A DIY Approach to Uni-Temporal Database Implementation *

Haitao Yang, Fei Xu, Lating Xia
GuangDong Construction Information Center (GDCIC)
Guangzhou, China

Abstract—when historical versions of data are concerned for a MIS (Management Information System) we naturally might resort to temporal database products. These bi-temporal products, however, are often extravagant and not easily mastered to most of MIS practitioners. Hence we present a plain DIY (do it yourself) solution, the Audit & Change Logs Mechanism-based approach—ACLM, to meet the uni-temporal requirement from restoring historical versions of data. With ACLM programmers can code SQL scripts on demand to trace and replay any snapshot of historical data version via RDBMS built-in functions, they need not to shift away from their usual way of coding stored procedures for data maintenance. Besides, the ACLM approach is compatible with meta-data change, and its additive overhead was instantiated imperceptible for throughputs of routine access with a typical scenario.

Keywords—DIY solution; recurrence; historical snapshot; uni-temporal database; MIS

I. INTRODUCTION

Recent years’ practices in developing web creditable MIS for numerous users made us all realized that maintaining enormous records of users-oriented data are an unbearable task to anybody (individuals or organs). Regarding that it is users or clients’ own right and responsibility to keep their delivered data valid and complete, we were looking forward to an interactive and sharing pattern that all users involved should honestly maintain their information themselves, which is perhaps the only workable approach. Then, there comes the risk of abuse of self-maintenance right. To prevent such a risk we have no feasible solutions of instant response but can build a final line of defense by an ex post facto measure that is, logging all behaviors of maintaining data and offering a facility to restore or reveal any historical version of concerned data and the responsible manipulators. Herewith we get to the field of uni-temporal database application, and might assume products of temporal DBMS (in short, tDBMS) as a matter of course. tDBMS products, however, are bi-temporally-oriented, and not familiar to most of practitioners in ordinary MISs. Even worse, such products often offer extra functions well beyond need and bring with much greater complexity and higher cost than expected. Upon these considerations, we turned to explore an exercisable and methodological approach (that why we refer to it as DIY -- do it yourself).

II. RELATED WORK AND OUR DIRECTION

In realistic applications, data recorded in databases all have certain time properties either explicit or implicit, at least those indicate when the data are valid and when they are recorded [6] — the former is a time property with data semantics, classified as the valid-time property, and the latter is a time property with data operation, categorized into the transaction-time (time of manipulating data) property. Contemporary RDBMS products have granted us the ability to straightly store and manage all relational data including temporal data in the same database, notice that data’s time property is also a datum. To certain extent, temporal data is an issue of data versions that concerns with data recordation at different times. It is not feasible for all time versions of data are treated in equivalence, since eventually the ever-increasing amount of historical versions will become overwhelming on all aspects of data storage and usage. Approaching such a problem and its related, a study of temporal DBMS has been developed for decades [1]. Despite lots of research on tDBMS, practical tDBMS products are rare, and even more, most of them are in fact an extension of traditional RDBMS [11], in general developing a tDBMS application is still a tough and often individualized task for a MIS (Management Information System) developer team.

In usual practices of developing MIS, we normally design and develop a database application around usage of the newest data version, because in default, people much concern with the current status rather than those historical. If no requirement of recalling a historical “snapshot” (we use this term to refer to a picture of data at a historical time), historical statuses of data will be updated or overlaid by the newest one, and everything is just simple as usual. But if the responsibilities of conducting data change is of the concern, e.g., they must be audited or traced afterwards (a lot of crucial MIS applications have this requirement), in which historical statuses of data need to be carefully and explicitly addressed, we actually step in the scope of tDBMS. Up to now, tDBMS approaches in mainstream, such as the famous ATSQL2 proposal are conducted in a direction of treating time properties of data as an abstract or super attribute with special disposal [10], and they are based on relational data processing, of which the most concerned are often associated with their special temporal data type, temporal manipulation on table or column-level, and dedicated temporal relation constraints etc. In these practices, accordingly, special time attribute-oriented extensions to SQL must be introduced to and well supported by tDBMS. Despite temporal SQL-compliant research has been very comprehensive these days, however, the related SQL-level support mechanism, temporal database model theories, etc., are sophisticated and too much for most of applications just involved with some plain temporal requirements as in ordinary MIS. Most of MIS practitioners would rather treat temporal parts of MIS applications in a similar way as in ordinary DBMS programming practice, e.g.,

www.ijacsa.thesai.org
assigning each intended time property of data into a concrete data attribute, and so on. Thereby, we prefer a system mode of “traditional RDBMS” + “software”. Here, the “software” could be programs as a part of the hosting application itself, or in an embedded type as a third-product software product (often as a middleware), e.g., the well-known TimeDB [12] is a RDBMS-based embedded middleware for temporal data applications, TimeDB runs as a frontend to the hosting RDBMS (e.g., Oracle) and supports the temporal query language ATSQL2, where finally ATSQL2 statements are compiled by TimeDB into (sequences of) SQL-92 statements which are executed by the underlying RDBMS backend. The pure temporal disposal part (software) of TimeDB is to interface between the temporal usages (delivered in ATSQL2 statements by users) and SQL-92 executions.

As we know, tDBMS products such as TimeDB often store the transaction-time of data in the same data tuple. Such a device is inefficient for OLTP (On-Line Transaction Processing), considering that if data items are frequently updated, the data table where these items reside will soon be overwhelmed by historical versions of data, which we figured as a so-called 99 to 1% phenomenon, i.e., 99% (symbolizing most) data records are for past statuses while 1% (symbolizing a little proportion) for the current or latest status, while most of accesses to the data table are just for the 1% records. On this aspect, we believe that many MIS practitioners like us would rather try an on-hand and less costly scheme than take an abstruse academic approach or purchase an often too costly or heavy tDBMS product.

For generality and practicability, basing on the above consideration and rules of engineering we believe that a good approach for the issue discussed should be a methodological one with ease of use or duplication, in the other word, a DIY (Do It Yourself) type, and which should adopt an outline pattern of separating historical versions of data from the current one, and provide guidelines for designing fundamental maintenance, management and utility services of data. Along this direction, we start our approach by introducing several key concepts in a simple but typical example about temporal data recordation:

P1 = (“John”, 2000, interval_1) | a data record with its valid time indicating John has a salary of two thousands dollar.

P2 = (P1, 11/5/2012 4:44 PM) | the above data record P1 was created or updated at 11/5/2012 4:44 PM.

The statement from P1 is true only for its valid time period interval_1, but what from P2 that recorded a fact is always true. The valid period interval_1 can be definite as [time1, time2], or indefinite as [time1, unknown] that spans from time1 until something happens (e.g., John’s salary is changed or he is dismissed, etc.) when the unknown becomes a certain value. Generally we are not likely to maintain valid time properties via an automatic mechanism since they are associated with concrete semantics of the data they modify, as in the above simple example, when and how to make the unknown time known is up to the intelligence of realizing the corresponding event and its relevancy; but it is different with transaction time properties since they simply denote a data manipulation event that can be monitored via certain DBMS built-in mechanisms.

We doubt in nature there is any universal automatic scheme to cope well with storage, management and usage of valid time property of data, despite lots of techniques on related issues. In the other side, for a real relation object its valid time attribute and its other attributes are all in an equal position with respect to relational data theory and application semantics, thus they could be and should be treated equally if convenient.

Further, we clarify three key facts which are often ignored: 1) the valid-time property of data virtually can only be actively determined by who understanding the data meaning, perhaps an intelligent software can do this, but developing an intelligent software is far beyond the scope of applied tDBMS research; 2) for web data applications, the responsibility audit about data manipulation could not be done within DBMS since conventionally different web users share a common DBMS account; 3) data structure changes cannot be excluded in real applications, for instance, adding or retiring a field in a data table (in practices, a relation is often instantiated as a table of records, an attribute as a field of record in the table) for one or other reason is allowable.

Accordingly, we have three keynotes for a feasible tDBMS implementation: (1) the valid-time property of data should be considered in the context of data application; (2) the responsibility audit of data manipulation needs participation from higher layers of application outside DBMS; (3) a good implementation mechanism for tDBMS should be compatible with ordinary structure change of data tables. Following these guidelines, towards a generic design scheme for tDBMS-related MIS applications we focus on the transaction-time property of data (so we call this approach as of the uni-temporal database implementation) and treat it as a common attribute [9], this is contrasted with the nowadays so-called “bitemporal database” [11], i.e., a general temporal database.

III. V+A FRAME FOR TDBMS APPLICATIONS

Along the above decided direction of investigation, the underlying thing is to set up a software frame for tDBMS applications.

Firstly, concerning temporal evolvement of data content we noticed two main disposals of transaction-time of data: (1) using self-contained temporal recordation of data manipulation, often in a vitae form, i.e., each maintenance manipulation on a data item should append its execution time to all data records changed, there is no need for additional logging mechanism; (2) devising dedicated temporal logging mechanism for recording data manipulation activities, which notes down the transaction-time in a log separate from the data table.

Secondly, for the sake of practicability we shall take into account a common phenomenon of meta-data change — change to the composition of data table’s PK (primary key), such as using different component fields or altering the data type of some component fields — which was often ignored by most of tDBMS approaches.

Thirdly, Application requirements on storing, managing, and hereby using time properties of data are versatile, but for usual cases of MIS they can be classified into two types: the time property that is used frequently or routinely should be accessed easily, whereas the others without routine usage can
do with less convenience of access for a much lower cost of implementation.

Accordingly, we proposed the Vita + Audit (in short, V+A) frame. The kernel of V+A frame consists of DRB (direct-retrieval base) + ACLM (audit & change logging mechanism). DRB is used to store usual data content, i.e., current-status data and temporal recoredation in a vita form for direct accesses of routine transactions. Contrasting with DRB ordinary services for direct content access, ACLM is for dedicated audit accesses regarding data manipulations with transaction time — it keeps trace of each activity of data manipulation, memorizes into the change log the data snapshot of the data version just before the data manipulation exerts on DRB each time, and at the same time inserts into the audit log a record about what kind of data manipulation and who makes that manipulation. Under ACLM we should not miss any historical version of data being audited though we could not view directly its content in a single SQL manipulation.

In general, data query operations need not being logged in the audit log except for applications with extremely high safety demand since they do not create any new version of data, neither content of an insert operation needs recordance since it has no previous version. But the insert operation itself shall be recorded in the audit log in order to restore historical versions of data table before the operation timestamp. One main usage of the audit log is to record the responsible subjects of data maintenance — the actual operators from client end (terminal users) instead of those common DBMS accounts on the web DBMS. In convention of software industries, user identity certification for web applications is fulfilled before calling functions of web data layer, and normal accesses to a web DBMS are requested via some shared DBMS account. To log the identity of a user (who instructed DBMS to execute a data manipulation) into a record of the audit log, the web user certification information should be passed into a corresponding inner procedure of the web DBMS. Manipulation of changing data content (Update, Delete, or Insert) and its recordance in the audit log and change logs should be treated within a single DBMS transaction as an atomic action (either both succeeded or anything they did will be withdrawn completely afterwards). Such transactions shall be coherently fulfilled through a stored procedure of DBMS script on the intermediate layer.

A. Audit Log

For each application the audit log is unitary, it is used in a way similar to keeping accounts of any change or comment on any data record of DBR: (1) recording any SQL-update, delete, and insert manipulation; and (2) logging any responsible comment on a data snapshot. The former is oriented to generic syntactic audit while the latter is about important semantic audit. The audit log in ACLM is application-oriented, i.e., all data tables from the same application share a unitary audit log. The structure of the audit log is defined as relation Adt_log described in Table I (data type in this paper are all given as in Oracle DBMS). Complementarily, a PK specification defined as relation PK_spec in Table II is introduced for all involved versions of PK structure of each data table from the same application, where one row of specification is for a member attribute of a PK.

</table>

Further explanation of the audit log’s definition and related usage are detailed as follows:

1) The basic design of the audit log is applied directly to data tables with a single attribute PK (unitary PK). In relation Adt_log, attributes D_table_name is used to store the name of the data table being audited, D_key_value is used to store the PK value of the data record being audited. As to data tables without a unitary PK, more additive disposal is needed, see later in section IV. In relation PK_spec, PK_attribute_seq=0 is corresponding for unitary PK cases, while PK_attribute_seq>0 for non-unitary PK cases.

2) In fact, all MISs should know the PK composition of their data tables via something like PK_spec in advance of executing data maintenance. With PK_spec we need not include PK_attribute_name in Adt_log, which can prevent a transition dependency <D_table_name, PK_attribute_name> occurs in Adt_log.

3) To cope with meta-data changes, Struct_Valid_S_time attribute of relation PK_spec is set to indicate the start time that a version of PK composition became valid. The expired time of a valid PK composition is given subsequently by a next value of Struct_Valid_S_time in sequences for the same data table.

4) Attribute Operation_type has a set of basic values (D (Delete), U (Update), N (Insert)) and an extended value C (Comment). Attribute Comment is used to record any responsible literal comment (including endorsement) on the data record being audited, it is left empty (assigned a null value) when Operation_type>0. Value usages of attribute Comment can be extended and further categorized if needed in applications, e.g., classified into Censor and Verification, etc.

5) Attribute Timestamp is used to note down the time when the current audit record was created. To avoid ambiguity it is stipulated that the time of a web server’s clock be adopted, and relevantly-logged data changes take effect just after the instant of Timestamp.
6) Signature is for storing the result of RSA calculation of Hash value of objects being signed by terminal users with their private key [8, 3]. A signed object consists of all content attributes (except maintenance and auxiliary attributes) of the data record under audit, and attributes from seq. 1 to 7 in Adt_log. The Hash value of a signed object is computed on the concatenated contents (all converted into the string type) of each involved attribute.

7) Any Update manipulation to alter a PK’s value shall be equivalently decomposed into a Delete manipulation on the data record with the present PK value, and a subsequent iNsert manipulation of the updated data record with a new PK value.

Locking a data table during submitting a comment on its data record could lower the risk of mismatching the comment with a newer data version that was being created in the same time. Of course, freezing the data table for the whole process of comment action can exclude such a risk completely, but which will bring along with a more serious problem that normal data maintenance might be blocked for an uncertain (at worse often rather long) time by some comment activity, and the situation probably become even worst if the comment right is abused. Thus we in practice shall set a threshold of time limit for locking (e.g., 10 minutes) to avoid involving sophisticated lock/unlock mechanism. Conclusively, we have several more principles of using audit log:

- Applicable to record verification results in a generalized form of literal comment.
- To log each behavior of deleting, inserting, updating or verifying a data record, and the manipulator’s digital signature about the essential content of the audit record in the same audit record.
- Separating historical data’s storage, i.e., they are kept elsewhere (in the change log).

B. Change Log

The direct usage of change log is to record any data version just before it become outdated, which enables the occurrence of any historical data snapshots later. We shall record in the change log the current value of each data attribute bound for a content change just before the change operation is carried out, and the change operation being taken shall be noted down in the audit log at the same time. The data structure of change log is as defined in Table III, where attribute valbfchg stores the value-before-change for attribute chgfldname that stores the name of an attribute undergoing a value change, while the expiration time of content of valbfchg is indicated by attribute timestamp from a correlated record (being correlated through the value of Audit_ID) in the audit log Adt_log. For example, Adt_log.timestamp="time1", Chg_log.chgfldname="name" and Chg_log.valbfchg="John smith" specified that data attribute name had a value of "John smith" just before time "time1".

The value-before-change of each data attribute (indicated with the content of chgfldname) that underwent a value change, except of lob type (Clob/Blob) shall be consistently converted into the string type and then put in attribute valbfchg. If a changed attribute is of lob type, its value-before-change shall be deposited in attribute lob_value while valbfchg is left empty.

For data attributes of binary lob type, we shall use an additive attribute ContentType [4] to further specify their content type to facilitate web applications for presenting such content.

C. ACLM Operation

The procedure of ACLM operation is outlined as follows:

1) A web service of data maintenance calls a DBMS stored procedure [7] to execute a dedicated data manipulation (iNsert | Update | Delete | Comment), noticing that C type operation is writing to the comment attribute of the audit record;

2) The DBMS stored procedure fulfills the data change on each target data table and correspondingly inserts a new audit record into the audit log with the matched type assigned to the attribute Operation_type within a single transaction;

3) Triggers of each target data table are ignited [7] to insert corresponding log records into the change log.

This software mechanism is illustrated as Fig.1.

![Fig. 1. Diagram of tDBMS software operation](image)

Under ACLM, whenever calling a DBMS stored procedure to fulfill a process of data change (Update, Delete, iNsert) or data inspection (Comment) it is requested to specify whether to simultaneously write the audit and change logs, if yes (ACLM function enabled normally) then the calling program shall also ascertain the timestamp of logging a record into the audit log through an interface of the invoked DBMS stored procedure, regarding that a web server’s clock is adopted, see paragraph 5) of subsection III.A. Since digital signature can only be made in
client ends where user private keys are available, and attribute timestamp in relation Adt log is one of digital signature objects, thus the client end must get the time of web server just before user making digital signature. An individual ACLM operation involves two basic actions: A1 — exerting data changes, and A2 — logging such actions in both the audit and change logs. We propose not to execute A1 and A2 in separate web services, since combining two web services as a transaction (all done or nothing) will involve very sophisticated disposal, e.g., if A1 is successful but A2 is not, A1 has to be rolled back, then we have to pay off the cost of rolling back A1 due to A2; and what is more, sometimes (due to poor communication qualities) we cannot judge if A2 is successful or not (it might succeed but its reply was lost or simply delayed), unless we decide according to a time limit, but specifying a time limit is a trade-off issue, often very subtle.

Thus, we shall request a DBMS to conduct both A1 and A2 via a single web service call, which means whenever submitting a data change call we should have the companying signature value prepared for the audit record at the same time (must in advance obtain the values of timestamp and Audit_ID as parts of content to sign).

The above description implies a sequence of steps for carrying out a data change manipulation under ACLM: (1) pre-read content of a target data record to prepare the change action, (2) get the server’s time for digital signature, (3) submit the manipulation request to the hosting DBMS via a web service, (4) log the manipulation into the audit and change logs. Here, we have an order of timestamps: timestamp (pre-read) < timestamp(signature) < timestamp(submit) < timestamp(log). For better uniform simplicity, timestamp (pre-read) is adopted to substitute the rest of timestamps. This is because:

1) it wouldn't influence consistency of retrospecting historical snapshots; (2) be competent for re-showing historical snapshots for cases without demand of extremely precise accuracy; (3) is impossible within a one-off web calling to include into the digital signature a precise time of writing data table. Regarding that the web server functions as the centrum of ACLM, it is proper to grant attribute timestamp with the reading of the web server’s clock.

Note:

1) Triggers of data table need to read contents of attribute Audit_ID and timestamp from the corresponding record of the audit log. Each record of the change log correlates to a unique record of the audit log, whereas each record of the audit log correlates to a group of records of the change log except those audit records of non-change type (no changing any existent data, e.g., insert or comment type), records from both logs are correlated via values of a common attribute Audit_ID.

2) If a round of data change process begins at a halfway phase (one or several rounds of data change were executed before, but none of them are regarded complete, i.e., all of their execution results are halfway, and saved into their DRB data table temporarily), then we strongly suggest that only enabling ACLM logging function for the first round of operation process since all midway versions of data change in the same process transaction need not logging.

3) We shall not enforce ACLM function indiscriminately for all data tables without considering the additive overhead. For example, when all historical data versions of a data table are in fact presented as direct content, there is no need to log data changes anyway. In developing ACLM for MIS, we suggest to set up a configuration table of data change audit individually per application to specify together all involved data tables and their involved fields whose value’s change need to be logged.

D. Typical Applications of Audit & Change Logs

1) Restore a record’s snapshot at an audit timestamp

Let’s take a scenario of reverting to a historical snapshot of data record at an audit timestamp. For data table Tx, let Ax be the audit log record with the timestamp ts, Kx be the PK value of Tx’s data record Rx that was audited by Ax at ts. If Ax is of C type, we have to track down along the time axis to the point (if any) when Rx underwent a change (update or deletion) after ts, see Fig. 2.

![Fig. 2. Snapshot Recurrence Scene concerning a Specific Attribute](image)

```
Create table snapshot fingertime string not null, value string null, auditID string null, chgtime timestamp null;
snapshot snapshot_D obj=new snapshot_D(ts, Tx, Kx);
Class snapshot_D {
  Var timestamp D_time=null;
  Public snapshot snapshot_D(timestamp ts=string time name, string keyval) {
    Insert into snapshot (fieldname) select column = from cols where
    table_name=time_name;
    Var string auditID=null;
    Select min(a.timestamp) into D_time From adt_log a Where
    a.timestamp=tstamp and a.D_table_name=table_name and
    a.D_key_value=keyval and Operation_type="D";
    If D_time=null then exit; /* after tstamp Rx was not ever deleted */
    Select a.Audit_ID into auditID From AuditID a Where a.timestamp=D_time and
    a.D_table_name=table_name and a.D_key_value=keyval and
    a.Operation_type="D";
    Update snapshot s Set value = (Select b.valb from cch_log b Where
    b.Audit_ID=auditID and b.ChgIdName=s.fieldname);}
```

Fig. 3. Recurrence of Rx snapshot just before Rx’s first deletion after ts

Regarding that Ax’s existence implies Rx existed at ts, so we can restore the snapshot of Rx at ts through the following processes (be succinct, no datum of lob type is involved here):

Step 1: We shall check if Rx underwent a D type change or a PK value change after ts — the later is equal to a D type change being followed by a N type one, since in ACLM it is implemented by deleting the current record and subsequently inserting a record with the new PK value — if yes, then we shall firstly restore the snapshot of Rx just before Rx’s first deletion after ts, e.g., just before point A as in Fig.2.
The process of this step is illustrated by a procedure coded in a pseudo-java-SQL language in Fig.3, where it is fulfilled by creating a class instance obj=Snapshot_DLL(D(ts, Tx, Kx)) regarding that obj.D_time!=null indicates yes.

Step 2: We shall search the earliest U type change during [ts, obj.D_time] for each attribute of Rx, and roll back together such a change (if any, e.g., at point B as showed in Fig.2) for any attribute whose value was changed during [ts, obj.D_time] to get the snapshot for Rx at time ts. The task of this step is illustrated by a procedure coded in a pseudo-java-SQL language in Fig.4, where it is carried out by setting roll_obj=Snapshot.Rollback(ts, obj.D_time, Tx, Kx), regarding that obj.D_time=null means no change of D type was on Rx after ts, and then not(a.timestamp>=Dtime) becomes true accordingly due to Dtime=null.

Notice: different fields of a data record might undergo a content change at different times. The correctness of executing SQL scripts in Fig. 3 and 4 (where the procedure of opening database is omitted) rests with that all audits on the same object are sequential, i.e., no more than one audit action exerting on the same object is allowed at the same time.

2) Recurring to a table's snapshot at arbitrary time
To recur to the snapshot of table Tx at a given time ts is to restore exactly all data records that appeared at ts. Supposed ACLM has been functioning since ts, and then the recurring procedure can be outlined as follows:

a) To retrieve those Tx's records that have not undergone any change since ts, we have

\[ S_1 = \{ \text{select } * \text{ from Tx where } (\text{Tx's PK }) \text{ not in } \{ \text{select D_key_value from adt_log where D_table_name='Tx' and operation_type<>'C' and timestamp>ts} \} \}

b) To restore \( S_2 = \{ \) those Tx's records that existed at ts and underwent a change after ts, we shall collect the set \( S_2 \) of any audit record that logged the first change data operation on the same data record after ts:

\[ S_2 = \{ \text{select Audit_ID, operation_type from adt_log where timestamp in } \{ \text{select min(timestamp) from adt_log where D_table_name='Tx' and operation_type<>'C' and timestamp>ts} \text{ group by D_key_value} \} \}

and then we exclude those audit IDs whose audit records logged a N type operation (As to a data record, after ts the first change data operation is of N type implies that the data record didn’t exist at ts otherwise it can not been inserted):

\[ S_{n}=\{\text{select Audit_ID from } S_1 \text{ where operation_type<>'N'}\}

3) For any audit record Ax whose ID is in \( S_n \) we restore the snapshot of the corresponding data record at Ax's timestamp through a process described in subsect.III.D.1.

It is easy to prove that \( \forall x \in S_2(\exists y \in S_0) \text{ that } y \text{ logged the first U or D change of } x \text{ after } ts, \text{ whereas } \forall x \in S_n(\exists y \in S_0) \text{ that the first U or D type change of } x \text{ after } ts \text{ was logged by the audit record with ID } y. \text{ As a result of the above process, we can regain each member of } S_2. \text{ The } S_1 \cup S_2 \text{ is the wanted.}

3) Practical simplicity for efficiency
The above applications are generally-oriented that each time a data record underwent a U type change the ACLM logged only those attributes that had undergone actual content change and their values. In practice, however, it was very clumsy to tell which field’s value of data input interface has actually been made different from its existent value in a web submission of data maintenance input, and if such actual value change is judged within a trigger procedure then the execution efficiency of the trigger and thereby the hosted DML operation will be greatly abated. For the sake of simplicity and efficiency, the data input submitted (if accepted) is directly delivered to DBMS for an update operation to replace the existent values of the object attributes respectively without further distinguishing the existent and new values. In addition, to make easier the snapshot recurrence we should set ACLM to log all attributes and their existent values into the change log at the same time whenever a U type operation encountered though at more cost of storage space. Such a disposal can save a lot of computation, regarding that in this way each time an audit record closest behind to the given time is enough for snapshot recurrence without bothering to dig out all involved audit records for all attributes’ snapshots that were logged at different timestamp.

IV. TESTING ACLM'S INFLUENCE ON DBMS OPERATIONS
Applying ACLM means appending certain additional audit and log tasks to normal DML operations in exchange for the competence of tracing versions and their responsible persons.

There comes an issue of evaluating additive overheads from ACLM. Intuitively, we have two plain measurements for this evaluation: (1) the perceptible performance decline, (2) the increment in comparative execution time. In fact, as for MIS applications featuring human-computer interaction it is the measurement (1) much more suitable than (2) though the latter is more precise than the former. The perceptible performance decline can be well evaluated in terms of success ratios of maintenance operation per unit time for a normal range of request throughput into the hosting DBMS. On this aspect we made a succinct test to checkout if the ACLM influence is acceptable or not: per one minute how many percentage of update or delete operations succeeded for a large scope of operations throughput. The data table for test is defined in Table IV, its content attributes (Citizen ID num, Reg_name, Reg_text) were under audit of ACLM. For comparison, during the test twin instances of relation Cer Reg were created such that one instance is ACLM-enabled while the other is non-ACL, and both were exerted hundreds of thousands Update
and *Delete* operations. The test results were depicted in Fig. 5
and 6.

</table>

For a widespread comparison of significance, we simulated a
broad range of data maintenance frequencies covering and well
beyond the statistic scope of page view (PV) of our web site (a
well known industry website in our province) whose home
page was accessed about 350 times per minute (on average the
frequency of home page access corresponds to that of the web
underlying DBMS inner DML request in the case of data
maintenance) at its all time peak -- in Fig.5 and 6 the peak PV
value was indicated by the vertical green line. Both Fig 5 and
Fig 6. actually recorded how many operations were
successfully fulfilled within one minute.

![Fig. 5. Test results on Update (U) operations](image)

![Fig. 6. Test results on Delete (D) operations](image)

As in Fig. 5, both the ACLM-enabled (labeled ACLM) and
ACLM-disabled (labeled non-ACLM) cases had similar
performance lines (all in values of logarithm to base 10) for
*Update* operations. Their success ratios held 100% from the
start at lower throughput of data operations up to some
thresholds well above the site peak PV frequency, and then
dropped rapidly as the impact of access throughput became
very heavy. Although the success ratio of the ACLM-enabled
system dropped relatively earlier, its abrupt decrease point only
came about as the access frequency reached an extremely high
level, say 150,000 times of inner update operations requested
per minute in the test, which is very rare for a normal website
and can be referred to as an ultra situation. Fig.6 told the same
thing about *Delete* operations, where, the ACLM-enabled one
encountered a threshold of success-ratio drop at 70,000 times
of inner delete operations per minute, and the test case should
be referred to as covering ultra situations too. Moreover, the
higher the computing power of server and client ends became,
the less the MIS performance loss from ACLM would be,
regarding that the hardware configuration of the test is quite
low (the hosting Oracle 9i DBMS was mounted on a Dell
PowerEdge2950 PC server -- Xeon E5430 CPU with a 2.66
GHz frequency and 1G memory), all these showed that the
performance decline of routine DBMS operation due to ACLM
is normally acceptable or even neglectable.

V. FURTHER CONCERNS ABOUT ATTRIBUTES OF LOGS

A. Log Attributes’ Minimization

First, relation *Adt_log* cannot be more simple, the reasons are:
1) attributes other than *Audit_ID* are semantic and all
indispensable to specify a data manipulation; 2) the auxiliary
attribute *Audit_ID* serves as a foreign key in *Chg_log* to
correlate together all data attributes being logged there for the
same data manipulation. Next, it is easy to verify that *Adt_log*
is in the third normal form (3NF), while *Chg_log* is nearly of
3NF except a functional dependency <*Lob_value*>→<*Hash*>.
Although <*Lob_value*→<*Hash*> brings some redundancy (a list
of *Hash* result), it in return offers a well-balanced performance
or efficiency in the value comparison of judging if the content of
a lob type attribute underwent an actual change, regarding that
a lob type attribute could have an unlimited variety of content
data sequence length, but it can be stood for by its fixed length
*Hash* value in comparison computing.

B. Logs Construction’s Completeness

The proposed audit & change logs enable restoring any data
record’s value (if existed) at an arbitrary given time *ts* for data
tables under ACLM governing: at first with them we can check
if the data record underwent a change manipulation after *ts*; if
no, the current status of the data record is the wanted, otherwise
we can take steps as described in subsection III.D.1) to restore
the data record’s value at *ts*.

C. Compatibility with data structure change

First, adding or retiring a non-PK attribute would make no
difference on restoring historical snapshots since the name and
value of newly added or historical attributes had been recorded
in attribute *chglfIdname* of *chgl_log* if they underwent a value
change. Secondly, altering data type of a non-PK attribute
would not mislead comprehension of the relevant record
content (if any) logged by the change log, since the attribute’s
previous content was always recorded in a uniform type of
character string (via *toString* translation) each time the attribute
content underwent a value change. Besides, an alteration of
data type without change content is of application-specific
disposal which is none of the business of ACLM. Notice:
normally retiring a data table field means that the field is no
longer maintained but its previous values are still kept there.
Similarly we can elucidate that ACLM still performs its normal functions when data tables undergo a structure alteration in their PK attributes (attributes were added or retired, or their data type were changed) with the complementary PK structure specification from relation \( \textit{PK\_spec} \) (see Table II). So, ACLM is compatible with data structure or meta-data change.

VI. HANDLE PRIMARY KEY OF MULTI-ATTRIBUTES

The above ACLM solution has a precondition: all data tables governed must have a unitary-attribute PK. In practices, it is the 1NF [2] instead of a unitary-attribute PK that shall be the minimal requirement for relational schema designs, i.e., there is a PK (probably with multiple attributes) to exclude duplicate rows — under 1NF at least all attributes together can uniquely fix on an instance of tuple. As to a data table without a unitary-attribute PK we shall introduce an artificial attribute to stand in as a unitary-attribute PK — named the Stand-In Unitary key, in short SIU key. Here, we propose two ways to set up an SIU key:

A. Map Multi-attributes into a unitary one

Let \( \text{PK} = (F_1, F_2, \cdots, F_k) \), which is an ordered tuple of names of all attributes from the PK, where the subscript numbers are defined by the \( \text{PK\_attribute\_seq} \) in relation \( \text{PK\_spec} \) regarding the \( \text{PK\_attribute\_name} \) (see Table II). If \( \forall j \) (\( \text{chr}(d) \neq \text{str}(F_j) \)) and \( \forall j (F_j \leftrightarrow \text{str}(F_j)) \) we have

\[
(F_1, F_2, \cdots, F_k) \leftrightarrow \text{str}(F_j) + \sum_{j=2}^{k} (\text{chr}(d)+\text{str}(F_j)) = \text{SIU}.
\]

Where, \( \text{chr}(d) \) denotes the character whose decimal ASCII code is \( d \) providing that \( \text{chr}(d) \) shall not appear in content of any involved relation attributes on high level MIS applications, “+” is the concatenating operator of character string, \( \text{str}(X) \) is the function that converts the value of variable \( X \) into a character string, “ \( \leftrightarrow \)” stands for a one-to-one mapping relation. Normally we choose \( d = 24 \) for \( \text{chr}(24) \) is a non-printable character for a cancel signal in hardware control. Further, we recommend to turn SIU into a fixed length by Hash (SIU) for a better space efficiency and well balanced performance of comparative computation. Often a hash algorithm named \( \text{SHA1} \) is adopted to map different SIU values into distinct strings of 40 hexadecimal characters.

B. Create a DBMS self-maintained field as SIU key

Such built SIU key is normally self-incremental, it can label distinctly data records existed, and grant each newly inserted data record with a unique identity. In semantics, a SIU key is equal to its original PK for all \textit{Update} manipulations except those altering any existent PK value. Whenever a data record underwent first a \textit{Delete} and subsequently an \textit{Insert} operation (an equivalence of the \textit{Update} operation altering an existent PK value), it will be assigned a new SIU key value different from its previous ones.

In this sense, any audit record of \( N \) type does not link to a historical snapshot of the data record it audited with respect to the PK value of that data record, because the PK value of the newly-inserted data record should not appeared before (the audit timestamp). As usual, the audit records of \( N \) type are used to exclude data records that are inserted after a given historical time in restoring the historical snapshot of a whole data table from its current status. But for restoring a specific data record with a given PK value (each member attribute value is given) at a given time it turns to be rather clumsy: we need to search the change log thoroughly for any \textit{Audit ID} value that is with each member attribute of the PK in change log records, and each member attribute from these records at least matched one time with their given value, this is because we don’t know directly the SIU value at that given moment. But, if ACLM is merely oriented to the time property of data maintenance and historical snapshots of data table, this SIU key approach is to some extent simple and feasible.

VII. DISCUSSION AND CONCLUSION

The ACLM function is based on two basic conditions: 1) accurately logging all timestamps of maintenance operations that should be governed by ACLM and values of each involved attribute of the object data record just before each operation of change data; 2) being able to correlate together the values of all member attributes in the data tuple of snapshot. As illustrated in section III, the design and application of audit and change logs themselves have directly satisfy the second condition, and such a condition would be hold met ever since it was satisfied since both the audit and change logs permit only Insert-SQL maintenance manipulations; while the first condition is met by enabling DBMS trigger mechanism [5] that surely captures any event of maintenance operation.

Under ACLM we can flexibly program SQL scripts to recall any historical snapshot without difficulty. Compared with those powerful but extravagant tDBMS products, our ACLM-based solution is economical and exercisable (of DIY type) for MIS. This is because a) implementing ACLM is plain: three specific relational tables for logs and PK specification, a short script additive to usual RDBMS stored procedures of business logic, and a piece of SQL script (alone or embedded in existent SQL scripts) added in triggers of each data table audited, and b) the merits from ACLM: being compatible with changes to meta-data, and programmers can code in their usual way, e.g., implementing data maintenance via RDBMS stored procedures.

In fact, our ACLM approach does reflect a reality that actual tDBMS implementation is a workable evolution of RDBMS application rather than an innovation of nowadays RDBMS. The most valuable point thereby is, ACLM can be plainly deployed on current prevailing RDBMSs with less interference in routine MIS program practices, normal MIS users except who conduct audit would feel they are working with a familiar RDBMS for the current version data access as usual. We can conclude that the ACLM approach is a good option to replace current bitemporal database solutions for uni-temporal MIS applications in order to avoid unexpected or unnecessary cost and complexity.

ACKNOWLEDGMENT

The authors thank all members of their team and correlative colleagues for applying and validating ACLM in several e-
government MIS projects with requirements of uni-temporal database applications.
