sick image, which may be used for training and testing purposes. The test picture dataset was verified by using the extracted characteristics of Pepper leaves as well as the results of ten-fold cross-validation, which are shown in Fig. 11(c). Table X shows that the majority of the Tuned models got improved classification results, with TKNN (Tuned K Nearest Neighbor) reaching an accuracy of 99.25% and MCNN achieving a greater accuracy of 99.50.

TABLE X. PERFORMANCE METRICS OF PEPPER LEAVES

ML classifier	Parameter	Pepper				Accuracy %
		Healthy	Cercospora_1 eaf_spot	Common rust	Northern_Leaf_Blight	
TLR	P	1.00	0.95	1.00	0.90	96.25
	R	1.00	0.90	1.00	0.96	
	F1	1.00	0.93	1.00	0.93	
TSVM	P	1.00	0.97	1.00	0.92	97.12
	R	1.00	0.92	1.00	0.97	
	F1	1.00	0.94	1.00	0.94	
KNN	P	1.00	0.97	1.00	1.00	99.25
	R	1.00	1.00	1.00	0.97	
	F1	1.00	0.99	1.00	0.98	
TRF	P	1.00	0.99	1.00	0.99	99.50
	R	1.00	0.99	1.00	0.99

C. Second Phase DLPDS

The Tomato, Tomato, and Pepper leaf pictures were used to train the chosen DL Architectures and the experimental findings were represented by validation, training accuracy/loss, Precision, F1 Score, and Recall. The model or optimizer that achieves the highest possible Validation accuracy and F1 score is taken into consideration to be the best option for the Second Phase DLPDS that is being suggested. The accuracy and loss measurements in the training and validation stages need a combined total of 20 epochs in order to converge.

1) *Performance of pretrained models*: Accuracy, sensitivity, selectivity, kappa coefficient, and mean square

error are some of the several performance metrics that are taken into consideration. The following is a representation of the notations that are used in the computation of the metrics: TP - true positive, TN - true negative, FN - false negative, TP - positive, TN - negative, FN - false negative. The following is the calculation for the performance metrics:

- Accuracy: It is the measure of how well the classifier correctly identifies whether the leaf is healthy or diseased.

$$\text{Accuracy} = \frac{\text{True Positive} + \text{True Negative}}{\text{Positive} + \text{Negative}} \quad (3)$$

- Sensitivity: It is also known as recall and it represent the measure of proposition of diseased leaf correctly identified as such.

$$\text{Sensitivity} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}} \quad (4)$$

- Specificity: It is also termed by True Negative Rate, and it represents the proportion of healthy leaf correctly identified.

$$\text{Specificity} = \frac{\text{True Negative}}{\text{False Positive} + \text{True Negative}} \quad (5)$$

- Kappa Coefficient: The kappa coefficient is used to determine how closely the original values and the graded values are related to one another. A kappa score of one shows that all respondents are in complete agreement, while a value of 0 indicates that there is no consensus. Here is how it is figured out,

$$\text{Kappa} = \frac{z \sum_{j=1}^n m_{jj} - \sum_{j=1}^n (G_j C_j)}{z^2 - \sum_{j=1}^n (G_j C_j)} \quad (6)$$

where j is the number of the class, Z is the total number of graded values that are compared to the original values, m (i,j) is the number of values belonging to the truth class j that have been classified as class j, Cj is the total number of expected values belonging to class j, and Gj is the total number of truth values belonging to class j. where j is the number of the class, Z is the total number of graded values that are compared

During the second phase, RT is used to pinpoint the precise location of the leaf illness as well as determine its degree of severity shown in Table XI.

TABLE XI. COMPARISON OF PROPOSED TRAINING FUNCTION AND TRAINBR

Sl.No	Training Function	MSE	Accuracy	Kappa Coefficient
1	Trainbr	0.03	93.4	0.892
2	Proposed Method	0.02	95.64	0.928

The categorized picture is then put through RT in order to pinpoint the area that is affected by the illness. If the picture is determined to be a disease, a morphological operation is performed on it, coupled with the determination of an appropriate threshold, in order to differentiate the sick area from the backdrop. The segmented output is created by applying a morphological opening operation with a square structural element to the identified picture. This results in the

output being segmented. The RT is applied to the sick leaf that has been segmented. The results of the morphological operation are first segmented, and then the RT is applied to the results of that segmentation. The RT output provides evidence that the disease node is present in the leaf. The radon transform is useful for pinpointing exactly where the sick area is located in the body.

There is no indication of either underfitting or overfitting in the experimental findings of the pre-trained models using the Pepper picture dataset. From Fig. 12(b) Enhanced GoogleNet was able to achieve the highest possible level of Validation accuracy by making use of the idea behind the Inception module. The Improved GoogleNet and SGD optimizer, together with a comparative study of the several models shown in Table XII, led to the best possible F1 score of 0.993.

TABLE XII. PERFORMANCE OF PRE-TRAINED MODELS

Parameters	MobileNetV2	Improved GoogleNet
Training Accuracy	98.99	98.99
Validation Accuracy	97.73	99.92
Training Loss	0.220	0.021
Validation Loss	0.285	0.002
Precision	0.982	0.991
F1 Score	0.986	0.993

(a): No DATA.

(b) Yes DATA.

Fig. 12. Training and testing data.

TABLE XIII. ANALYSIS OF SEGMENTATION

Raw Input Image	K-Means Clustering	Fuzzy Logic	Region-Based Segmentation	HSV Color Segmentation
Tomato blight disease	0.684	0.82	0.8843	0.8368
Tomato Leaf Spot	0.66	0.856	0.801	0.8465
Tomato Powdery Mildew	0.68	0.861	0.8154	0.8624
Pepper blight disease	0.803	0.865	0.8266	0.868

Fig. 13. DSC Performance of segmentation techniques.

Fig. 13 makes it abundantly evident that the indices-based intensity histogram segmentation technique assures a somewhat superior performance value for various plant leaves, such as those affected by tomato blight disease, tomato spot, tomato powdery mildew, and Pepper blight disease, respectively. The divided components each provide important information that may be utilized to examine the characteristics and facts connected to the condition. Table XIII presents the results of the mutual information calculation for the segmented area.

TABLE XIV. MUTUAL INFORMATION FOR SEGMENTATION RESULT

Raw Input Image	K-Means Clustering	Fuzzy Logic	Region-Based Segmentation	MCNN
Tomato blight disease	0.67	0.75	0.83	0.85
Tomato Leaf Spot	0.68	0.78	0.86	0.86
Tomato Powdery Mildew	0.73	0.80	0.88	0.868
Pepper blight disease	0.76	0.83	0.82	0.878

According to what is shown in Table XIV. It is abundantly obvious that the indices that are based on the intensity of the histogram include various information about impacted diseases in an efficient way. Indices Based Intensity Histogram Segmentation approach segment region contain significant information because it assures the largest mutual information value. This can be understood since the technique for indices-

based intensity histogram segmentation segments the histogram based on its intensity. Fig. XIV is a graphical depiction of the linked data for the mutual information value, and it was created using Table XIV.

Fig. 14. Mutual information for different segmentation methods.

According to Fig. XIV, a technique to segmenting intensity histograms that is based on indices assures a high mutual information value for various plant leaves, such as those affected by tomato blight disease, tomato spot, tomato powdery mildew, and Pepper blight disease. The divided components each provide important information that may be utilized to examine the characteristics and facts connected to the condition. Effective retrieval of disease-related information from the segmented area is accomplished, and the accuracy of the segmented region's diagnostic performance is evaluated by means of the sensitivity and specificity metrics that are shown in Table XIV.

Fig. 15(a) and (b) shows that using a strategy that segments intensity histograms based on indices assures a high sensitivity and specificity value for various plant leaves, such as those affected by tomato blight disease, tomato spot, tomato powdery mildew, and Pepper blight disease. The segmented sections include valuable information that can be used to assess the disease-related characteristics and information that can be used to obtain disease-related information with the maximum possible accuracy, as seen in Table XV.

The results shown in the preceding Table XV make it abundantly evident that the indices based on the intensity histogram segmented area include a high degree of accuracy (88.78%) about the afflicted illness portion in an efficient way.

2) Discussion: The experimental results show that the enhanced versions of GoogleNet and MobileNetV2 using SGD Optimizer with ImageNet weights achieve a significantly more acceptable degree of validation accuracy. These two models are compared using five different optimizers and the same amount of epochs in an effort to improve classification

accuracy. Based on the data in Table XI, we may make the following inferences:

Training the pre-trained models with various optimizers led to notable improvements in validation, training accuracy/loss, F1 Score, precision, and recall.

(a)

(b)

Fig. 15. (a) Sensitivity and (b) Specificity.

TABLE XV. ACCURACY FOR SEGMENTATION RESULT

Raw Input Image	K-Means Clustering	Fuzzy Logic	Region-Based Segmentation	MCNN
Tomato blight disease	82.1	83.5	86.34	87.31
Tomato Leaf Spot	82.8	83.88	85.134	87.543
Tomato Powdery Mildew	83.1	84.21	86.43	88.46
Pepper blight disease	83.78	84.72	86.83	88.78

The best validation accuracy may be achieved with the use of optimizers such as Adam, SGD, and Adadelta.

- Enhanced GoogleNet with Adam Optimizer achieved a 99.95% success rate and an F1 score of 0.997, demonstrating the efficacy of the proposed tuning strategy. The results of this experiment are also significantly improved upon when compared to those of previous studies. Therefore, the given technique may be used to a wide range of plant diseases.
- The F1 score and validation accuracy for MobileNet were both improved by using the Adam and Adadelta optimizers.

However, it is possible to see a decrease in performance after switching from SGD to RMSProp and Adamax for improved GoogleNet and MobileNetV2. This is the case despite the fact that these algorithms are designed to improve performance.

V. CONCLUSION AND FUTURE WORK

Plant disease and pest attack is a major threat to the farmers and the farming industries. It impacts the economy majorly by destroying the plants and production quality. An automatic plant disease detection system is a key factor in the growth and benefit of farm production. This research is carried out based on the image-based automatic disease detection system which includes various image processing and CNN techniques. The proposed methods are developed to enhance the detection system and classify diseases. Training, validation, and testing were conducted on various publicly available datasets. The datasets consist of images captured under different lighting conditions, resolution, position, and complex background to train the system with all possible complexities to avoid the misclassification rate. When compared to ML models, the F1 Score and Accuracy of the Enhanced GoogleNet and MobileNetV2 models were shown to be superior. The best results for differentiating between photos of diseased and healthy tomato leaves were achieved using the DL model and optimizer combination known as Improved GoogleNet with the Adam optimizer, which achieved a validation accuracy of 99.5% and an F1 score of 0.997%. Furthermore, two distinct DL architectures were tweaked with five distinct DL Optimizers to enhance classification accuracy. The future research in the automatic plant disease and pest detection method focuses mainly on increasing the efficiency of the system by reducing the computational time. It also further focuses on treatment and prevention methods based on the severity of the impact. The entire system should be implemented in real-time using mobile and web applications, where the test images can be taken using any device including mobile cameras, drone cameras, satellite images and sensor images. The real-time applications store and retrieve all the information based on cloud services. Which enables the farmers to operate the farming portal to detect the disease or pest attack based on the captured images and based on the impact and severity of the disease the portal provides a solution to the farmer by prescribing the procedure for the treatment and prevention techniques like cross farming, seedling selection, ground detection, canopy estimation, water level detection,

phenotype, and genotype evaluation to avoid the further occurrence of the same disease or pest attack.

Nanchang 330000, Jiangxi, China

Abstract—Lung cancer is a significant health issue affecting millions of people worldwide annually. However, current manual detection methods used by physicians and radiologists to identify lung nodules are inefficient because of the diverse shapes and locations of the nodules in the lungs. New methods are needed to improve the accuracy and speed of detecting lung nodules. This is important because early detection of nodules can increase the likelihood of successful treatment and recovery. This paper introduces a new LLC-QE model that combines ensemble learning and reinforcement learning to classify lung cancer. Initially, the model undergoes pre-training through the utilization of the Artificial Bee Colony (ABC) algorithm. This approach aims to decrease the probability of the model getting stuck in a local optimum. Subsequently, a set of convolutional neural networks (CNNs) is used to simultaneously derive feature vectors from input images, which are subsequently combined for classification in downstream processes. The LIDC-IDRI dataset, predominantly composed of cases without cancer, was employed to train and evaluate the model. To mitigate the dataset imbalance, the training procedure using reinforcement learning is formulated as a series of interconnected decisions. During this process, the images are regarded as states; the network acts as the agent, and the agent is given a greater reward/punishment for accurately/incorrectly classifying the underrepresented class compared to the overrepresented class. The LLC-QE model achieves excellent results (F measure 89.8%; geometric mean 92.7%), outperforming other deep models. Identifying the optimal values for the reward function and determining the ideal number of CNN feature extractors in the ensemble are achieved through experiments conducted on the study dataset. Ablation studies that exclude ABC pre-training and reinforcement learning from the model confirm these components' independent positive incremental impact on the model's performance.

Keywords—Lung cancer; ensemble learning; reinforcement learning; artificial bee colony; convolutional neural network

I. INTRODUCTION

In recent years, the global mortality rate for lung cancer has risen significantly. This indicates that lung cancer has emerged as among the deadliest forms of cancer in recent decades [1]. However, over 50% of lung cancers can be treated successfully if detected early [2, 3]. Automatic cancer detection can significantly reduce the time required for diagnosis, leading to timely treatment. Sufficient forms of lung cancer are not visible to the naked eye, making automated diagnosis a valuable tool in reducing human error [4]. The computer-aided diagnosis (CAD) system can assist radiologists in rapidly and precisely detecting and diagnosing abnormalities. This can aid in

identifying and diagnosing lung cancer at an earlier stage, resulting in more effective treatment options [5].

Computed tomography (CT) is a widely used method for detecting lung cancer, leading to an increase in CT images and putting pressure on radiologists [6]. To ease this burden, Computer-Aided Diagnosis (CAD) systems have been developed to aid in nodule detection [7, 8]. Detecting nodules is a complex task given their various sizes, shapes, and positions. Deep learning, particularly in CAD, has shown potential to enhance nodule detection. Examples include ZNET [9] using the U-Net architecture [10], Resnet utilizing a 3D CNN, and JianPeiCAD [11], which employs a multi-scale rule-based approach followed by a broad-channelled 3D CNN. While 3D CNNs capture CT scans' details, they come with longer training times and higher storage needs. The varying slice thickness in CT scans complicates 3D imaging, making 2D imaging more suitable in terms of training duration and resource use, making it a preferred method for nodule identification.

Imbalanced class distribution is a pressing issue in deep learning, especially in lung cancer classification, where the uneven spread between positive and negative cases hampers model accuracy [12]. To address this, data-level methods like over-sampling and under-sampling are employed. Over-sampling, such as Synthetic Minority Oversampling Technique (SMOTE) [13], creates synthetic examples for the minority class, while under-sampling techniques like NearMiss [14] reduce majority class instances. However, these can lead to overfitting or loss of vital data. Algorithm-level solutions amplify the minority class's influence using ensemble learning, cost-sensitive methods, and decision threshold adjustments. Cost-sensitive techniques assign different misclassification costs, ensemble methods utilize multiple classifiers, and threshold adjustments modify the classification threshold during tests. Some deep learning strategies focus on learning distinct features in unbalanced data or ensure balanced mini-batch training in convolutional networks. These approaches aim to improve classification precision in the face of imbalanced data [15].

In the past several years, deep reinforcement learning (DRL) [16] demonstrated successful applications in various areas, including computer games, robot control, and recommendation systems. DRL helps in removing noisy data and enhancing features, which ultimately boosts the performance of the classification system [17]. The classification process is a sequential decision-making task that requires the acquisition of an optimized policy. However, the

computational time required for the process is amplified due to the elaborate simulations conducted between agents and environments. Some researchers have utilized deep reinforcement learning to learn valuable data features and enhance the useful features of the classifier [18-21]. An ensemble pruning approach has also been developed, which selects the best sub-classifiers with the help of RL, which is effective for small data [22]. However, there has been a minimal investigation into using DPL in imbalanced classification, particularly in medical images. DPL is suitable for imbalanced classification as it rewards or penalizes the minority class more to attract more attention.

ABC [23] is utilized for optimization, inspired by the manner in which honeybees hunt for food. The algorithm imitates the way bees search for food sources by using three components: employed bees, onlooker bees, and scout bees. Bees in the workforce have the duty of finding food sources and communicating their whereabouts to other bees by performing a waggle dance. Onlooker bees then choose the most promising food sources based on the information they received from the employed bees. Scout bees search for new food sources when the current ones are depleted. ABC has proven effective in tackling multiple optimization problems [24], one of which is the initialization of neural network weights [12]. It has shown promising results in improving the performance of deep neural networks and reducing the effect of suboptimal solutions caused by parameter initialization [25]. In addition, the ABC algorithm is a straightforward approach that causes tuning only a few parameters and is simple to implement. As a result, it can be considered a dependable and effective substitute for backpropagation in the training of neural networks.

This paper presents a model called LLC-QE based on deep Q-learning and ensemble learning, combined with the ABC algorithm for weight initialization. Classification is considered a guessing game using a Markov decision process within an RL framework. The state of the environment is represented by a CT image of the patient, and the agent is a deep neural network comprising several parallel convolutional feature extractors. To start the game, the investigation revolves around employing the ABC algorithm in LLC-QE. This algorithm targets the discovery of weight initializations for CNNs and feed-forward networks within the backpropagation algorithm. The agent then decides whether the patient is healthy or ill, and the decision is rewarded with correct decisions receiving positive rewards and incorrect ones receiving negative rewards. In order to address the dataset imbalance, a greater absolute value of the reward is given to the minority class. The aim of the agent is to maximize its cumulative rewards throughout the sequential decision-making process, which involves classifying the samples with the highest possible accuracy. The performance of the LLC-QE model is evaluated on the widely used LIDC-IDRI dataset, and the results show its superiority over other approaches that rely on random weight initialization.

The article is structured in this manner: Section II gives a broad summary of various techniques employed in examining lung nodules. Section III delves deep into the methodology we suggest. Section IV outlines the dataset used for the research and showcases the experimental outcomes. Lastly, Section V

wraps up the discussion and proposes potential avenues for further study.

II. RELATED WORK

CAD is a popular technique for detecting pulmonary nodules in medical images [26]. Conventional methods usually require manually creating features, such as setting pixel thresholds, grouping voxels, and using morphological characteristics. However, these methods are often limited by their ability to detect nodules accurately and to distinguish them from false positives [27]. Tan et al. [28] created a CAD system based on CNN that uses a nodule segmentation technique to detect nodule clusters' central positions in the detection phase. The method integrates computed divergence features with nodule and vessel enhancement filters. In the classification stage, distinctive features that are invariant and defined on a gauge coordinate system are employed to distinguish genuine nodules from certain types of blood vessels that can result in inaccurate positive identifications. Another approach to CAD system development is to merge two or more existing CAD sub-systems to improve accuracy. Traverso and colleagues [29] developed a CAD system that operates through the web and cloud by merging two separate CAD sub-systems: the Channeler Ant Model and the Voxel-Based Neural Approach (VBNA). Both algorithms share a starting point, which involves utilizing a three-dimensional (3D) region-growing segmentation method to obtain the parenchymal volume while simultaneously eliminating the trachea and dividing the two lungs. The Channeler Ant Model utilizes an ant-colony optimization algorithm to identify nodule candidates, while the VBNA uses a multi-layer perceptron neural network to classify them.

In recent times, the field of computer vision has undergone a revolution with the emergence of deep learning, especially CNNs. CNNs have demonstrated remarkable performance in extracting pertinent features from images that can be employed for tasks, such as object detection and classification [30, 31]. This has led to significant advances in fields ranging from medical imaging to autonomous driving. One of the key advantages of CNNs is their ability to learn features in an end-to-end method with no hand-crafted features or feature engineering. This means that CNNs can learn to recognize complex patterns and features in images, such as edges, corners, and textures, by processing the raw pixel values directly. This has led to significant improvements in image classification accuracy on benchmark datasets, such as ImageNet, where CNNs have achieved human-level performance. Another important advantage of CNNs is their ability to generalize to new tasks and datasets. Transfer learning refers to a methodology that enables pre-trained CNNs to apply to new datasets or tasks. This can be done by fine-tuning the model on the new data or by employing the network as a fixed feature extractor. This has been effective for a wide range of tasks, from medical image analysis to natural language processing. There are several well-known frameworks for object detection that utilize CNNs, such as Faster R-CNN [32], SSD [33], and R-FCN [34]. These frameworks use a combination of CNNs and additional modules to generate candidate bounding boxes for objects in an image, which can then be classified and refined to produce the

final object detection output. One of the key advantages of these frameworks is that they can produce highly accurate object detections in a one-stage manner with no complex post-processing or refinement steps.

With the increasing prevalence of deep learning, a growing number of researchers in the field of medical imaging are currently focusing on integrating deep learning into their investigations [35]. For example, many recently proposed CAD systems for identifying pulmonary nodules utilize CNNs to achieve fast and accurate diagnoses. A survey discussed in [36] reveals that multiple CAD systems have emerged to detect nodules comprehensively. ZNET leverages CNNs for detecting candidates and reducing false positives. The input slices are cropped to dimensions of 512×512 , and a U-Net model applies to each axial slice to create a probability map, which is utilized for identifying candidates. Subsequently, a threshold is used to obtain potential nodule regions, which is established with the objective of identifying the maximum possible number of nodules, based on the validation subset. Afterward, a 4-neighborhood kernel is applied for morphological erosion, which aids in eliminating the partial volume effects. A connected component analysis is utilized to group the candidates together, and the coordinates of the candidates are determined based on the centroid of the components. To decrease the occurrence of false positives, ZNET uses wide residual networks [37] and captures $64 * 64$ image sections from the axial, sagittal, and coronal perspectives for each candidate, which are subsequently fed into the networks for independent processing. JianPeiCAD uses a rule-based screening at multiple scales to obtain potential nodules. To decrease false-positive results, a 3D CNN is employed with broad channels and is trained using data augmentation techniques. MOT_M5Lv1 [38] utilizes a technique called 3D region growing to obtain the lung volume, along with specific steps for excluding the trachea and separating the lungs. The

algorithm for detecting candidates is derived from the approach presented by Messay et al. [39], which uses morphological processing and multiple gray-level thresholding to segment nodules. The elimination of false positives is carried out through the calculation of 15 features, which include geometrical and intensity features, and then classification is accomplished by utilizing feedforward neural networks. Resnet [40] suggests a framework for nodule detection using a 3D CNN. This framework screens candidates with a fully convolutional network and selects locations with high probabilities as candidates. To decrease the number of false positives, the recommendation is to incorporate multi-level contextual details surrounding pulmonary nodules by merging a collection of 3D CNNs with distinct receptive field sizes. This approach enables better differentiation of nodules from their challenging imitators. M5LCAD [41] uses ant colonies to segment the lung structures and performs a repetitive process of applying threshold values on the pheromone maps to obtain a set of possible candidates. To reduce the number of false positives, candidates are classified using a feedforward neural network based on a collection of 13 features, which encompass attributes related to spatial positioning, intensity values, and shape characteristics.

III. PROPOSED METHOD

A deep learning framework is being used for binary classification, as shown in Fig. 1. The CT image is taken as input and processed by three CNN feature extractors simultaneously. These extractors individually create a feature vector from the image, and the resulting vectors are merged and passed through fully connected layers, with the last being a Softmax layer that makes the final decision. Using an ensemble of extractors enables the model to generate multi-scale features, which enhance its capabilities and yield better outcomes than a single deep network.

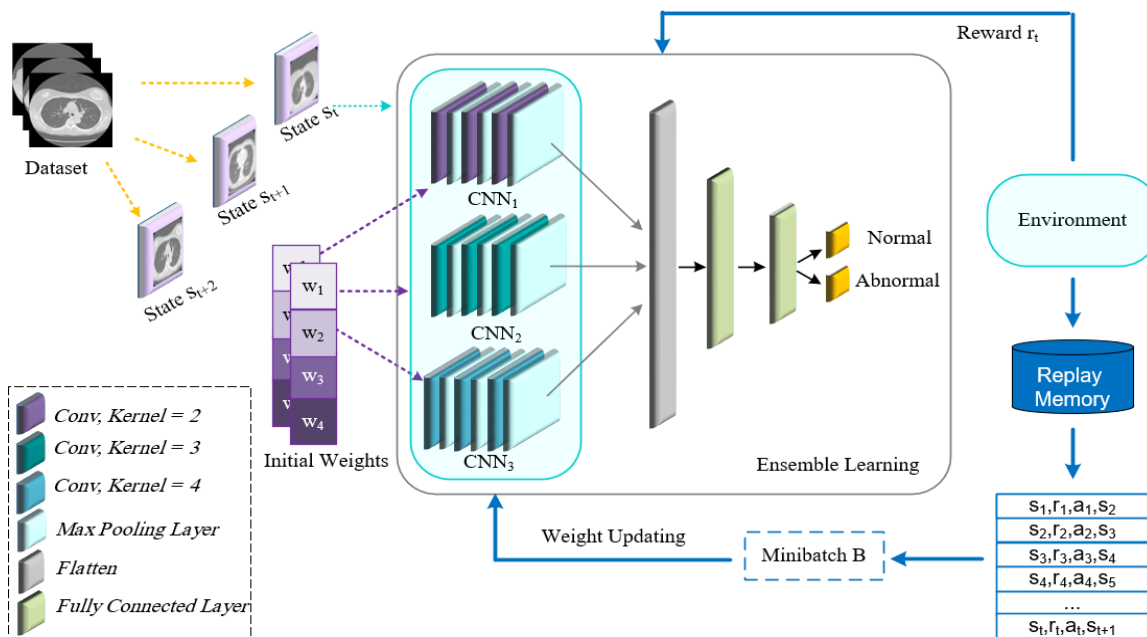

Fig. 1. The LLC-QE model.

The study utilized a CNN network architecture comprised of five convolution layers in two dimensions. The number of filters used in these layers was 128, 64, 32, 16, and 8. Each convolution layer has a kernel size of 2, stride of 3, and padding of 4 for both dimensions. The max-pooling layer has dimensions of 2×2 , and there are three fully connected layers with hidden layer sizes of 128, 64, and 32. In order to avoid overfitting, early stopping and dropouts with a probability of 0.4 are utilized. The batch size for all experiments is 64, and the images in the dataset are gray scale, with light intensities mapped to the range [0,1].

A. Training

The training phase consists of two distinct and sequential steps: ABC pre-training is performed, and deep Q-network training is carried out. The ABC pre-trained weights are used to initialize the deep Q-network training.

1) *ABC pre-training*: The process helps established the network's initial values, increasing the probability of quicker convergence and reducing the chances of getting stuck in local optima. Initially, the weights of the CNN and feedforward layers are transformed into one unified vector, illustrated in Fig. 2. After that, the parameters of each convolutional layer and feedforward layer are compressed and combined into a single vector. Each potential solution for the flattened and concatenated vector is considered a food source in the ABC algorithm. The quality of a solution is evaluated by:

$$Fitness = \frac{1}{\sum_{i=1}^N (y_i - \hat{y}_i)^2} \quad (1)$$

The formula evaluates the performance of the algorithm using N training images in the dataset. It considers the actual label y_i and the predicted label \hat{y}_i of the i -th data.

2) *Deep Q-network training*: Every CT image in the training set represents an environmental condition, while the system acts as the operative that performs a series of identifications across all CT pictures. When the operative determines the category tag of the CT picture, it is enacting a step: the picture observed at the t -th instance is the condition s_t , and the identification made is a_t . Consequently, the environment grants a benefit, r_t , to direct the operative. Reward figures are allocated in a manner where identifying an example from the dominant category earns a lesser absolute figure compared to the less common category. The reward function is:

$$r_t(s_t, a_t, y_t) = \begin{cases} +1, & a_t = y_t \text{ and } s_t \in D_S \\ -1, & a_t \neq y_t \text{ and } s_t \in D_S \\ \lambda, & a_t = y_t \text{ and } s_t \in D_H \\ -\lambda, & a_t \neq y_t \text{ and } s_t \in D_H \end{cases} \quad (2)$$

where D_S and D_H denote the less frequent and more prevalent classes, respectively. Properly or improperly categorizing an instance from the dominant class results in a reward of $+\lambda$ or $-\lambda$, with $0 < \lambda < 1$.

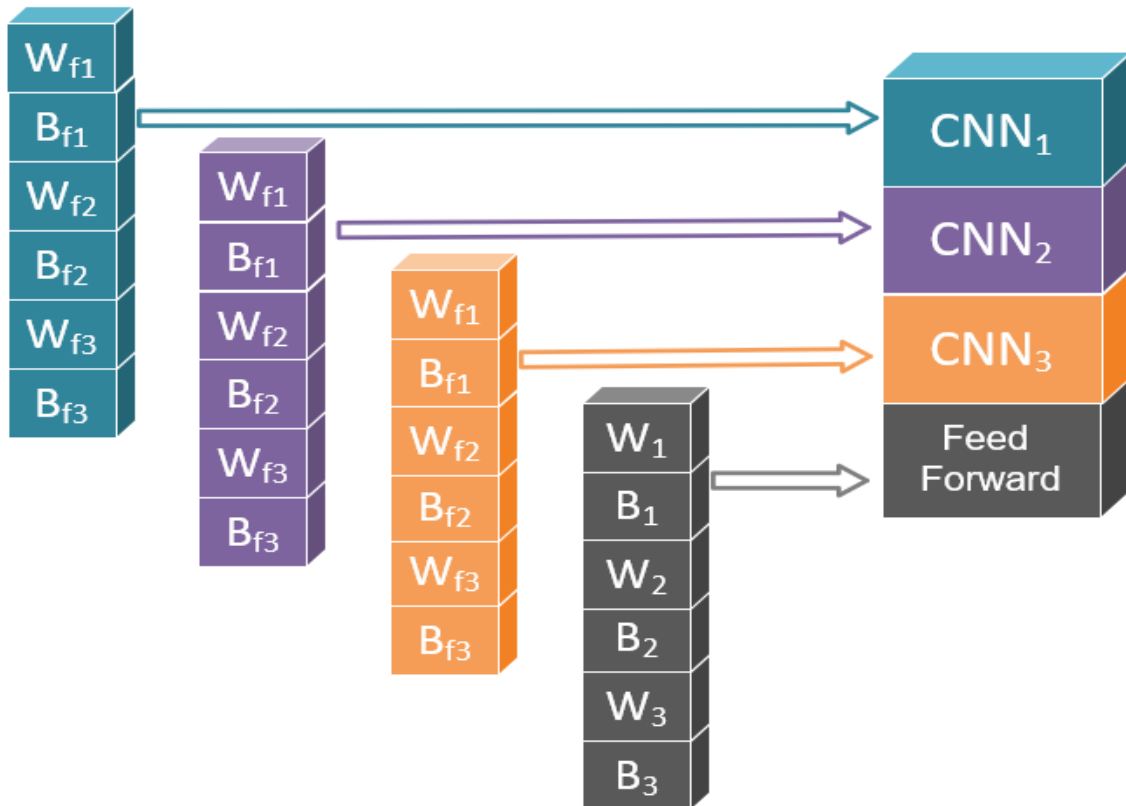

Fig. 2. The weights and biases of the neural network, starting from the initial convolutional layer up to the fully connected layers, are arranged and represented as individual elements in a large vector.

IV. EMPIRICAL EVALUATION

A. Dataset

The Lung Image Database Consortium picture archive (LIDC-IDRI) [42] was established by the Foundation for the National Institutes of Health (FNIH) in collaboration with the Food and Drug Administration (FDA). This collection features a chest CT scan paired with an XML file, which records the annotations made by four radiologists, across 1,018 CT scans from 1,010 listed patients. The marking process comprises two phases aiming to pinpoint every nodule in the CT scans with the utmost precision. During the initial phase, termed the blinded-read phase, each radiologist individually reviewed the scans and identified lesions, noting them as “nodule <3 mm” or “non-nodule ≥3 mm”. In the subsequent unblinded-read phase, each radiologist went over their annotations individually, while being conscious of the undisclosed annotations made by their peers. Within the collection, 7,371 lesions were identified as nodules by at least one radiologist. Out of these, 2,669 lesions were labeled as “nodule 3 mm” by at least one out of the four radiologists, with 928 being agreed upon by all. The 2,669 identified lesions were also provided with detailed nodule characteristics and defined outlines.

B. Experimental Results

Under prior experiments, k-fold cross-validation was employed throughout the study. In pursuit of this aim, the dataset is partitioned into k segments, assigning one for testing while employing the remaining for training. This process is reiterated k times, ensuring each datum is used once for testing and once for training. The resulting cross-validation statistical

outcomes encompass metrics such as minimum, median, maximum mean, and standard deviation. However, mean values are used for comparative analysis.

The proposed approach is compared with ten state-of-the-art systems, including 3D-CNNs [43], ESB-ALL [44], Ali et al. [45], MGI-CNN [46], ODN [47], Xie et al. [8], WOA_AP [48], MEMCAP [4], LungNet-DL [49], and MetaCNN-LC [50]. In addition, comparing the proposed model with three primary methods unveils the impact of the ABC and RL components on the model’s performance. The CNN + random weight method is a model that employs only the CNN network without the ABC algorithm and Reinforcement learning, while the CNN + ABC and CNN + RL models apply ABC and RL, respectively. The model performance on the LIDC dataset with the previously specified criteria is given in Table I and II. Achieving an Accuracy of 92.90%, a Recall of 92.00%, a Precision of 87.70%, an F-measure of 89.80%, a Specificity of 93.40%, and a G-means of 92.70%, the model shows notable distinctions from other deep models. LungNet-DL and MetaCNN-LC are the top two models after the algorithm, with 30% and 40% errors compared to LLC-QE + ABC, respectively. The proposed model reduces the error by over 60% compared with other deep algorithms. Comparing the LLC-QE + ABC model with the LLC + ABC and LLC + ABC models suggests that ABC and RL gimmicks have effectively reduced error by over 52% and 47%, respectively. The worst base model, LLC-QE + random weight, has been improved by approximately 67% by the proposed model.

The aim is to carry out an additional experiment to assess the influence of employing distinct algorithms for initializing the model parameters. To achieve this aim, in order to maintain a fair assessment, all components of the model will remain unchanged—encompassing reinforcement learning and the CNN structure—with alterations limited solely to the initialization

algorithm. Substitution of the algorithmic instructor will involve five established conventional algorithms, including GDM [51], GDA [52], GDMA [53], OSS [54], and BR [55], and four metaheuristic algorithms, including GWO [56], BA [57], COA [58] and WOA [59]. The ABC algorithm used in the model outperforms all other meta-heuristic algorithms (Table III and IV).

TABLE III. THE RESULTS OF ACCURACY, RECALL, AND PRECISION FOR THE CONVENTIONAL AND METAHEURISTIC ALGORITHMS

Method	Accuracy					Recall					Precision

1) *Impact of the reward function:* The rewards for accurate and erroneous categorizations are given to the predominant and less frequent classes as ± 1 and $\pm \lambda$, respectively. The λ value is influenced by the ratio of dominant to fewer common examples, and it is expected that as this ratio rises, the ideal λ value will drop. To explore the influence of λ , we evaluated the suggested model's effectiveness across various λ values, which spanned from 0 to 1, at 0.1 intervals, while keeping the rewards for the dominant class unaltered. These outcomes are depicted in Fig. 3. When λ is zero, the dominant class's influence is minimal, and at $\lambda = 1$, both classes have equivalent influences. Fig. 3 reveals that

the model's optimal performance is achieved when λ is 0.4, across all evaluated metrics. This suggests that the best λ value is neither zero nor one, but falls somewhere between these extremes. It is crucial to highlight that, while it is essential to reduce the dominant class's influence by tweaking λ , setting it excessively low might degrade the model's overall effectiveness. The findings indicate that selecting an appropriate λ value profoundly affects the LLC-QE model's efficiency. The best λ value is influenced by the respective quantities of dominant and less frequent examples, making it crucial to determine it prudently for optimal outcomes.

Fig. 3. LLC-QE model performance metrics plotted against the value of λ in the reward function.

2) *Impact of the number of CNNs*: The LLC-QE model uses a group of CNNs to derive feature vectors from input images simultaneously. The number of CNN feature extractors can significantly impact the model's overall performance. Using too few CNNs could cause insufficient feature extraction, while using too many CNNs could lead to overfitting or redundant information extraction, both of which may negatively impact the model's performance. The performance of the LLC-QE model was assessed by altering the count of CNN feature extractors across the range of one to seven. This variation is aimed at identifying the optimal number of extractors. The findings indicated optimal performance was achieved when three CNNs were used, as shown in Fig. 4. The model's performance decreased as the number of CNNs increased, with performing six and seven CNNs being worse than that of a single CNN. The optimal number of CNNs was determined based on performance metrics.

3) *Impact of the loss function*: Classification problems caused by imbalanced datasets can also address using conventional methods, such as altering the loss function and using data augmentation. However, their effectiveness depends highly on the specific problem being addressed.

Meanwhile, the loss function plays a more significant role, as it can give more prominence to the minority class. To study the inefficiency of the loss functions on the training ANN, the selection encompassed five functions, including Weighted Cross-Entropy (WCE) [60], Balanced Cross-Entropy (BCE) [61], Dice Loss (DL) [62], Tversky Loss (TL) [63], and Focal Loss (FL) [64]. WCE and BCE both assign weights to positive and negative samples. FL, suited for imbalanced data, outperforms the other loss function (Table V) but is still inferior to the RL used in the model.

4) *Impact of pre-trained models*: Comparing the performance of the CNN ensemble model with that of alternative pre-trained feature extraction models involved replacing the model with transfer learning counterparts, such as AlexNet [65], GoogleNet [66], ResNet [67], DenseNet [68], and MobileNet [69]. Limiting the training solely to the feedforward network, superior performance is exhibited by the model's ensemble of CNNs. This ensemble, trained from the ground up, surpasses the performance of pre-trained networks (AlexNet, GoogleNet, ResNet, DenseNet, and MobileNet), as demonstrated in Table VI. The reason behind this is that the ensemble of CNNs is more capable of extracting discriminative features specific to cancer diagnosis.

TABLE V. PERFORMANCE OF THE PROPOSED MODEL FOR DIFFERENT LOSS FUNCTIONS

Method	Accuracy	Sensitivity	Precision	F-measure	Specificity	G-mean
WCE	0.830	0.885	0.790	0.803	0.778	0.845
BCE	0.822	0.821	0.783	0.745	0.824	0.822

TL	0.825	0.834	0.78	0.747	0.816	0.827
FL	0.861	0.889	0.826	0.819	0.833	0.868

Fig. 4. The performance metrics plotted vs the number of convolutional feature extractors working in the ensemble.

TABLE VI. PERFORMANCE OF THE PROPOSED MODEL FOR DIFFERENT PRE-TRAINED MODELS

Method	Accuracy	Sensitivity	Precision	F-measure	Specificity	G-mean
AlexNet	0.773	0.836	0.719	0.724	0.715	0.790
GoogleNet	0.789	0.768	0.737	0.676	0.811	0.784
ResNet	0.764	0.794	0.709	0.683	0.736	0.772
DenseNet	0.753	0.759	0.696	0.651	0.748	0.755
MobileNet	0.784	0.806	0.731	0.703	0.762	0.789

V. CONCLUSION

This article proposes a novel deep-learning approach that uses RL and evolutionary computation to classify lung cancer in CT images. To avoid the model getting trapped in local optima, the network weights are first initialized using the evolutionary ABC algorithm. The network architecture comprises an ensemble of CNNs that extract features in parallel and then concatenate them for downstream classification. The model uses RL to address the dataset imbalance. The proposed LLC-QE model achieves excellent results compared to other deep learning models and pre-trained transfer learning models when trained on the LIDC-IDRI dataset. The optimal value for the reward function and the optimal number of CNN feature extractors in the ensemble are determined through experiments on the study dataset. Separate ablation studies, excluding ABC pre-training and RL, confirm the positive incremental impact of these components on model performance. Notably, the ABC algorithm and RL outperform various meta-heuristic initialization algorithms and loss functions.

Future work aims to develop deep learning segmentation methods that can detect not only the presence of cancer but also the location and extent of the disease on CT images, which may be useful for prognostication and therapeutic monitoring. One area of research that holds particular promise is the use of multi-modal imaging data, which can provide a more comprehensive view of the tumor and its surroundings. For example, combining CT with MRI data could allow for more accurate identification of the tumor boundary and help differentiate between different cancers.

FUNDING

Abstract—Smart homes are smart spaces that contain devices that are connected to each other, collecting information and facilitating users' comfortable living, safety, and energy management features. To improve the quality of individuals' life, smart device companies and service providers are collecting data about user activities, user needs, power consumption, etc.; these data need to be shared with companies with privacy-preserving practices. In this paper, an effective approach of securing data transmission to the service provider is based on local differential privacy (LDP), which enables residents of smart homes to provide statistics on their power usage as disturbances bloom filters. Randomized Aggregatable Privacy-Preserving Ordinal (RAPPOR) is a privacy technique that allows sharing of data and statistics while preserving the privacy of individual users. The proposed approach applies two randomized responses: permanent random response (PRR) and instantaneous random response (IRR), then applies machine learning algorithms for decoding the perturbation bloom filters on the service provider side. The simulation results show that the proposed approach achieves good performance in terms of privacy-preserving, accuracy, recall, and f-measure metrics. The results indicate that, the proposed LDP for smart homes achieved good utility privacy when the value of LDP $\epsilon = 0.95$. The classification accuracy is between 95.4% and 98% for the utilized classification techniques.

Keywords—Smart homes; security; privacy-preserving; differential privacy; RAPPOR; randomized responses

I. INTRODUCTION

As more people seek to automate their homes and improve their quality of life, the popularity of smart homes increases. A smart home is a residence that contains remote-controllable devices, such as smart thermostats, security systems, lighting, and entertainment systems. These devices are internet-connected, allowing homeowners to control them remotely using smartphones or other internet-connected devices [1]. Convenience is the main advantage of a smart home it enables users to control the temperature, lighting, and security of your smart home from anywhere in the world. The ability to turn off lights, adjust the temperature, and view security cameras from your smartphone makes it simple to keep your home comfortable and secure. Smart homes can also reduce your energy costs, smart thermostats can automatically adjust your home's temperature based on your preferences and your presence, saving you money on heating and cooling expenses. Similarly, intelligent lighting systems can turn off lights automatically when no one is in a room, thereby reducing energy consumption [2].

A smart home also provides better protection; with intelligent security systems, you can monitor your house from anywhere and receive warnings if suspicious behavior is detected [3]. You can also lock and unlock doors remotely, allowing you to let guests or service personnel in without being present. Smart homes can also improve your entertainment experience. You can control your television, music, and other entertainment systems from anywhere in your smart home. Even your smart home can be integrated with your voice assistant, making it simple to control your entertainment with voice commands.

Data gathered from smart homes can be used in a variety of ways to improve services across a range of industries. These services such as smart home activity prediction [4], smart healthcare for patient treatment [5], disorder assessment, and smart city pedestrian monitoring [6], energy management. In this context, businesses have discovered the potential of using the data gathered from smart homes to improve their products and services.

However, data collectors must consider the confidentiality of these data. If data is not correctly managed, it could cause significant issues. So, to address these concerns, a new system that maintains both privacy and utility has been proposed. Remote health systems necessitate the collection, disclosure, and utilization of personal health information, which raises grave privacy concerns. For many individuals, the household is their most private environment. A glucometer measuring the blood sugar level, a spirometer tracking the air entering and exiting the lungs, and a sleep monitoring sensor recording the sleep conditions can potentially reveal whether a resident has diabetes, seasonal allergy-induced asthma, or a depressive disorder. Patients are inclined to restrict access to these data to a small group, such as their personal physicians, out of concern for their privacy.

Differential Privacy [7] is a privacy preservation mechanism that has gained popularity. The main idea behind differential privacy is that a user is given plausible deniability by adding random values to their input. This approach provides strong privacy guarantees for users, protecting their data against adversary entities, such as service providers and outsiders. In the centralized differential privacy setting, noise is added to the database and apply a differential privacy aggregation algorithm. RAPPOR [8] is a privacy preservation technology that allows for the sharing of statistics while preserving the privacy of individual users. By using randomized response, RAPPOR ensures that no individual's data is

disclosed to the data collector. This approach has shown great promise, as it allows for the sharing of valuable data while protecting users' privacy.

This paper aims to present an approach for securely transmitting household data to the aggregator, while accounting for the presence of malicious aggregator nodes. To address this concern, we apply LDP to the real-time data collected from residences. Prior to transmission, the data is subjected to a process of privacy preservation. The proposed model utilizes the RAPPOR algorithm to encrypt the data, thereby ensuring that the aggregator cannot ascertain the identity of the householder, thereby preserving anonymity. To achieve the goal of secure data transmission, we propose a three-step approach. Firstly, bloom Filter mechanism is applied to the raw data collected from the residences. Next, the data is privatized using the RAPPOR algorithm to ensure that the identity of the householder remains unknown. Finally, the aggregator employs machine learning algorithms to decode the data into a form that is acceptable and useful.

The proposed model has several advantages over existing approaches. By employing RAPPOR, we are able to ensure that the data is secure and anonymous, thereby preventing malicious aggregator nodes from accessing sensitive information. Moreover, the use of machine learning algorithms by the aggregator allows for efficient decoding of the data, making it more accessible and user-friendly. The remainder of this paper is organized as follows. Section II surveys existing privacy preservation techniques used in smart homes and highlighting their deficiencies. Section III gives the useful background about Local Differential Privacy and RAPPOR. Then our approach is described in Sections IV and introduces the system model. In section V, the performance of the scheme is analyzed from two aspects of security and efficiency.

II. RELATED WORK

In recent years, LDP has emerged as a promising technique for privacy-preserving data analysis in various domains. This section provides an overview of some well-known LDP use cases and privacy-preserving systems that have used LDP. In [8] Google proposed RAPPOR as an LDP-based system for collecting aggregate statistics from users without compromising their individual privacy. It randomizes user responses to a question with a bloom filter and randomized response, allowing the server to compute meaningful statistics about the aggregate responses while ensuring individual privacy. The authors in [9] proposed an approach called a differential privacy-based system to guarantee thorough security for data produced by smart houses. At the aggregator level, they used the Hidden Markov Model (HMM) technique and applied differential privacy to the personal information obtained from smart homes.

In healthcare field the authors in [10] proposed an improved approach based on k-anonymity and differential privacy to enhance privacy protection by mitigating re-identification risks through generalization and suppression techniques. This study [11] concentrates primarily on identifying the security issues that can arise from the use of a large number of Internet of Things (IoT) devices connected to provide a smart home facility in Saudi Arabia. [12] proposed an approach called

LATENT, suggests an intermediate layer in deep learning models that satisfies LDP. LATENT allows a data owner to perturb the data on their device before it reaches an untrusted machine learning service, thereby protecting the privacy of the owner's data. By adding noise to the data in a controlled manner, LATENT ensures that the machine learning model can still provide useful insights while preserving the privacy of the individual data points. In Microsoft, LDP is used to collect data about the time users spend in different applications, which enables the identification of their favorite ones and improves their user experience [13]. This approach still preserves user privacy while providing valuable insights for application developers. LDP has also been used to reduce potential privacy leakage in deep learning models.

Differential privacy is a privacy-preserving technique that has been extensively researched for various applications in computer science. One of the most popular applications is in recommendation systems, where differential privacy is used to protect the privacy of user preferences and behavior while still allowing the system to make accurate recommendations [14], [15]. Data mining is another field that benefits from differential privacy, as it allows for the analysis of sensitive data without revealing individual records [16]. Differential privacy is also used in crowd-sourcing [17]. In network measurements, differential privacy is used to ensure that the privacy of individuals' network traffic data is protected while still allowing for useful aggregate network measurements to be obtained [18]. In intelligent transportation systems, differential privacy is used to protect the privacy of users and their data [19].

These approaches have a few disadvantages or limitations compared to our approach, they use a trusted third party to collect data from users, apply some algorithms, and take some privacy-preserving data analysis by adding "noise". This leads to a reduction in the accuracy of data analysis and inference. The noise introduced to protect privacy may make it challenging to obtain precise information or draw accurate conclusions from the collected data. Our solution uses differential privacy at the data source, thereby providing greater privacy. In addition to the use of LDP, researchers have also put forth schemes that employ data masking techniques [20–24]. These approaches involve masking the data submitted by users with a specific masking value, ensuring that other entities cannot access the actual value unless they possess knowledge of the masking value. By incorporating data masking alongside LDP, these schemes offer an extra layer of privacy protection and enhance the security of sensitive information in the context of data sharing and analysis. In each of these applications, differential privacy should provide a way to perform valuable computations on sensitive data while ensuring that the privacy of individual users is protected. By adding controlled noise to the data, differential privacy makes it difficult for attackers to identify any specific individual in the dataset, while still allowing for meaningful analysis and insights to be drawn from the data.

III. PRELIMINARIES

This section provides background information on LDP and the randomized response approach. It also discusses RAPPOR, which is a method for implementing the randomized response

strategy. In addition to this, it investigates the machine learning methods that have been implemented, such as K-nearest neighbours (KNN), Support vector machines (SVMs) and XGBoost. In the final part of this discussion, we will examine the performance and assessment measures that are utilized in this paper to evaluate the performance of the proposed scheme.

A. Local Differential Privacy (LDP)

LDP is a privacy-preserving technique that aims to protect the privacy of individual data contributors while enabling statistical analysis and inference on the aggregated data. Unlike other privacy-preserving methods that rely on centralizing and anonymizing data, LDP allows data contributors to locally perturb their data before sharing it.

Definition: A randomized algorithm T satisfies the ϵ -local differential privacy where $\epsilon > 0$ if for all pairs of the client's values a and b and for all $S \subseteq \text{range}(T)$:

$$Pr[T(a) \in S] \leq e^\epsilon Pr[T(b) \in S]. \quad (1)$$

The definition introduces ϵ , called the privacy budget. It quantifies the level of privacy protection provided. By satisfying ϵ -Differential Privacy, a mechanism provides a strong privacy guarantee, indicating that an adversary cannot significantly differentiate between the presence or absence of an individual's data based on the mechanism's output, thereby safeguarding individual privacy during data analysis or release.

B. Randomized Response

The Randomized Response (RR) method, introduced by H. Warner et al. in 1965 [7]. With RR, when an end user is asked a binary question (e.g., "yes" or "no"), a coin is flipped with a probability of p for heads. To maintain the user's privacy, RR allows the user to provide the opposite response when heads are shown. Consequently, the data aggregator is unable to confidently ascertain the true response for a specific user, ensuring their privacy is preserved.

Definition: The RR mechanism is a mapping with $X = Y$ that satisfies the following equality:

$$Q(x|y) \begin{cases} \frac{e^\epsilon}{|Y|-1+e^\epsilon}, & \text{if } x = y \\ \frac{1}{|Y|-1+e^\epsilon}, & \text{if } x \neq y \end{cases} \quad (2)$$

Here, $Q(x|y)$ is the conditional probability, Y is the true dataset, X is the privatized dataset, $y \in Y, x \in X$, $|Y|$ is the size of set Y , and ϵ is the privacy parameter.

C. RAPPOR

Privacy-Preserving Aggregatable Randomized Response is a real world application of LDP has been made by Google for collecting statistics from the end user, and client side software, in a way that provides robust privacy protection using randomize response techniques [8]. RAPPOR's applies randomized response to bloom filters [25] with strong ϵ -differential privacy guarantees. Bloom filter is a simple space-efficient randomized data structure for representing a set in order to support membership queries.

The RAPPOR algorithm takes in the client's true value v and parameters of execution k, h, f, p, q and is executed locally on the client's machine performing the following steps:

- 1) Signal: Hash client's value v onto the bloom filter B of size k using h hash functions.
- 2) Permanent randomized response: For each client's value v and bit $i, 0 \leq i < k$ in B , create a binary reporting value B_i^v which equals to

$$B_i^v = \begin{cases} 1, & \text{with probability } \frac{1}{2}f \\ 0, & \text{with probability } \frac{1}{2}f \\ B_i, & \text{with probability } 1 - f \end{cases} \quad (3)$$

where f is a user-tunable parameter controlling the level of longitudinal privacy guarantee. Subsequently, this B_i^v is memoized and reused as the basis for all future reports on this distinct value v .

- 3) Instantaneous randomized response: Allocate a bit array S of size k and initialize to 0. Set each bit i in S with probabilities

$$P(S_i = 1) = \begin{cases} q, & \text{if } B_i^v = 1. \\ p, & \text{if } B_i^v = 0. \end{cases} \quad (4)$$

D. Machine Learning Techniques

The K-nearest neighbors (KNN) classifier is one of the most basic yet essential classification algorithms in Machine Learning. It belongs to the supervised learning domain and finds intense application in pattern recognition, data mining, and intrusion detection [26]. KNN algorithm helps us identify the nearest points or the groups for a query point. But to determine the closest groups or the nearest points for a query point we need some metric. For this purpose, we use below distance metrics:

$$d(x, y) = \left(\sum_{i=1}^n (x_i - y_i)^p \right)^{\frac{1}{p}} \quad (5)$$

Support vector machines: the support vector machines, is a powerful supervised learning algorithm used for classification tasks. It works by finding an optimal hyperplane in a high-dimensional feature space that separates different classes of data points. The hyperplane is chosen in such a way that it maximizes the margin, which is the distance between the hyperplane and the closest data points of each class [27]. This helps to achieve better generalization and robustness of the model.

Hyperplane Equation: The SVMs algorithm seeks to find a hyperplane in the feature space that separates the data points. The hyperplane equation can be written as:

$$w \cdot x + b = 0 \quad (6)$$

where:

w is a weight vector orthogonal to the hyperplane. x is the feature vector of a given data point. b is the offset or distance of the hyperplane from the origin along the normal vector w .

Classification:

$$f(x) = \text{sign}(w \cdot x + b) \quad (7)$$

where

$\text{sign}(\cdot)$ is the sign function that returns -1 or 1 depending on the sign of its argument. If $f(x) < 0$, the point is classified as one class, and if $f(x) > 0$, it is classified as the other class.

XGBoost is an implementation of gradient boosted decision trees. XGBoost models majorly dominate in many Kaggle Competitions. In this algorithm, decision trees are created in sequential form. Weights play an important role in XGBoost [28]. XGBoost objective function:

$$\text{Obj}^{(t)} = \sum_{i=1}^n L(y_i, \hat{y}_i^{(t-1)}) + \sum_{j=1}^T \Omega(f_j) \quad (8)$$

where

$\text{Obj}^{(t)}$ is the objective function at the t th iteration. n is the total number of training examples. y_i is the true label of the i th training example. $\hat{y}_i^{(t-1)}$ is the predicted value of the i th example at the $t-1$ th iteration. T is the total number of trees in the ensemble. f_j is the j th tree in the ensemble. $\Omega(f_j)$ is the regularization term that penalizes the complexity of the tree.

E. Performance Evaluation Measurements

In this paper, the classifiers performance has been analyzed by using Precision, Recall and F-measure, which are obtained from the confusion matrix as shown in Table I. These metrics are described as follows.

TABLE I. CONFUSION MATRIX

	P*(Predicted)	N*(Predicted)
P (Actual)	TP	FN
N (Actual)	FP	TN

- Precision: measures the relevant actions found against all actions found i.e. the percentage of selected actions that are correct and is defined by the following equation.

$$\text{Precision} = \frac{TP}{(TP + FP)} \quad (9)$$

- Recall: measures the relevant actions found against all relevant actions i.e. the percentage of correct actions that are selected and is defined by the following equation.

$$\text{Recall} = \frac{TP}{(TP + FN)} \quad (10)$$

- F-measure: is weighted harmonic mean between precision and recall and is defined by the following equation.

$$F\text{-measure} = \frac{2 * \text{Precision} * \text{Recall}}{(\text{Precision} + \text{Recall})} \quad (11)$$

Fig. 1. Encoding algorithm maps C_i devices into bits in a bloom filter.

IV. THE PROPOSED PRIVACY-PRESERVING MODEL IN SMART HOMES

This section introduces and describe the proposed model and methodology. It outlines the key concepts and principles that underpin our approach, as well as explain the data collection process, preprocessing techniques used, and any specific algorithms or techniques used within the model.

A. Assumptions

Assume that there is a smart home which contains a set of devices and each device has its own sensor to measure power consumption, and there is a set of classes $C_i, i \in \{1, \dots, l\}$ where l denotes the maximum number of supported classes, these classes represent the priority of each device, each class is composed of groups of devices D_{ij} (i.e. $j \in \{1 \dots g\}$) where g represents the maximum number of groups of interests for class i , devices like (lights, TVs, laptops, sound system, alert systems, air condition systems, laundry devices, camera systems, garden lights, garage lights/motors, fans). RAPPOR is used to send power consumption statistics to service providers/electricity products companies.

B. System Model and Overview

Based on the basic idea of bloom filter and RAPPOR, the proposed approach consists of two phases: data perturbation phase and decoding phase. These two phases are described as follows:

1) *Smart home data perturbation*: In this phase, the proposed approach determines the set of devices and each device has its own sensor to measure power consumption, and there is a set of classes $C_i, i \in \{1, \dots, l\}$ where l denotes the maximum number of supported classes, classes represent the priority of each device, each class is composed of groups of devices D_{ij} (i.e. $j \in \{1 \dots g\}$) where g represents the maximum number of devices of interests for class i . The proposed approach uses the following steps.

- 1) *Encoding* is the first step of the data perturbation process, the encoding algorithm maps C_i devices into bits in a bloom filter. Fig. 1 illustrates the bloom filter implementation using 2 hash functions, h_1 and h_2 , on the TV class.

Empty Bloom filter of size $m=10$

Fig. 2. Bloom filter B is initialized with all “0” values and size $m = 10$.

To compute the optimal bloom filter size m , given the maximum number of devices encoded into the bloom filter (*i.e.* $n = l * g$ if each class includes the same number of groups), and a fixed false positive rate f_p , according to Eq. 12:

$$m = -\frac{n \times \ln(f_p)}{(\ln 2)^2} \quad (12)$$

Then, the optimal number of hash functions is computed as given by Eq. 13

$$k = \frac{m}{n} \times \ln 2 \quad (13)$$

After selection of m and k appropriate values, the bloom filter B is initialized with all “0” values, as given in Fig. 2. For feeding B with the set of devices values v, C first applies the k hash functions to v , and feeds B with the hash output providing indices. Example: let us consider a bloom filter of size $m = 10$ bits, with $k = 2$ hash functions (h_1, h_2), and two devices {TV, Reception lights} to be included into the bloom filter. As given in Fig. 1, C first computes the two hashes of the TV device, and gets the results $h_1(TV) = 4$ and $h_2(TV) = 7$, thus leading to positioning the 4th and the 7th bits of the bloom filter to value 1. The same applies for the reception lights as depicted in Fig. 2 where h_1 (Reception lights) = 2 and h_2 (Reception lights) = 8.

- 2) *Permanent randomized response (PRR)*: This first level perturbation applies over the bloom filter B obtained through the encoding phase. This step is executed once over a set of devices v . A noisy bit is derived from each bit of B thus resulting in a perturbed bloom filter vector B' . The derivation is compliant with the RAPPOR works and considers the following probabilistic processing:

$$B'[i] = \begin{cases} 1 & \text{with probability } \frac{1}{2}f \\ 0 & \text{with probability } \frac{1}{2}f \\ B[i] & \text{with probability } 1 - f \end{cases} \quad (14)$$

- 3) *Instantaneous randomized response (IRR)*: To guarantee stronger privacy, this second level perturbation is executed for each request done by P Providers. After getting B' , the user initializes a bit vector S with all zeros and then applies the following probabilistic processing Eq. 15:

$$P(S[i] = 1) \begin{cases} q & \text{if } B'[i] = 1 \\ p & \text{if } B'[i] = 0 \end{cases} \quad (15)$$

Where p denotes the probability of flipping a bit that equals to 0 into 1 whereas q represents the probability

of keeping bits equal to 1. This second level perturbation IRR algorithm is ϵ -differential privacy with the following quantified ϵ_2 privacy budget Eq. 16:

$$\epsilon_2 = k \ln \left(\frac{q'(1-p')}{p'(1-q')} \right) \quad (16)$$

Where p' , resp. q' is the probability of observing 1 given that the same bloom filter bit was set to 0, resp. 1, as defined in the following Eq. 17 and 18.

$$p' = \frac{1}{2}fq + (1 - \frac{1}{2}f)p \quad (17)$$

$$q' = (1 - \frac{1}{2}f)(1 - q) + \frac{1}{2}f(1 - p) \quad (18)$$

- 4) Algorithm 1, shows the steps of this recognition phase:

Parameters:

- hash functions k : This is the number of hash functions used in the bloom filter. The specific value is determined by Eq. 13.
- bloom filter size m : This is the size of the bloom filter, which is determined by Eq. 12.
- privacy budget ϵ : This is a parameter related to the privacy level. Its specific value is determined by the user or the privacy configuration.

Input:

- x : This is a single row of data from a smart home, representing a specific event or measurement.
- f : This represents the privacy level configured by the homeowner. Its specific value is not mentioned in the code.

Output:

- Perturbed bloom filter vector S : This is the resulting vector after applying perturbations to the bloom filter, calculated using Eq. 15.

Steps:

- Set $x \in \mathcal{U}$ this indicates that the smart home data, represented by x , belongs to the set \mathcal{U} , which includes all available data in the smart home.
- Convert x to bloom filter vector B of size m : This step involves converting the smart home data, x , into a bloom filter vector B , of a specified size m .
- Apply permanent randomized response on B and get vector B' of size m .
- Apply instantaneous randomized response on B' and return vector S of size m .

C. Decoding Phase

In this phase, three machine learning algorithms KNN, SVMs and XGBoost were selected for their ability to work on perturbed data. Those algorithms are calibrated to fit the specification the following datasets, thus resulting into 3 configurations as detailed below:

Algorithm 1: Data perturbation

Parameter: hash functions k given by Eq. 13, bloom filter size m given by Eq. 12, privacy budget ϵ

Input: Row of smart home data x , f is the privacy level configured by home owner.

Output: Perturbed bloom filter vector S given by Eq. 15

Data: set $x \in \mathcal{U}$: \mathcal{U} is the set of all available data in smart home

```

/* Encoding */
1 Convert  $x$  to bloom filter vector  $B$  of size  $m$ 
/* PRR function */
2 Initialize an empty vector  $B'$  of size  $m$  and set all bits = 0
3 for  $i = 0$  to  $BloomFilterSize$  do
4    $B'[i] = 1$  with probability  $\frac{1}{2}f$ 
5    $B'[i] = 0$  with probability  $\frac{1}{2}f$ 
6    $B'[i] = B[i]$  with probability  $1 - f$ 
/* IRR function */
7 Initialize an empty vector  $S$  of size  $m$  and set all bits = 0
8 for  $j = 1$  to  $NumberOfhashfunctions$  do
9   for  $i = 1$  to  $BloomFilterSize$  do
10    if  $B'[i] = 1$  then
11      $S[i] = 1$  with probability  $\frac{e^{-\frac{\epsilon}{2k}}}{e^{-\frac{\epsilon}{2k}} + 1}$ 
12    else
13      $S[i] = 1$  with probability  $\frac{1}{e^{-\frac{\epsilon}{2k}} + 1}$ 
14 Return vector  $S$ ;
```

- 1) The K-nearest neighbors (KNN) classifier: is a versatile algorithm that classifies data based on the majority class of its K nearest neighbors in a training set, making it suitable for both classification and regression tasks.
- 2) Support vector machines: The Support vector machines works by finding an optimal hyperplane in a high-dimensional feature space that separates different classes of data points. The hyperplane is chosen in such a way that it maximizes the margin, which is the distance between the hyperplane and the closest data points of each class. This helps to achieve better generalization and robustness of the model.
- 3) XGBoost configuration: XGBoost is a gradient boosting algorithm. Table III gives the parameters calibrated for each dataset to optimize the model's performances. As can be shown, the configuration is slightly the same, except for parameter Subsample.

V. EXPERIMENTAL AND ANALYSIS

To evaluate the proposed approach, a real dataset The MHEALTH [29] is used. It is a data file consisting of approximately 1 million records. The data primarily consists of numerical values. Specifically, it is referred to as the "Mobile HEALTH" dataset, which captures body motion and vital signs recordings. The dataset encompasses measurements from ten

volunteers with diverse profiles while engaging in various physical activities. Also colab notebook is used. Colab [30] is a research initiative for prototyping machine learning models on powerful hardware such as GPUs and TPU. Tables II and III provide the SVMs and XGBoost parameters, as well as the KNN with $K = 3$. These machine learning algorithms are used in the proposed method to test shred data in smart home environments.

TABLE II. SVMs CONFIGURATION

Parameter	Value
SVM Type	rbf
C	1000
Gamma	0.4

TABLE III. XGBOOST CONFIGURATION

Parameter	Value
N estimators	55
Max depth	6
Min child weight	7
num rounds	10
Gamma	0.4

A. Classification Evaluation

This subsection analyses the influence of different parameters on the classification results, including the privacy budget value ϵ , the bloom filter size M and the number of hash functions k . Knowing that the accuracy for the dataset without applying LDP were KNN: 97.8%, SVMs: 98.5% and XGBoost: 98%.

Fig. 3. Bloom filter size for $\epsilon = 0.95$ and $k = 5$.

Fig. 3 demonstrate the relationship between the accuracy of various classification methods and the size of the bloom filter. The bloom filter size ranges from 8 to 256, and it achieves accuracy within the following ranges: KNN (95.4%-95.7%), SVMs (96.8%-97.15%) and XGBoost (96.6%-97.0%). When

comparing these results with the accuracy obtained without applying LDP using the same machine learning algorithms (97.8%, 98.5%, and 98% respectively), there is an error margin of approximately 2%. However, this level of error does not significantly impact the overall accuracy.

Fig. 4. Number of hash functions for $\epsilon = 0.95$ and $M = 128$].

Fig. 4 shows the relationship between the accuracy of various classification methods and the number of hash functions. The number of hash functions ranges from 3 to 19, and it achieves accuracy within the following ranges: KNN (95.2%-95.8%), SVMs (96.65%-97.13%) and XGBoost (96.55%-96.9%). Also, the error margin is approximately (1%-2%) between the proposed LDP approach and without applying LDP using the same machine learning algorithms

Our experiment considers a minimum value of hash functions of 5, which corresponds to the optimal number of hash functions for $M = 128$, according to the Eq. 13. As depicted in the Fig. 4, the classification accuracy decreases when the number of hash function increases. This stems from an increasing number of hash collisions.

Fig. 5. Privacy budget for $M = 128$ and $K = 5$].

The relation between the accuracy of different classification algorithms and the Privacy budget is depicted in Fig. 5. The privacy budget varies from 0.1 to 1, and it achieves accuracy within the following ranges: KNN (67.2%-97.4%), SVMs

(81.65%-99.13%) and XGBoost (46.42%-97.3%). When comparing these results with the accuracy obtained without applying LDP using the same machine learning algorithms (97.8%, 98.5%, and 98% respectively).

As expected in Fig. 5, the classification accuracy is an increasing function of the privacy budget. Indeed, the higher the privacy budget, the lower the perturbation level, and the higher the accuracy. The preference dataset achieves better classification results.

B. Decoding Algorithms Evaluation

Table IV shows the accuracy of various classification methods on perturbed dataset using bloom filter size $M = 128$, privacy budget $\epsilon = 0.95$ and number of hash functions $k = 5$. Table V shows the accuracy of the same classification methods on the main dataset. As shown in both tables, an analysis of accuracy comparisons for main and perturbed data utilizing KNN, SVMs and XGBoost algorithms. This study evaluates the accuracy performance of KNN, SVMs and XGBoost algorithms when applied to a dataset consisting of 24,000 records and encompassing 12 distinct activities. The comparison focuses on the accuracy of predictions made using both the original dataset and a perturbed version.

Table VI illustrates the error margin between the accuracy of various classification methods on perturbed data and main dataset. The findings of this analysis indicate that the application of LDP techniques on the dataset did not introduce any significant impact on the decision-making process. The accuracy levels observed for the main dataset and the perturbed data remained consistent across the evaluated algorithms, namely KNN, SVMs, and XGBoost.

C. Security Analysis

In this part, we undertake security analysis using the fundamental adversary model. This model assumes that the attacker has access to the altered data disclosed by different individuals through the Local Differential Privacy (LDP) method. The primary objective is to ensure that despite the adversary's access to the perturbed data and some knowledge of the noise introduced during the LDP procedure, inferring sensitive information about any individual remains computationally infeasible or statistically improbable. The success rate of basic adversary can directly be obtained from the probability of Eq. 19 [31]

$$Pr(B'[i] = 1) \begin{cases} \frac{e^{\frac{\epsilon}{2k}}}{e^{\frac{\epsilon}{2k}} + 1} & \text{if } B[i] = 1 \\ \frac{1}{e^{\frac{\epsilon}{2k}} + 1} & \text{if } B[i] = 0 \end{cases} \quad (19)$$

Fig. 6 illustrates the relation between the success rate of basic adversary and ϵ and k values. The privacy budget ranges from 0.1 to 4, and the number of hash functions are ($k = 2, k = 7, k = 12$). This figure indicates that as the privacy budget increases, the probability that the adversary will win in the game also increases. However, as the number of hash functions increases, more wrong guesses occur. As expected, the probability of winning the game decreases when ϵ and k increase.

VI. CONCLUSION

In this study, we investigated the problem of sharing data in a smart home environment while preserving user privacy. The main contribution of this research is the development of an efficient method for secure data sharing in smart homes using local differential privacy and the Randomized Aggregatable Privacy-Preserving Ordinal technology. Individual users' privacy is protected while data sharing with service providers is facilitated by the proposed method. The simulation results demonstrate that the technique performs well in terms of privacy preservation, accuracy, recall, and f-measure metrics, achieving utility privacy with high classification accuracy of 95.4% to 98% when the privacy budget is set to 0.95. This research helps to improving data privacy and utility in the context of smart homes, as well as providing a valuable direction for privacy-preserving practices in the IoT domain. In future research, we aim to extend the research to consider privacy-preserving techniques for multi-modal data, such as combining data from various sensors and devices within a smart home environment.

Abstract—In order to study the technology of image conception, splitting, stitching and positioning in film and television production, this paper first discusses the relevant research literature, then designs an improved biomedical image segmentation convolution network model applied in film and television production, and then verifies the effectiveness of the proposed model. Ultimately, the paper summarizes the research findings. Aiming at the problem that the traditional image mosaic positioning model has poor robustness because of its insufficient ability to extract features and inaccurate segmentation and positioning areas, this study proposes a biomedical image segmentation convolutional network model that is based on dense block and void space convolutional pooling pyramidal module. Additionally, an attention mechanism is introduced to enhance the biomedical image segmentation convolutional network model. The results show that the accuracy, recall, and F1 value of the biomedical image segmentation convolutional network model are 96.48%, 95.24%, and 95.96%, respectively, on the Colombian uncompressed image stitching detection dataset, and the accuracy, recall, and F1 value of the improved biomedical image segmentation convolutional network model are 98.19%, 96.23%, and F1 value of 97.21%. In summary, the improved convolution network model for biomedical image segmentation has excellent performance, and it has certain application value in image conception, mirror splicing and positioning in film and television production.

Keywords—Convolutional neural network; attention mechanism; null space convolutional pooling pyramid; spatial rich model; dense block

I. INTRODUCTION

The field of cinema and television production has encountered novel challenges and made significant strides as a result of the ongoing advancements in science and technology [1-2]. As an essential pre-production step in film and television, the split screen is an intermediate medium for converting text into a three-dimensional audio-visual image and presenting it in a pictorial form [3-4]. Due to the increased functionality and user-friendliness of image editing software, producers can easily select areas of interest from other images to be cut and spliced into the split-screen image, which brings great convenience for creating the split-screen image, but also easily brings trouble to the film and television copyright [5]. To enhance split-screen imagery creativity in film and

television production and reduce the risk of copyright, it's crucial to prioritize research on image stitching and positioning technologies [6]. Image stitching is a semantic segmentation of features by dividing the stitching area into one category and the real area into another category. The CNBIS model is capable of extracting the stitched region from the real region. The traditional CNBIS model can achieve good results only when it is faced with simple semantic information of the same kind of content. However, in image mosaic and positioning, the mosaic area often comes from different semantic interference information, resulting in inadequate feature extraction and inaccurate segmentation and positioning area, which reduces the segmentation accuracy of the model [7]. The research aims to improve image semantic segmentation accuracy and make up for the deficiency of model extraction features caused by different semantic interference information. To overcome these issues, the study implements Dense Block (DB) and Atrous Spatial Pyramid Pooling (ASPP) modules to improve the CNBIS model and introduce the DACNBIS model. The research also incorporates the Attention Mechanism (AM) to enhance the DACNBIS model and create the AM-DACNBIS model, which increases the segmentation accuracy of the DACNBIS model. The primary contribution of the research is to broaden the application of image mosaic positioning technology in film and television production. The goal is to increase the diversity of split-mirror images, improve the reduction and richness of split-mirror in films, and make the storyline and the overall picture of film and television works more complete. The research focuses on two significant innovations. The first point is to improve the traditional CNBIS model by introducing DB module and ASPP module, and improve the DACNBIS model by combining attention mechanism. The second point is that AM-DACNBIS model is divided into three parts: parameter sharing, area monitoring and edge detection, and specific feature layers are used for each part to extract the corresponding task information. The study is primarily divided into four parts. The first part reviews relevant pertinent research findings. The second part constructs the construction of DACNBIS model and AM-DACNBIS model. The third part validates the two proposed models' validity in the study. The final part concludes the research.

II. RELATED WORK

Many image processing jobs start with the pre-processing stage of picture semantic segmentation, and many academics have written extensively about ways to increase segmentation accuracy in this process, Gao and co. To help the network better concentrate on object borders and small objects during the feature extraction process, a sensitive feature selection module was created to reweight each pixel on several channels. The findings of the experiments demonstrate that the sensitive feature selection module can aid in the semantic segmentation algorithm's high segmentation accuracy [8]. To reduce semantic information loss and improve image information, Zhou et al. proposed a semantic segmentation model based on dense convolutional separation convolution. This model also integrates multi-scale feature information for a broader perceptual field and captures more dense pixels. Simulation experiments demonstrate the superior performance and good performance of this model for image segmentation [9]. Zhang et al. proposed a system that utilizes the original semantic segmentation network to deal with the issue of missing static object segmentation occluded by dynamic scenes and combines it with image restoration [10]. Maurya et al. created a cross-form attention pyramid to extract multi-scale information using a pre-trained model in order to address the issues of feature redundancy and low discrimination in image semantic segmentation. An attention module in a spatial manner is then introduced to further improve the segmentation effect. With the addition of the attention pyramid and attention module, simulation results demonstrate that the semantic segmentation model has greater segmentation accuracy [11]. In order to tackle the problem of loss of image information caused by feature extraction in the process of image semantic segmentation, Chen constructs a semantic segmentation model with encoder-decoder as the basic structure. The research results verify the logic and effectiveness of the model [12].

CNBIS model is a very famous segmentation network model in the field of image segmentation, which has been widely used in various fields. In order to accurately divide non-enhanced tumor, enhanced tumor, tumor core and undamaged region in brain images, Teki et al. used CNBIS model to realize semantic segmentation of brain tumor images. The research findings demonstrate that the CNBIS model performs well in segmenting simple semantic information. However, in the presence of complex semantic interference information, the model exhibits insufficient feature extraction capability and low segmentation accuracy [13]. Singh et al. designed an improved Deep-CNBIS model for semantic segmentation of images using satellite images to extract vegetation cover. The simulation experiments show that the model has superior performance in semantic segmentation accuracy of satellite images [14]. Tiwari et al. proposed an improved CNBIS model for segmenting vehicles, which segmented the input images by successive encoding and decoding steps. The simulation results show that the improved CNBIS model outperforms other segmentation models in terms of segmentation accuracy [15]. Cheng et al. designed a separated convolutional CNBIS model combining

convolutional downsampling. The outcomes of the simulation experiment demonstrate that the model is capable of quickly and easily detecting fabric defects with high accuracy [16]. Mahmoud et al. developed a deep learning model based on the combination of CNBIS model. The simulation experiments demonstrate that the model performs significantly better than the traditional CNBIS model, exhibiting a higher accuracy rate [17]. Abdelraouf et al. proposed to use multi-gated expansion starting blocks. It is evident from the experimental results that the addition of multi-gate expansion start blocks improves the CNBIS model performance and demonstrates exceptional capability [18].

In summary, there are many research results on image semantic segmentation and CNBIS model applications. However, most of the image semantic segmentation studies use small data set samples, which do not sufficiently meet the deep learning requirement for extensive data training. The traditional CNBIS model has insufficient feature extraction capability, which leads to inaccurate image localization and poor robustness. The paper suggests the DACNBIS model to overcome the aforementioned issues and introduces an attention mechanism to enhance the DACNBIS model, resulting in the AM-DACNBIS model.

III. DACNBIS MODEL AND AM-DACNBIS MODEL CONSTRUCTION IN IMAGE STITCHING LOCALIZATION DETECTION

The purpose of image stitching, which separates the stitching area from the real area so that they are presented separately, can be thought of as a unique sort of semantic segmentation.

A. Construction of DACNBIS Model Based on CNBIS Model

As the initial stage of rendering text into images in film and television production, splitting is the process of dividing a film script into a series of shots that can be filmed and presented as images. Convolutional Neural Networks (CNN) are a deep learning model with learnable weights and bias constants that are suitable for processing image data processing through supervised learning [19-22]. The convolutional layer can extract features from images. Equation (1) expresses the parameters of this layer.

$$x_j^l = f \left(\sum_{i \in M_j} x_i^{l-1} * Kernel_{ij}^l + b^l \right) \quad (1)$$

In equation (1), x_j^l is the j neuron of the l layer, $Kernel$, $*$, and $f(\square)$ represent the convolution kernel, convolution operation, and nonlinear excitation function, respectively, a and M_j represent the bias term and the number of inputs of the j neuron, respectively. The pooling layer can reduce the risk of overfitting by reducing the dimensionality. The excitation layer introduces nonlinear features to the neural network, enabling it to approximate any nonlinear function. The activation function image is shown in Fig. 1.

Fig. 1. Schematic diagram of three activation functions.

The Sigmoid function, Tanh function, and ReLU function, respectively, are depicted in Fig. 1 where the expression of the Sigmoid function is shown in equation (2).

$$f(x) = \frac{1}{1 + e^{-x}} \quad (2)$$

The value range of equation (2) is (0,1), which corresponds to the probability value range (0,1). Equation (3) contains the Tanh function's expression.

$$f(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \quad (3)$$

The output of equation (3) is centered on 0, which can play the effect of data centering. Due to the saturation region of Sigmoid function and Tanh function, the gradient is prone to gradient disappearance when back propagation, and this phenomenon becomes more and more obvious. This issue is mitigated by the ReLU function, which is expressed mathematically in equation (4).

$$f(x) = \begin{cases} x, & x > 0 \\ 0, & x < 0 \end{cases} \quad (4)$$

The positive activation value derivative of the ReLU function in equation (4) is 1. In order to accomplish the image classification task, the fully connected layer must integrate the input image data and map the feature map from the convolution layer into a fixed-length feature vector, as shown in equation (5).

$$x_j^l = f\left(\sum_{i \in M_j} x_i^{l-1} * w_{i,j} + b_j\right) \quad (5)$$

In equation (5), $w_{i,j}$ and b_j denote the weight and offset between neurons, respectively. CNBIS, as a special semantic segmentation algorithm in the field of deep learning, is a derivative model of CNN and capable of addressing image stitching and localization issues.

The CNBIS model in Fig. 2 adopts a fully symmetric coding-decoding structure. The coding section is downsampled four times, and the decoding link is corresponding to the four stages of the coding link, each of which incorporates the feature information corresponding to that from the coding process. This results in the final feature map is restored to the original image size. Due to the small sample of dataset about image stitching at this stage, the neural network is prone to the risk of overfitting, the study

introduces the DB and ASPP modules to improve the CNBIS model, resulting in the DACNBIS model. The DB module is a CNN with tightly connected nature. The feature map resolution of each layer is of the same size, so the channels of each layer can be stitched together in dimension. Suppose the output channel of the l layer inside the DB module is X_l , then the expression of X_l is shown in equation (6).

$$X_l = H_l[X_{l-1}, \dots, X_1, X_0] \quad (6)$$

In equation (6), H_l is the nonlinear transformation function of the l layer, $[\]$ indicates that all output feature maps of the X_0, X_1, \dots, X_{l-1} layer are combined by channel, and the expression of the network input X_i of the i layer is shown in equation (7).

$$X_i = K_0 + (i-1) \times K \quad (7)$$

In equation (7), K is the number of output channels of the nonlinear function H , and K_0 is the number of input channels. The dense jump connection implemented inside the DB module causes the number of channels after the l layer to become large. The study adopts a convolution of 1×1 before the convolution of 3×3 in the DB module. The ASPP module aims to minimize the loss of accuracy generated by the feature map in the process of recovering the resolution size of the original image. It employs four varied expansion rates of the null convolution to capture multi-scale information. The specific structure of DACNBIS model is shown in Fig. 3.

In Fig. 3, the study introduces the DB module to replace the original CNBIS model upsampled by the 3×3 convolutional network. This enhances feature reuse and propagation, increasing the richness of feature extraction. The study also introduces the ASPP module to replace the fourth sampling session of the original CNBIS model. This module extracts multi-scale information, expands the network perceptual field, and improves the model's segmentation effects on spliced regions of different sizes.

Fig. 2. Schematic diagram of CNBIS model structure.

Fig. 3. Schematic diagram of DACNBIS model structure.

B. Construction of AM-DACNBIS Model based on DACNBIS Model

In order to avoid some redundant and useless low-level semantic information from interfering with the decoding process of the DACNBIS model, thereby affecting the influence of image sub-screening conception in the film and television production stage, the research combines AM to improve the DACNBIS model, resulting in the AM-DACNBIS model. It is based on the principle that humans selectively focus on the more interesting and informative visual areas when observing a scene, thus ignoring other irrelevant areas and thus improving the utilization of visual information. The study draws inspiration from AM and introduces a Global Attention Upsampling (GAU) module to provide global context as a low-level guide, see Fig. 4 [20].

Fig. 4. GAU module schematic diagram.

In Fig. 4, GAU first convolves the low-level semantic features with 3×3 . Since the AM-DACNBIS model ignores the differences between the essential attributes of images when performing image input, which in turn leads to large differences between the extracted real images and the stitched images and affects the splitting effect in the film and TV production process. In order to reduce the interference situation of different semantic information in the stitching region on the network's extracted features, the study implements the Spatial Rich Model (SRM) filter in the input stage to analyze the image features. SRM is a high-latitude steganographic model, when the image hides secret information, SRM will destroy the image attributes and extract the feature information from these images that are hidden information. Suppose the image pixel is X , the expression of image residual $R_{i,j}$ is shown in equation (8).

$$j = 1, 2, \dots, n_2, i = 1, 2, \dots, n_1, R_{i,j} = \hat{X}_{i,j}(N_{i,j}) - cX_{i,j} \quad (8)$$

In equation (8) n_1, n_2 denote the pixel points in horizontal and vertical directions respectively, $N_{i,j}$ is the field without the central pixel $X_{i,j}$, $\hat{X}_{i,j}(N_{i,j})$ refers to the estimated value of the central pixel $X_{i,j}$ in the region $N_{i,j}$, c is the residual order, when the magnitude of the residual pixel is large, the pixel correlation there will be reduced, so the study also needs to quantize and truncate the residual image, as shown in equation (9).

$$R_{i,j} \leftarrow Trunc_T \left(\text{round} \left(\frac{R_{i,j}}{Q} \right) \right), j = 1, 2, \dots, n_2, i = 1, 2, \dots, n_1 \quad (9)$$

In equation (10), Q is the quantization step, round indicates rounding, and $Trunc_T$ means the elements are truncated one by one by the threshold T , where $Trunc_T(x)$ is expressed as shown in equation (10).

$$Trunc_T(x) = \begin{cases} x, & x \in [-T, T] \\ T \text{sign}(x), & x \notin [-T, T] \end{cases} \quad (10)$$

In equation (10) $\text{sign}(x)$ is the symbolic function and the high-pass filter extracted from the SRM can be used for the extraction of RGB image noise, as shown in equation (11).

$$K = \frac{1}{2} \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -2 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (11)$$

The residual image resulting from the extraction of the SRM filter in equation (11) highlights edge features of the stitched region while suppressing other contents. In order to maintain sharing in the feature extraction process and minimize the risk of network overfitting, the study comprises of a multi-task learning output from the branching task of stitching edge localization using the DACNBIS model. According to Fig. 5, the hard parameter sharing and soft parameter sharing categories best describe the multitask learning structure.

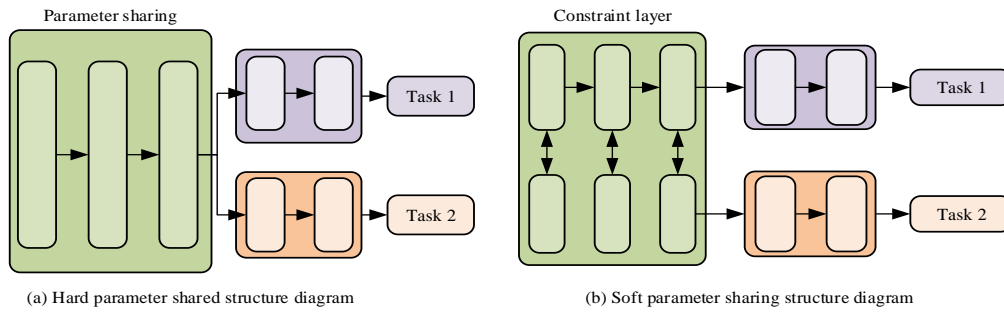

Fig. 5. Schematic diagram of multi-task learning structure.

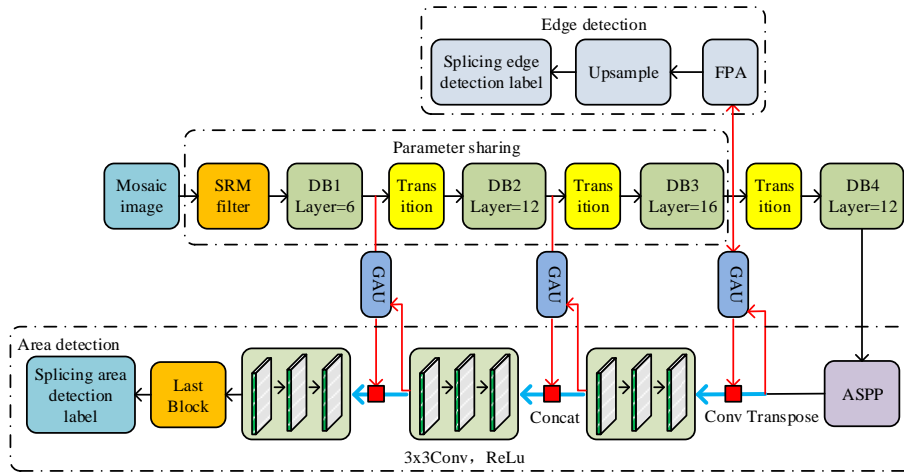

Fig. 6. Structural diagram of AM-DACNBIS model.

Fig. 5(a) shows the hard parameter sharing structure, in which the bottom layers of the network's input share parameters. This is known as bottom parameter sharing. Different learning tasks present different branches after sharing, and these tasks are trained in parallel with each other, and the feedback action is performed through the loss function each learning task. Fig. 5(b) shows the soft parameter sharing structure, in which every task has independent models and parameters. Every model can access the internal information of other models and regularize the distance between model parameters to ensure the similarity between parameters. Since the soft parameter sharing mechanism has separate models among multiple tasks. A schematic representation of the final AM-DACNBIS model structure is shown in Fig. 6. The study also embeds the data information of multiple tasks into a single semantic space and extracts the relevant task information for each task through a specific feature layer.

The model structure in Fig. 6 is mainly divided into three parts: parameter sharing, region monitoring, and edge detection. For the parameter sharing part, the AM-DACNBIS model adds SRM filters and completes the shared training for both region detection and edge detection tasks through the DB module in the pre-input phase of the network. It then embeds the information of both tasks into the same semantic space. For the region detection part, the study introduces the GAU module in the decoding process of the AM-DACNBIS model to provide global context as the underlying guidance to improve the sensitivity of important feature information. For the edge detection part, the study invokes the feature pyramid

attention module in the edge branch and learns better feature representation at the parameter sharing layer through this module. To evaluate the AM-DACNBIS performance, the study presents the performance metrics of accuracy, recall, and F1 value for testing, as shown in equation (12).

$$\begin{cases} R = \frac{TP}{FN + TP} \\ F1 = \frac{2PR}{R + P} \\ P = \frac{TP}{FP + TP} \end{cases} \quad (12)$$

In equation (12), P and R represent the precision and recall, respectively. TP is the actual stitched area pixels and the predicted stitched area pixels; FP is the actual real area pixels and the predicted stitched area pixels; FN is the actual stitched area pixels and the predicted real area pixels.

IV. ANALYSIS OF THE RESULTS OF DACNBIS MODEL AND AM-DACNBIS MODEL IN IMAGE STITCHING LOCALIZATION DETECTION

The section focuses on the examination of the experimental results of the DACNBIS model and the AM-DACNBIS model. To confirm the validity of the DACNBIS model and the AM-DACNBIS model, comparative tests were conducted on various data sets utilizing different model sets.

A. Experimental Data Preparation

The algorithmic model was developed with the PyTorch deep learning framework, and the hardware environment for the experiments was a workstation running Windows OS. This was done to compare the performance of the proposed models. With a stochastic gradient descent network training optimizer, a binary cross-entropy loss function, an initial learning rate of 0.01, momentum of 0.9, weight decay of 0.0005, and performance metrics of accuracy, recall, and F1 value. The Chinese Academy of Sciences Institute of Automation 1 (CASIA1) dataset, CASIA2 dataset, Columbia Uncompressed Image Splicing Detection (CUIS) dataset, and the Chinese Academy of Sciences Institute of Automation 1 (CASIA2) dataset are used for the study. For the experiments, the Image Splicing Detection (CUISD) datasets are utilized, and the specific experimental data are divided as shown in Table I.

TABLE I. PARTITION RESULT OF DATA SET

Data Set	CASIA1	CASIA2	CUISD
Training set	1050	7000	175
Verification set	300	2000	50
Test set	150	1000	25

1500 samples total for the CASIA1 dataset, 10,000 samples total for the CASIA2 dataset, and 250 samples total for the CUISD dataset are shown in Table I, where the training, validation, and test sets account for 70%, 20%, and 10% of the corresponding datasets. To enhance the understanding of the datasets, the schematic diagram of some data sets is selected, as shown in Fig. 7.

Fig. 7. Sample diagrams of three data sets.

Fig. 7(a) is a schematic diagram of the CASIA1 dataset with stitching areas of different sizes and arbitrary boundaries such as circles, triangles and rectangles. Additionally, Fig. 7(b) illustrates the CASIA2 dataset, which is an upgrade of the CASIA1 dataset with more data and better production. Fig. 7(c) displays the CUISD dataset which provides labels with red and green colored edge templates, and the edge labeling error is larger.

B. Performance Analysis of DACNBIS Model

To verify the performance of DACNBIS model, the study conducted comparison experiments using Fully Convolutional

Networks (FCN), CNBIS, and Pyramid Scene Analysis Network (PSAN) models. The number of model iterations was increased from 10 to 100 in epoch.

Fig. 8. Accuracy and recall results of four models.

The change curves indicated in Fig. 8 illustrate the precision rate and recall rate of the four models. As the number of iterations increases, the precision rate and recall rate of the four models improve. In Fig. 8(a), the accuracy rate for the four models is displayed, showing that the DACNBIS model has a precision rate of 96.48%. The precision rates for the PSAN, CNBIS, and FCN models are 94.87%, 94.23%, and 93.75%, respectively, at 100 epochs. Fig. 8(b) shows the recall variation curves of the four models, and the recall rates of DACNBIS, PSAN, CNBIS, and FCN models are 95.24%, 93.52%, 93.17%, and 92.91%, respectively, when the number of iterations is 100 epoch.

Fig. 9. F1 value results of four models.

Fig. 9 shows the results of the F1 values of the four models, which all increase with the number of iterations. When the number of iterations is 10 epoch, the F1 values of the DACNBIS, PSAN, CNBIS, and FCN models are 94.30%, 93.81%, 93.54%, and 93.26%, respectively. When the number of iterations is 100epoch, the F1 value of DACNBIS model is 95.96%, surpassing the 94.58% of the PSAN model, the 93.99% of the CNBIS model, and the 93.71% of the FCN model. In summary, the DACNBIS model proposed in the study has higher segmentation accuracy compared to other models and performs well in the field of split-screen image stitching localization in film and TV production.

C. Performance Analysis of AM-DACNBIS Model

In order to verify the validity of AM-DACNBIS model, literature [14], DACNBIS model and AM-DACNBIS model were set up for comparative experiments.

Fig. 10. The experimental results of three models in CASIA1 and CASIA2 data sets.

Fig. 10 shows the experimental results of three models in CASIA1 and CASIA2 data sets. Fig. 10(a) shows the results of accuracy, recall and F1 value of the three models on the CASIA1 data set. The accuracy of AM-DACNBIS model is 98.19%, and that of study [14] and DACNBIS model is 97.21% and 97.97% respectively. The recall rates of AM-DACNBIS, study [14] and DACNBIS models are 96.23%, 95.68% and 95.87% respectively, and the F1 value of the AM-DACNBIS model is 97.21%, which is higher than that of study [14] and DACNBIS model, which is 96.57% and 96.92%. Fig. 10(b) shows the results of accuracy, recall and F1 value of the three models in CASIA2 data set. The accuracy of AM-DACNBIS model is 98.76%, and that of study [14] and the DACNBIS model is 97.59% and 98.45% respectively. The recall rates for the AM-DACNBIS, study [14] and DACNBIS models are 96.54%, 95.51% and 96.01% respectively. The F1 value for the AM-DACNBIS model is 97.65%, which is higher than that of study [14] and the DACNBIS model, which are 96.73% and 97.23%.

Fig. 11 shows the detection results of the DACNBIS model and AM-DACNBIS model on two data sets; Fig. 11(a) displays the outcomes for both models in the CASIA1 dataset. The detection results for both models in the CASIA2 dataset are shown in Fig. 11(b). The figure shows that the AM-DACNBIS model has better performance in detection and can significantly amplify the sensitivity of key features, and can filter out key feature information. To further verify the robustness of the AM-DACNBIS model, the study performs two operations of compression and Gaussian blurring on the CASIA1 test set images, where the image compression factors

are 95, 90, 80, and 70, and the standard deviations of Gaussian blurring are set to 0.5, 1.0, 1.5, and 2.0. The results of the model tests are shown in Table II.

Table II shows that the accuracy, recall, and F1 values of both models decrease as the picture compression factor drops and the Gaussian fuzzy standard deviation rises. The AM-DACNBIS model's accuracy, recall, and F1 values are 76.58%, 59.63%, and 62.99%, respectively, when the image compression factor is 70, while those of the DACNBIS model are, respectively, 70.28%, 40.21%, and 50.31%. When the Gaussian fuzzy standard deviation is 2.0, the accuracy rate of AM-DACNBIS and DACNBIS models are 85.07% and 78.74%, the recall rates of AM-DACNBIS and DACNBIS models are 85.41% and 74.31%, and the F1 values of AM-DACNBIS and DACNBIS models are 85.21% and 76.64%. The combined results show that AM-DACNBIS can effectively reduce the risk of overfitting and is more suitable for split-screen image conception in the film and television production than the DACNBIS model.

Fig. 11. Test results of two models in CASIA1 and CASIA2 data sets.

TABLE II. DETECTION OF TWO MODELS UNDER DIFFERENT COMPRESSION FACTORS AND GAUSSIAN FUZZY STANDARD DEVIATION ATTACKS

Model Type		AM-DACNBIS			DACNBIS		
Performance index		Precision	Recall	F1	Precision	Recall	F1
Compressibility factor	95	87.95%	78.27%	82.81%	87.03%	70.54%	77.74%
	90	86.94%	67.61%	75.94%	80.51%	62.41%	70.24%
	80	81.47%	60.41%	64.12%	79.74%	44.09%	55.89%
	70	76.58%	59.63%	62.99%	70.28%	40.21%	50.31%
Gaussian fuzzy standard deviation	0.5	87.41%	85.54%	86.48%	86.31%	78.79%	82.45%
	1.0	87.02%	86.21%	85.84%	84.29%	77.59%	80.81%
	1.5	86.83%	85.77%	85.64%	80.87%	75.47%	78.54%
	2.0	85.07%	85.41%	85.21%	78.74%	74.31%	76.64%

V. CONCLUSION

As image editing software becomes more functional and easier to use, the stitching and positioning techniques for splitting images, a crucial step in pre-production for film and TV, is imperative. The traditional stitching and positioning techniques have limited segmentation accuracy and poor robustness due to inadequate feature extraction capabilities in the sampling process and inaccurate positioning segmentation for different shapes. To address the above problems, a DACNBIS model based on DB module and ASPP module is proposed. The results show that when the number of iterations is 100 epoch, the accuracy, recall and F1 values of DACNBIS model under CUISD dataset are 96.48%, 95.24% and 95.96%, respectively, which are higher than 94.87%, 93.52% and 94.58% of PSAN model. Under the CASIA2 dataset, the AM-DACNBIS model exhibited higher accuracy, recall, and F1 values than the DACNBIS model with scores of 98.76%, 96.54%, and 97.65%, respectively, which were improved by 0.31%, 0.53%, and 0.42%. Under the CASIA2 dataset, the F1 values of the AM-DACNBIS model are 62.99% and 85.21% when the image compression factor and Gaussian fuzzy standard deviation are 70 and 2.0, respectively, which are higher than those of the DACNBIS model by 50.31% and 76.64%. In summary, the DACNBIS model proposed in the study performs well with the AM-DACNBIS model, but in the CASIA1 and CASIA2 datasets, the AM-DACNBIS model performs significantly better than the DACNBIS model and is more suitable for the image splitting conceptualization applications in film and television production. However, there are still shortcomings in the study, and the image quality of the CUISD, CASIA1, and CASIA2 datasets is somewhat different from the demand of multi-scope image stitching, and the subsequent study will further construct a high-quality and complex professional stitching dataset.

Rural Landscape Design Data Analysis Based on Multi-Media, Multi-Dimensional Information Based on a Decision Tree Learning Algorithm

Ning Leng¹, Hongxin Wang^{2*}

Guangdong Peizheng College, Guangdong, China¹
University of Sanya, Hainan, China^{2*}

Abstract—This paper analyzes and studies the design characteristics of multi-dimensional information rural scenes. For data mining and the Decision Tree (DT) calculation method, the pre-processing system and method of multi-dimensional information rural award design are put forward again. Through the analysis of the multi-dimensional value of multi-dimensional multimedia mountain villages, the form of planning and design analysis and corresponding methods are based on the analysis. Using one village as a case study, we were able to investigate the villagers, roads, services, greening, ecology, and other aspects of the village in complete detail and then implement the multi-media, multi-resource village's detailed planning and design.

Keywords—Multi-media multi-dimensional information rural landscape; data mining; decision tree; data preprocessing

I. INTRODUCTION

In recent years, with the rapid development of building automatic control systems and building management systems, which have been widely used (such as large-scale public multimedia multidimensional information rural scenery supervision and management platform and landscape measurement project successively conducted by several provinces and cities in China), extensive multimedia multidimensional information rural scenery design resources are loaded. These resources are the most direct data on the operation of buildings, systems, and equipment and are highly valued. Cities nationwide have been paying attention to the call to reform rural areas in recent years [1-3]. A loss of the original rural characteristics develops in some cities because of rural urbanization, which impacts the landscape by destroying old buildings and building high-rise structures. A decline in rural scenes has resulted from cultural pressures, resulting in a loss of rural characteristics. Destruction of ecosystems directly results from financial growth and poor resource management in rural areas [4-7]. *E.g.*, reducing land in rural fields and reducing natural spot areas. Rural ecosystems are damaged by the excessive use of chemicals such as pesticides, herbicides, and fertilizers, and the township businesses' rapid processing also increases pollution.

In order to obtain high-quality mining data, the results of the data to guide practical operation through the construction of a data pretreatment system, using the Decision Tree (DT) method to calculate the missing data of construction data, abnormal data, multi-dimensional data for data analysis, data pretreatment system and methods in the practical case, to obtain superior results.

II. FEATURES OF BIG DATA AND DATA PREPROCESSING SYSTEM OF MULTI-MEDIA MULTI-DIMENSIONAL INFORMATION RURAL LANDSCAPE (MMMDIRL) DESIGN

It is already under study; the relevant research on the application of data mining in architecture focuses on regular mining using data mining algorithms. MMMDIRL analysis, landscape and load prediction, fault diagnosis, optimization of operation control, and other data pretreatment research and results are limited. This section will refer to the data preprocessing processes and methods in other fields (*e.g.*, big Internet data.) and propose the preprocessing system and methods for building data after analyzing the characteristics of multi-dimensional information rural landscape data in multimedia.

DT learning algorithm variables are represented by a triple array (r_1, r_2, r_3) $r_1 < r_2 < r_3$ consisting of zeros, whose dependent function is EQU (1).

$$\mu(x) = \begin{cases} \frac{x - r_1}{r_2 - r_1}, & \text{if } r_1 \leq x \leq r_2 \\ \frac{x - r_3}{r_2 - r_3}, & \text{if } r_2 \leq x \leq r_3 \\ 0, & \text{others} \end{cases} \quad (1)$$

Set DT learning algorithm $\alpha = (a_1, a_2, a_3)$, $\beta = (b_1, b_2, b_3)$ according to the DT learning algorithm number of addition and extension principle of power, EQU (2).

$$\mu_{\alpha+\beta}^-(z) = \sup\left\{\min\left\{\mu_{\alpha}^-(x), \mu_{\beta}^-(y)\right\} \mid z = x + y\right\} = \begin{cases} \frac{z - (a_1 + b_1)}{(a_2 + b_2) - (a_1 + b_1)}, & a_1 + b_1 \leq z \leq a_2 + b_2 \\ \frac{z - (a_3 + b_3)}{(a_2 + b_2) - (a_3 + b_3)}, & a_2 + b_2 \leq z \leq a_3 + b_3 \\ 0, & \text{others} \end{cases} \quad (2)$$

That is, the sum of the DT learning algorithm is the DT learning algorithm, and there are EQ. (3) and EQ. (4)

$$\bar{\alpha} + \bar{\beta} = (a_1 + b_1, a_2 + b_2, a_3 + b_3) \quad (3)$$

From $\mu_{\lambda\bar{\alpha}}^-(z) = \sup\{\mu_{\alpha}^-(x) \mid z = \lambda x\}$
get

$$\lambda\bar{\alpha} = \begin{cases} (\lambda a_1, \lambda a_2, \lambda a_3), & \lambda \geq 0 \\ (\lambda a_4, \lambda a_3, \lambda a_2), & \lambda < 0 \end{cases} \quad (4)$$

It $\bar{\alpha}_i = (a_{i1}, a_{i2}, a_{i3}) \quad i = 1, 2, \dots, m$ is the DT learning algorithm, the non-negative linear combination and DT learning algorithm programming $\bar{\alpha}_i$ are obtained, EQ. (5)

$$\sum_{i=1}^m \lambda_i \bar{\alpha}_i, \lambda_i \geq 0 \quad (5)$$

It is still a DT learning algorithm, and EQ. (6)

$$\sum_{i=1}^m \lambda_i \bar{\alpha}_i = \left(\sum_{i=1}^m \lambda_i a_{i1}, \sum_{i=1}^m \lambda_i a_{i3} \right) \quad (6)$$

The DT learning algorithm is a random plan with constraints, such as random parameters, and chance is used to show precisely how probable it is that constraints will be set. A constraint programming environment enables the use of possibilities as constraints [8-10]. Random DT learning algorithm and DT learning algorithm control plan are powerful tools for solving optimization problems with random parameters and DT learning algorithm parameters. Compared with other industries, due to the early construction of landscape supervision and management platforms, design points are designed and evaluated in advance in the process of scheme customization. At the same time as data redundancy, the pre-set data attributes and accuracy in the database of the landscape management platform are avoided as far as possible. Problems such as incomplete data accuracy and inconsistent format will occur, so data redundancy, format contradiction, and accuracy are problematic [11-13].

Based on the above analysis, this paper proposes a pre-processing system of MMMDIRL design big data based on the characteristics and corresponding processing methods of MMMDIRL design big data, as shown in Fig. 1.

A. Significance of Rural Landscape Planning (RLP) and Design

The purpose of RLP and design is to optimize the environment of human settlements. At the same time, it is the direction of the future development of the rural environment. It is the ideal structure of the rural ecosystem. The primary purpose of RLP is to coordinate rural landscape and ecological development.

To make the relationship between man and nature more harmonious, China's new socialist rural construction is still in its infancy. RLP is the exploration and attempt of rural construction mode and the key to determining the quality of rural residents' environmental construction.

The key point is that RLP aims to optimize the rural environment and meet local ecological needs. The functions of rural landscape construction are as follows:

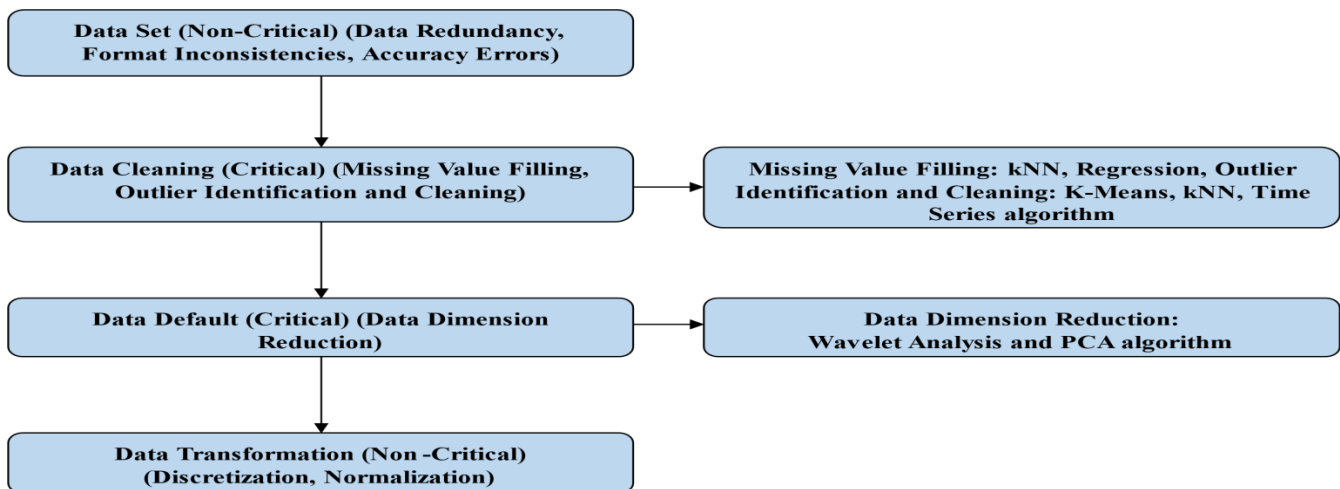

Fig. 1. Big data preprocessing technology system of MMMDIRL design.

B. Promoting Rural and Local Economic Development

RLP and design optimize and adjust the rural industrial structure, promoting the development of the local economy. The practice results in many rural areas show that while optimizing the industrial structure, the regional economy is multiplied, and the output of various crops will increase. Taking Lijiahe Township, Xuanen County, Hubei Province as an example, the adjustment of industrial structure has significantly increased the income of tobacco farmers and brought considerable tax revenue to the local finance. Another example is the "Farmhouse Fun" Ecological Sightseeing Park, which mainly displays local folk customs and promotes agricultural development by providing leisure and entertainment activities, which has extensively promoted the construction of local rural areas.

RLP focuses on the overall planning of the rural environment to realize the transformation from design to reality. RLP and design consider the balance between man and land, economic development, and environmental protection.

C. Conducive to the Inheritance and Development of National Culture

RLP is conducive to the layout of rural villages and the protection of local national culture. For example, local architectural concepts and literary works can inherit national cultural characteristics. The local architectural landscape is the carrier of national culture and fully reflects the local folk characteristics. Therefore, the rural landscape is the most essential way for people to get familiar with the traditional culture, protect the rural characteristics to the greatest extent and realize the inheritance of regional culture.

III. BUILDING DATA PREPROCESSING TECHNOLOGY BASED ON THE DT LEARNING ALGORITHM

Because of the characteristics of multimedia multi-dimensional information rural landscape design big data, in the above mentioned, the identification of abnormal data is K-ManASKNN, such as time series and other algorithms. This paper uses only one specific method to pre-process the related data quality problems; fill in missing data, determine the DT learning algorithm, and clean outliers to reduce data volume, identify outliers, and determine the DT learning algorithm.

IV. DATA QUALITY ANALYSIS

Infrastructure built on multimedia landscape and electronic network maps is well-known and durable. 200 multimedia design landscapes that won professional recognition were used as a statistical sample. The formation mechanism of the landscape's ornamental nature was assumed as the classification benchmark. The sample of 100 landscape cases has 17 active multi-media landscapes; 17% of the total. While ornamental landscapes have 78 active and passive loads, passive loading in multimedia landscape architecture causes a subject of 6% of the overall. The prototype spatial interface pattern is controlled in multiple dimensions, primary visual data is gathered at eye level, and stable triangular composition is maintained to achieve 78% of the total. The absolute

proportion of multimedia landscape architecture with a multi-dimensional dominant space interface is 85%. Data quality is assessed before mining in MMDIRL designs, which frequently use plain ornamental subjects (Table I).

TABLE I. SHOWS THE ACTUAL RUNNING DATA OF THE COUNTRYSIDE WITH MULTI-MEDIA, MULTI-DIMENSIONAL INFORMATION

S/N	P/kW	Q_{ch} /kW	T_{ci} /°C	T_{co} /°C	T_{ei} /°C	T_{eo} /°C
1	35.5	54.9	20.4	20.7	14.3	12.7
2	35.5	54.9	21.3	21.6	13.3	11.8
3	37.6	54.9	23.1	23.1	13.5	12
...
35378	97.8	504.7	28.5	33	16	10.2
35379	97.9	536.8	27.3	32.4	18.7	11.5
35380	99.5	536.8	27	31.8	21.8	14.8

A. Missing Data

The data from 35,380 groups are classified and statistically analyzed according to their attributes. Data of different attributes are missing to their extent. The degree of missing data attributes is shown in Table II. According to the analysis of data in the Table II, the missing data of the mechanical landscape attribute is the largest, with 576 missing data, accounting for 1.6%, and the loss of the remaining attribute data is small. Due to the integrity of data mining conclusions, these false data need to be filled in the pre-processing stage.

TABLE II. DISTRIBUTION OF MISSING DATA BY ATTRIBUTE

Missing Data Attribute	The Number of/a	Percentage of Missing Data /%
MMDIRL (P)	574	1.67
Load (Q_{ch})	216	0.66
The outlet temperature of chilled water (T_{eo})	168	0.56
The inlet temperature of chilled water (T_{ei})	173	0.45
Cooling water outlet temperature (T_{co})	305	0.87
Cooling water inlet temperature (T_{ci})	71	0.34

B. Abnormal Data

Abnormal performance and data transmission cannot be avoided when devices such as multimedia multi-dimensional information villages and sensors are in extreme action. In data preprocessing, it is necessary to identify and clean these abnormal data.

C. Multidimensional Data

There are many design variables related to multi-dimensional information on rural landscapes. According to relevant theories and empirical models, the influencing factors of multimedia in multidimensional information rural manufacturing are attributed to five factors: load (Q_{ch}), the

outlet temperature of cold water (T_{eo}), immersion temperature of cold water (T_{ei}), the outlet temperature of cold water (T_{ci}) and immersion temperature of cold water (T_{co}). There are several specific influencing factors. Whether the dimension of data continues to decline needs to be analyzed in the pre-processing stage.

At the same time, in the process of data sorting, there are fewer problems such as redundancy of points, repeatability of fields, lack of data accuracy, and format contradiction so that it is screened and processed in a simple, fast, and one-sided.

Given the above data quality analysis, this project must conduct data preprocessing, focusing on abnormal data and multidimensional data. It is the following primary research work.

V. MISSING DATA FILLING BASED ON THE DT LEARNING

DT learning algorithm is a classification algorithm based on analogy learning, which learns by comparing the given check object data with similar training data [14-15]. The missing-value processing step of the DT learning algorithm compares a sample data set with labels to determine the correlation between the data and classification. The features of the sample set are compared to the newly entered unlabeled data, and the classification labels that correspond to the most similar features are extracted. This approach ensures that the data is correctly classified. Generally speaking, only the k most similar data in the first part of the data set are selected, and the most common classification among the k most similar data is selected as the new data classification to realize the filling of missing values.

A simple data analysis of Table I shows that the original running data has a continuous data missing phenomenon. As shown in Table III, see lines 34145-34149 for missing data. The missing attribute is the multi-dimensional information rural landscape (P) value, while the other attributes are complete. The kNN method populates the data to get the missing attribute values.

The classic process of taking advantage of kNN: First, have exclusive properties. ($P, Q_{ch}, T_{ci}, T_{co}, T_{ei}, T_{eo}$) For each missing data, select $k=3$, and finally close to ". Distance quote: The known data values are populated as unknown attributes. Get all unknown data values. Through kNN program processing, the values of the unknown data P in the data in lines 34145-34149 are shown below.

TABLE III. MISSING DATA IN THE ACTUAL RUNNING DATA

S/N	P/kW	Q_{ch} /kW	T_{ci} /°C	T_{co} /°C	T_{ei} /°C	T_{eo} /°C
34145	-	515.1	24.3	28	17.1	12.4
34146	-	483.0	29.8	33.7	13.4	9
34147	-	515.1	23.1	28	16.8	12.1
34148	-	496.7	24.5	33.7	13.3	8.8
34149	-	494.7	27.6	33.7	13.6	9.1

The DT learning algorithm is set for similar processing for other missing values in the original data.

VI. ABNORMAL DATA IDENTIFICATION AND CLEANING BASED ON THE DT LEARNING ALGORITHM

DT learning algorithm analysis, the essence of the principle is to collect similar things, not similar things, into distinct kinds of processes. Data set 'D' contains 'n' objects, generated clusters 'K', and the clustering algorithm divides them into clusters EQ. (7) and EQ. (8).

$$k(k \leq n) C_1, \dots, C_k \quad 1 \leq i, j \leq k \quad C_i \subset D \quad (7)$$

$$C_i \cap C_j = \emptyset \quad (8)$$

The DT learning algorithm identifies data outliers by assuming that objects belong to large, dense, small, sparse, or none of these clusters. An overview of the above ideas as a general method of outgroup point (outlier) identification is as follows.

As illustrated in Fig. 2, a data object is regarded as an outlier if it does not fit into any of the clusters that have been created.

Fig. 2. a is abnormal data.

Outliers are depicted in Fig. 3 and occur when a data object is located far from the center of the cluster to which it belongs.

Fig. 3. a and b are abnormal data.

Fig. 4. a and b are abnormal data.

As seen in Fig. 4, if a data object is included in a minor or sparse cluster, then every object included in that cluster is considered an outlier.

In general, if the abnormal data does not belong to any cluster, as shown in Fig. 2, or belongs to a smaller cluster than the others, as shown in Fig. 4, the cluster data is deleted and ignored (even if the deletion does not affect the data sample capacity). As shown in Fig. 3, abnormal data must be cleaned correctly if it is far from the cluster center. In this paper, based on the DT learning algorithm, the cluster subset is clustered, and the abnormal data is replaced with the central value of the subset group to which the abnormal data belongs.

In order to study the relationship between multi-dimensional information about rural landscapes and a single variable, it is necessary to classify the data in detail. When the rural load rate of multimedia multidimensional information is fixed (66%) and the immersion temperature of cooling water (28.3°C), the rural landscape of multimedia multidimensional information constitutes a changing 2D array. The total number of data groups is 176, as shown in Table IV.

The DT learning algorithm was applied to perform cluster analysis on the above data, and the number of categories $k=4$ of the DT learning algorithm was selected to achieve the clustering results, as shown in Fig. 5.

Based on the above abnormal data identification principle, the cluster results in Fig. 5 are analyzed, and it is found that there are abnormal data in Fig. 5, which requires sub-cluster data cleaning and processing.

Take the cluster in the upper left corner of Fig. 5. The data set comprises 56 groups of data objects and data objects. (7.6,58.4), (7.5,58.4) are abnormal data (separated from the center of each cluster), and the tree learning algorithm of the cluster object is re-determined to take the number of cluster categories $k=4$. If cluster results, data object (7.5,58.3), (7.6,58.5) and other owning cluster center is (8.2,58.3), and cluster center (8.1,59.1) replaces (7.5,58.5), (7.6,58.4) and other abnormal data, abnormal data is cleaned.

Similarly, the data in the lower left, upper right, and right corners of Fig. 5 is cleaned using a similar determination tree learning algorithm. Fig. 6 shows the results of re-clustering the cleaned data. Comparing Fig. 6 vs. Fig. 5, it is found that the data distribution is centralized, which is a good clustering result.

TABLE IV. SHOWS THE ACTUAL RUNNING DATA OF THE COUNTRYSIDE WITH MULTI-DIMENSIONAL MULTIMEDIA INFORMATION

S/N	P/kW	Q_{ch} /kW	T_{ci} /°C	T_{co} /°C
1	59.5	354.6	29.5	8.7
2	60.6	354.7	29.6	8.8
5	59.7	354.7	29.6	8.9
175	60.8	354.7	29.6	11.2

VII. DATA DIMENSION REDUCTION BASED ON THE DT LEARNING ALGORITHM

Principal Component Analysis (PCA) is a method of multiple statistical analysis that uses a linear transformation to reduce the number of different indexes to a small number of comprehensive indexes uncorrelated. By analyzing the characteristics of the matrix, the original data is projected in linear space to reduce the dimension of the data. The central principle is based on each component's cumulative dispersion contributions to determine the principal component.

The core process of principal component analysis is as follows: (a) The covariance matrix of the eigen-centralization matrix. (b) Computing the eigenvector associated with the covariance matrix's eigenvalue is necessary. (c) Calculate the dispersion contribution rate of each component. (d) Calculate the cumulative dispersion contribution rate.

In the core process, primary element analysis accumulates dimensional scattered data contribution rate to a manually set limit. This data influence represents the entire data set and creates high-order relegation data.

The most original problem of regression research is to study the relationship between multi-dimensional information

rural landscape (P) and load (Q_{ch}), the outlet temperature of cold water (T_{eo}), immersion temperature of cold water (T_{ei}), the outlet temperature of cold water (T_{co}), immersion temperature of cold water (T_{ci}) and other factors. From the perspective of variables, it is related to six-dimensional variables. If we dig down all six variables, there may be some insignificant factors. It will do useless work and will waste many computing costs. This section used the PCA method to analyze six-dimensional variables to obtain the main influencing factors. The results of the DT learning algorithm are shown in Table IV.

The results of the DT learning algorithm in Table V are analyzed, showing that the cumulative dispersion contribution rate of the upper four variables reaches 99.93%. Since the dispersion contribution rates of the first four components and the last two components show a significant difference in the number of digits, the first four components are the main components, and the six-dimensional data in this data set is maintained at four-dimensional data. Through the follow-up data, freezing waters found that there is a direct relationship between the multi-dimensional information rural landscape (P) and load (Q_{ch}), the outlet temperature of cold water (T_{eo}), and the immersion temperature of cold water (T_{ci}), and the corresponding mathematical relationship is obtained. The rationality and applicability of data degradation of the DT learning algorithm have been proved here.

TABLE V. RATE OF VARIANCE CONTRIBUTION AND CUMULATIVE RATE OF VARIANCE CONTRIBUTION

S. No. of Composition	Rate of Variance Contribution (%)	Rate of Cumulative Variance Contribution (%)
1	83.951	82.851
2	17.758	99.309
3	2.014	100.023
4	1.47	100.193
5	1.304	100.197
6	1.303	100

VIII. CONCLUSION

Given the characteristics of multi-dimensional information data in rural landscape design, the general steps and methods of data preprocessing applied in some other fields cannot be directly applied to the big data preprocessing of buildings. The data preprocessing system of multi-dimensional information rural landscape design suitable for multimedia and the corresponding data quality problem processing methods are presented.

Abstract—The demand for the reliability of power grid systems is gradually increasing with the development of the power industry. And it is necessary to promptly identify and eliminate the hidden dangers. To meet the needs of online monitoring and the early warning of electrical equipment, an intelligent detection system based on deep learning and infrared image processing technology is proposed in this study. Firstly, the infrared image is preprocessed for noise reduction. Then, an improved SSD (Single Shot MultiBox Detector) network is used to optimize the infrared image detection method. Based on this, an intelligent detection system for electrical equipment is designed. The results show that the mAP value of the improved SSD network after 1200 iterations is about 92.58%, and its area under the Precision Recall (PR) curve is higher than other algorithms. The simulation analysis results of the detection system show that the improved method detects a fault degree of 57.85%, which is closer to the 59.74% in the real situation. The experimental results indicate that the newly established intelligent detection system for electrical equipment can effectively detect its abnormal situations.

Keywords—Deep learning; infrared images; electrical equipment; intelligent detection; adaptive median filtering

I. INTRODUCTION

With the rapid development of the power industry, the requirements for the reliability of the power grid system are becoming increasingly high. Equipment fault detection is a key to intelligent detection for electrical equipment. Electrical equipment faults have randomness, periodicity, concealment, and multiple occurrences, requiring constant attention to the status of electrical equipment [1-2]. Online monitoring and security warning have become important functional requirements for the power grid system. However, in order to timely identify problems and eliminate hidden dangers, a large amount of manpower and objects need to be consumed, so the intelligence and automation of the power grid are gradually being put on the agenda. The infrared image detection method is a very effective online monitoring method. It can not only detect defects through online detection, but also be combined with other methods. It can locate the fault and bring great convenience to maintenance [3]. In recent years, deep learning technology has made rapid progress. And more and more image recognition tasks have achieved good performance in deep learning solutions. It is increasingly applied to various industries, greatly promoting industry reform and innovation. Image processing, as an important branch, is becoming

increasingly intelligent with the promotion of neural network. Simultaneously, deep learning can improve the accuracy and efficiency of neural network image feature extraction and classification [4]. The long-term development of the power grid system has accumulated a large amount of infrared detection data, which can be applied to artificial intelligence technology. Based on image classification technology and automatic analysis and processing of electrical images, the current difficulties in manual data management can be effectively overcome, reducing on-site measurement and post maintenance workload. Therefore, achieving intelligent recognition of temperature anomalies in infrared images is a necessity for the development of power systems. Improving the efficiency of monitoring and ensuring the smooth operation of the power grid also inevitably requires the large-scale application of such automation technologies. Research has shown that deep learning techniques based on neural networks can improve the accuracy of image processing [5]. The combination of methods can improve the accuracy of equipment fault detection. However, improving the accuracy of equipment fault detection can easily lead to a decrease in the efficiency of the method. In order to meet the needs of online monitoring and early warning of electrical equipment, an intelligent detection system based on deep learning and infrared image processing technology was proposed in this study. Firstly, preprocessing such as noise reduction was performed on the infrared image. Then, an improved SSD (Single Shot MultiBox Detector) network was used to optimize the infrared image detection method. On this basis, an intelligent detection system for electrical equipment was designed. It is hoped to further improve the practical application effect of electrical equipment testing methods.

II. RELATED WORKS

The maintenance of power equipment is related to the safety of production, so it is necessary to improve the accuracy and effectiveness of equipment fault detection methods [6]. The abnormal situation detection of device can be judged using information from infrared images. In power equipment fault detection, infrared images can reflect the basic information of the equipment. Wang et al. designed an online electrical equipment fault detection method based on infrared images and developed relevant software. This method can perform state evaluation based on real-time device status, and its effectiveness has been proven in practical applications [7]. After obtaining the infrared image of the device, DL

model can classify the obtained image features for fault diagnosis and analysis [8]. In Shen et al.'s study, they used DL for feature extraction and classification after feature extraction of infrared images. The improved method can improve the accuracy of the detection method [9]. In the fault detection of power equipment, researchers have designed a fault detection method based on infrared images. And this method uses DL and infrared images for defect recognition and classification. Finally, through the combination of methods, the reduction of operation and maintenance costs was achieved, and the efficiency of fault detection was improved [10]. Siah et al. showed that DL combined with this technology can play a role in detecting abnormal situations in the examination of respiratory equipment. Based on infrared imaging technology, they can use infrared images to analyze whether there is an air leak in the respirator. This can effectively control the widespread spread of the virus and reduce the likelihood of public health crises [11].

The infrared images can effectively reflect the basic situation of the device. But during the image acquisition, the clarity of the image may be reduced due to the noise. To reduce the noise impact on image clarity, researchers used filtering algorithms for fault detection, which showed high image processing performance. The filtering algorithm can perform segmentation preprocessing on the collected images, thereby improving the quality of the detected image. In the study by Jayanthi et al., the improved filtering algorithm can improve the quality of collected images for tumor detection. The results confirm that the new method can assist in tumor detection and improve the accuracy of patient diagnosis [12]. The combination of median filtering and clustering algorithm can realize the image super pixel segmentation. This method can reduce noise impact and improve the quality of infrared image acquisition. Infrared images can effectively reflect the abnormal situation of device after segmentation [13]. In relevant research, filtering algorithms can significantly reduce noise impact after being weighted. And this method combines mean algorithm, which effectively protects the details of the image, improves the information processing ability and the detection performance of the image [14]. To obtain more fault information, Zhang et al. proposed the introduction of DL technology to improve filtering algorithm. This new method can mine more time-related data information. In fault recognition simulation experiments, this method can effectively extract fault features and perform accurate classification [15]. In DL, Single Shot MultiBox Detector (SSD) is a high-precision algorithm that can be used for image information processing. After continuous method improvements, Leng et al. were able to fuse features from different levels during the image sampling process. At the same time, the uniform generation of image anchors improves the accuracy of detection while ensuring the efficiency [16]. In the study by Zhou et al., SSD can use residual networks for image feature extraction when detecting sample targets. This method exhibits stronger target detection ability and higher detection accuracy in performance comparison [17].

In the above research, infrared images, filtering algorithms, and SSD have shown good performance in object detection, image processing, and feature extraction. And the combination

of methods improves the equipment fault detection accuracy. However, improving equipment fault detection accuracy can easily lead to a decrease in the efficiency of the method. To improve this situation, after preprocessing the infrared image, the improved SSD was used for image processing. It is hoped to further improve the practical application effect of electrical equipment testing methods.

III. INTELLIGENT DETECTION SYSTEM FOR ELECTRICAL EQUIPMENT BASED ON DL AND INFRARED IMAGE PROCESSING TECHNOLOGY

A. Construction of an Intelligent Detection System for Electrical Equipment and Research on Infrared Image Preprocessing

To ensure the long-term stable operation of electrical equipment detection system, system design should follow the principles of safety, adaptability, practicality, maintainability, and scalability. The framework of detection system is Django, which mainly includes the model, template, and view layer. Business logic is one important core in this framework, including infrastructure, application, model layer, etc. According to the actual needs of electrical equipment testing, this system is divided into four management modules: infrared image recognition, inspection tasks, image management, and personnel management in Fig. 1.

Infrared image recognition is the core part of the detection system, which requires preprocessing of infrared images to achieve functions such as temperature extraction, device recognition, and anomaly detection. Periodic inspections are required in inspection tasks management, as well as re-inspection and timely warning of any abnormal equipment. In image data management module, personnel can transmit image samples and view the running status and related data. The permission management of staff is the main function of the personnel management module, which can view the basic data information of relevant personnel.

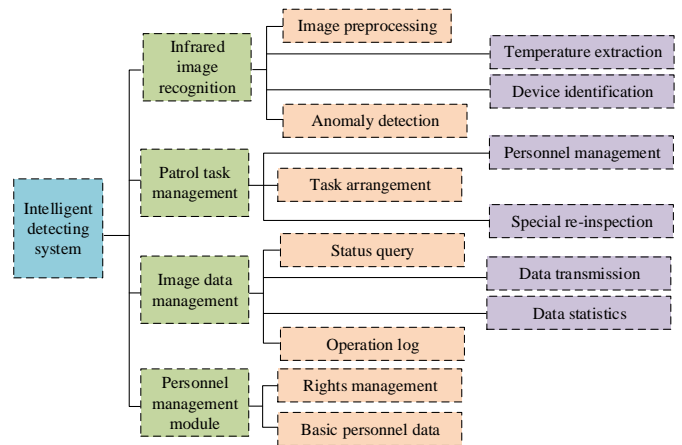

Fig. 1. Functional architecture of electrical equipment intelligent detection system.

In Fig. 2, the infrared image recognition module mainly includes image reading, image preprocessing, temperature extraction of electrical equipment, infrared image segmentation, and electrical equipment recognition. In this

study, the infrared image recognition module focuses on the noise processing of electrical equipment infrared images, as well as extraction and classification of image features. In response to the issue of infrared images being susceptible to factors such as noise, a series of processing measures were carried out. It has improved the research content of the infrared image recognition module in the intelligent detection system of electrical equipment.

Fig. 2. Infrared image recognition module.

Noise characteristic analysis is one of the main characteristics of infrared image characteristics, and image noise has a certain degree of randomness and regularity. Noise has a significant impact on the detection of electrical equipment images, mainly including background noise, detector noise and amplifier noise, etc. The infrared image can be denoised by using Gaussian filter, mean filter, median filter, and other methods. The median filter can calculate the results in linear time. This method is simple in calculation and can perform fast filtering processing. The noise processing process of median filter algorithm includes the following contents. First, all pixel values in the neighborhood of pixel to be processed are arranged into a sequence according to the size of the pixel value. The pixel value at the interval position is the desired median. Then, the pixel values that need to be processed are replaced with median values to improve the closeness between the neighboring pixel values and the true values in Fig. 3.

Fig. 3. Schematic diagram of the principle of median filtering.

In the median filtering algorithm, a window is defined that it is mostly odd with a length of $L = 2N + 1$, and N is a positive integer. The sample signal $\{X(i - N), \dots, X(i + N)\}$ can be obtained. Formula (1) is the output value of the median filter.

$$Y(i) = MED\{X(i - N), \dots, X(i), \dots, X(i + N)\}, i \in Z \quad (1)$$

In formula (1), $X(i)$ is the value of window center signal sample, $N = (L - 1) / 2$, and Z represents the set of integers. The median filtering template is larger, the noise removal effect is better, but the clarity of the infrared image decreases. To effectively remove noise and ensure the details in infrared images, researchers propose an AMF. This method can automatically select template size and select the smallest

template for filtering processing when corresponding pixel value noise removing. It can simultaneously remove noise and ensure image clarity. In AMF, the window corresponding to the image pixel (x, y) during filtering is first defined as S_{xy} , and then the following two processing processes are performed. The first step is the processing of the first layer in formula (2).

$$Z_{A1} = Z_{med} - Z_{min}, Z_{A2} = Z_{max} - Z_{med} \quad (2)$$

In formula (2), Z_{min} , Z_{med} , and Z_{max} represents the minimum, median, and maximum values of pixel grayscale in window S_{xy} , respectively. If $Z_{A1} > 0$ and $Z_{A2} < 0$, it needs to be transferred to the second algorithm layer. On the contrary, it is necessary to increase the size of window S_{xy} . If the size is less than or equal to the maximum window size allowed by S_{xy} , then the processing of the first layer needs to be repeated. Otherwise Z_{med} will be output. Formula (3) is the processing method for the second layer.

$$Z_{B1} = Z_{xy} - Z_{min}, Z_{B2} = Z_{max} - Z_{xy} \quad (3)$$

In formula (3), Z_{xy} is the grayscale value at pixel point (x, y) . If $Z_{B1} > 0$ and $Z_{B2} < 0$, the current Z_{xy} is output, otherwise Z_{med} is output. AMF can be used to filter out salt and pepper noise. During image processing, it needs to preserve image details as much as possible while removing noise. After denoising, infrared images become blurry, making it difficult for subsequent feature extraction and recognition. Therefore, image enhancement processing is also required after denoising [18]. The grayscale histogram of infrared images can provide information such as the overall contrast, average brightness, and dynamic range of image pixel values. To enhance the clarity of infrared image gray histogram, piecewise linear transformation, gamma correction and histogram equalization can be used to enhance the clarity of image details. In this experiment, the adaptive histogram equalization method is selected for image enhancement. The main improvements of this method in image processing include two points. Firstly, the grayscale threshold of the histogram is set, and the parts exceeding the threshold are cropped. And it is evenly divided into various gray levels to avoid excessive enhancement of noise points. Secondly, interpolation methods are used to accelerate the equalization of grayscale histograms. After the equalization of adaptive histogram, the gray histogram of infrared image can enhance image contrast without obvious noise enhancement.

B. Intelligent Detection Algorithm based on DL and Infrared Images

After preprocessing the infrared image, it is necessary to extract and classify the image features. SSD can classify the feature maps of the infrared image according to their size for target detection at various scales. When conducting intelligent detection of electrical equipment, the first step is to input the infrared image of the electrical equipment. After the feature extraction through convolutional layers, feature maps with different scales are generated. Then, prior boxes of different

scales are generated on these special maps with different scales, and the predicted target boundary boxes are detected and classified. On this basis, redundant detection boxes are suppressed and deleted, and finally detection results are

generated. The method of suppressing detection boxes is processed using non-maximum values. Fig. 4 shows the flowchart of the SSD algorithm.

Fig. 4. Flowchart of SSD.

The length and width of prior boxes number and prior boxes in SSD need to be set in advance. These parameters can significantly affect the efficiency and accuracy of algorithm [19]. In response to the characteristics of electrical equipment fault detection, appropriate prior boxes need to be set, so SSD can be improved. The improved SSD first utilizes the K-means algorithm to iteratively analyze data targets and find the optimal number of prior boxes. Due to the fact that Euclidean distance is a commonly used method in K-means, this method can increase the computational error of the larger prior boxes. The intersection over union (IOU) of two prior boxes is selected as the standard for method judgment in formula (4).

$$IOU = \frac{Detection \quad Result \cap Ground \quad Truth}{Detection \quad Result \cup Ground \quad Truth} \quad (4)$$

In formula (5), *Detection Result* is the predicted bounding box and *Ground Truth* represents the true bounding box. IOU value reflects the proximity between the predicted bounding box and the true bounding box, which is proportional to each other. Formula (5) is the Euclidean distance calculation based on IOU as the standard.

$$d(box, centriod) = 1 - IOU(box, centriod) \quad (5)$$

In formula (5), *box* is the prior box and *truth* represents the true box. Formula (6) is the objective function of K-means.

$$S = \min \sum_{i=1}^k [1 - IOU(box - truth)] \quad (6)$$

When $k=4$, the clustering objective function remains basically stable, so the number of prior boxes is set to 4. After determining the setting of prior box parameters, improvements are made to the basic network. VGG-16 is used for extracting features, which has high testing accuracy but high computational complexity. To reduce the computational difficulty and improve the computational speed, researchers proposed the MoblieNet network structure [20]. MoblieNet

network can convert ordinary convolutions into a combination of deep convolutions and point convolutions using deep separable convolutions. Formula (7) is the calculation of deep separable convolutions.

$$F \times F \times D \times N \times N + 1 \times 1 \times D \times K \times N \times N \quad (7)$$

In formula (7), F means convolution kernel dimension, D is input depth, N refers to input width and height, and K represents output depth. By comparing deep separable convolutions computational complexity with that of standard convolutional networks, the comparison result representation method in formula (8) can be obtained.

$$\frac{F \times F \times D \times N \times N + 1 \times 1 \times D \times K \times N \times N}{F \times F \times N \times N \times D \times K} = \frac{1}{K} + \frac{1}{F^2} \quad (8)$$

If 3×3 convolutional kernel is used in the calculation, the computational difficulty can be reduced by 8-9 times. The MoblieNetV2 network structure uses 1×1 convolutional layer to expand the number of feature map channels. Then, the feature extraction of infrared images was carried out, and 3×3 deep separable convolution method is used. Next, the extracted image features were dimensionally reduced, and 1×1 convolutional layer was selected. In MoblieNet V2 network structure, the linear activation function is used at the low dimension layer, and the feature reuse structure of ResNet is introduced to improve the low dimension data collapse and the lack of reuse features in the MoblieNet V1 network. It can improve the accuracy of the algorithm and reduce latency. To make the network layer thinner, the width scaling factor α is introduced in the MoblieNet V2 network structure, which changes the depth of the input and output channels to αD and αK , respectively. In formula (9), the computational complexity of the MoblieNet V2 network can be reduced to α^2 of the original computational complexity.

$$F \times F \times \alpha D \times N \times N + 1 \times 1 \times \alpha D \times \alpha K \times N \times N \quad (9)$$

MoblieNet V2 network structure optimizes the network structure and activation function on the basis of MoblieNet V1. While improving testing accuracy, it can also save more feature information, reducing computational difficulty.

Therefore, in this experiment, the VGG-16 basic network of the SSD algorithm will be replaced with the MoblieNet V2 network structure. The improved SSD algorithm is developed to improve the algorithm's computational speed and testing accuracy.

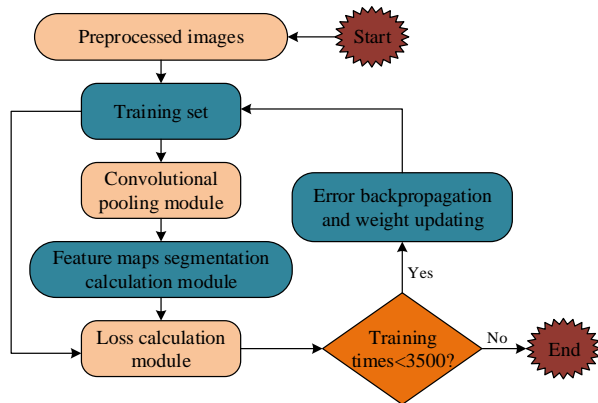

Fig. 5. Training flowchart of improved SSD algorithm.

Fig. 5 shows the training flowchart of the improved SSD algorithm. When algorithm training, the loss function uses the weighted sum of the position error loc and the confidence error $conf$ of SSD in formula (10).

$$L(x, c, l, g) = \frac{1}{N} (L_{conf}(x, c) + \alpha L_{loc}(x, l, g)) \quad (10)$$

In formula (10), N means positive samples number, c represents the confidence value of the predicted category, l stand for the position of the predicted corresponding bounding box, g represents the position parameter of the true bounding box, and α refers to the weight coefficient. For loc , the $smooth_{L1}$ loss function in formula (11) is used.

$$smooth_{L1}(x) = \begin{cases} 0.5x^2 & |x| < 1 \\ |x| - 0.5 & otherwise \end{cases} \quad (11)$$

From this, the calculation of L_{loc} in formula (12) can be obtained.

$$L_{loc}(x, l, g) = \sum_{i \in Pos} \sum_{m \in \{cx, cy, w, h\}} x_{ij}^k smooth_{L1}(l_i^m - \hat{g}_j^m) \quad (12)$$

In formula (12), cx, cy are the center coordinates of the positioning box, w, h are the width and height of the positioning box, and \hat{g} is the value obtained after encoding. Formula (13) is the encoding method for central coordinate.

$$\begin{cases} \hat{g}_j^{cx} = (g_j^{cx} - d_i^{cx}) / d_i^w / variance[0] \\ \hat{g}_j^{cy} = (g_j^{cy} - d_i^{cy}) / d_i^h / variance[1] \end{cases} \quad (13)$$

In formula (13), d represents the prior box position, and

$variance$ is hyperparameter, and \hat{g} can be scaled. Formula (14) is the encoding method for width and height.

$$\begin{cases} \hat{g}_j^w = \log(g_j^w / d_i^w) / variance[2] \\ \hat{g}_j^h = \log(g_j^h / d_i^h) / variance[3] \end{cases} \quad (14)$$

For $conf$, the softmax loss function in formula (15) is used.

$$L_{conf}(x, c) = - \sum_{i \in Pos} x_{ij}^p \log(\hat{c}_i^p) - \sum_{i \in Neg} \log(\hat{c}_i^0) \quad (15)$$

In formula (15), $x_{ij}^p \in \{1, 0\}$, which represents the parameter indicator. $x_{ij}^p = 1$ means that the predicted boundary box i is in a state of coincidence with the actual boundary box j . At this point, the category is p , and the higher the probability prediction, the smaller the loss. Therefore, the probability passes and softmax is generated.

IV. EXPERIMENTAL RESULTS AND ANALYSIS

A. Performance Verification Experiment of Intelligent Detection Algorithm

AMF can effectively reduce the interference of salt and pepper noise, and the processed infrared image quality can be improved with less external influence, making the process more convenient and faster. The denoising performance of AMF is compared with that of Gaussian filter, mean filter, and median filter algorithm. Signal to Noise Ratio (SNR), Peak Signal to Noise Ratio (PSNR) and Mean Square Error (MSE) are selected as performance comparison indicators. SNR and PSNR are larger, as well as MSE is smaller, algorithm's denoising effect is better. The deep learning framework is Tensorflow-1.13.0rc2. During network training, the initial learning rate is set to 0.0001, the beam size is 16, the encoding scaling factor variable = [0.1 0.1 0.1 0.2 0.2], and the weight coefficient of the loss function is $\alpha=0.2$. The results are shown in Table I.

From Table I, the SNR and PSNR of AMF are greater than those of Gaussian filter, mean filter, and median filter algorithms under different noise concentrations. The MSE of AMF is less than that of Gaussian filter, mean filter, and median filter algorithms. The performance comparison results of different noise processing methods show that AMF is better than Gaussian filter, mean filter, and median filter algorithms in infrared image noise processing.

In Fig. 6, the filtered images of different methods were compared when the noise concentration was 0.02. From the figure, AMF has a higher clarity of the filtered image and better similarity to the original image. Compared to other image processing methods, AMF exhibits better image processing performance. This method can effectively handle the impact of noise and has better denoising effect.

TABLE I. RESULTS OF DIFFERENT NOISE TREATMENT METHODS

Mean average precision (mAP) can be used to evaluate the performance of network models. In the performance research of the intelligent detection algorithms based on DL and infrared images, mAP was used to evaluate the performance. Fig. 7 shows the mAP curve in validation set. From Fig. 7, as the number of training sessions increases, the mAP value of the proposed model continues to increase. In 0-1200 iterations,

the mAP value changes the most significantly and the accuracy increases significantly, indicating that the model is still in the learning stage in the 0-1200 iterations. When iterations exceed 1200, the mAP value gradually stabilizes and the curve gradually converges. After the model was trained in the validation set, its average accuracy was tested in the test set, and the final mAP value measured was 92.58%.

Fig. 6. Filter images of different algorithms.

Fig. 7. mAP curve.

Fig. 8. Change of loss function value and quasi curvature.

The loss function can be used to describe the convergence degree of algorithm, and the accuracy can reflect algorithm precision. Therefore, this study will compare the performance of the proposed algorithm with VGG-16, MoblieNet V1, and MoblieNet V2 in Fig. 8. The algorithm in this paper tends to be stable after 500 iterations and reaches the convergence state. Its final loss function value is 0.31. Its accuracy stabilized after 950 iterations, and its final accuracy was 92%. Compared to VGG-16, MoblieNet V1, and MoblieNet V2, this algorithm has higher convergence speed and accuracy.

Fig. 9. Comparison of PR curves.

Precision (P) and Recall (R) are used to describe sample classification accuracy and have many applications in evaluating model performance. The Precision Recall (PR) curve is a comprehensive judgment of P and R. This study compared performance of our algorithm with VGG-16,

MoblieNet V1, and MoblieNet V2. The results are shown in Fig. 9. From Fig. 9, the area under PR curve of the proposed algorithm is higher than that of VGG-16, MoblieNet V1, and MoblieNet V2 algorithms, proving that the optimized SSD algorithm has good accuracy. The image feature extraction accuracy in improved algorithm is good, and the running time is shortened, which has good detection and classification performance.

Fig. 10. Comparison of ROC curves.

In Fig. 10, the receiver operating characteristic curve (ROC) of different algorithms was simultaneously verified. From the figure, the area under ROC curve of the algorithm proposed in this experiment is the largest, and the validation results of ROC curve are consistent with those of PR curve. Based on the above performance analysis results, the algorithm proposed in this experiment has high accuracy, short running time, and good performance.

B. Simulation Analysis of Intelligent Detection System for Electrical Equipment

Circuit breakers in electrical equipment may be damaged if they are out of oil or in other abnormal conditions. In severe cases, explosions may occur and intelligent detection of circuit breakers is necessary. In the simulation analysis of the intelligent detection system for electrical equipment, the experiment selected the fault detection of circuit breakers for example analysis. Firstly, pre-processing such as noise reduction and image enhancement was performed on the collected infrared of the circuit breaker. Then, an improved algorithm was used for graphic feature extraction and classification. By comparing abnormal and normal images, the abnormal condition of the circuit breaker was analyzed and judged. To verify the superiority of the intelligent detection method for electrical equipment based on deep learning and infrared processing technology, the threshold method, region method, clustering method, and the methods in this experiment were compared for anomaly detection of circuit breakers. The results are shown in Fig. 11.

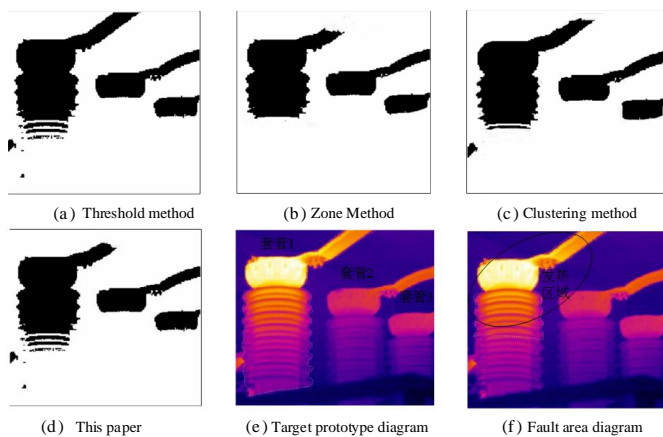

Fig. 11. Comparison of infrared image analysis of circuit breakers.

From Fig. 11, in the original image of the circuit breaker, there is a large heating area in sleeve 1. After the judgment and analysis, the contact of sleeve 1 has a heating situation, and there is also a problem of poor contact, resulting in abnormal heating of the sleeve. After comparing four detection methods, it can be seen that the improved infrared image is closer to the real image. At the same time, the fault degree of various detection methods was compared. The improved method detected a fault degree of 57.85%, which is closer to the 59.74% in the real situation. Its fault detection accuracy is higher. The intelligent detection system established in this experiment can be better applied to the fault detection of electrical equipment. In order to verify the effectiveness of the proposed method in detecting fault states, comparative experiments were conducted on a test set for 20 types of faults. At the same time, the fault detection rates of different detection methods [21-22] were compared, as shown in Table II. The best detection results for each type of fault in the table are highlighted in bold. The experimental results show that the proposed method achieved the best results 14 times, which is higher than other methods. At the same time, the proposed method has a detection rate of more than 10% higher than other methods for faults 16 and 19. The above

simulation results confirm that the proposed method exhibits high detection performance in electrical equipment fault detection.

TABLE II. RESULTS OF FAULT DETECTION RATES

Fault type	Reference 21	Reference 22	Reference 23	This paper
Fault 1	99.38	99.40	94.53	100.00
Fault 2	99.25	97.61	98.51	98.75
Fault 3	28.16	67.46	92.54	56.52
Fault 4	99.50	99.50	91.54	100.00
Fault 5	34.46	99.40	92.54	91.79
Fault 6	100.00	100.00	100.00	100.00
Fault 7	100.00	100.00	100.00	100.00

Fault 13	84.95	91.44	89.55	97.01
Fault 14	99.50	99.50	96.52	100.00
Fault 15	34.06	65.17	32.84	52.34
Fault 16	54.97	87.26	87.56	98.26
Fault 17	94.77	92.44	91.54	94.72
Fault 18	90.05	91.24	88.56	100.00
Fault 19	41.92	75.02	45.37	87.94
Fault 20	62.07	86.37	81.59	89.68
Average value	74.46	88.82	83.26	90.92
Optimal number	6	3	3	14

V. CONCLUSION

The electrical equipment detection system requires accurate status recognition and judgment of electrical equipment to ensure the safety of production practice. In this design of the electrical equipment intelligent system, deep learning technology and infrared image processing technology are used to identify and judge the abnormal situations of electrical equipment. The experimental results of noise processing shows that the SNR and PSNR values of AMF are higher than those of Gaussian filter, mean filter and median filter algorithms. The MSE values of AMF are lower than those of other algorithms. In the research of infrared image processing, when the iterations exceed 1200, the mAP value of the improved SSD gradually stabilizes and the curve gradually converges. After this model was trained in the validation set, the improved algorithm was tested for average accuracy in test set, and the final mAP value measured was 92.58%. The area under PR curve of improved SSD algorithm is higher than that of VGG-16, MoblieNet V1, and MoblieNet V2 algorithms, demonstrating its good accuracy. In actual fault detection experiment of electrical equipment, the fault degree of various detection methods was compared. The

improved method detected a fault degree of 57.85%, which is closer to the 59.74% in real situation, and its fault detection accuracy is higher. The intelligent detection system established in this experiment can be well applied to electrical equipment fault detection. This study is based on a deep learning system for anomaly recognition of electrical equipment, which can automatically recognize infrared images of equipment captured during inspection tasks. When the equipment is abnormal, a warning message is issued to remind the staff to inspect and repair it, so that problems can be detected in a timely manner. This can prevent larger grid failures and greatly reduce economic waste and human and material resources. At present, this method is still in secondary development and testing, and has not been widely applied in the power grid. The main reasons are as follows. Firstly, most of the samples of infrared devices come from daily infrared charged detection, which has problems such as a small sample size, inconsistent format, non-standard shooting, and lack of data labeling. These issues directly constrain the improvement of diagnostic accuracy of infrared devices based on big data. Moreover, the appearance of different devices varies, which can have an impact on the adaptability and accuracy of recognition and partitioning algorithms. At present, the deep neural network used for infrared image partitioning requires a large amount of computation, mainly relying on the computing power of the backend server. From a practical application perspective, there is an urgent need for real-time diagnosis in infrared detection sites. Real time diagnosis can provide more timely equipment defect prompts for professionals, avoiding unnecessary retesting and retesting. However, due to the large amount of image information and the large number of image files, the use of background diagnosis mode requires high transmission bandwidth. They increase the burden on communication links and network backend, and also reduce the reliability of the entire diagnostic system. Therefore, further improvements are needed in future research on this detection method.
