Deep Learning-Optimized CLAHE for Contrast and Color Enhancement in Suzhou Garden Images

Chuanyuan Li[1], Ziyun Jiao[2]
School of Architecture, Sanjiang University, Nanjing, Jiangsu 210000, China[1]
School of Architecture, Sanjiang University, Nanjing, Jiangsu 210000, China[2]

***Abstract*—Suzhou gardens are renowned for their unique color palettes and rich cultural significance. This study introduces a deep learning-optimized Contrast Limited Adaptive Histogram Equalization (CLAHE) method to enhance image contrast and improve color extraction accuracy in Suzhou garden images. An initial collection of 18,502 images was refined to 11,526 high-quality images from a single dataset. A pre-trained VGG16 convolutional neural network was used to extract image features, which were then employed to dynamically optimize the CLAHE parameters, thereby preserving the original color tones while enhancing contrast. The optimized CLAHE achieved significant improvements in the Structural Similarity Index (SSIM) by 24.69 percent and in the Peak Signal-to-Noise Ratio (PSNR) by 24.36 percent, and a reduction in Loss of Edge (LOE) by 36.62 percent,compared to the standard CLAHE. Additionally, enhanced structural detail and color complexity were observed. High-Resolution Network (HRNet) was utilized for semantic segmentation, enabling precise color feature extraction. K-means clustering was used to identify key color characteristics and complementary relationships among the primary and secondary colors in Suzhou gardens. A mathematical model capturing these relationships was developed to form the basis of a color palette generator, which can be applied to digital archiving, cultural preservation, aesthetic education, and virtual reality.**

Keywords*—Deep Learning-Optimized CLAHE; image contrast enhancement; color extraction; Suzhou gardens; VGG16; semantic segmentation

I. Introduction

Suzhou gardens are widely regarded as quintessential examples of Chinese classical garden design, embodying rich cultural and historical values. Zhang and Lian [1] describe these gardens as masterpieces that harmonize architecture, water bodies, and vegetation, reflecting cultural ethos across dynasties [2]. Jiang et al. [3] emphasize their role as cultural heritage sites illustrating aesthetic principles and socio-economic changes from the Tang to Qing Dynasties. He and Chu [4] further highlight the significance of both tangible and intangible heritage values in contemporary urban development.

However, digitally preserving the visual authenticity of these heritage sites presents significant challenges. Variations in lighting conditions across different images can lead to inconsistent color representation and contrast, complicating accurate analysis and preservation efforts. Moreover, existing color extraction methods often fail to capture the full spectrum of colors inherent in the intricate designs of Suzhou gardens, resulting in incomplete analyses that do not fully reflect the gardens' aesthetic and cultural richness.

Nallaperumal et al. [5] note difficulties in maintaining visual fidelity, while Kulkarni et al. [6] observe that color extraction methods struggle to capture the diverse color ranges in complex environments like Suzhou gardens due to shading, lighting variations, and color shifts. Additionally, Chen and Gu [7] point out that many current studies emphasize individual color properties rather than conducting comprehensive color analyses, limiting our understanding of the full color spectrum that contributes to the gardens' aesthetic and cultural essence.

To address these issues, we propose an optimized Contrast Limited Adaptive Histogram Equalization (CLAHE) method enhanced by deep learning techniques. Traditional CLAHE relies on fixed parameter settings, which may not be optimal for the diverse and complex images of Suzhou gardens [8]. By leveraging VGG16, a deep convolutional neural network, we dynamically optimize CLAHE parameters—specifically the Clip Limit and Tile Grid Size—based on high-level image feature extraction [9]. This optimization allows CLAHE to adaptively enhance contrast while preserving original color tones, addressing the limitations of fixed parameter selection.

Furthermore, we incorporate High-Resolution Network (HRNet) for semantic segmentation to isolate garden-related elements from background noise, thereby refining color feature extraction [10].

This study advances digital heritage preservation and sustainable design by introducing a deep learning-optimized CLAHE method for color enhancement in Suzhou garden images. Enhanced color accuracy facilitates digital archiving and cultural preservation while promoting the integration of traditional aesthetics into sustainable design practices. These contributions provide valuable insights for eco-friendly applications in cultural conservation and modern design.

The main contributions of this study are summarized as follows:

1) Deep learning-enhanced image enhancement: We develop a novel method that dynamically optimizes CLAHE parameters using VGG16, significantly improving contrast and color preservation in Suzhou garden images.

2) Advanced semantic segmentation: We incorporate HRNet for precise segmentation of garden-related features, reducing noise and enhancing the accuracy of color extraction.

3) Color clustering analysis: Using K-means clustering in Lab color space, we identify primary and secondary color characteristics, uncovering complementary color relationships unique to Suzhou garden aesthetics.

4) Digital preservation and design applications: We create a color palette generator based on the identified color

relationships, providing practical tools for digital archiving, cultural preservation, aesthetic education, and virtual reality applications.

This paper is organized as follows: Section II presents an overview of related work, focusing on the traditional CLAHE method and advancements in semantic segmentation and color extraction techniques. Section III elaborates on the research methodology, including the optimization of CLAHE parameters using deep learning, semantic segmentation with HRNet, and color clustering. Section IV discusses the experimental setup, results, and analysis. Finally, Section V concludes with the implications of this study, its limitations, and potential future directions.

II. Overview of Related Work

A. CLAHE Color Correction Technique

Contrast Limited Adaptive Histogram Equalization (CLAHE) is an image processing technique designed to enhance local contrast, thereby improving overall image quality. Unlike conventional methods such as Global Histogram Equalization (GHE), Gamma Correction, and Retinex algorithms, which apply uniform adjustments across the entire image, CLAHE operates on small sections independently, providing optimal representation for each region with greater efficiency.

CLAHE has been widely adopted across various fields of image processing, demonstrating its effectiveness in numerous applications. For instance, Kim et al. [11] combined CLAHE with Retinex to improve color uniformity while reducing image interference, significantly enhancing image quality. In medical semantic segmentation, Nizamani et al. [12] showed that CLAHE can significantly improve segmentation accuracy. Additionally, CLAHE has been utilized as a preprocessing step in Convolutional Neural Networks (CNNs) to enhance the accuracy of identifying agricultural diseases, as demonstrated by Sayyid [13].

Further advancements in CLAHE have focused on noise suppression and detail enhancement in various imaging tasks, leading to superior performance [14]. Similarly, Soniminde and Biradar [15] applied CLAHE in multi-scale image fusion, resulting in improved image clarity and contrast. Its application has extended to enhancing complex images, as shown by Karthikha and Jamal [16]. In low-light conditions, Yuan et al. [17] utilized CLAHE to increase target detection accuracy. Ren and Xu [18] developed an improved CLAHE algorithm for enhancing dot-matrix invisible code images, effectively improving contrast in low-quality images. He et al. [19] applied CLAHE to low-illumination image processing in shield tunnels, achieving remarkable results and showcasing CLAHE's versatility in image enhancement tasks.

Despite its widespread adoption, traditional CLAHE methods are often hindered by fixed parameter settings that do not account for diverse lighting conditions and complex color distributions, particularly in culturally significant images like those of Suzhou gardens. Recent studies by Rahman et al. [20], [21], [22], [23], [24] have proposed advanced image enhancement models that adaptively address uneven illumination, noise suppression, and color preservation. These works highlight the importance of leveraging techniques like multiscale decomposition, Retinex models, and dynamic parameter optimization to handle diverse imaging scenarios effectively.

Inspired by these approaches, our study introduces a novel method that leverages VGG16, a deep convolutional neural network, to dynamically optimize CLAHE parameters. By utilizing VGG16 for high-level feature extraction, our method adjusts CLAHE's Clip Limit and Tile Grid Size based on each image's unique characteristics. This deep learning-based optimization addresses the challenge of parameter selection in CLAHE, allowing it to adaptively enhance contrast while preserving original color tones. This approach is particularly advantageous for processing complex scenes, such as those found in Suzhou gardens.

B. Semantic Segmentation and Color Extraction

High-Resolution Network (HRNet) is a robust deep neural network architecture tailored for semantic segmentation, excelling in maintaining high-resolution representations while integrating multi-scale features. Enhancements such as attention mechanisms have significantly improved HRNet's segmentation accuracy, as demonstrated by Lai [25] in breast ultrasound imaging and Jin et al. [26] in landslide segmentation from remote sensing data. Liu et al. [27] utilized HRNet's superior localization to capture intricate details in retinal vessel images by introducing deformable convolutions, while Yan et al. [9] improved semantic segmentation with a boundary detail enhancement module. Kim et al. [28] further enhanced HRNet's effectiveness across various datasets through attention modules, and Sadeghi et al. [29] confirmed HRNet's superiority in high-resolution semantic segmentation through comparative analyses.

Following segmentation, K-means clustering is employed for color extraction due to its effectiveness in identifying dominant colors by minimizing the distance between data points and cluster centroids. Zhu et al. [30] demonstrated K-means' effectiveness in cultural heritage analysis by clustering colors in traditional Yi costumes. Kristanto et al. [31] enhanced segmentation accuracy in microbial images by combining K-means with Gabor filters for texture and color feature extraction. Jardim et al. [32] utilized K-means with the watershed algorithm for complex segmentation tasks, while Abernathy and Celebi [33] developed an enhanced online K-means algorithm that improved color quantization performance through incremental processing and better initialization. Bhuvanya and Kavitha [34] integrated K-means with other clustering techniques to advance image feature extraction and classification accuracy. Additionally, Kalaivani and Vimaladevi [35] improved endmember extraction in hyperspectral images by leveraging the relationship between K-means and the Pixel Purity Index, showcasing its versatility across various image analysis domains.

Integrating optimized CLAHE for color correction, HRNet for precise semantic segmentation, and K-means for effective color clustering enhances the accuracy of color extraction. This composite approach provides a solid foundation for digitally preserving the heritage of Suzhou gardens through improved color extraction techniques, enabling detailed analysis and accurate representation of their unique color palettes.

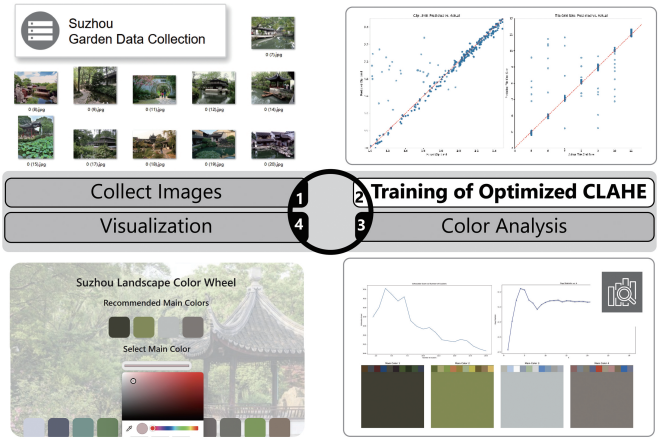

Fig. 1. Methodological roadmap.

III. Research Methodology

The methodological roadmap of this study is shown in Fig. 1.

This study integrates an optimized Contrast Limited Adaptive Histogram Equalization (CLAHE) method with a High-Resolution Network (HRNet) and K-means clustering to enhance contrast and color extraction in Suzhou garden images. To address lighting variations and incomplete color analyses, the optimized CLAHE is dynamically refined using VGG16 for effective contrast adjustment, while HRNet is employed for multi-scale semantic segmentation. K-means clustering is then applied to the segmented images to identify key color patterns and relationships.

A. Training of Optimized CLAHE

CLAHE's performance critically depends on its parameters: Clip Limit and Tile Grid Size. The Clip Limit controls maximum local contrast, reducing noise amplification, while the Tile Grid Size determines the level of local detail by segmenting the image into blocks. Traditional regression-based methods [36] have optimized these parameters; however, this study employs a deep learning-based approach for more adaptive enhancement. For the discrete Tile Grid Size, we treated optimization as a classification problem with 13 classes, corresponding to Tile Grid Sizes ranging from 8 to 32 in increments of 2. This allows the model to predict the most suitable Tile Grid Size category for each image effectively. The continuous Clip Limit is predicted using a linear activation function for fine-grained adjustments.

1) Role of VGG-16 in parameter optimization: VGG16, renowned for its deep convolutional architecture and effective feature extraction [37], is employed to capture high-level image features such as brightness, contrast, and fine-grained textures characteristic of Suzhou garden images. Leveraging pre-trained weights from extensive training on large datasets like ImageNet, VGG16 facilitates efficient transfer learning, enabling the model to generalize effectively across diverse image types while minimizing the need for extensive retraining.

VGG16 was chosen for its simplicity and proven effectiveness in feature extraction tasks. Compared to more recent architectures like ResNet or EfficientNet, VGG16 offers a balanced depth and computational efficiency, making it ideal for our parameter optimization without introducing excessive complexity. Its robust feature representation from ImageNet pre-training generalizes well to various garden images.

2) Feature extraction and parameter selection: The VGG16 model processes each image to extract high-dimensional features, which serve as inputs for optimizing CLAHE parameters. These features are passed through a global average pooling layer to reduce dimensionality, ensuring computational efficiency while retaining essential information:

$$f_{\text{VGG}} = \text{GlobalAveragePooling2D}(\text{VGG16}(x)) \tag{1}$$

Image contrast is quantified by calculating a brightness histogram and contrast ratio:

$$l_h = \frac{\text{calcHist}([Y], [0], \text{None}, [256], [0, 256])}{\sum_{i=0}^{255} \text{calcHist}([Y], [0], \text{None}, [256], [0, 256])_i} \tag{2}$$

$$\text{contrast} = \frac{\text{std}(Y)}{\text{mean}(Y)} \tag{3}$$

To enhance dataset diversity and improve model robustness, a series of data augmentation techniques were employed:

- Rotations: Random rotations within $\pm 20^\circ$ to simulate diverse perspectives and improve spatial feature recognition.
- Flipping: Horizontal and vertical flips, each applied with a probability of 50%, enhancing the model's robustness to symmetric structures.
- Brightness and Contrast Adjustments: Random changes within $\pm 20\%$ to account for lighting variations.
- Scaling: Random resizing between 80% and 120% of the original image dimensions to accommodate scale diversity.
- Noise Addition: Gaussian noise was applied to simulate real-world interference and improve noise tolerance.

These augmentation techniques were specifically designed to address the unique visual complexity and dynamic conditions of Suzhou garden images. Experimental results revealed an improvement of over 10% in validation accuracy when augmentation was applied, demonstrating its critical role in enhancing model performance.

3) Model construction and training: Fig. 2 illustrates the workflow of the model training and evaluation process. It begins with input data (images) that undergo data preparation, including train-validation splitting and data augmentation. The model initialization uses the VGG16 architecture with random weight initialization. In the training loop, processes such as optimization, forward and backpropagation, learning rate reduction, and early stopping are applied. Once trained, the

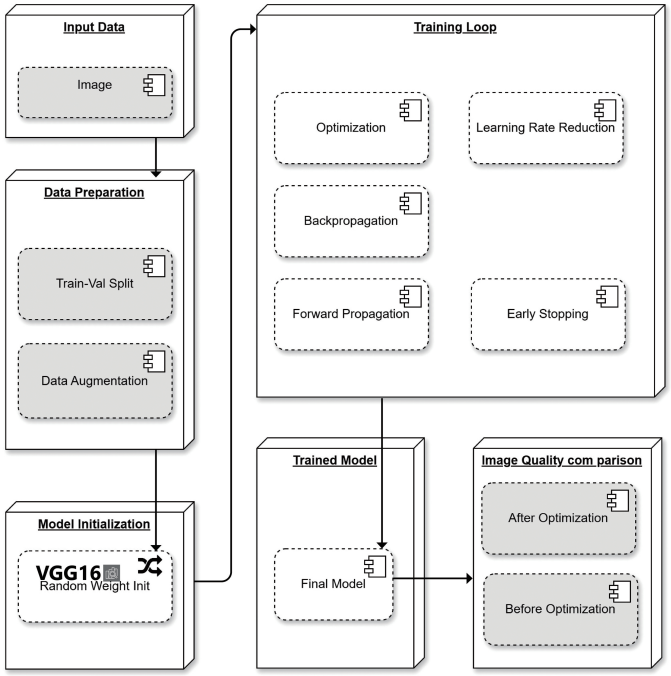

Fig. 2. Model training and evaluation workflow.

final model is evaluated by comparing image quality before and after optimization.

The model architecture comprises an input layer followed by fully connected layers to reduce the dimensionality of the feature space:

$$x_{i+1} = \text{ReLU}(\text{Dense}(x_i, \text{units} = n)) \tag{4}$$

Residual connections are incorporated to prevent gradient vanishing:

$$x_{\text{new}} = \text{add}([x_{\text{prev}}, \text{Dense}(x_{\text{prev}}, 512, \text{'relu'})]) \tag{5}$$

Using Early Stopping and ReduceLROnPlateau, the model outputs continuous predictions for optimized Clip Limit and Tile Grid Size:

$$\text{clip\_limit\_output} = \text{Dense}(1, \text{activation} =' \text{linear}')(x) \tag{6}$$

$$\text{tile\_grid\_size\_output} = \text{Dense}(13, \text{'softmax'})(x) \tag{7}$$

The neural network was trained over 200 epochs with a batch size of 64, utilizing 80% of the data for training and 20% for validation. After VGG16-based feature extraction, the network architecture included fully connected layers with batch normalization and dropout regularization to ensure stability during training. Residual connections were employed to retain

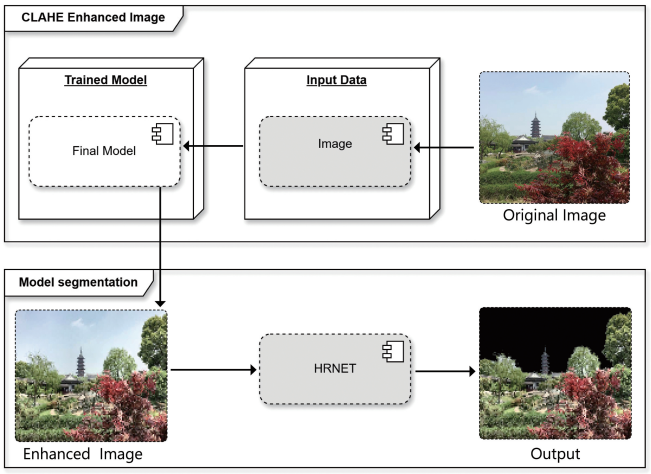

Fig. 3. HRNet flowchart.

essential information across layers, particularly at the 512-dimensional layer. This enhances gradient flow and improves learning efficiency.

The Adam optimizer was used with an initial learning rate of 0.001, which was dynamically adjusted using ReduceLROnPlateau based on the root mean squared error (RMSE) of the validation loss for the outputs. Early Stopping was applied with a patience of 20 epochs to prevent overfitting, restoring the best model weights.

B. Application of HRNet in Semantic Segmentation

HRNet is applied to CLAHE-optimized images for multi-scale feature extraction, preserving high-resolution details. Four parallel convolutional branches process features at varying scales, which are then fused for refined segmentation:

$$F_{\text{fusion}} = \sum_{i=1}^{N} \alpha_i \cdot F_i \tag{8}$$

The fused output enables precise identification of relevant garden regions, enhancing the accuracy of color feature extraction. Final segmentation is defined as:

$$Y_{\perp}^{*} = \text{argmax}(\text{softmax}(F_{\text{fusion}})) \tag{9}$$

To improve segmentation accuracy, we applied morphological operations to remove small non-garden-related elements such as sky regions and transient objects like people and cars. Additionally, connected component analysis was performed to retain only the largest contiguous garden regions, ensuring the exclusion of irrelevant areas. The HRNet flowchart is shown in Fig. 3.

C. Color Clustering and Analysis

The segmented RGB images are converted to Lab color space for better perceptual uniformity in color representation:

$$L = 116 \cdot f\left(\frac{Y}{Y_n}\right) - 16,$$
$$a = 500 \cdot \left(f\left(\frac{X}{X_n}\right) - f\left(\frac{Y}{Y_n}\right)\right),$$
$$b = 200 \cdot \left(f\left(\frac{Y}{Y_n}\right) - f\left(\frac{Z}{Z_n}\right)\right) \quad (10)$$

K-means clustering identifies primary and secondary colors, measuring distances using Euclidean metrics:

$$\text{Distance}(x, y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2} \quad (11)$$

Cluster centers are updated iteratively, with Euclidean distance determining dominant color clusters:

$$\mu_j = \frac{1}{n_j}\sum_{i=1}^{n_j} x_i \quad (12)$$

The distance between primary and secondary colors is calculated as:

$$\text{distance} = \sqrt{(L_1 - L_2)^2 + (a_1 - a_2)^2 + (b_1 - b_2)^2} \quad (13)$$

Linear regression is then applied to model color relationships:

$$Y = \beta_0 + \beta_1 \cdot \text{MC } L + \beta_2 \cdot \text{MC } a + \beta_3 \cdot \text{MC } b + \beta_4 \cdot \text{SC } L + \beta_5 \cdot \text{SC } a + \beta_6 \cdot \text{SC } b \quad (14)$$

D. Validation and Visualization of Cluster Numbers

The optimal number of clusters is validated using Gap Statistic and Silhouette Score for robust clustering results. Principal Component Analysis (PCA) reduces color data dimensionality to visualize clusters effectively:

$$X_{\text{pca}} = X \cdot V_k \quad (15)$$

PCA-reduced color data undergoes K-means clustering to form primary and secondary color clusters, providing a structured analysis of color distributions in Suzhou garden images.

IV. Experiments and Results

A. Experimental Setup

1) Optimized CLAHE processing:

a) Suzhou garden data collection: An automated function was developed to collect images from the internet, specifically targeting names associated with famous classical gardens or landmarks in Suzhou. The selection criteria required that these sites be recognized as World Cultural Heritage sites. These include "Canglang Pavilion," "Huanxiu Mountain Villa," "Lingering Garden," "Couple's Retreat Garden," "Lion Grove Garden," "Retreat and Reflection Garden," "Garden of the Master of the Nets," "Art Garden," and "Humble Administrator's Garden." Additionally, the keywords "Classical gardens of Suzhou," "Suzhou Garden," and "Suzhou Classical Gardens" were used as supplements. Based on these search terms, images were collected from Baidu Images, resulting in a total of 18,502 images. The original image data are shown in Table I.

TABLE I. Original Image Data

Keywords	Number of Pictures
Classical Gardens of Suzhou	352
Suzhou Garden	145
Canglang Pavilion	1758
Huanxiu Mountain Villa	1263
Lingering Garden	1853
Couple's Retreat Garden	1581
Lion Grove Garden	1508
Classical Suzhou Gardens	1623
Suzhou Yuanlin	1862
Retreat and Reflection Garden	1380
Garden of the Master of the Nets	1755
Art Garden	1595
Humble Administrator's Garden	1827

An Average Hash (AHash) algorithm was employed to identify and remove duplicate images from the collected dataset by computing the hash value for each image and deleting any identical photos. The formula for calculating the average hash is:

$$\text{average\_hash} = \sum_{i=0}^{n} 2^i \cdot I(v_i > \text{mean}) \quad (16)$$

Following this, all images were manually reviewed to remove any non-Suzhou garden-related photos from the dataset. After this refinement process, the final number of preprocessed images was 11,526.

b) Training and evaluation of optimized CLAHE: The processed images of Suzhou gardens underwent necessary preprocessing steps before model training. The model was trained using the formulas provided in Eq. (1) to (7) and evaluated on a validation set. The evaluation process involved tracking changes in loss and error metrics throughout the training process and assessing regression performance using metrics such as Mean Squared Error (MSE) and R-squared (R^2).

c) Comparison of predicted and actual values: For the Clip Limit, most data points align closely with the red dashed line, indicating that the model achieves high predictive

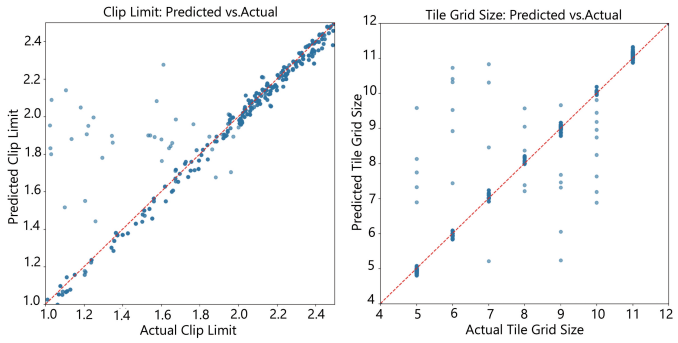

Fig. 4. Comparison of predicted value and actual value.

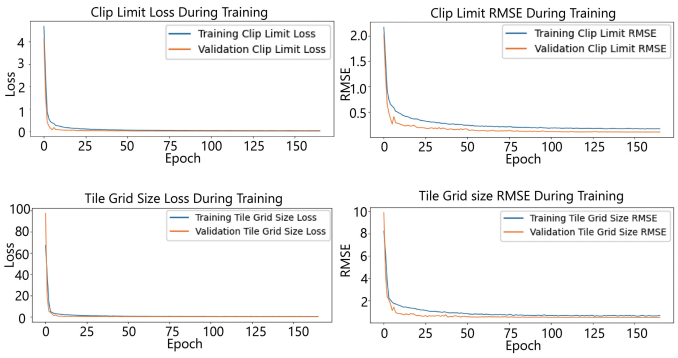

Fig. 5. Training history chart.

accuracy in the majority of cases. A few data points exhibit significant deviations, suggesting that the model may struggle with predictions under certain extreme conditions or specific scenarios. For the Tile Grid Size, the predicted values generally follow the trend of the actual values, though some deviations are noted at higher grid sizes. Despite these outliers, they are relatively rare, indicating that the model's predictions are accurate in most situations. The analysis data is shown in Fig. 4.

d) Training history chart analysis: The training and validation loss, along with Root Mean Squared Error (RMSE), decreased rapidly during the initial stages of training and gradually stabilized, indicating that the model effectively learned the data features early on and converged progressively. The application of data augmentation techniques further contributed to minimizing overfitting and improving generalization. Notably, rotations and flips enhanced the model's ability to generalize across diverse spatial features, while brightness and contrast adjustments improved its robustness to varying lighting conditions. The Training History information is shown in Fig. 5.

The model demonstrates strong performance in predicting the clip_limit parameter, achieving minimal prediction error and exhibiting a concentrated distribution of predictions, reflecting its robust generalization capability. While the prediction of the tile_grid_size parameter is generally good, it exhibits some limitations at larger grid sizes, suggesting areas for potential optimization in future work.

e) Comparison of CLAHE and optimized CLAHE: To objectively evaluate the performance of the optimized CLAHE method against the standard CLAHE, we applied three key image quality metrics: Structural Similarity Index (SSIM), Peak Signal-to-Noise Ratio (PSNR), and Loss of Edge (LOE). These metrics were calculated by comparing the CLAHE-enhanced images with the original images in the dataset.

SSIM measures similarity between two images by considering luminance, contrast, and structural details, where higher values indicate better structural preservation. PSNR, on the other hand, quantifies the ratio between the maximum possible signal power and the noise power; higher PSNR values imply better image quality and less noise. LOE evaluates the preservation of edge details in the images, where lower values indicate better edge retention.

The average SSIM, PSNR, and LOE values for all images were computed for both the standard CLAHE and Optimized CLAHE methods, as shown in Table II.

TABLE II. AVERAGE SSIM, PSNR, AND LOE VALUES FOR STANDARD AND OPTIMIZED CLAHE

Metric	Standard CLAHE	Optimized CLAHE	Improvement (%)
SSIM	0.4437	0.5532	+24.69%
PSNR (dB)	13.22	16.45	+24.36%
LOE	0.2314	0.1466	-36.62%

The results indicate that Optimized CLAHE achieved significant improvements over standard CLAHE, with a 24.69% increase in SSIM (from 0.4437 to 0.5532), a 24.36% improvement in PSNR (from 13.22 dB to 16.45 dB), and a 36.62% reduction in LOE (from 0.2314 to 0.1466). This demonstrates that Optimized CLAHE not only enhances contrast but also better preserves structural integrity and significantly reduces edge loss, thereby maintaining critical image details.

Fig. 6 illustrates overall performance comparisons for SSIM, PSNR, and LOE metrics. These enhanced metrics confirm that Optimized CLAHE contributes to more vivid and accurate color representation in the images, capturing the intricate details and richness of Suzhou gardens.

The evaluation results strongly suggest that the Optimized CLAHE model provides superior performance, making it a promising approach for applications requiring high-quality image enhancement.

2) HRNet Processing and Color Extraction: After applying the Optimized CLAHE processing to all images, semantic segmentation was performed using Eq. (8) and (9) to remove non-garden-related elements such as people and cars. To ensure the accuracy of color extraction, the sky was excluded before proceeding to subsequent steps.

When executing the calculations according to Eq. (10) to (12), the maximum number of clusters generated by the algorithm for each image was limited to 30. All extracted color data were converted into a DataFrame format and saved. The generated data includes the LAB values of the primary and secondary colors for each image, and Table III provides information about an image named "Image1".

Eq. (13) and (14) generate the color clustering formulas as follows:

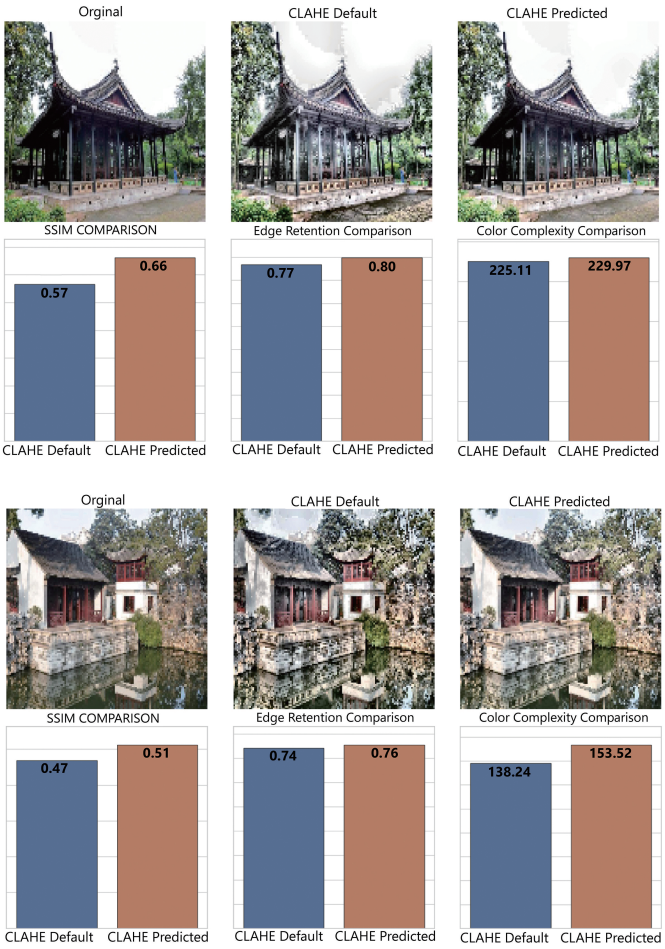

Fig. 6. Performance comparison of CLAHE and enhanced CLAHE.

TABLE III. COLOR CARD LAB VALUES - IMAGE 1

76.0309	3.2525	-0.4037	0.0474
37.9928	3.8353	-6.3526	0.0169
57.2163	2.3148	-4.1065	0.0217
46.6206	5.3030	3.2603	0.0373
86.9956	3.5583	3.1048	0.0817
44.1516	0.0378	12.3873	0.0390
40.4602	9.3195	15.2071	0.0118
55.0158	2.8220	5.9573	0.0556
68.0085	7.8041	27.5084	0.0391

$$Y = 35.78 + 0.19 \cdot \mathrm{MC}L + 0.002 \cdot \mathrm{MC}a - 0.28 \cdot \mathrm{MC}b - 0.22 \cdot \mathrm{SC}L + 0.10 \cdot \mathrm{SC}a + 0.46 \cdot \mathrm{SC}b \quad (17)$$

The range of Y is [0.0,163.32] and its data distribution is shown in the figure below. To control the range, the values between the 25th and 75th percentiles are selected as the

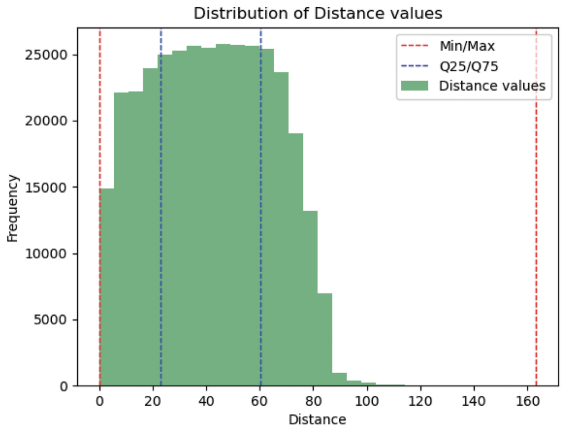

Fig. 7. Y Value range definition.

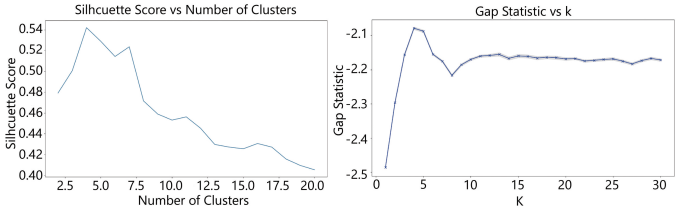

Fig. 8. Cluster quantity analysis.

controlled range for Y. The final range of Y is [22.84, 60.38]. The relevant information is shown in Fig. 7.

The Gap Statistic and Silhouette Score were compared for different numbers of clusters, revealing that the optimal number of clusters is 4. This suggests that the clustering effect is best when the number of primary colors is 4. The Cluster Quantity Analysis is illustrated in Fig. 8.

Using Eq. (15), the reduced-dimensional color data was clustered using the K-means algorithm to identify the main color cluster centers (primary colors). For each primary color, the corresponding secondary colors were further clustered using the K-means algorithm, with the cluster centers selected to represent these secondary colors. To aid in visualization, the maximum number of clusters for secondary colors corresponding to each primary color was limited to 10, ensuring clarity and manageability in the resulting visual representation. Information called "Color Card LAB Values" is shown in Tables IV, V, VI, and VII. Each support color represents a secondary color that complements the main color within its group, contributing to the overall color harmony observed in Suzhou gardens.

The final visualization image generated by this process is shown in Fig. 9.

B. Results and Analysis

Using Eq. (17), our analysis reveals that the color design of Suzhou classical gardens exhibits a complementary relationship in terms of lightness (L) and the blue-yellow channel (b). Specifically, there is a positive or negative correlation between "Main Color L" and "Support Color L" as well as between

"Main Color b" and "Support Color L." The Euclidean distance of color differences predominantly falls within the range of [22.84, 60.38], which is considered the "harmony" standard in garden color design.

This harmony is achieved through the subtle control of contrast in secondary colors, reflecting the traditional philosophy of "harmony between humans and nature" and the concept of "calm and introspection." Suzhou gardens create a rich visual experience by uniting the stability of primary colors with the diversity of secondary colors. The study also indicates that secondary colors, particularly those in the blue-yellow spectrum (such as tones of sunlight, water surfaces, and autumn leaves), significantly influence the overall visual experience and play a crucial role in determining the color difference distance (Y). In contrast, the influence of the main color's a value is found to be minimal.

Building on these findings, we developed a color palette generator program designed to automatically create color schemes that align with the design principles of Suzhou gardens. This tool provides practical applications for heritage preservation, garden design, aesthetic education, and virtual reality. The development program is shown in Fig. 10.

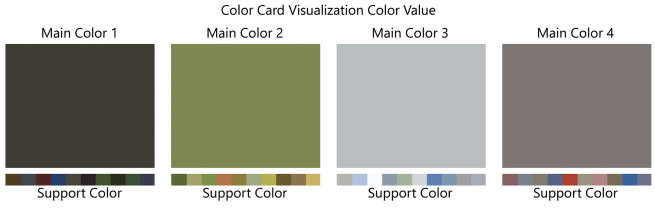

Fig. 9. Color card visualization of color value.

C. Limitations

1) Clustering method: While K-means clustering effectively identified dominant color clusters, its assumption of spherical clusters may not capture the nuanced color variations inherent in Suzhou gardens. Alternative methods like Gaussian Mixture Models (GMM) or DBSCAN could potentially model more complex color distributions.

2) Parameter optimization robustness: The deep learning-based optimization of CLAHE parameters, though effective, may require further refinement to handle extreme lighting conditions or highly complex scenes beyond the current dataset.

3) Dataset diversity: The dataset, while extensive, may still lack certain variations in garden scenes, such as seasonal changes or rare architectural elements, potentially limiting the universality of the model.

D. Future Work

Future research could address these limitations by exploring more sophisticated clustering techniques and improving the robustness of parameter optimization. Expanding the dataset to include a wider variety of garden scenes and conditions would further enhance the model's generalizability. Additionally, integrating reinforcement learning for real-time parameter adjustments and exploring end-to-end deep learning models for simultaneous enhancement and color extraction present promising directions. Applying this methodology to other culturally significant heritage sites could also validate its versatility and effectiveness across diverse contexts.

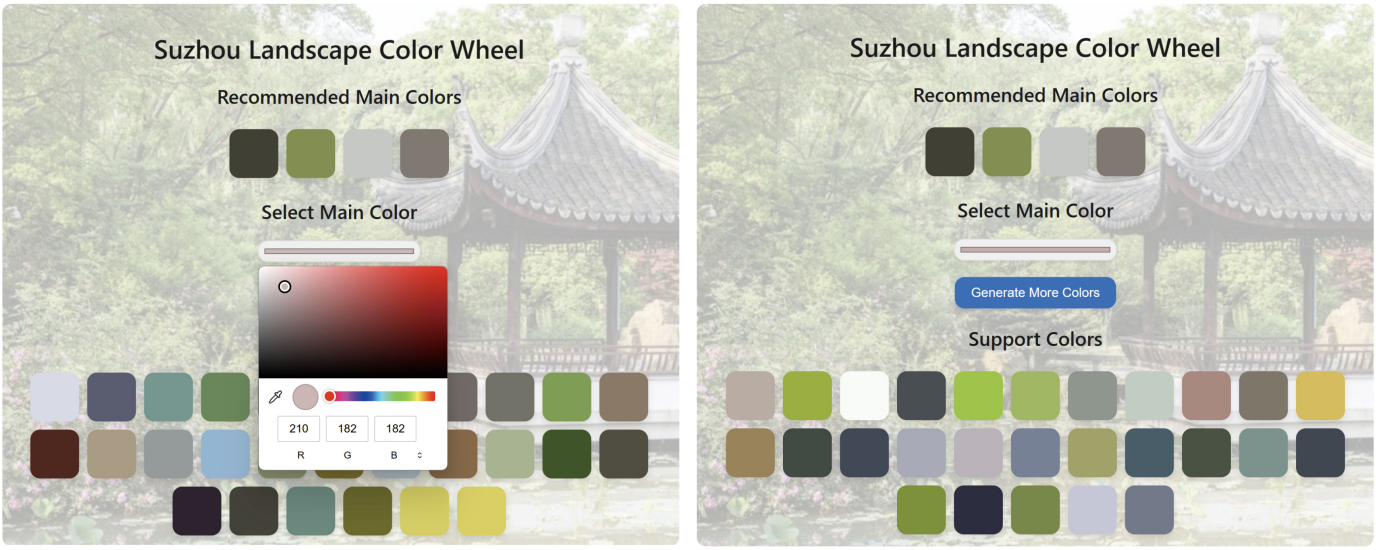

Fig. 10. Color palette generator development program

V. Conclusion

This study explored the integration of an optimized Contrast Limited Adaptive Histogram Equalization (CLAHE) algorithm for enhancing image contrast and accurately extracting colors from images of Suzhou gardens. The findings demonstrated the potential of this approach to improve the visualization of fine details, preserve structural integrity, and capture a richer spectrum of colors in heritage images. Specifically, the optimized CLAHE showed a 24.69% improvement in Structural Similarity Index (SSIM), a 24.36% increase in Peak Signal-to-Noise Ratio (PSNR), and a 36.62% reduction in Loss of Edge (LOE), alongside enhanced color complexity and edge preservation.

The use of VGG16 for dynamic parameter optimization allowed CLAHE to adapt to each image's unique characteristics, ensuring consistent enhancement across varied lighting and shading conditions. High-Resolution Network (HRNet) further refined the segmentation process, isolating garden-related elements and enhancing the accuracy of color feature extraction. K-means clustering effectively identified primary and secondary color clusters, revealing complementary color relationships that align with the traditional aesthetics of Suzhou gardens.

Despite these advancements, some limitations remain. The reliance on the K-means algorithm for color clustering, while effective for basic categorizations, may not fully capture the nuanced color variations characteristic of Suzhou gardens. Additionally, while deep learning (DL) was utilized to optimize CLAHE parameters, further refinement is needed to make this approach robust across diverse imaging scenarios. Future work could explore more sophisticated clustering techniques, such as Gaussian Mixture Models (GMMs) or advanced deep learning methods, to provide a more comprehensive understanding of color relationships in heritage contexts.

The findings of this study have several implications for future research. First, there is potential to expand the application of this method beyond Suzhou gardens to other complex imaging scenarios, such as urban landscapes, natural reserves, or historic façades. Such explorations could validate the generalizability and utility of the proposed techniques across diverse cultural heritage sites. Second, further advancements in adaptive parameter optimization for CLAHE, possibly using reinforcement learning or other machine learning approaches, could enhance the adaptability and effectiveness of image enhancement techniques in real-time applications.

Overall, this study contributes to the field of cultural heritage preservation by demonstrating the value of integrating advanced image processing techniques with deep learning algorithms to enhance the analysis and documentation of classical Chinese gardens. By addressing current limitations and exploring new research directions, future studies can further refine these methods and expand their applicability, ultimately advancing the digital preservation and understanding of cultural heritage.

This work lays a foundation for more sophisticated tools that not only preserve the aesthetic qualities of heritage sites but also enhance their accessibility and comprehensibility for future generations.

***Abstract*—Surface roughness is a pivotal indicator of surface quality for machined components. It directly influences the performance and lifespan of manufactured products. Precise prediction of surface roughness is instrumental in refining production processes and curtailing costs. However, despite the use of identical processing parameters, the final surface roughness would be different. Thus, it challenges the effectiveness of traditional prediction models based solely on processing parameters. Current prevalent approaches for surface roughness prediction rely on handcrafted features, which require expert knowledge and considerable time investment. To address these challenges, we comprehensively consider the advantages of various deep learning methods and propose a novel end-to-end architecture. It synergistically integrates convolutional neural networks (CNN), bidirectional temporal convolutional networks (BiTCN), and attention mechanism, termed the CNN-BiTCN-Attention (CBTA) architecture. This architecture leverages CNN for automatic spatial feature extraction from signals, BiTCN to capture temporal dependencies, and the attention mechanism to focus on important features related to surface roughness. Experiments are conducted with popular deep learning methods on the public ACF dataset, which includes vibration, current, and force signals from the end milling process. The results demonstrate that the CBTA model outperforms other compared models. It achieves exceptional prediction performance with a mean absolute percentage error as low as 0.79% and an R^2 as high as 99.81%. This validates the effectiveness and superiority of CBTA in end milling surface roughness prediction.**

***Keywords*—Surface roughness prediction; end milling; CNN-BiTCN-Attention; deep learning**

I. Introduction

End milling is a machining process, which utilizes the cutting edges of a rotating cylindrical cutter to remove material from a workpiece. This method is extensively used for the production of parts with intricate shapes and stringent precision requirements. The control of surface roughness during end milling is essential for ensuring product quality, as it directly affects the appearance and wear resistance of parts as well as the compatibility with other components [1]. Hence, it is necessary to predict the surface roughness in end milling. This holds significant importance for optimizing machining parameters and enhancing both the efficiency of the process and the quality of the workpiece.

Methods for predicting surface roughness in end milling can be categorized into three main types: physical modeling, statistical analysis, and artificial intelligence based approaches. Firstly, the physical modeling methods are highly reliant on expert experience and prior knowledge, and they may struggle to accurately depict actual conditions due to the complex nonlinear characteristics of the end milling process [2]. Secondly, statistical analysis methods, which mostly consider only the influence of machining parameters, fail to address the situations where surface roughness differs despite identical machining parameters during the actual end milling [3]. Finally, the AI-based methods mainly focus on the impact on surface roughness from machining parameters, handcrafted features, or single signal. Moreover, their architectures are relatively simple, and handcrafted features also depend on the expertise of researchers [4].

In light of the above analysis, there is a need to propose an end-to-end deep learning method that fuses multiple signals for surface roughness prediction. After a thorough consideration of the advantages and disadvantages of various deep learning methods, we introduce the CNN-BiTCN-Attention (CBTA) architecture for the first time to predict surface roughness. This architecture employs convolutional neural network (CNN) for feature extraction, Bidirectional Temporal Convolutional Network (BiTCN) to capture long-term dependencies in signals, and incorporates an attention mechanism to allocate reasonable weights to different signals and features. Experiments are conducted on the public ACF dataset, which is collected during end milling of 45# steel and includes vibration, current, and force signals, each with three components. In this study, CBTA is compared with three popular deep learning models, and their performance is evaluated when using both multi-signal fusion and single-signal inputs, in order to assess the robustness and effectiveness of our proposed model.

The remainder of this paper is organized as follows: Section II presents related works. Section III introduces the surface roughness prediction model and data processing methods. Section IV details the experimental design, results, and discussion. The main conclusions of this study are presented in Section V.

II. Related Work

The traditional prediction of end milling surface roughness is primarily achieved through physical modeling methods. These methods analyze and establish mathematical models based on the physical phenomena occurring during the machining process. Feng et al. [5] proposed an analytical model to predict surface roughness during laser-assisted end milling of Inconel 718, based on tool movement and elastic response of the workpiece. Zhang et al. [6] developed an analytical model for surface roughness in particle-reinforced metal matrix composites. Their model utilized an undeformed chip thickness approach based on the Rayleigh probability distribution. Wang

*Corresponding authors.

et al. [7] developed a prediction model for surface roughness in milling. This model combined the effects of elastoplastic deformation, cutter parameters, microhardness, cutting force, and material properties with geometric and mechanical models. Jiang et al. [8] explored the influence of process parameters on cutting forces and surface roughness. They proposed a mathematical model to predict the milling forces and surface roughness of carbon fiber reinforced polymers, through a combination of theoretical and experimental approaches.

Statistical regression analysis is also a classic technique for predicting surface roughness, typically focusing on the relationship between machining parameters and surface roughness. Huang et al. [9] proposed a grey online modeling surface roughness monitoring system for end milling, based on grey theory and bilateral optimal fitting methods. Misaka et al. [10] employed the Co-Kriging method in conjunction with measurement data and analytical model to predict surface roughness in Computer Numerical Control (CNC) turning. The measurement data included cutting speed, feed rate, depth of cut, and acceleration. Gao et al. [11] developed an empirical model based on multiple regression analysis for dry face turning of AZ31B magnesium alloy. The model enabled the prediction of surface roughness through cutting speed, feed rate, and cutting depth. Sekulic et al.[12] utilized Response Surface Methodology (RSM) to predict surface roughness in ball-end milling of hardened steel, with spindle speed, feed per tooth, axial depth, and radial depth as input parameters.

In addition, machine learning and deep learning methods are also applied to surface roughness prediction especially with the rapid advancement of artificial intelligence. Chen et al. [13] proposed a backpropagation neural network (BPNN) to predict surface roughness in end milling, which utilizes spindle speed, feed rate, cutting depth, and milling distance as inputs. Li et al. [14] used cutting parameters and tool wear as input variables to propose a milling surface roughness prediction method which based on particle swarm optimization least squares support vector machine (PSO-LSSVM). Wu et al. [15] extracted time-domain and frequency-domain features from vibration signals through statistical calculations, and then input these features and cutting parameters into an Artificial Neural Network (ANN) to predict surface roughness of S45C steel. Shehzad et al. [16] introduced a CNN-LSTM model designed for the online monitoring of surface roughness in copper workpieces during ultraprecision fly cutting. This model employs vibration signals for its predictions and underwent a robustness assessment through validation cohort analysis. Guo et al. [17] collected an ISSA-optimized Deep Belief Network (DBN) model for surface roughness prediction. They gathered vibration and force signals during the milling process of P20 die steel, and subsequently extracted and filtered the time-frequency domain features of these signals to serve as inputs for the model.

In conclusion, the surface roughness prediction methods presented in the aforementioned literatures have achieved remarkable results in certain specific scenarios. Their research primarily relies on machining parameters or handcrafted features for prediction, while the use of fused signals and automatic feature extraction remains lacking. These methods suffer from issues such as neglect of dynamic factors, time-consuming processes, and an inability to comprehensively describe the entire machining process. To address these challenges, we propose an end-to-end deep learning architecture that fuses multiple signals.

III. Methodology

A. Surface Roughness Prediction Model

Deep learning models do not rely on handcrafted features, and directly utilize raw signals as input. Given the substantial volume and complex characteristics of vibration, current, and force signals, the model must possess capabilities for dimensionality reduction and feature extraction. Since these signals are time series data, the model requires strong temporal analysis capabilities. Additionally, these signals have different importance for surface roughness, and it is necessary to assign appropriate weights to the model. Based on these considerations, we propose the CBTA architecture, as illustrated in Fig. 1. Below is an introduction to each component of CBTA.

1) Convolutional Neural Network block: CNN is employed for dimensionality reduction and automatic feature extraction from signals in this paper. CNN is widely utilized in computer vision and speech recognition due to its robust spatial feature extraction capability. In the realm of intelligent manufacturing, applications of CNN include bearing remaining useful life prediction [18], tool wear estimation [19], and surface roughness prediction [20]. The CNN block comprises an input layer, convolutional layers, and pooling layers. The input layer receives the signal data. The convolutional layers contain a set of convolutional kernels, and one-dimensional convolution kernels are adopted in order to process time-series data. After the convolutional layer generates feature maps, the pooling layer uses the max pooling operation to reduce the number of network parameters and retain key features. By stacking multiple convolutional and pooling layers, CNN can extract deep features from signals and filter out redundant features. Furthermore, rectified linear unit (ReLU) [21] is utilized as the activation function to avoid overfitting and enhance convergence speed. The expressions for the convolution and pooling layers are as follows:

$$\mathrm{Y}_{m,k} = f\left(\sum_{i=1}^{n} X_i * w + b\right) \tag{1}$$

$$\mathrm{Z}_{m,l} = \max\left(\mathrm{Y}_{m,k}\right) \tag{2}$$

where $Y_{m,k}$ and $Z_{m,l}$ represent the outputs of the convolutional layer and the pooling layer, respectively; f denotes the activation function ReLU, X_i signifies the number of samples, w refers to the size of the convolutional kernel, and b represents the bias vector.

2) Bidirectional Temporal Convolutional Network block: TCN was proposed by Bai et al. [22], and has been proven superior to Long Short-Term Memory (LSTM) in various fields such as multivariate time series analysis and natural language processing [23]. Inspired by Bidirectional Long Short-Term Memory (BiLSTM) [24], we introduce BiTCN for surface roughness prediction. The deep features extracted by CNN are fed into BiTCN for analysis. As depicted in Fig. 1, BiTCN consists of a pair of parallel TCNs, termed Forward

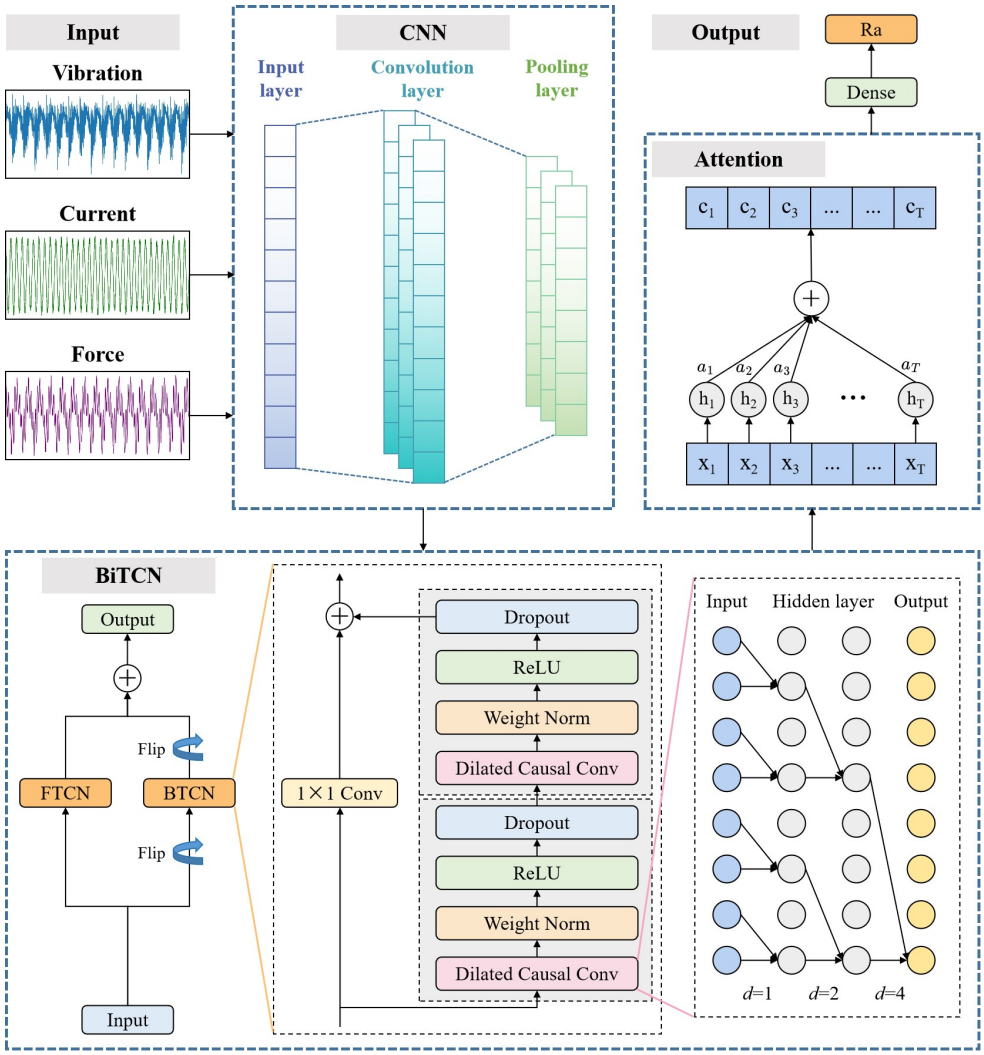

Fig. 1. CBTA architecture.

TCN (FTCN) and Backward TCN (BTCN), respectively. Their primary distinction lies in the order of input sequence, i.e. FTCN processes the sequence in the forward direction, while BTCN processes it in the reverse direction. Apart from this difference, the structures of FTCN and BTCN are identical.

TCN adheres to two principles: the output length of the network equals the input length, and future information cannot be leaked to the past. To satisfy these principles, 1D fully-convolutional network (1D-FCN) and causal convolution are introduced. The 1D-FCN ensures that the input and output lengths of each hidden layer remain identical. The causal convolution restricts the leakage of future information by simply padding the beginning and end of the time series, and then discards the excess padding values after convolution. It also limits the sliding direction solely from the past to the future. However, the modeling length of simple causal convolution is constrained by the size of the convolutional kernel. To establish long-range dependencies, numerous layers would need to be stacked, which can complicate the model and increase the risk of overfitting. To solve this issue, dilated convolution is introduced. The formula for dilated convolution is shown in Eq. (3).

$$F(s) = (X * df)(s) = \sum_{i=0}^{k-1} f(i) \cdot X_{s-d \cdot i} \tag{3}$$

In Eq. (3), $X = (x_1, x_2, \ldots, x_l)$ represents the feature sequence output by the CNN, where l is the sequence length. The symbol $*$ denotes the convolution operation, d is the dilation factor, k is the filter size, and $s - d \cdot i$ indicates the direction of the past. The dilation factor can be viewed as the sampling stride between adjacent filters, typically recommended to be 2^n, where n is the number of hidden layers. When d is equal to 1, the dilated convolution degrades to a regular convolution. The increase of d allows the TCN to achieve a broader receptive field, as illustrated in Fig. 1. This mechanism enables the network to capture long-range dependencies efficiently, and enhance its ability to analyze complex temporal patterns in the data.

Additionally, as a deep neural network model, even with the use of dilated causal convolution, TCN may still encounter

some issues such as vanishing gradients or network degradation. To address them, TCN incorporates residual blocks [25] to enhance its stability and generalization ability. This residual block comprises two layers of dilated causal convolution, where each layer utilizes weight normalization [26] for normalization and employs the ReLU activation function to expedite convergence. Moreover, dropout is applied for regularization. The output of residual function F is then added to the input x of residual block, as shown in Eq. (4).

$$O = Activation(x + F(x)) \tag{4}$$

Since the number of channels in x and $F(x)$ may not be consistent, the TCN employs a 1×1 Conv. This ensures that x matches the shape of $F(x)$ after a simple transformation.

3) Attention mechanism block: Traditional neural networks treat different features equally, which makes it difficult to distinguish important features. However, different features of different signals have varying degrees of correlation with surface roughness. To solve this problem, we introduced an attention mechanism. It assigns weights to enable the model to focus on features that are more important for surface roughness and reduce attention to less important information. For the computation of the attention mechanism, we adopt the commonly used *Bahdanau* algorithm with the following formulas:

$$e_{ij} = \tanh\left(W_1 * h_i + W_2 * h_j + b\right) \tag{5}$$

$$a_{ij} = softmax(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{k=1}^{T} \exp(e_{ik})} \tag{6}$$

$$c_i = \sum_{j=1}^{T} a_{ij} * h_j \tag{7}$$

where, e_{ij} represents the degree of match between hidden layer states h_i and h_j, W is a learnable weight parameter, b is a bias vector, a_{ij} denotes the attention weight of the network, and c_i is the final output of the attention layer. By means of the attention mechanism, the computational efficiency of the model is enhanced, and the influence of noise and outliers is suppressed.

B. Data Processing Method

The public ACF dataset [27], derived from Shang et al.'s work, is employed for surface roughness prediction. This dataset captures end-milling operations on a 45# steel workpiece, which is performed with a four-flute carbide tool on a CNC machining center. It encompasses vibration, current, and force signals from the end milling process, along with corresponding surface roughness measurements. Each signal contains three directional components. All signals were sampled at a frequency of 20kHz to ensure synchronous and consistent data collection.

In this paper, our data processing is conducted on the ACF dataset, which involves two main steps: data segmentation and sample amplification, as shown in Fig. 2.

1) Data segmentation: Since the tool does not contact the workpiece before the actual milling process starts and after it ends, the raw signals consist of redundant data with values close to zero, as depicted in Fig. 2(a). Hence, it is necessary to identify and remove these redundant data segments and retain only valid segments from the actual machining process.

The method to extract valid data segments involves several steps. First, the original X-direction vibration data is divided into multiple segments through a fixed-length window. Secondly, the standard deviation for each segment is calculated according to Eq. (8). Thirdly, segments with standard deviation above a certain threshold are selected as valid data segments. Finally, valid segments from the other raw data are extracted based on the same positions. As shown in Fig. 2(b), the standard deviation of redundant data segments are significantly lower than those of valid data segments. Therefore, the threshold is set to a value slightly lower than the standard deviation of valid data segments. This method ensures that only the segments containing relevant machining activity are retained for further analysis, and enhance the precision and reliability of the data.

$$S = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \overline{x})^2}{n}} \tag{8}$$

2) Sample augmentation: Even after data segmentation, a single valid data segment still contains a large number of data points, which may hinder the learning speed and efficiency of deep learning models. Moreover, the quantity of samples can also impact the performance of these models. When the original sample size is limited, to improve the prediction accuracy of the model, sample augmentation can be employed to generate additional samples [28]. Specifically, the valid data segments are divided into N sub-signals using a fixed time step window without overlapping, as shown in Fig. 2(d). Each sub-signal is subsequently treated as a sample. By setting N to 50 and 100, we obtained two different datasets, namely ACF-50 and ACF-100, which divided the valid data segments into 50 and 100 equal parts respectively.

IV. Experiments

After data processing, we conduct experiments on the datasets ACF-50 and ACF-100, in order to evaluate the effectiveness of the CBTA model in predicting surface roughness. Each dataset is randomly split in a 4:1 ratio, with 80% used as the training set and 20% as the test set. In these experiments, CNN, BiTCN, and LSTM-Attention (LSTM-A) are employed as baseline models for comparison. The performances of models are evaluated by three common metrics: Root Mean Square Error (RMSE), Mean Absolute Percentage Error (MAPE), and the Coefficient of Determination (R^2). Their formulas are shown in Eq. (9), (10), and (11). Smaller values of RMSE and MAPE, along with larger values of R2, indicate better model performance.

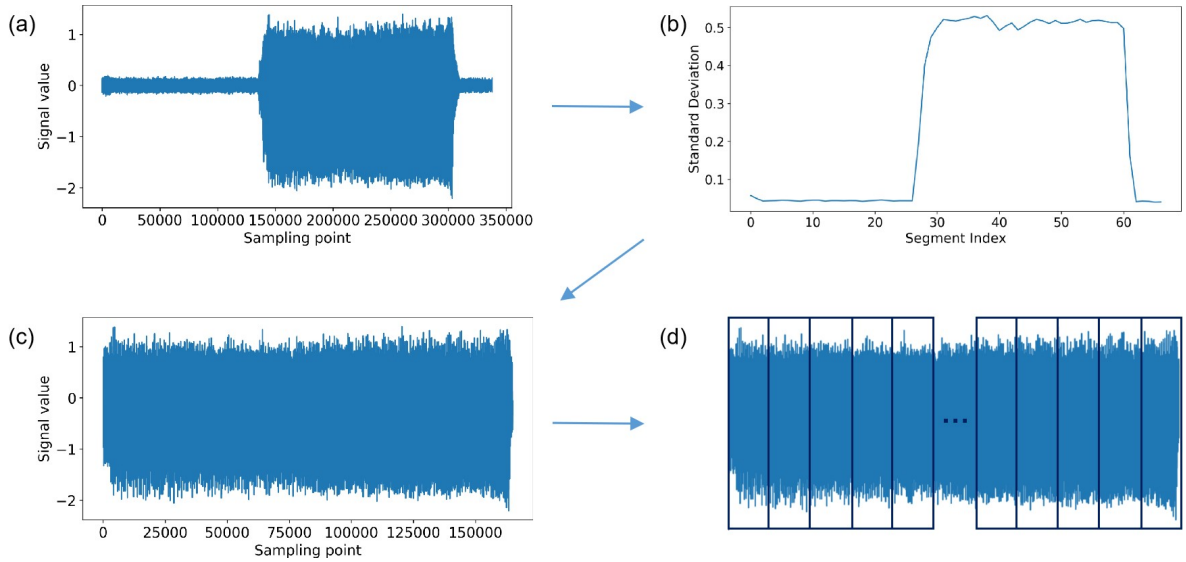

Fig. 2. Data segmentation and sample augmentation.

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \widehat{y_i})^2} \tag{9}$$

$$\text{MAPE} = \frac{100\%}{n}\sum_{i=1}^{n}\left|\frac{y_i - \widehat{y_i}}{y_i}\right| \tag{10}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \widehat{y_i})^2}{\sum_{i=1}^{n}(y_i - \overline{y})^2} \tag{11}$$

A. Model Parameters Settings

The experiments are conducted with Python 3.8 programming language and TensorFlow 2.9.0 framework. All models share the same common hyperparameters, i.e. a batch size of 32, a learning rate of 0.0005, the Adam optimizer, and a training epoch count of 200. All data are standardized before being input into the models, in order to eliminate the impact of different scales on the training process.

Table I presents the network structure of LSTM-A, while the structure of CBTA is detailed in Table II. The core network structures of the CNN and BiTCN models are identical to the CNN block and BiTCN block in CBTA, respectively. In our study, the number of stacks of residual blocks in TCN is set to 1, and the kernel initializer uses glorot uniform. According to the receptive field calculation formula (Eq. (12)) of TCN, the dilations in CBTA are set to [1, 2, 4, 8, 16] to ensure that the receptive field can fully cover the input sequence. As for BiTCN model, since there is no CNN block for data dimensionality reduction, the dilations are set to [1, 2, 4, 8, 16, 32, 64].

$$R_{field} = 1 + 2 \cdot (K_{size} - 1) \cdot N_{stack} \cdot \sum_{i} d_i \tag{12}$$

TABLE I. NETWORK STRUCTURE OF LSTM-A

LSTM block	LSTM	32	Tanh
Attention block	Attention	16	-
Output block	Dense	-	-

B. Training Loss

Training loss plot is crucial for evaluating model performance. Fig. 3 illustrates the training losses of various models on ACF-100. To prevent overfitting, an early stopping strategy was employed during the training process in our experiments. This strategy halts iterations when the training loss of models ceases to decrease. Both CNN and BiTCN demonstrate rapid convergence rates, and achieve convergence within 50 epochs. CNN stops training early due to the activation of the early stopping mechanism, while BiTCN's loss continues to decline slightly. LSTM-A has a slower convergence rate, and stabilizes around 90 epochs. It also triggers early stopping. CBTA exhibits the fastest convergence rate, and it achieves convergence within 30 epochs with the lowest loss.

C. Prediction Results

To investigate the effectiveness of various models in utilizing fused multi-process signals for prediction, we employed vibration, current, and force signals as inputs. Fig. 4 showcases the performance of different models on the ACF-50 and ACF-100 test sets. The prediction results and absolute errors of each model on ACF-50 are illustrated in Fig. 5, with only 50 samples displayed due to space limitations. Evidently, CBTA achieves the best performance on both datasets, followed by LSTM-A, while CNN and BiTCN exhibit similar effectiveness. Moreover, CBTA achieves RMSE, MAPE, and R^2 values of 0.0844, 2.76%, and 98.48% respectively on the ACF-50 dataset, while 0.0284, 0.79%, and 99.81% on the ACF-100 dataset. These results indicate that our proposed method

achieves satisfactory prediction accuracy, and demonstrate outstanding performance and robust prediction ability.

D. Comparison Under Single Signal Input

In order to evaluate the performance of each model with a single signal input, we conducted experiments on the ACF-100 dataset for predicting surface roughness with only vibration data. The results are shown in Fig. 6. It is evident that the performance of models declined to varying degrees when solely vibration signal is used, compared to the performance when employing a fusion of vibration, current, and force signals as inputs. However, CBTA is the least affected, and still achieves excellent results, with MAPE of 1.80% and R^2 value of 99.09%. This demonstrates that the fusion of multiple process signals contributes to improve accuracy, and also validates the effectiveness and robustness of CBTA in surface roughness prediction.

E. Result Discussion

Given the above experimental results, along with different model frameworks, the superiority of CBTA is analyzed from the following aspects:

- The CNN block possesses remarkable capabilities in feature extraction. In the milling process, the generated vibration, current, and force signals are intricate and multidimensional. They encompass not only spatial features, such as waveforms and frequency distributions, but also temporal features, like trends and periodicity. Compared with BiTCN and LSTM-A models, the CNN block, through its unique convolutional and pooling layer structure, can automatically extract local features related to surface roughness from the raw data. These features serves as input variables in subsequent blocks.
- The BiTCN block enables the model to comprehend temporal dependencies within the data. In comparison to CNN and LSTM-A models, TCN expands the network's receptive field through dilated causal convolutions, which allows it to more effectively capture long-term dependencies across time steps. Moreover, the bidirectional architecture of the BiTCN block enables the model to harness information from the entire signal sequence, encompassing both antecedent and subsequent data. This capability not only bolsters the precision of predictions but also amplifies the model's robustness.
- The attention mechanism enhances CBTA to concentrate on the critical segments of the input sequence. During the milling process, certain fluctuations in the vibration signal may arise from external disturbances rather than actual changes in surface quality. Compared to CNN and BiTCN models, the attention mechanism helps CBTA discern those irrelevant fluctuations by assigning weights to different time steps or features. This allows the model to concentrate on the information most relevant to surface roughness. This targeted method not only enhances the reliability of the model but also equips it with greater resilience against noise and irrelevant data.
- Each component offers complementary advantages. The integration of CNN, BiTCN and attention mechanism equips our model with the ability to handle complex nonlinear relationships between input signals and surface roughness, as well as to model temporal dependencies. This hierarchical approach enables CBTA to conduct a profound and meticulous analysis of the milling process and ultimately achieve precise roughness predictions.

V. CONCLUSION

This study investigates a deep learning-based approach for surface roughness prediction in end milling with the fusion of multiple process signals. Initially, through data segmentation and sample augmentation, two distinct datasets are developed

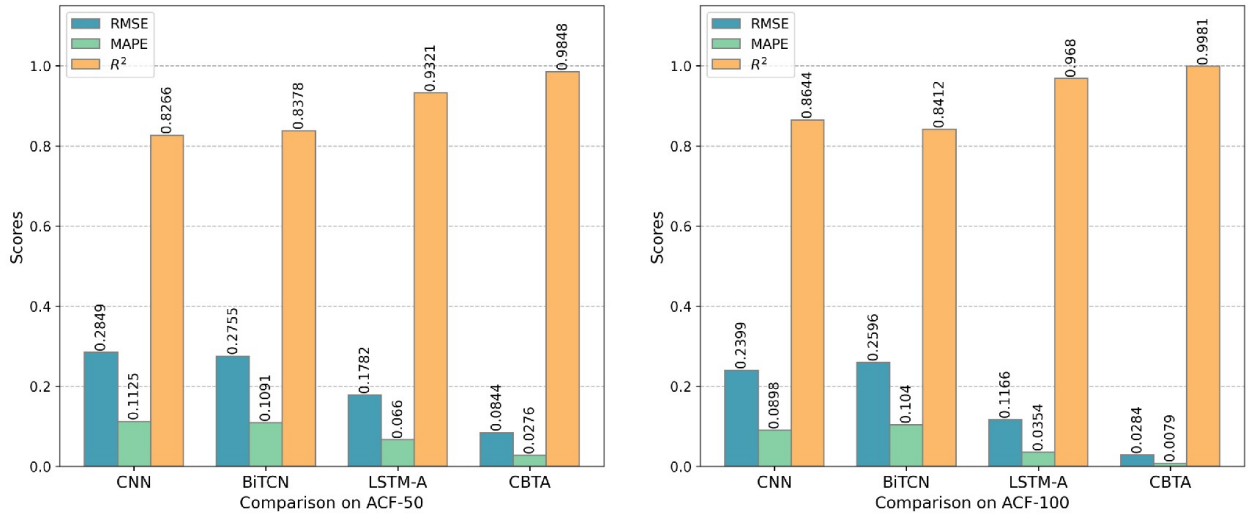

Fig. 4. Comparison of different models on the ACF-50 and ACF-100 test sets.

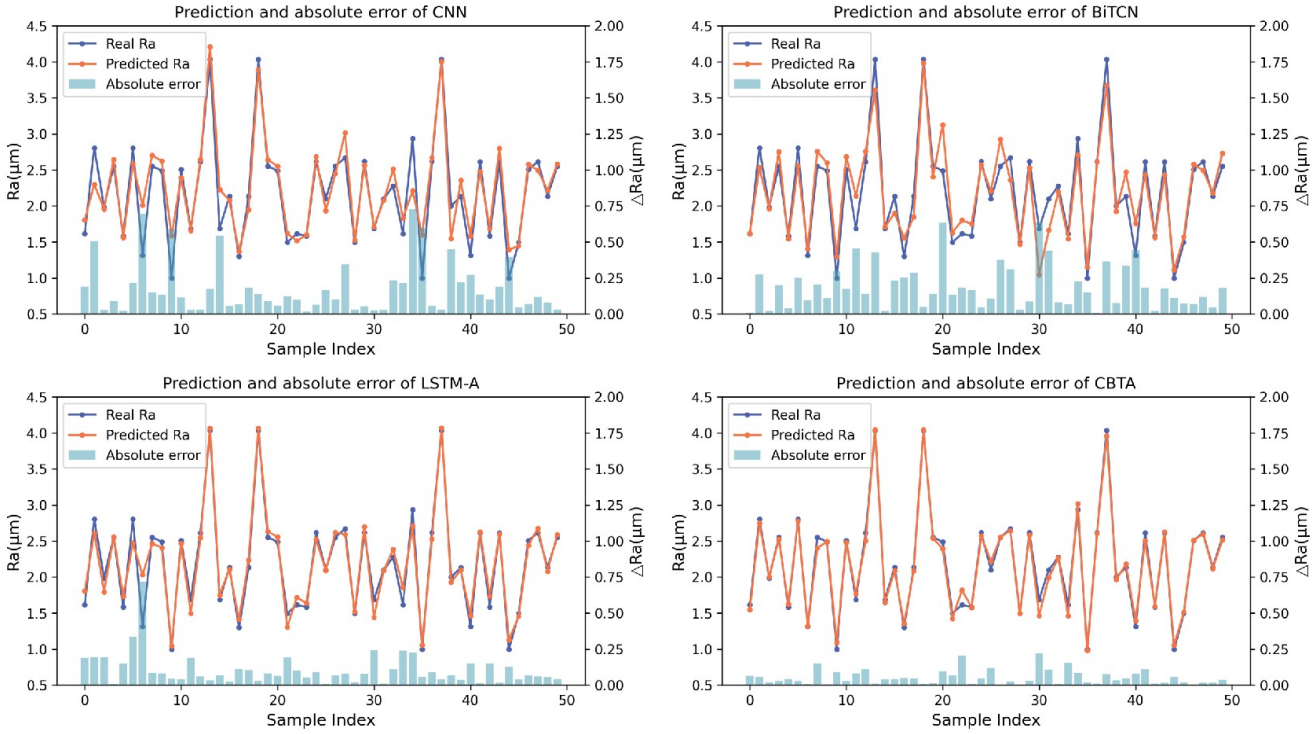

Fig. 5. Surface roughness prediction results and absolute errors of each model on the ACF-50 test set.

from the ACF dataset for model training and evaluation. Subsequently, the complementary strengths of CNN, BiTCN and attention mechanism lead to the proposal of an end-to-end CNN-BiTCN-Attention architecture (CBTA). This architecture possesses the capabilities to extract spatial features, capture temporal dependencies and allocate appropriate weights.

Three different deep learning architectures are utilized in experiments for comparison with CBTA. The results show that CBTA achieves high prediction accuracies of 98.48% and 99.81% on the two datasets, respectively, along with low MAPE values of 2.76% and 0.79%. These metrics indicate that CBTA outperforms other models in terms of precision. Additionally, the effectiveness of surface roughness prediction is examined by using only vibration signal. The results show that CBTA maintains excellent prediction results although the performance of other models decline, which highlight its robustness and effectiveness.

Despite its excellent performance on public datasets, CBTA still has some limitations. For instance, as a deep learning architecture, it lacks interpretability, which hinders fault diagnosis and process optimization in industrial applications. Additionally, as the performance of machining equipment may

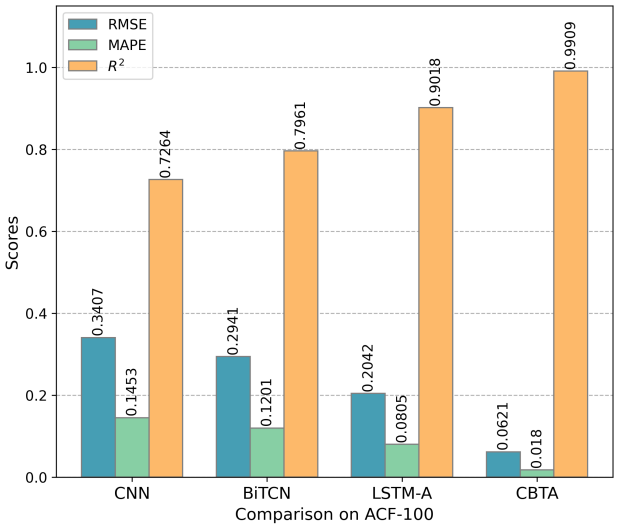

Fig. 6. Comparison of model prediction performance on the ACF-100 dataset using only vibration signal as input.

change over long-term operation, the prediction accuracy of the pre-trained model could decline. In such cases, it becomes necessary to adjust model parameters or retrain the model to maintain its effectiveness.

Enriching Sequential Recommendations with Contextual Auxiliary Information

Adel Alkhalil

University of Ha'il, Ha'il, 81481, Saudi Arabia

***Abstract*—Recommender Systems (RS) play a key role in offering suggestions and predicting items for users on e-commerce and social media platforms. Sequential recommendation systems (SRS) leverage the user's previous interaction history to forecast the next user-item interaction. Although deep learning methods like CNNs and RNNs have enhanced recommendation quality, current models still face challenges in accurately predicting future items based on a user's past behavior. Transformer-based SRS have shown a significant performance boost in generating accurate recommendations by using only item identifiers which are not sufficient to generate meaningful and relevant results. These models can be improved by incorporating descriptive features of the items, such as textual descriptions. This paper proposes a transformer-based SRS, ConSRec, Contextual Sequential Recommendations, that incorporates auxiliary information of the items, such as textual features, along with item identifiers to model user behavior sequences for producing more accurate recommendations. ConSRec builds upon the BERT4Rec model by integrating auxiliary information through sentence representations derived from the textual features of items. Extensive experiments conducted on several benchmark datasets demonstrate substantial improvements compared to other advanced models.**

***Keywords*—Recommender system; sequential recommendation; auxiliary information; sentence transformer; sentence embedding**

I. Introduction

A Recommender system (RS) is designed to predict user preferences based on user intent, which can vary over time [2], [1], [3], [4]. To better capture users' dynamic preferences, several sequential recommendation (SR) techniques have been recently introduced. These methods utilize a user's past interaction history to predict the next item they are likely to engage with [7], [6], [5], [8], [9].

Earlier SR models relied on Markov Chain models to capture user preferences and predict the next item in the sequence [10], [6]. With the rise of deep learning, many SR models have transitioned to using neural network architectures like RNNs [12], [11] and CNNs [13]. Later, attention-based Transformer models [14], [32] were introduced to address SR problems, such as SASRec [8] employs a uni-directional attention mechanism, which limits its ability to capture comprehensive user preferences. BERT4Rec [9] addresses this by adopting a bi-directional transformer architecture to learn contextual relationships from both directions. However, both models rely primarily on item identifiers and fail to incorporate auxiliary contextual data, such as textual descriptions or reviews, which are critical for improving recommendation accuracy, especially under sparse data conditions.

KeBERT4Rec [15] incorporated keywords along with item identifiers in BERT4Rec model by concatenating the keyword representation with items by using one-hot encoding to generate the keyword vector, which did not capture the contextual meaning of keywords. Although, these SR models show significant performance gain, however, they do not exploit contextual features to generate meaningful representations.

Incorporating such contextual auxiliary information into SR models not only improves recommendations, particularly under sparse situations but also has significant practical implications in real-world applications. For instance, in e-commerce, enriching recommendations with textual features like product descriptions can enhance personalized shopping experiences, leading to increased user satisfaction and higher sales conversion rates. Similarly, in media streaming services, leveraging textual metadata such as genre descriptions or user reviews can better align recommendations with user preferences, enhancing user engagement. To achieve this, we propose a model called ConSRec, Contextual Sequential Recommendations, a modification of the BERT4Rec model, which includes contextual descriptions. The proposed model, ConSRec, leverages a transformer-based architecture to incorporate contextual auxiliary information, such as textual descriptions and user reviews, into sequential recommendation tasks. This design makes it highly effective in addressing key challenges like sparse user-item interactions and the inability of existing models to utilize rich contextual data. By integrating multi-head self-attention mechanisms, ConSRec ensures the effective fusion of sequential and contextual data, providing a robust solution to improve recommendation accuracy. The major objectives of the paper can be outlined as below:

- Introduce a model that incorporates the user sequences with contextual item descriptions using Masked Language Model (Close Objective Task) and bidirectional transformers.
- Generate meaningful representations using contextual description of the items using Sentence-BERT.
- Evaluation and performance comparison of the model against existing leading models.

The article is structured as follows: Section II provides a review of the relevant literature, while Section III offers a detailed explanation of the proposed model. Section IV covers the experimental evaluation of the work, and Section V concludes the paper.

II. Literature Review

Sequential recommendation system is a type of RS that exploits the user interaction sequences to infer the successive

item [17]. The aim of SR is to recommend future product by considering historical behavior of users. This historical behavior is also known as next item prediction. Earlier, the SRS were introduced using Markov Chains (MC) models for capturing sequential patterns from the user historical preferences [18], [10], [19]. The next item preferred by the users are predicted depending upon the last item, thus interpreting only the adjoining sequential behavior.

Recurrent Neural Network (RNN) based models exploiting Gated Recurrent Unit (GRU) [20], [12] and Long Short-Term Memory (LSTM) [39] have showed substantial performance gain for SR [25], [21], [22], [11], [12], [24], [23]. RNNs enforce rigid sequential patterns for encoding user preferences for making predictions. Besides RNN, a number of Convolutional Neural Network (CNN) [26], [27] based RS have also been introduced that also target problems related to the sequential recommendation. For example, Tang and Wang *et al.* [13] exploit CNN for capturing local sequential features using more recent behaviors.

Recently, Transformer models based on the attention mechanism [14] have achieved outstanding results in various deep learning tasks, including text classification [28], image captioning [29], and machine translation [30]. Initially developed for natural language processing, Transformers have also transformed the field of sequential recommendation (SR) [17] by leveraging the encoder component to process sequential data. This converts the sequence of items, representing the user's interaction history, into a sequence of vector representations [14]. The input sequence of items is first embedded and then concatenated with positional embeddings capturing the item's position in the sequence.

TABLE I. COMPARISON OF SR MODELS

Model	Pros	Cons
GRU4Rec	GRU model of RNN with ranking-based loss function.	Aimed for session-based recommendation systems using RNN.
SASRec	First unidirectional self-attention sequential model based on Transformers for next-item recommendation.	Uses only left-to-right attention, limiting its ability to learn hidden representations bidirectionally.
BERT4Rec	Bidirectional model employing Transformer architecture with multi-head self-attention to analyze user behavior sequences.	Lacks incorporation of additional information to produce meaningful predictions.
KeBERT4Rec	Extension of BERT4Rec leveraging keywords alongside item identifiers for next-item prediction.	Keyword representations are not derived using contextual embedding techniques.
FDSA	Segregated attention blocks exploit items and their features to predict the next item.	Heterogeneous item characteristics make it challenging to determine user preferences accurately.
S3Rec	Self-supervised model utilizing attribute data to learn correlations among items.	Does not use descriptive information for generating meaningful representations.

Most of recent sequential models shown in Table I follows the transformer architecture comprising of encoder block [31], [8], [9], [15] and using the item identifiers for next item recommendation. A feature level deeper self attentive model [16] introduced by T. Zhang *et al* exploits segregated attention blocks for items and their associated features to predict next item. In [33] proposed S3Rec, a self supervised SR model that utilized the attribute data of item to learn the correlation among them. KeBERT4Rec [15] leverages the keyword by integrating them with item identifier for the prediction of next item in sequence.

Existing sequential recommendation models, such as SASRec and BERT4Rec, rely primarily on item identifiers and focus on implicit feedback for next-item prediction. SASRec's uni-directional attention mechanism limits its ability to fully capture sequential dependencies, while BERT4Rec's bi-directional architecture, although more robust, still neglects auxiliary information like textual descriptions and user reviews. These omissions reduce the models' effectiveness in scenarios with sparse data or ambiguous user-item interactions, which necessitate richer contextual representation. To address this we proposed ConSRec, a model that combines auxiliary information and item identifiers to create embeddings using the Sentence BERT [34] embedding technique. This enhances item recommendation and prediction accuracy by capturing contextualized representations.

III. METHODOLOGY

The suggested framework "ConSRec - Contextual Sequential Recommendation System" is depicted in Fig. 1. The proposed paradigm is developed based upon Transformer architecture that adapted the deep bidirectional BERT model for SR prediction task (Fig. 2).

Fig. 1. Proposed methodology outline diagram.

A. System Overview

Before passing the sequence of items to the model proposed, the auxiliary features of these items are taken as input to the Sentence-BERT. This auxiliary information is the textual description of the items in the form of sentences that are processed to extract the contextual dense feature representation. These dense embedding are extracted prior to training phase to reduce the model training time.

Subsequently, during the training process, the auxiliary information's embeddings of items within a sequence are extracted and then passed to the embedding layer. These embeddings are subsequently combined with the item's embedding and positional embedding to capture the sequential behavior of the items. Only the encoder part of Transformer is used to compute the hidden representation using self attention mechanism for each item.

This resultant concatenated item's representations of sequence are then processed through stack of Transformer layer from [14] where hidden features for each item are calculated simultaneously at each layer. These layers share information bidirectionally across each position in hierarchical manner. After processing through all layers, a final learned hidden representation is projected at output layer that contemplated the future item recommendation for a user.

Several experiments were carried out on three benchmark datasets—MovieLens-1M, MovieLens-20M, and Amazon Beauty—to validate the effectiveness of the proposed model. The model's architecture includes an embedding layer, a transformer layer, and an output layer.

B. Mathematical Formulation of Proposed Model

Let set of users be shown mathematically as $\mathcal{U}$ = $\{u_1, u_2, u_3, ..., u_{|\mathcal{U}|}\}$ $\mathcal{M}$ = $\{m_1, m_2, m_3, ..., m_{|\mathcal{M}|}\}$ be the set of items. For each item, there is some item description (auxiliary information) that is in textual form denoted as $\mathcal{TD}$ = $\{des_1, des_2, des_3, ..., des_{|\mathcal{M}|}\}$. The items interacted in the sequence $\mathcal{S}$ in historical order for a user u is denoted as $\mathcal{S}$ = $\{m_1, m_2, m_3, ..., m_n\}$ where m_n is a particular item from $\mathcal{M}$, the user has acted upon previously. Given the sequence history $\mathcal{S}$, the objective of the SRS is to anticipate the future item m_n+1, the model will predict as:

$$\mathcal{P}(m_n\text{+1} = m|\mathcal{S})$$

C. Embedding Layer

The recommendation model in [9] makes use of the positional embedding along with the item identifier embedding to maintain the sequence of the items, thus memorizing the sequential order of the input. However, the pair alone does not describe the contextual representation of the input. It also does not recommend contextually especially under sparse conditions. To overcome this limitation, ConSRec incorporates additional auxiliary information based on contextualized description of items. The model utilizes the Sentence-BERT [34] for capturing contextual representation of the item descriptions. The architecture of Sentence-BERT for extracting sentence embedding is depicted in Fig. 3.

Sentence-BERT first utilizes BERT to generate word/ token embedding. Input in the form of sentences or text of various length is injected to the selected SBERT model, that generates contextualized word embedding for all input tokens in the sentence. Secondly, these word embedding are passed through a pooling layer to generate a fixed-sized vector representation. Among various pooling options available, the model utilizes the mean pooling in which mean of all contextualized token embedding is calculated to produce a fixed dimensional output embedding vector. Given the item descriptions of various length of all items, $\{\mathcal{TD}\}$ as input, the model produces 384 dimensional dense vector representation $\{Emb_{\mathcal{TD}}\}$ as in Eq. 1. These 384 dimensional embeddings are then used along with the item identifier and position embedding to produce information rich vector representations as shown in Eq. 2.

$$SBERT(\{\mathcal{TD}\}) = \{Emb_{\mathcal{TD}}\} \tag{1}$$

In the proposed model, *d* dimensional embedding layer is constructed by summing up the item identifier embedding, the position embedding and the additional auxiliary information (item description) extracted from $\{Emb_{\mathcal{TD}}\}$. Thus, for a given item m_i, the input embedding matrix $\mathcal{EM}$ is formulated by adding the corresponding item embedding E_m, position embedding E_{pos} and textual description embedding E_{des} as:

$$\mathcal{EM}_m = E_m + E_{pos} + E_{des} \tag{2}$$

D. Transformer Layer

The summed embedding $\mathcal{EM}$ becomes the input to the transformer layer that iteratively calculates the hidden representations of each item at each layer.

The structure of transformer layer or simply the encoder layer is build using the "multi-head attention". The layer piles up multiple encoder blocks [14] each consisting of "Multi-Head Self Attention" sub-layer and a "Position-wise Feed Forward Network". Given that $\mathcal{E}^{\curlywedge} = [\mathcal{EM}_{\curlywedge}^{\curlywedge}, \mathcal{EM}_{\curlywedge}^{\curlywedge}, ...\mathcal{EM}_{\approx}^{\curlywedge}]$ depict the dense vector embedding of the user sequence to the transformer, multi head self attention layer, MHSA is defined as:

$$MHSA(\mathcal{E}^l) = [h_1; h_2; ....h_h]W^0 \tag{3}$$

$$h_i = Attn(\mathcal{E}^l W_i^Q, \mathcal{E}^l W_i^K, \mathcal{E}^l W_i^V) \tag{4}$$

where W_i^Q, W_i^K and $W_i^V \in \mathbb{R}^{dxd/h}$ are the three learnable projection weight matrices and $W_i^0 \in \mathbb{R}^{dxd}$. $\mathcal{E}^l W_i^Q$, $\mathcal{E}^l W_i^K$, $\mathcal{E}^l W_i^V$ are the three linear transformation of input vector representation $\mathcal{E}'$ for Query, Key and Value (Q,K,V) vectors. Here, the attention function is scaled dot product [14] computed as:

$$Attn(Q, K, V) = \sigma\left(\frac{QK^T}{\sqrt{d/h}}\right)V \tag{5}$$

where the Query, Key and Value matrices are denoted by Q, K, V respectively and σ is the softmax function. Let MHSA at the l^{th} layer be S_i. Since, the MHSA block is based on linear projections, thus, the non-linearity to the MHSA is empowered by applying position-wise feed-forward network layer, PFN on all MHSA(S_i) separately.

$$PFN = [FNL(S_1^l)^T, FNL(S_2^l)^T .....FNL(S_n^l)^T] \tag{6}$$

$$FN(S_i) = GELU\big(S_i W^{(1)} + b^{(1)}\big)W^{(2)} + b^{(2)} \tag{7}$$

A smoother GELU activation function is used inline with BERT [5] and OpenAI GPT [40]. $W^{(1)}, b^{(1)}, W^{(2)}$, and $b^{(2)}$ are hyper-parameters communicated at all layers. Complexity of the model is reduced using residual connection at each sub layer. Dropout is applied followed by layer Normalization, LNorm. Thus, the sub-layer output at each level is $LNorm(x + Dropout(sublayer(x)))$. Input at each layer is denoted by x in the LNorm and represented as:

$$\mathcal{E}^l = Trm\big(\mathcal{E}^{l-1}\big), \quad \forall i \in [1, 2, ...L] \tag{8}$$

$$whiteA = Dropout\big(PFN(S_i^{l-1})\big) \tag{9}$$

$$Trm(\mathcal{E}^{l-1}) = LNorm\big(S_i^{l-1} + A\big) \tag{10}$$

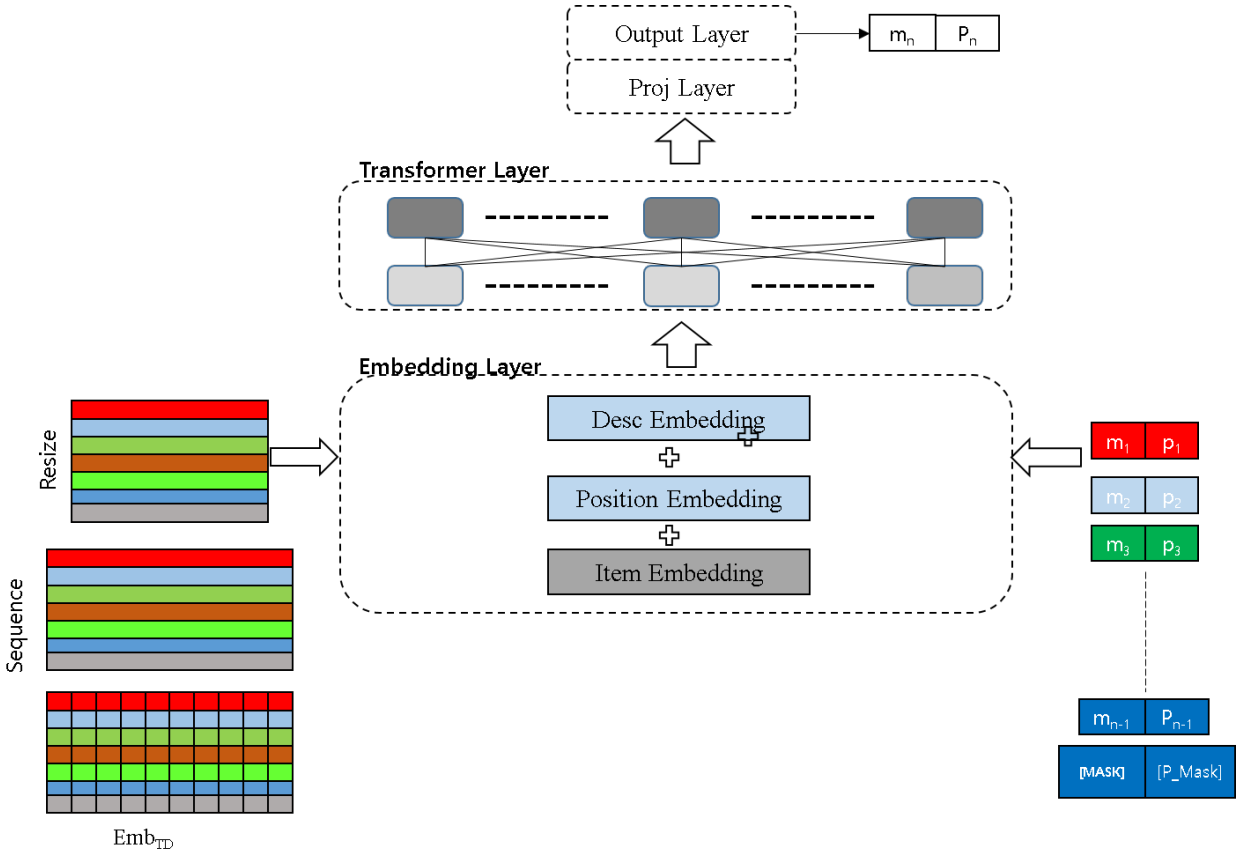

Fig. 2. Model architecture of contextual sequential RS.

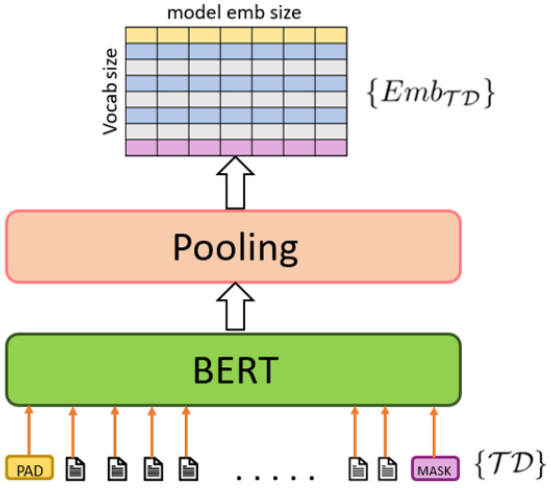

Fig. 3. Design architecture of sentence-BERT.

$$whiteB = Dropout\big(MHSA(\mathcal{E}^{l-1})\big) \tag{11}$$

$$S_i^{l-1} = LNorm\big(\mathcal{E}^{l-1} + B\big) \tag{12}$$

E. Output Layer

After passing through L layers and shared representations bidirectionally over each position in hierarchical manner, a final learned hidden representation $\mathcal{E}^{\mathcal{L}}$ is projected at output layer for all input item sequences. Considering the last item m_n in the sequence is masked, m_n is anticipated using embedding sequence $\mathcal{E}^{\mathcal{L}}$ that is depicted in Fig. 2. The last layer applies linear transformation twice followed by softmax function to predict the masked item.

$$whiteG = GELU\big(\mathcal{E}_t^L W^P + b^P\big) \tag{13}$$

$$P(m) = softamx\big(G(\mathcal{E}\mathcal{M}^T) + b^O\big) \tag{14}$$

where b^P and b^O are the bias at projection layer and W^P is the projection matrix. $\mathcal{E}\mathcal{M}^T$ is the item embedding matrix comprising of item identifier, positional and auxiliary information embedding. Here, shared item embedding is applied to minimize model size and relieve over-fitting.

IV. Experimental Configurations and Results Analysis

The datasets used to evaluate the proposed model and their preparation followed by experiment setup, evaluation metrics and performance comparison are presented in this section.

Most of the State-of-the-art SRS are trained on benchmark datasets that includes MovieLens, Amazon – Beauty. To effectively compare the improvements in the proposed model, these models are chosen. Moreover, auxiliary information of these datasets are also available and can easily be incorporated in these datasets. The auxiliary information, movie plot summary, of MovieLens dataset has been obtained through IMDbPy and for the Beauty Dataset, the description is chosen as a auxiliary information which is extracted from the meta file associated with the beauty dataset. Any item lacking auxiliary information has been ignored.

A. Dataset Pre-processing

Performance of proposed model is demonstrated through experiments carried out on three benchmark datasets including movielens-1m , movieLens-20m (ml-1m[1] and ml-20m[2]) and Amazon-Beauty[3] as described below:

1) MovieLens: A well-known dataset most commonly used for evaluating the performance of SRS. MovieLens ratings dataset contains the user id, item id (IDs of the movies from "movies" table), ratings and timestamp for movie ratings from each user. The auxiliary information (movie plot summary) for MovieLens is extracted through IMDbPY[4] using the **ImdbId** unique identifier, thus, making it information rich dataset.

2) Amazon - Beauty: It is a set of dataset comprising of reviews of a number of products extracted from "Amazon.com". The data is split into multiple datasets based upon product categories on Amazon. In our experiments, "Beauty" category is chosen that has a "rating" and a "meta" file. To incorporate the auxiliary information in the "rating" dataset, "description" of each product is extracted from the "meta" dataset.

The following Table II summarizes the dataset statistics.

TABLE II. DATASETS STATISTICS

Dataset	#users	#items	#interactions	Sparsity
ML-1m	6,040	3,706	1.0m	95.16%
ML-20m	138,493	26,744	20.0m	95.53%
Beauty	22,363	12,101	0.2m	99.93%

B. Evaluation Metrics

To measure the overall SR behavior, widely used leave-one-out strategy [8], [9], [15] is employed. The last item in each user's sequence is used for testing for every user, the second-to-last item is used for validation, and the remaining interaction items are utilized for training. For fair assessment, commonly used sampling practice [8], [9], [15] i.e. the ground truth object is coupled item with 100 negative items in test set based on how popular they are.

For evaluating all methods, "Normalized Discounted Cumulative Gain" (NDCG), "Hit Ratio" (HR) and "mean reciprocal rank" (MRR) are calculated. Higher values of these metrics depicts how better the recommendation performance is. Hit Ratio (HR) is used for measuring the ranking accuracy by comparing the test item set (T) with the ranked list. Mathematically it is expressed as:

$$HR@K = \frac{Numberof Hits@K}{|T|} \tag{15}$$

HR@K calculates the number of hits in a K-sized list. A hit occurs if the item tested is available in ranked list. Whereas the relative position of that item is assessed using NDCG in the ranked list. It assigns higher scores if the item is present at top position in the list. Mathematically it is evaluated by following formula:

$$NDCG@K = N_K \sum_{j=1}^{K} \frac{2^{z_j} - 1}{log_2(j+1)} \tag{16}$$

where N_K is the normalizer and z_j being the item's graded relevance at position j. We compute both the metrics of every test user items and then take their mean.

C. Baselines

For performance comparisons, we consider the following methods.

1) BPR-MF: [35] This model is the first one that uses the Bayesian personalized ranking loss for the optimization of matrix factorization (MF).

2) NCF: [36] This model utilizes MLP for capturing the item sequence interacted by user instead of using inner product in MF.

3) FPMC: [6] Combines MF with first-order MC to capture the long-term preferences of the user.

4) GRU4Rec: [12] It models the user click sequences using RNN-GRU for session based recommendation.

5) SASRec: [8] It is a unidirectional (left-to-right) self attentive model for next item prediction.

6) BERT4Rec: [9] This top of the line model uses bidirectional self attentive blocks and Cloze [37] masking for the recommendation task.

7) KeBERT4Rec: [15] This model extends BERT4Rec [9] by integrating keywords as additional input layer.

D. Implementation Details

The proposed model is trained on machine having 16 GB RAM and NVIDIA GTX 3080Ti (11GB). The training of proposed model is done using Adam Optimizer [38] with initial learning rate lr) of 0.001 and weight decay of 0.01. The hidden dimension is set to 128, dropout to 0.1 and 200 value used for maximum sequence length for MovieLens datasets and 50 value for Amazon Beauty. The masking probability of 0.15 is set for ML-20m and ML-1m. A 256 of batch size is used to train the proposed model.

The code provided by the corresponding authors of the respective baselines models were executed on the same machine. The optimized settings for hyperparameter values are used for all baseline models. The *hidden dimensionality* is tested from {64,128,256}, *dropout* from {0.1-0.9}, l_2 *regularizer* from {0-0.0001}.

E. Comprehensive Performance Analysis

Tables III, IV and V presents the optimized outcomes of each baseline models on benchmark datasets. The highest scores in each table are shown in bold, while the 2nd place scores are underlined. The last row in each table displays how the proposed model performs in comparison to the best baseline model. The advantage of FPMC over BPR-MC is that it sequentially models users' previous records. From this observation, the importance of taking sequential pattern in consideration for recommendation systems can be ascertained.

Comparing the sequential baseline models, SASRec model outperforms GRU4Rec and FPMC on all benchmark datasets. This observation demonstrate that use of transformer based self attention models are more accurate than using traditional mechanisms. However, SASRec performance fall behind as compare to BERT4Rec which depicts that bidirectional model like BERT4Rec is more powerful as compared to unidirectional model like SASRec. BERT4Rec is a SR model that relies only on the item identifiers for the purpose of generating representation/ embedding. This model ignores the auxiliary information that is already provided with the datasets. However, KeBERT4Rec, a variant of BERT4Rec, has modified the representation by adding keywords describing the items e.g. Genre of movie.

	HR@10	0.4983	0.5012	0.5296	0.5321
	NDCG@5	0.3079	0.3160	0.3256	0.3261
	NDCG@10	0.3187	0.3251	0.3361	0.3394
	MRR	0.2263	0.2476	0.2509	0.2517

The addition of this keywords embedding in the model makes KeBERT4Rec perform better than BERT4Rec. Thus, suggesting that incorporating some kind of side information along with item can improve the recommender's performance. It is evident from Table III that outcomes of all the sequential models like GRU4Rec, BERT4Rec, SASRec etc outperformed the non-sequential models like BPR-MC and NCF on dataset ml-1m. Our model outperformed in all baseline metrics showing the accuracy of model by incorporating the additional auxiliary information.

Result depicted in Table IV also indicates the importance of using Sentence-BERT to incorporates the contextual meaning of addition auxiliary information alongwith the item identifiers. Our model outperforms all baseline models. ConSRec gains an improvement of 5.62% on HR@10 and 10.27% on NDCG@10.

In accordance with the results, on the beauty dataset, Table V shows that our proposed model, ConSRec clearly

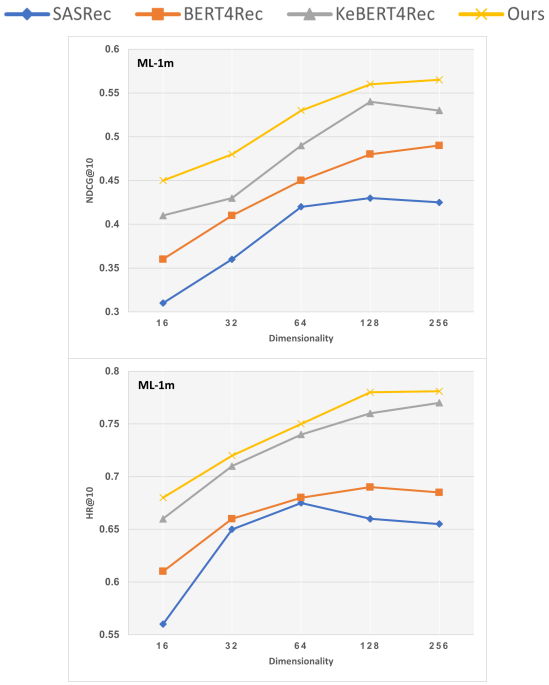

Fig. 4. Hidden dimensionality, d impact on NDCG@10 and HR@10 for ml-1m.

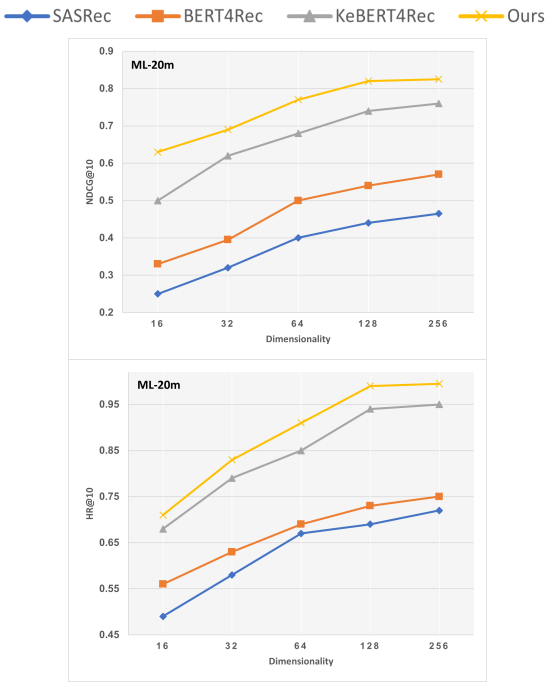

Fig. 5. Hidden dimensionality, d impact on NDCG@10 and HR@10 for ml-20m.

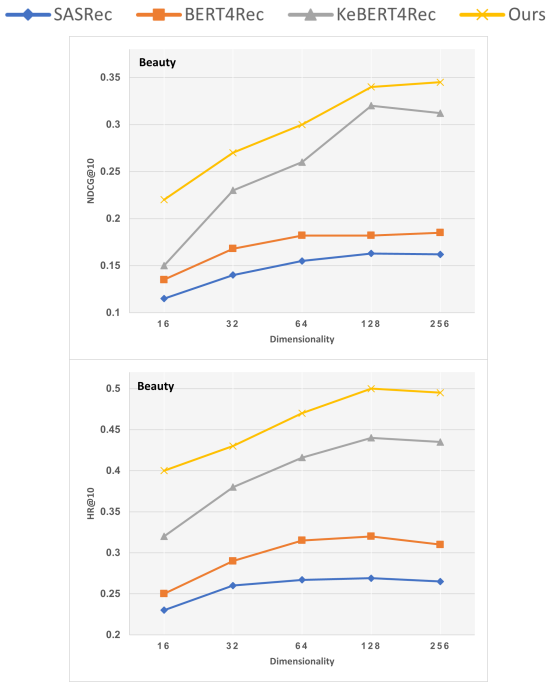

Fig. 6. Hidden dimensionality, d impact on NDCG@10 and HR@10 for beauty.

outperforms all baseline methods. The proposed model gains an average improvement of 11.95% on "HR@10" and 7.27% on "NDCG@10" as compared to the best baselines.

F. Evaluating Effect of "Hidden Dimensionality"

The hidden dimensionality *d* has a great impact on the performance of recommendation system that is studied in this section. Fig. 4, 5 and 6 exhibits the values of HR@10 and NDCG@10 on different baseline sequential model by varying hidden dimensionality *d* ranges between 16,32,64,128,256. The remaining of the hyperparameters are constant and kept to their optimal values.

The performance of ml-20m on varying dimensionality has very less impace on NDCG@10 and HR@10 as depicted in Fig. 5. However, bigger value of hidden dimensionality doesn't always yield accurate results.

It is obvious from Fig. 6 that with the increase of dimensionality, the graph of each model converges. However, improved model performance is not always achieved with bigger value of hidden dimensionality, particularly on sparse datasets, such as Beauty.

G. Impact of Integrating Auxiliary Information

As stated earlier, BERT4Rec only incorporated the embeddings of item identifiers along with its positional embedding in the input layer. However, in the proposed model, these embeddings are further enhanced and improved by incorporating additional contextual embedding layer of auxiliary information which is in the form of sentences.

The embeddings of this auxiliary information is extracted through Sentence-Transformer model that generates contextualized word embedding for all input tokens in the sentence.

To visualize this impact of using contextual information along with item identifier, the proposed model is initially trained by excluding the contextual information (ConSRec*). The results are then compared with the ConSRec i.e. by integrating side information. It is evident from the results that auxiliary information can enhance the productivity of SR system. Only the results on ml-1m and beauty dataset with batch size 128 are reported above in Table VI due to space limitations which clearly depicts that excluding the side information from proposed model degrades the performance.

H. Ablation Study

Finally, to visualize the impact of incorporating auxiliary information, some ablation experiments were conducted. Sentence-Transformer is used to train the proposed model which is a pre-trained model for generating embedding of item's side information. To analyze the impact of using contextual embedding instead of traditional techniques, the proposed model is tested using one hot encoding techniques to generate textual embedding.

As depicted in Table VII, By the use of Sentence Transformer to generate embeddings, the results of proposed model on ml-1m and beauty datasets outperforms all other non-contextual methods like word2vec, doc2vec, etc. This also emphasize the use of meaningful and context embedding generating technique for model training to produce relevant results.

V. Conclusion

Self Attention and Transformer based recommendation system have proven to be more precise and accurate as compared to traditional RS. In this paper, a transformer based sequential RS have been proposed that enhances recommendation accuracy by incorporating contextual auxiliary information of items in a sequence. The paper also uses contextual auxiliary information of items, such as descriptions or reviews, to enhance the recommendations. A contextual based pre-trained model sentence-transformer is used to generate meaningful embedding of auxiliary information. The experiments on various datasets show significant improvements over the state-of-the-art models.

However, ConSRec reliance on textual features as well as generalizability across highly diverse datasets beyond the domain of e-commerce and media streaming services poised limits to its capability. In future integration of additional multimodal data sources to further improve its performance and robustness.

King Faisal University, Alhufof 31982, Saudi Arabia

***Abstract*—Transportation systems are moving towards autonomous and intelligent vehicles due to advancements in embedded systems, control algorithms, and wireless communications. By enabling connectivity among vehicles, a vehicular network can be developed which offers safe and efficient driving applications. Security is a major challenge for vehicular networks as application reliability depends on it. In this paper, we highlight the security challenges faced by a vehicular network especially related to jamming and data integrity attacks. Such attacks cause major disruptions in the wireless connectivity of users with the centralized servers. We propose a context-aware anomaly detection technique for vehicular networks that considers factors such as signal strength, mobility, and data pattern to find abnormal behaviors and malicious users. We further discuss how an intelligent learning system can be developed using efficient anomaly detection. We implement a vehicular network scenario with malicious users and provide simulation results to highlight the performance gain of the proposed technique. We also highlight several appropriate future opportunities related to the security of vehicular network applications.**

***Keywords*—Fog computing; load balancing; task offloading**

I. Introduction

Intelligent Transportation Systems (ITS) are an important component of smart cities. The goal of ITS is to introduce intelligence, connectivity, and control capabilities in the vehicles such that driving can be more safer and comfortable [1]. A vehicular network is an important part of ITS as it provides wireless communication between different components of ITS [2], [3], [4], [5], [6], [7], [8]. The major advantage of vehicular networks is that it can continuously monitor the location of all vehicles within the city and guide the vehicle to make intelligent driving decisions [9], [10], [11]. This can be particularly useful for managing city level traffic flow and accident free driving on the roads [12], [13], [14], [15], [16], [17].

Security and privacy are important aspects of future wireless communications and vehicular networks [18], [19], [20], [21], [22], [23], [24]. Without secure communications, many vehicular network applications can be compromised and sensitive data can be leaked. Thus, security is an important part of reliable communications [25], [26], [27], [28].

Vehicular networks suffer from many attacks by intruders and malicious nodes [29], [30], [31]. These attacks impact the quality of wireless communications, the confidentiality of data transmission, the integrity of messages shared between nodes, and the availability of information among all the devices. By ensuring all these requirements of secure communications, applications' reliability can be significantly improved [9].

Few cyber attacks that target vehicular applications include data integrity attacks, eavesdropping, and jamming. In data integrity attacks, malicious users send wrong information to the server so that data used for making decisions can be polluted [32], [33], [34]. Since most decisions made by the applications rely on the quality of data and its accuracy, it is critical to detect these types of attacks [35], [36], [37].

In eavesdropping attacks, the malicious user captures the data sent between the vehicles and the server [38], [39], [40]. This can be dangerous for applications where sensitive information can be captured and used to impact the vehicle safety [41], [42], [43]. In jamming attacks, malicious users transmit signals to cause interference for other users in the network. This reduces reliability of communications as signal to noise ratio is reduced [44], [45], [46], [47], [48], [49].

To overcome these challenges in the security of vehicular network applications, cryptographic schemes such as Elliptic Curve Digital Signature (ECDSA) are commonly used. By adding extra encryption information to the original message, it is made secure and can only be decoded by users with the correct key information. While ECDSA can make the information and data transmission secure, it is still impacted by cyber-attacks. Particularly, all messages are verified for correct signature information at the receiver. As a result, a lot of time is wasted verifying fake messages by malicious users. This impacts the Quality of Service (QoS) of applications as a large end-to-end delay is incurred.

The data generated by the malicious users can be considered an anomaly or abnormal behavior [50], [51], [52], [53], [54]. The anomalies need to be efficiently detected in a secure system and malicious user data should be recorded for future attack prevention. The goal of anomaly-based security is to complete the process of detection in a quick time and with good accuracy [55], [56], [57], [58].

In this paper, we present a new framework for anomaly detection and verification in vehicular network applications. The key idea of the proposed framework is to develop a trust table in the server for all associated vehicular nodes in the network. The framework uses contextual information related to message physical parameters, mobility of the user, and data patterns to compute trust and detect anomalies. Moreover, the framework also includes an anomaly verification procedure so that the trust values in the trust table can be updated periodically on the server. Simulation results in MATLAB provide a detailed performance evaluation of the proposed technique compared to the other recent techniques in the literature. Finally, we also present several research challenges and future opportunities in the area of vehicular network security.

Table I below shows the anomaly detection techniques in the literature.

II. Literature Review

Security and privacy in vehicular and IoT systems have been explored in several papers in the literature. Similarly, anomaly detection techniques have been part of many proposals. We discuss some of these techniques in this section.

The work in [59] proposes a novel anomaly detection technique for IoT networks. The major problem addressed in this paper is related to class imbalance i.e. when normal data is much larger than the abnormal one or vice versa. The data set considered in this paper is Network Security Laboratory-Knowledge Discovery and Data Mining Tools Competition (NSL-KDD). The technique used in this paper is reinforcement learning in which actions are classification of input data into normal and malicious categories. The states in the paper are the data type. As the data in an IoT network can be of different types. Hence, the state takes into account the data category. The reward function in the paper is anomaly prediction accuracy. The proposed work shows better accuracy, recall, and F1 score.

In [60], the authors focus on a network related to Industrial IoT (IIoT). The goal is to detect cyber attacks and a federated learning-based approach is used in this regard. The major advantage of the federated learning approach is its privacy preservation as data is only shared locally. In the proposed work, universal anomaly detection is achieved with the help of different local Anomaly Detection Centers (ADC). Moreover, anomalous ADCs are also detected with the proposed technique. There is also an appeal procedure reserved for users that are declared anomalous. The accuracy and throughput of the proposed technique are shown to be better than other related techniques.

The work in [61] deals with traffic flow monitoring applications for Software Defined Networks (SDN). The goal of the technique is to choose traffic flow monitoring granularity. There exists a tradeoff between accuracy and network load. More accurate techniques may incur a large network load, hence a balancing technique is needed. The proposed technique uses Deep-Q learning to detect anomalies. The proposed technique achieves quick and optimal policy evaluation. Particularly against the Denial of Service (DDoS) attacks, the proposed technique performs efficiently. The accuracy and detection time of the proposed technique has been shown to perform better than other techniques in the literature.

In [56], the authors considered an Internet of Vehicles (IoV) scenario where vehicles share information about the surrounding traffic. Parameters such as traffic density, vehicles in an emergency, vehicle speeds, etc. are shared with infrastructure Road Side Units (RSUs). Malicious users launch data integrity attacks i.e., they change the information about traffic density and send wrong information. As a result, the traffic density estimation is corrupted and wrong decisions are made. To overcome this problem, the authors propose an isolation forest-based anomaly detection algorithm. The anomalies are verified using probe messages that are sent to vehicles in the neighborhood of malicious users. A communication mechanism is also designed to share the verification information. Results in terms of accuracy, recall, and F1 score of the proposed technique is enhanced.

The social networks are considered as part of the work in [62]. The main problem addressed is related to feature learning and combining information from the neighborhood. Based on feature gathering, Graph Neural Network (GNN) technique is proposed that uses GNN based encoder for feature learning. For efficient training, pattern mining algorithms are used by the proposed technique. A novel loss function is also proposed in the work. Metrics such as precision, recall, and F1 score are shown to be improved as compared to other techniques.

The work in [63] deals with improving the security of the Domain Name System (DNS). The key idea used is to make the system topology aware and consider the structural properties of the network. The technique used is the exponential random graph model and the topology is converted into the graph format. A time series analysis is also applied for anomaly detection. The autoregressive moving average is used for the time series analysis. The precision and recall of the system are improved as compared with other techniques.

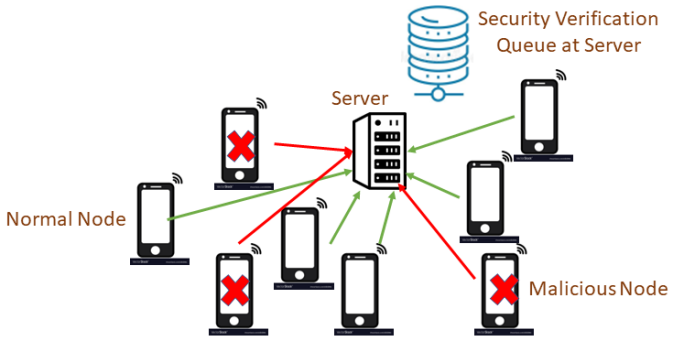

Fig. 1. Considered system model.

III. System Model

In this paper, we consider a wireless transmission scenario where several vehicular nodes are sharing their data with a centralized server or Road Side Unit (RSU) as shown in Fig. 1. This data can be traffic mobility information, tasks for offloading, service query requests, etc. The server authenticates each vehicular user using traditional cryptographic mechanisms. Moreover, vehicular users also share their messages using digital signature schemes.

Several malicious vehicle nodes are also present in the vicinity of the normal vehicle nodes and servers. These users can carry out several types of attacks such as jamming signal transmissions, eavesdropping, data integrity attacks, etc. These attacks can significantly disrupt the data security and reliability of the wireless system.

The server receives messages from both normal vehicle users and malicious vehicle users. These messages are placed in a queue and a digital signature verification algorithm is applied to messages one by one. The messages from malicious users result in additional queuing delays at the server. Some messages may be discovered to be malicious after the signature

TABLE I. ANOMALY DETECTION TECHNIQUES IN THE LITERATURE

Network	Main Idea	Technique Used	Results
IoT [59]	Anomaly Detection Class imbalance problem NSL-KDD data set	Reinforcement Learning Action - Classify input data State - Data type Reward - Prediction accuracy	Accuracy Recall F1 score
IIoT [60]	Detect cyber attacks Federated learning Privacy preservation	Universal anomaly detection Anomalous ADC detection Appeal procedure for users	Accuracy Throughput
SDN [61]	Traffic flow monitoring Monitoring granularity Accuracy vs network load	Deep Q leaning Quick optimal policy evaluation DDoS attack detection	Accuracy Detection time
IoV [56]	Data Integrity attacks Traffic density information Information checking	Isolation Forest Verify anomalies Neighborhood verification	Accuracy Recall F1 score
Social networks [62]	Feature learning Combine neighborhood information	Graph Neural Network (GNN) GNN encoder for feature learning Pattern mining algorithms for training Novel loss function	Precision Recall F1 score
DNS [63]	Topology aware Structural properties of network	Exponential Random Graph Model Time series analysis Auto regressive moving average	Precision Recall

verification, but the time spent in their verification causes an extra delay for the messages.

In addition, some malicious messages have the correct digital signature but are launched to disrupt the wireless transmissions. These messages pass through the digital signature verification stage but impact the system latency. Without an efficient anomaly detection technique, these messages can not be detected on the run. Even their malicious behavior is not learned due to the absence of an anomaly detection mechanism and can not be detected in the future.

IV. PROPOSED ANOMALY DETECTION FRAMEWORK

The proposed anomaly detection framework is shown in Fig. 2. The server maintains an anomaly detection module in its storage. The anomaly detection module consists of several blocks which are explained in the following subsections. The goal of the proposed framework is to shortlist and sideline anomalies so that server does not waste time in signature verification of malicious user messages.

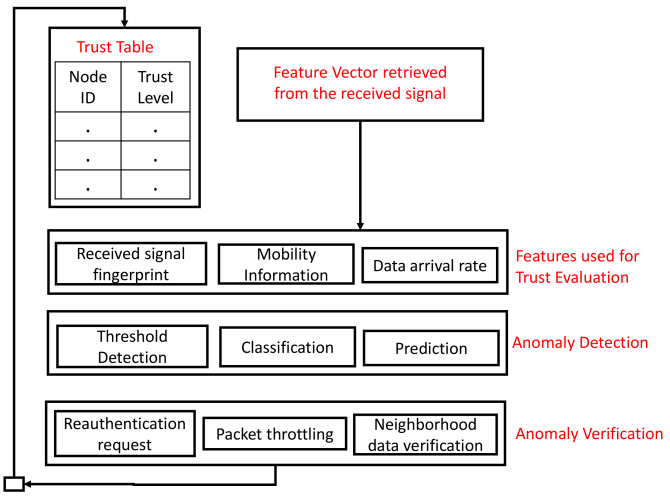

Fig. 2. Proposed context-aware anomaly detection framework.

A. Trust Table

Each server maintains a trust table that contains trust levels computed for each vehicle in the network. The trust table is a lookup table that contains two columns and several rows. The columns include information about node ID and trust level. The rows are equal to the number of vehicles in the network of the server.

A new vehicle that is entered in the coverage range of the server is registered in the trust table once it starts sharing its data with the server. Based on the data received from the vehicle nodes, the trust table is updated on regular basis i.e., the trust values are updated.

A timer value is used by the server to keep a check on the current status of the vehicle nodes in the network. Vehicles that do not send data for a long time are removed from the trust table. The reason for this is that either the vehicles have moved out of the coverage range of the server or the device has been turned off. As a result, the trust look-up table is shortened by the removal of such devices. This reduces the search time for a device's trust from the look-up table.

Trust table is evaluated based on fuzzy logic as shown in Table II. We explain the features used for developing the trust table in the next subsections.

TABLE II. TRUST EVALUATION BASED ON FUZZY LOGIC

Trust Feature	Trust Value Threshold		
	Low	Medium	High
Received Signal Fingerprint (F_{inc})	≥ 0.6	0.3-0.6	0-0.3
Mobility Information (T_r^{inc})	0-100 ms	100 ms-500 ms	500 ms-1 s
Data Arrival Rate (D_A)	$\geq 20p/s$	10-20 p/s	0-10 p/s

B. Trust Evaluation

Trust evaluation is the most critical block of the anomaly detection module. Trust in our proposal is computed based on several features considering the general behavior of malicious vehicles. The proposal is context-aware in the sense that the environment, data transmission, and mobility factors related to vehicular network are considered while evaluating trust.

The trust evaluation in our proposal is based on both the historic long-term data of the used features as well as the current feature vector. An average value of the features used in our proposal is maintained by the server. The advantage of storing long-term data is to evaluate the trend of the features and efficiently detect anomalies.

The following vehicle features are used for the trust evaluation in the proposed framework. The evaluation mechanism of each feature and its rationale are presented below. It is to be noted that these are physical features that are obtained using the obtained signal. These features are selected before the signature verification mechanism so that malicious messages are not verified.

1) Received signal-based fingerprint: The received signal can provide useful identification of devices in the network. In this regard, Signal Interference and Noise Ratio (SINR) and Angle of Arrival (AoA) retrieved from the signal can act as a fingerprint for a device. The received power from a device can be calculated as follows:

$$P_r = G_c \frac{P_t}{d^\gamma} \tag{1}$$

Here P_r is the received power, G_c is the channel gain, P_t is the transmitted power, d is the distance between the transmitter and the receiver, and γ is the path loss index. The value of the path loss index can vary between 2 and 4 depending on the scenario. The channel gain also varies depending on the channel conditions. In many scenarios, multi-path fading introduces varying channel gains depending on the amount of reflection and refraction from different objects.

The SINR at the server can be computed from the following equation:

$$SINR = \frac{P_r}{I + N_O} \tag{2}$$

where

$$I = \sum_{v=1}^{M} P_{r,v} \tag{3}$$

From Eq. (2), SINR is evaluated from the ratio of received power P_r and total noise in the system. There are two components of total noise. One is the background noise N_O and the other is the total interference. If the server receives v signals at the same time, the total interference can be computed from Eq.(3). This is the summation of all signals transmitted from those v vehicles.

Using the received signal, a map between physical location and user is developed. Any malicious user that is sending wrong location information to launch jamming attacks may be identified. The fingerprint can also be used to find areas that are critical concerning security and have more density of malicious users.

As shown in Table II, we map the received signal finger print value to the trust value using three categories; low, medium and high. The server tracks the fingerprint value of each vehicle based on its current location as follows:

$$F = \frac{SINR}{d} \tag{4}$$

The incremental change in fingerprint F_{inc} is given as

$$F_{inc} = \frac{|F_{new} - F_{old}|}{F_{old}} \tag{5}$$

If F_{inc} is greater than 0.6, the corresponding trust value can be mapped to a low value. Similarly, a medium trust value means a F_{inc} value between 0.3 and 0.6. Lastly, a high trust value means a low F_{inc} value of less than 0.3. The rationale behind this approach is that malicious vehicles will be sending

either wrong location information in its message or using high transmit power from its correct location for the attack. This factor is captures in the metric F_{inc}.

2) Mobility information: Mobility is an important parameter that can provide useful information about the normal behavior of nodes. Malicious users may periodically change their position to transmit their information so that they are off the radar. As a result, the percentage change in location of nodes is determined and those devices whose position is changing randomly in an abnormal manner is shortlisted for anomaly evaluation.

Since mobility information can only be obtained once the message is verified and decoded, it is not possible to get this information at the physical level. To overcome this problem, signal power is used as an estimate of the position of the sender. In literature, some techniques can estimate the location of the sender using received signal power [64]. The sender location is estimated in the form of distance bins rather than the exact longitude and latitude.

The distance bin of the initial location of the sender is noted based on the last message sent to the server. The node ID of the sender is noted down once the signature of the message is verified. A local map for node ID and its distance bin is stored in the server. Once, the same node changes its location and distance bin by a certain threshold for the next message, the node is marked as a possible malicious node and short-listed for the verification phase.

In Table II we use time to reach from vehicle to server (T_r) as the metric to evaluate change in sudden location of the vehicle. T_r is evaluated as follows:

$$T_r = \frac{d}{speed} \tag{6}$$

The incremental change in T_r^{inc} is given as

$$T_r^{inc} = |\frac{T_r^{new} - T_r^{old}|}{T_r^{old}} \tag{7}$$

A low trust value refers to a high T_r^{inc} which means either the speed of the vehicle or the location of the vehicle obtained from the received message is suddenly changed.

3) Data arrival rate: The data arrival rate can also provide information about the possible malicious behavior of a node. Malicious users may try to jam the network by sending repeated requests for task computation or sending incorrect data messages as part of data integrity attacks. The data inter-arrival rate for a particular node is computed as the difference between the time when the current message is received and the time when the last message was sent. This time is computed once the messages are verified for digital signature correction.

To overcome this problem, the inter-arrival time between two messages is checked regularly. Once a certain arrival rate is crossed, those nodes is marked as malicious for checking. Besides data arrival rate, message size can also be checked as malicious users may transmit large packets to negatively impact the bandwidth usage and increase the signature verification time.

4) Data variation: The data variation is a critical metric that can be used to detect anomalies specifically in the cases of malicious users that are sending wrong unrelated information. An example of this data integrity attack could be a traffic management application where wrong traffic density values are shared with the server. As a result, data variation sent from sensors located in a geographical location should raise alarms and should be checked for anomalies. In Table II, we utilize a data arrival rate of greater than 20 packets per second (p/s) to be marked as a value with low trust. This is because generally, the packet frequency of vehicular network varies from 1 to 10 packets/second. Hence, we give a higher trust value to nodes which conform with this requirement and send packets within the allowed range of 1-10 packets per second.

C. Anomaly Detection

In this phase, nodes that are marked as anomalous or malicious are noted down and a list is maintained. This list includes all the nodes that are on the radar for anomaly detection and a further investigation of their status is needed. For maintaining this list, techniques such as threshold detection, cumulative distribution function evaluation, standard deviation, etc. is applied to the features data from the previous block.

There exists a trade-off between the accuracy of anomaly detection and the time for evaluating the anomaly. If the threshold is kept too strict, only a few users may be marked as anomalous and anomaly verification is done quickly. However, many malicious nodes may be missed. On the other hand, if the threshold is kept too loose, many users will be short-listed for anomaly verification. This will need more message overhead and time needed to verify each anomaly. As a result, extra bandwidth and time will be needed.

In this work, we utilize fuzzy logic to evaluate anomalies. We first calculate trust levels based on individual features as described in Table II. Finally, we utilize majority voting to find the overall trust level. This means that the trust level is categorized as high if the trust based on at least two of the features are evaluated as high. Data from all nodes which have a low and medium trust levels are marked as anomalous.

D. Anomaly Verification

In this block, the shortlisted malicious users is tracked for further verification so that actual anomalies are picked up. For this, short-listed users send a message to inform them about their entry into the malicious node list. Those nodes may need to re-authenticate themselves before sending any further messages. All those nodes that can re-authenticate are allowed to start transmitting their messages again.

Another way to verify anomalies used in the proposed technique is packet throttling requests. The users are asked to reduce their data rates. All users that follow this request are allowed to continue sending messages. However, those nodes that do not follow the instructions and keep on sending a large number of messages which are marked as malicious users who are launching jamming attacks.

One technique to verify anomalies is neighborhood verification. This is particularly useful for data integrity attacks. The area of those nodes that are sending wrong information

and marked as possible malicious nodes are noted down. The list of neighboring nodes are sent probe messages to find if the information sent by malicious nodes is correct or not. This technique however is suited for those applications in which the sensed information in the neighborhood is nearly the same, for example, temperature monitoring in an area, average vehicle traffic density on a road segment, etc.

TABLE III. SIMULATION PARAMETERS

Simulation Parameter	Value
Number of vehicular nodes	200
Packet Generation Rate	10 per second
Number of Malicious users	50-200
Security Algorithm	ECDSA
Hash Function Used	SHA-256
Message size	7400 bits
Security overhead	1600 bits
Total Packet Size	9000 bits
Security Verification Time	0.5ms
Packet expiry time	3ms

V. PERFORMANCE EVALUATION

In this section, the performance evaluation of the Proposed Technique (PT) is presented. The results are compared with two other techniques. The first one is the Outlier Detection, Prioritization, and Verification (ODPV) algorithm which uses an isolation forest algorithm to detect anomalies. The second algorithm is the K-Nearest Neighbor (KNN) algorithm which uses majority voting to make decisions about the anomaly.

A. Simulation Model

The simulation model is developed in MATLAB and its parameters are given in Table III. The number of vehicular nodes is taken as 200. The packet generation rate of each vehicular node is 10 packets per second. The number of malicious users is 50-200. The malicious users also generate packets at the same rate as the malicious users with wrong information about the sensing parameters and causing data integrity attacks. Also, the malicious users continuously change their positions. As a result, received signal strength, mobility, and data variation factors come into play.

The security algorithm used is the Elliptic Curve Digital Signature (ECDSA) algorithm and the hash function used is the Secure Hashing Algorithm (SHA) with a key size of 256 bits. The message size generated by vehicular devices is 7400 bits and the security overhead for the ECDSA algorithm is 1600 bits [9]. The total packet size is 9000 bits. The security verification time for each packet is 0.5ms. The packet expiry time is 3ms.

B. Results

For results, we take the following four metrics defined as follows:

1) Security verification time: This is the time needed to verify the digital signature as per the ECDSA algorithm. The security verification time depends on the key bit size used by the ECDSA algorithm. Moreover, the security verification time increases with the number of messages.

2) Total delay: The delay is the sum of the transmission time and security verification time. The transmission time depends on the message size and data rate.

3) Percentage of packets expired: The percentage of packets expired includes the percentage of packets that could not be verified within the time limit of 3ms.

4) Shortlisted packets and anomaly packets: The shortlisted packets include the number of packets that were originally shortlisted by the anomaly detection technique. The anomaly packets are the number of packets that were declared as anomaly after verification.

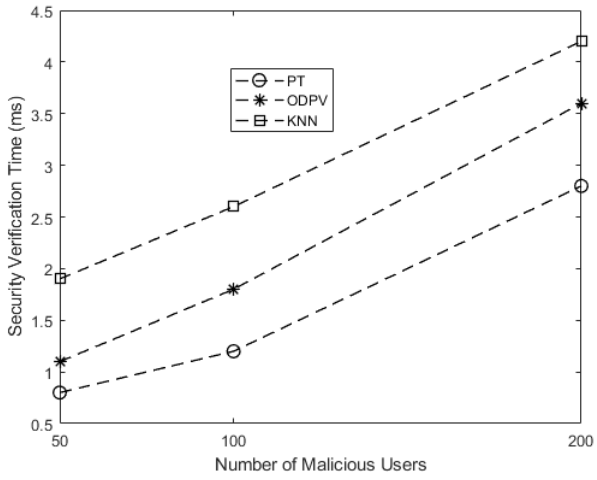

Fig. 3. Security verification time vs Number of malicious users.

Fig. 3 shows the security verification time of packets as the number of malicious users is increased from 50 to 200. The results show that the security verification time of the proposed technique is up to 1ms better than the other two techniques namely, ODPV and KNN. This is due to using context-aware parameters for trust evaluation and anomaly detection. As a result, the anomaly packets are identified after the first few iterations, and the overall network load on the server is reduced. This results in reduced security verification time.

In Fig. 4, the plot of malicious users vs total delay is shown for the three algorithms. The proposed technique has the least delay in packet transmission and hence, is very useful for vehicular applications. As compared to ODPV and KNN, the delay values of the proposed technique show up to 50% reduction. As the number of malicious users increased up to 200, the results of the proposed technique are much better than the other two techniques.

Fig. 5 shows the results of the percentage of packets expired for the three algorithms. The proposed technique has excellent results with only less than 10% packet expiry rate

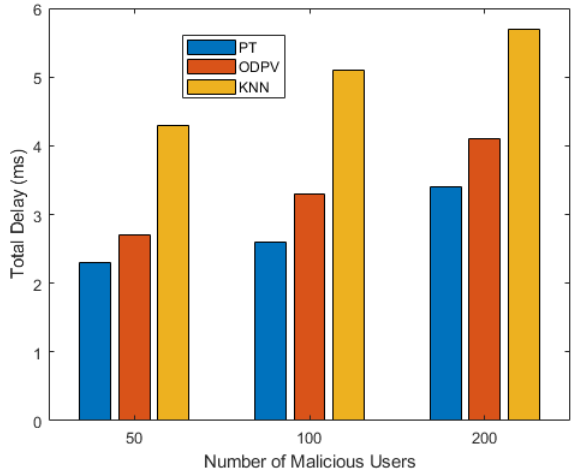

Fig. 4. Total delay vs Number of malicious users.

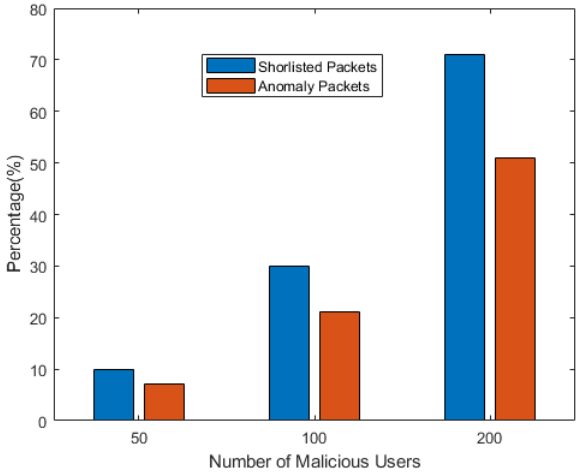

Fig. 6. Shortlisted packets vs Anomaly packets by the proposed technique.

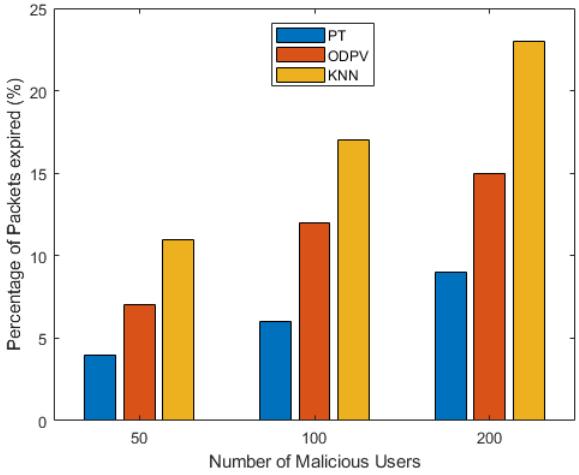

Fig. 5. Percentage of packets expired vs Number of malicious users.

as compared to the ODPV and KNN that has up to 15% and 22% packets expiry rate.

Lastly, Fig. 6 shows the anomaly detection accuracy performance of the proposed technique. The proposed technique almost accurately shortlists the packets which are anomalous when the number of malicious users is 50. As the malicious users increased, the difference between shortlisted packets and anomaly packets increased. This is because, at a lower number of nodes, the anomalous packets are easier to detect after a few iterations. As the number of packets is increased, less number of packets meet all the context-related conditions and hence fall into the likely malicious category. However, after verification, the anomaly packets out of the shortlisted ones are picked up by the algorithm.

VI. Future Opportunities

In this section, future opportunities are provided related to the challenges in the security of vehicular applications.

A. Learning based Algorithms

Machine learning-based algorithms can be designed to adaptively vary the trust levels using context-aware data from different vehicular devices. Appropriate neural networks can be developed to predict the users which are malicious or geographical areas where malicious users reside. Moreover, reinforcement learning algorithms can also be useful for optimal security-related policy design such as priority-based security verification of incoming messages. Similarly, anomaly detection can also be improved using classification algorithms based on data of malicious and normal users. Related with the current work, a learning algorithm can be used to find the appropriate threshold for anomaly detection based on incremental changes in the fingerprint, location and speed values of the vehicles.

B. Graph based Algorithms

Graph theory algorithms are very useful for evaluating the trust of vehicular devices. For example, metrics such as centrality and degree of nodes can be taken into account when evaluating the trust. Stable matching algorithms can also be used for sending authentication requests by vehicular devices to appropriate servers depending on factors such as data rate, and load on the servers. Similarly, breadth-first search and depth-first search algorithms can be used for searching anomalies from the data sets, and also for finding an efficient route for reaching the nodes for data verification. Graph theory algorithms can also be used to verify anomalies from vehicles with high centrality values or vehicles with highest trust values. This will improve the accuracy of the verification process.

C. Blockchain Techniques

Besides, trust-based anomaly detection techniques, blockchain security mechanisms can also be used to enhance the privacy of data sharing. With blockchain, smaller key sizes of the ECDSA algorithm can be used as added security will be provided with blockchain. However, a major challenge in designing such techniques will be the delay in mining the blockchain nodes and appropriate consensus

algorithms. The proposed work of anomaly detection can also be used to find malicious mining nodes which can disrupt the security of blockchain. Moreover, new context-aware algorithms considering different features can be designed for the particular blockchain mining application.

VII. Conclusion

In this paper, we present an overview of anomaly detection for vehicular applications. We discuss recent work in the literature related to anomaly detection. We present a novel framework for anomaly detection which uses context-related information such as physical signal parameters to classify anomalies without security verification. The proposed technique also includes an anomaly verification phase and develops a trust table for each node in the network. Finally, we highlight several important research directions in the area of security of vehicular and anomaly detection.

TLDViT: A Vision Transformer Model for Tomato Leaf Disease Classification

Sami Aziz Alshammari
Department of Information Technology-Faculty of Computing and Information Technology
Northern Border University, Saudia Arabia

***Abstract*—Accurate and efficient diagnostic methods are essential for crop health monitoring due to the substantial impact of tomato leaf diseases on crop yield and quality. Traditional machine learning models, such as convolutional neural networks (CNNs), have shown promise in plant disease classification; however, they often require extensive data preprocessing and struggle with complex variations in leaf appearance. This study introduces TLDViT (Tomato Leaf Disease Vision Transformer), a Vision Transformer model specifically designed for the classification of tomato leaf diseases. TLDViT reduces the need for preprocessing by learning disease-specific features directly from raw images, leveraging Vision Transformers' ability to capture long-range dependencies within images. We evaluated TLDViT on the Plant Village Dataset, which includes healthy and diseased samples across multiple classes. For comparative analysis, two Vision Transformer models, ViT-r50-l32 and ViT-l16-fe, were tested. Among these, ViT-r50-l32 achieved the highest performance, surpassing both ViT-l16-fe with an accuracy of 98%. These findings highlight TLDViT's potential as an effective tool for crop health monitoring and automated plant disease diagnosis.**

***Keywords*—Tomato Leaf Disease; Vision Transformer (ViT); crop health monitoring; plant disease classification**

I. Introduction

Agriculture is fundamental to global food security, and enhancing crop health management is crucial for maintaining production and reducing economic losses. Tomato (Solanum lycopersicum) is among the most extensively farmed crops globally, however it is very vulnerable to several foliar diseases, such as early blight, late blight, and leaf mold. These illnesses, mostly induced by pathogens including fungus, bacteria, and viruses, result in substantial decreases in production and quality [1], [2]. Accurate early detection and classification of these illnesses is essential for facilitating prompt and focused therapies, which may help reduce future transmission and harm. Conventional techniques for diagnosing plant diseases depend significantly on manual visual assessment and expert expertise, which are labor-intensive, expensive, and susceptible to subjective inaccuracies [3]. Advances in artificial intelligence (AI) and machine learning (ML) have shown potential to overcome these constraints through the automation of disease diagnosis. Convolutional neural networks (CNNs), a prevalent deep learning methodology, have shown efficacy in recognizing intricate patterns in plant disease imagery, attaining high accuracy in classification tests across several crop illnesses [4]. The authors of [3] used CNNs on an extensive dataset of plant diseases, achieving classification accuracies of 90% across 26 distinct crops. In [4], authors introduced advanced CNN architectures to improve the categorization of plant diseases, particularly those impacting tomatoes, but with considerable preprocessing and computing demands. These studies highlight the promise of CNNs while also exposing significant obstacles, including their reliance on large labeled datasets, susceptibility to overfitting, and constraints in capturing non-local connections in images [5]. Researchers have investigated different models and strategies to enhance the resilience and efficiency of plant disease classification systems, addressing these constraints. The author in [6] integrated handmade features with deep learning models, enhancing the robustness of CNNs against variability in image data, while [7] supplemented restricted datasets with synthetic images to elevate CNN performance. Notwithstanding these efforts, CNN-based models exhibit constraints in their ability to apprehend global spatial linkages within images, a factor that is especially critical in plant disease categorization, where symptoms may appear in non-contiguous areas on the leaf.

In recent years, Vision Transformers (ViT) have surfaced as a formidable alternative to CNNs for identification of images tasks [8], [9], [10], [11]. In contrast to CNNs, which depend on local convolutional filters for hierarchical feature extraction, ViT use self-attention processes to capture long-range relationships over the whole image. The global attention mechanism enables ViT to comprehend spatial connections from a comprehensive viewpoint, making them especially adept at image processing tasks that need acute sensitivity to spatial intricacies. The author in [12] shows that ViT may get superior performance on extensive image classification datasets, surpassing CNNs in both precision and efficiency. In [13], the author emphasized the promise of ViT in applications necessitating intricate spatial analysis, including medical imaging and remote sensing. The author in [14] used Vision Transformers for agricultural disease detection, proving their efficacy in identifying disease patterns in crops such as rice and wheat; nevertheless, research on their application to tomato leaf diseases is still scarce.

This paper presents TLDViT (Tomato Leaf Disease Vision Transformer), a Vision Transformer model particularly developed for the classification of tomato leaf diseases, motivated by recent breakthroughs. Our methodology utilizes the ViT architecture's capacity to capture long-range relationships, allowing it to identify nuanced and intricate disease patterns that CNNs may overlook. TLDViT, in contrast to CNN-based methods that need considerable preprocessing and data augmentation, is designed to immediately learn disease-specific features from minimally processed images, enhancing its adaptability and efficiency for practical agricultural applications.

Our study provides multiple contributions to the field of automated plant disease identification. The proposal introduces

TLDViT, a new Vision Transformer model tailored for the classification of tomato leaf diseases. Furthermore, two Vision Transformer models, ViT-r50-l32 and ViT-l16-fe, were employed to establish a comparative framework, ensuring that all models were trained on the Plant Village Dataset for consistency and robustness. A comprehensive comparison of model performances demonstrated that TLDViT exhibits superior accuracy compared to CNN-based methods and the two Vision Transformer models, underscoring its efficacy in this context. The study illustrates the benefits of Vision Transformers in agricultural diagnostics, emphasizing their sensitivity to spatial details, which is crucial for precise disease identification. These contributions enhance the application of Vision Transformers in plant disease detection and establish a basis for wider use in agricultural diagnostics.

The rest of the paper is structured as follows: Section II introduces the Literature Review, where we discuss related work on plant disease classification, highlighting the advantages and limitations of existing deep learning approaches, including Convolutional Neural Networks (CNNs) and Vision Transformers (ViTs). The proposed methodology for classifying tomato leaf diseases is presented in Section III, which also covers the TLDViT model architecture, training procedures, and data preparation. The findings and discussion, together with performance comparisons and analysis, are presented in Section IV. Finally, Section V concludes the paper and outlines future research directions.

II. Literature Review

The latest developments in deep learning have markedly improved systems for the identification and categorization of plant diseases. Numerous research have investigated alternate methods to enhance the precision and efficacy of these systems. Initial approaches mostly depended on manually produced features and traditional machine learning methodologies [15], [16]. Convolutional neural networks (CNNs) exhibit exceptional performance in image-based illness classification; yet, their dependence on considerable preprocessing and difficulty in capturing global picture dependencies provide significant problems [17]. Hybrid models that combine CNNs with alternative architectures have shown enhanced robustness to fluctuations in picture quality [18], [19]. The advent of Vision Transformers (ViTs) has offered a persuasive alternative to CNNs for agricultural applications. Vision Transformers use self-attention processes to record long-range dependencies, allowing for the analysis of complex spatial patterns in pictures [20], [21]. Applications of Vision Transformers (ViTs) in the identification of plant diseases, including those affecting rice, wheat, and grapes, have shown enhanced efficacy relative to conventional Convolutional Neural Networks (CNNs) [22]. Recent research has used transfer learning with transformer architectures to address data scarcity challenges in agricultural datasets [23]. The integration of transformers with real-time systems and edge devices is becoming prevalent, with the objective of implementing disease detection models directly in agricultural fields for practical use [24]. Nevertheless, few research has concentrated especially on tomato leaf diseases, highlighting the need for a specialized Vision Transformer model to fill this void.

III. Proposed Approach-Based Tomato Leaf Disease Classification

This section describes our method to diagnosing tomato leaf illnesses using TLDViT (Tomato Leaf Disease Vision Transformer), a hybrid Vision Transformer model designed to capture both localized and global patterns in leaf photos. TLDViT combines ResNet-50's feature extraction powers with Vision Transformers' self-attention capabilities, resulting in a robust tool for detecting and recognizing disease signs in tomato leaves. We describe the major processes in our technique below, which include data preparation, model construction, training, and evaluation.

A. Data Preprocessing

Data preprocessing is a crucial phase to guarantee the quality and uniformity of the pictures used for training the TLDViT model. The dataset consists of images of tomato leaves, classified into six categories: Healthy, Bacterial Spot, Early Blight, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. The dataset used for this study is the publicly available Plant Village Dataset [25], which provides a comprehensive set of labeled images representing various plant diseases. This dataset is widely used for plant disease classification tasks and offers high-quality images that ensure accurate training and evaluation of the TLDViT model. All images are scaled to 224x224 pixels to standardize input dimensions, so minimizing computing effort while preserving enough information for precise categorization. Each pixel intensity is standardized to the interval [0, 1], enhancing the stability of the training process and facilitating more effective model learning. To improve the model's resilience and mitigate overfitting, many data augmentation methods are used, such as rotation, horizontal flipping, and brightness modifications. These changes create variances in the dataset, allowing TLDViT to generalize well across diverse lighting and ambient circumstances, which is essential for practical use.

Fig. 1 depicts the class distributions of tomato leaf disease images before to and after to data augmentation. Before augmentation (blue bars), the dataset comprised a total of 10,958 images unevenly allocated among six categories: Bacterial Spot (1,925 images), Early Blight (1,702 images), Healthy (1,920 images), Late Blight (1,705 images), Septoria Leaf Spot (1,745 images), and Yellow Leaf Curl Virus (1,961 images). Following augmentation (orange bars), the dataset dramatically increased to 13,603 images, enhancing class equilibrium. The post-augmentation dataset comprises 2,084 photos of Bacterial Spot, 2,352 images of Early Blight, 2,358 photographs of Healthy specimens, 2,267 images of Late Blight, 2,140 images of Septoria Leaf Spot, and 2,402 images of Yellow Leaf Curl Virus. This augmentation approach guarantees a more equitable dataset, which is essential for training machine learning models to generalize proficiently across all categories.

The used dataset is partitioned into three subsets: training (70%), validation (20%), and test (10%), allowing an equitable assessment of the model's efficacy on novel data. The training set is used to train the model, the validation set is applied for hyperparameter optimization and monitoring throughout training, and the test set offers a conclusive evaluation of the model's classification accuracy across six categories.

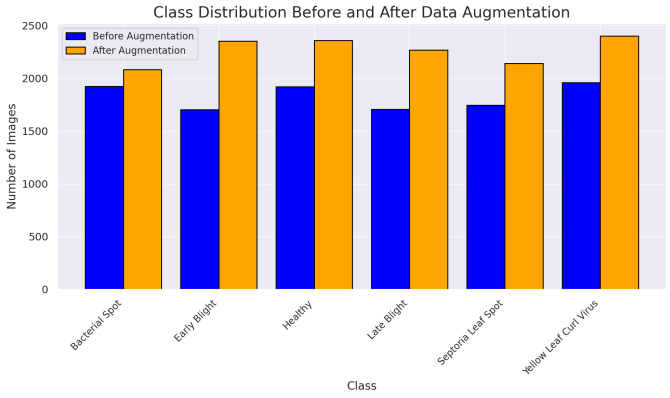

Fig. 1. Tomato class distribution.

B. TLDViT Model (Tomato Leaf Disease Vision Transformer)

The Vision Transformer (ViT) architecture, as presented in Fig. 2, has been customized to classify tomato leaf maladies into six categories: Healthy, Bacterial Spot, Early Blight, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. The model is highly effective in capturing complex disease patterns by combining local feature extraction with global context modeling.

1) Image patch division and flattening: The first phase is partitioning each input picture of a tomato leaf into a grid of smaller segments. A 224 x 224-pixel image may be divided into 32 x 32 pixel patches, resulting in 49 patches arranged in a 7 x 7 grid. Subsequently, each patch is transformed into a one-dimensional vector. This patch-based method collects intricate local details inside each leaf segment, enabling the model to identify localized disease indicators such as spots, discolorations, and texture alterations unique to certain illnesses.

2) Linear projection of flattened patches: The flattened patches undergo a linear projection layer, converting each patch into a high-dimensional vector appropriate for further processing in the Vision Transformer. This transformation produces a series of patch embeddings that preserve the localized features of each patch while mapping them into a higher-dimensional space, allowing the model to interpret the picture as a sequence instead of a grid.

3) Positional embedding and class token: Positional embeddings are included into each patch embedding to maintain the spatial configuration of patches inside the original image. The positional embeddings provide the model with data on the location of each patch inside the image, which is essential for comprehending spatial links among illness symptoms. Furthermore, an additional learnable class token is attached to the series of patch embeddings. The class token engages with the patch embeddings throughout the transformer layers and ultimately retains the information required to generate the final classification label.

4) Transformer encoder: The fundamental component of the design is the Transformer Encoder, including numerous layers that integrate self-attention mechanisms with feed-forward neural networks. Each encoder layer has many essential components: The Multi-Head Self-Attention mechanism, which allows the model to concentrate on several sections of the leaf concurrently, therefore capturing both local intricacies and overarching patterns within the picture. This multi-head attention enables the model to discern intricate relationships across patches, facilitating the identification of disease-related patterns that may be distributed over different areas of the leaf. Normalization (Norm) layers are used to stabilize the learning process and mitigate overfitting by guaranteeing that inputs to each layer possess a standardized distribution, facilitating model convergence and enhancing generalization. Subsequent to the self-attention mechanism, a Multi-Layer Perceptron (MLP) introduces non-linear changes to the representations, therefore augmenting the model's capacity to discern intricate patterns pertinent to each illness type and boosting classification precision. This encoder architecture enables the model to analyze the whole image as a series of patches, use self-attention to discern correlations both internally and externally among the patches. This is especially beneficial in the categorization of plant diseases, where symptoms may manifest in scattered patterns or as nuanced textural alterations on the leaf.

5) MLP head and classifier: The class token's embedding is supplied into a Multi-Layer Perceptron (MLP) head and subsequently into a classifier, which generates the final prediction, after passing through the transformer layers. The classifier attributes the image to one of the six classes, thereby designating the leaf as healthy or indicating the specific type of disease present. The MLP head is the ultimate stage in the processing process, incorporating all the information acquired by the transformer layers to provide a precise diagnosis.

This ViT architecture is particularly effective for the classification of tomato leaf diseases because it can manage both local and global image features. The self-attention mechanism enables the model to interpret relationships across the entire image, while the patch-based approach captures detailed visual features within small sections, which is essential for identifying disease-specific symptoms. The distinction between diseases that may appear visually similar but have unique patterns or spread across various areas of the leaf is dependent on the combination of local and global context.

C. Training Methodology

In order to optimize the performance of TLDViT, we implement a systematic training approach that incorporates exhaustive evaluation techniques, optimization, and regularization. In order to reduce prediction errors across all disease classes, categorical cross-entropy loss is implemented, as this is a multi-class classification problem. The Adam optimizer is employed with an initial learning rate of 0.0001, which is progressively reduced by a learning rate scheduler as training progresses. This approach assists in the stabilization of the model and the enhancement of convergence, while also preventing overshooting. The high model complexity necessitates the use of regularization methods, such as dropout layers inside the transformer component, to prevent overfitting. In order to avoid superfluous epochs and overfitting, early stopping is sometimes used. This involves monitoring validation accuracy and ending training as performance stabilizes. To achieve a happy medium between computing efficiency and enough iteration for learning, the model is trained with a batch size of 64 for 25 epochs.

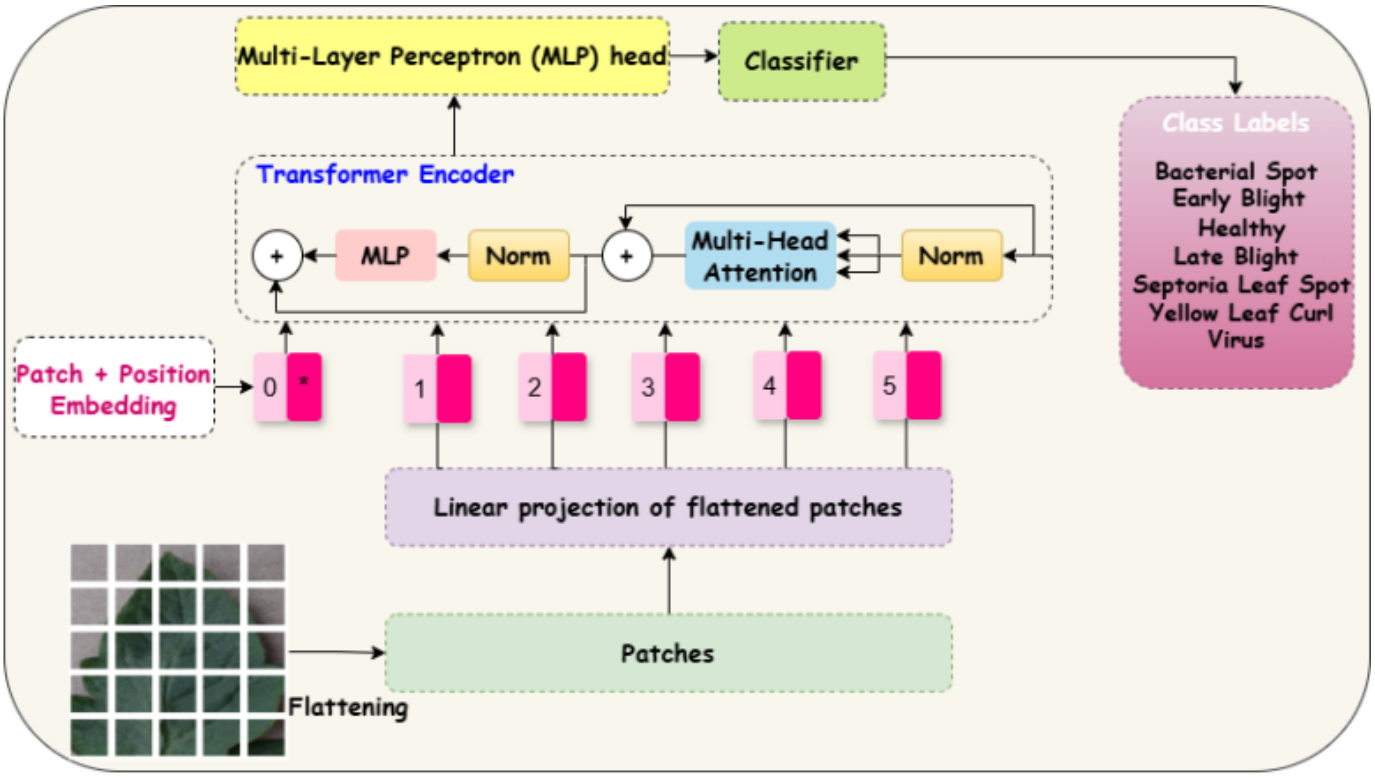

Fig. 2. TLDViT architecture.

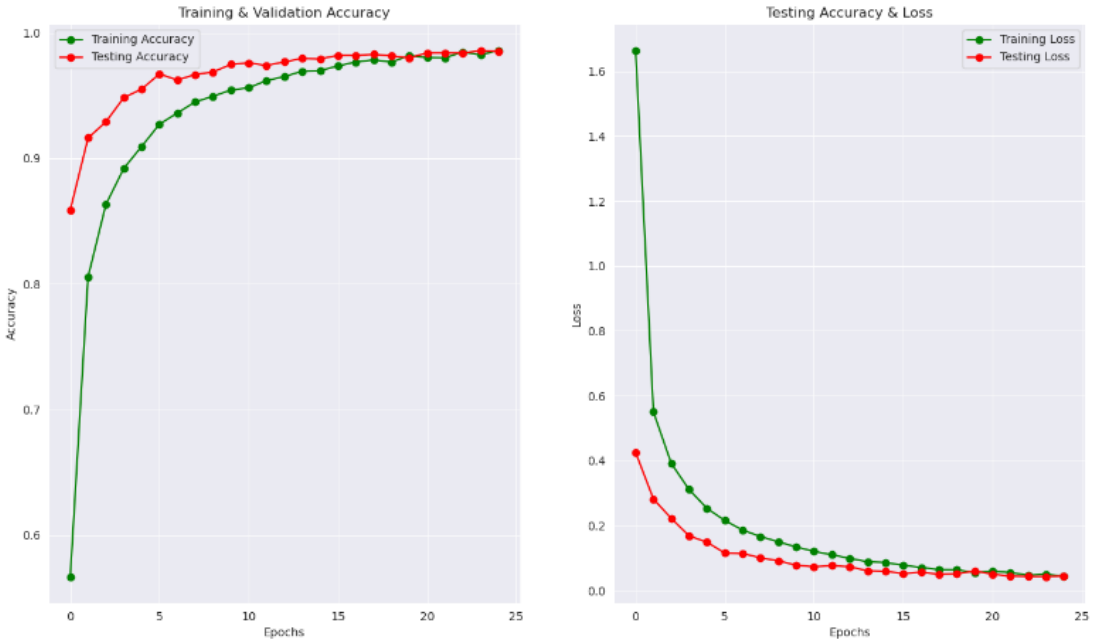

Fig. 3. Accuracy and loss curve of ViT-r50-l32 model.

We evaluate TLDViT's efficacy in accurately categorizing tomato leaf diseases using the following metrics: accuracy, F1-score, precision, recall, and confusion matrix. Making ensuring the model satisfies all criteria, this assessment checks it thoroughly. Additionally, we use ROC curves as a measure to evaluate the model's performance across multiple thresholds, especially when distinguishing across interrelated illness types. To find out how well the model can distinguish between classes at various decision thresholds, we build ROC curves for each class and then measure the area under the curve (AUC). The following equations introduced the performance evaluations:

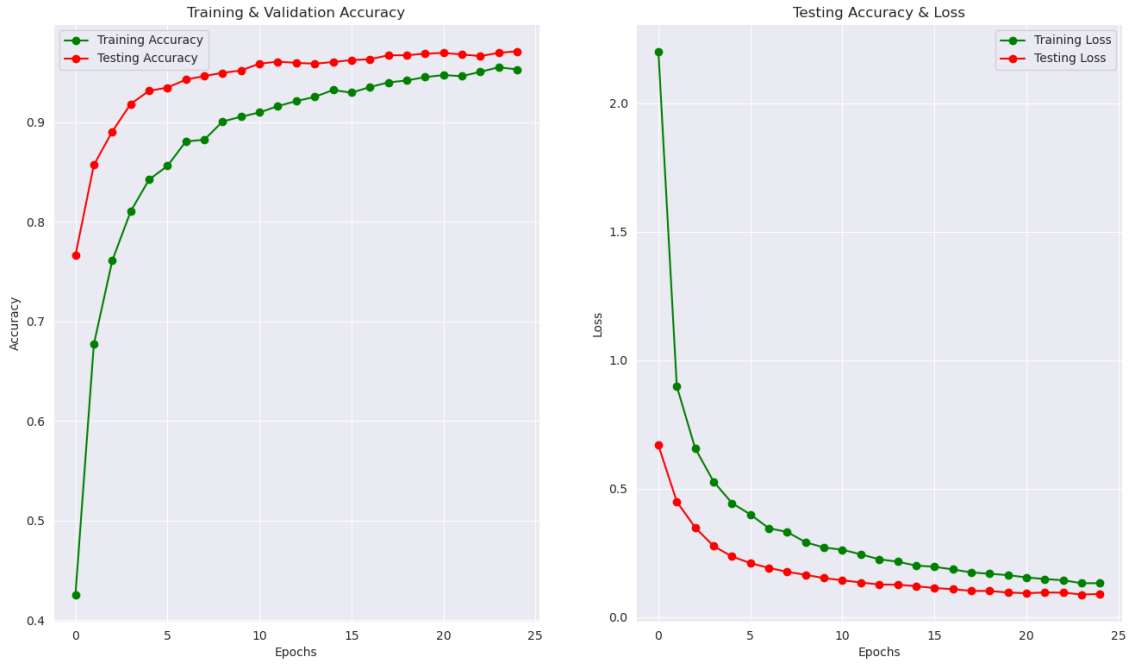

Fig. 4. Accuracy and loss curve of ViT-l16-fe model.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{3}$$

$$F_1 \text{ Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{4}$$

- True Positives (TP): Correctly predicted positive samples.
- True Negatives (TN): Correctly predicted negative samples.
- False Positives (FP): Incorrectly predicted positive samples.
- False Negatives (FN): Incorrectly predicted negative samples.

IV. Experimental Results

The experimental findings of the proposed TLDViT model for categorizing tomato leaf diseases into six labels are shown in this section. These categories are Healthy, Bacterial Spot, Early Blight, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. For the purpose of conducting a complete evaluation, we evaluate the performance of the model using a number of different measures, such as accuracy, precision, recall, F1-score, and area under the ROC curve (AUC).

A. Classification Accuracy and Loss

Fig. 3 shows that training and testing accuracy increase with epochs in the ViT-r50-l32 model, stabilizing at high values. Within a few epochs, the model converges, with training accuracy around 99% and testing accuracy close behind. Regularly decreasing loss curves for training and testing indicate good learning without overfitting. The tight alignment of training and testing performance implies that ViT-r50-l32 can generalize to new data and discriminate tomato leaf disease classes. Fig. 4 shows that ViT-l16-fe has slower convergence and larger loss values during training, suggesting a weaker generalization capacity than ViT-r50-l32. Although ViT-l16-fe is accurate, it lacks the stability and minimum loss of ViT-r50-l32. These findings show that ViT-l16-fe is effective but may not capture disease-specific aspects as well as ViT-r50-l32.

The results of this study reveal that ViT-r50-l32 outperforms ViT-l16-fe in accuracy and loss measures, evidenced by its fast convergence, elevated final accuracy, and reduced loss levels throughout training and testing. The exceptional efficacy of ViT-r50-l32 indicates that its integration of a ResNet-50 backbone with Vision Transformer layers is especially adept at collecting complex illness characteristics, enabling more precise differentiation across disease categories. The constant and consistent performance shown in both training and testing reinforces the resilience of ViT-r50-l32.

B. Performance Comparison of Tomato Leaf Disease

Table I shows the classification performance of two models, ViT-r50-l32 and ViT-l16-fe, on tomato leaf disease categories, including Precision, Recall, F1-Score, and Overall Accuracy. F1-Scores of 0.95 or better are achieved by the ViT-r50-l32 model in all categories. It has excellent precision and recall for "Late Blight" and "Septoria Leaf Spot," an F1-Score of 1.00 for both, and an accuracy of 0.98, showing good generalization. Though scoring lower in several areas, the ViT-l16-fe model performs well. For "Late Blight" it has an F1-Score of 0.94 owing to a minor loss in accuracy, but it has good precision and recall across most classes, especially for "Yellow Leaf Curl Virus" with 1.00 precision. Though somewhat lower than ViT-r50-l32, ViT-l16-fe has solid classification performance with an accuracy of 0.97. In conclusion, both models have good accuracy and F1-Scores across all categories, although ViT-r50-l32 may be preferable for tomato leaf disease classification in this dataset.

TABLE I. PERFORMANCE CLASSIFICATION OF TLDVIT MODELS

Model	Class	Precision	Recall	F1-Score
ViT-r50-l32	Bacterial Spot	0.93	0.98	0.95
	Early Blight	1.00	0.96	0.98
	Late Blight	1.00	1.00	1.00
	Septoria Leaf Spot	1.00	1.00	1.00
	Yellow Leaf Curl Virus	0.96	1.00	0.98
	Healthy	1.00	0.96	0.98
	Overall Accuracy		0.98	
ViT-l16-fe	Healthy	0.96	1.00	0.98
	Bacterial Spot	0.98	0.92	0.95
	Early Blight	0.98	1.00	0.99
	Late Blight	0.90	0.98	0.94
	Septoria Leaf Spot	1.00	0.95	0.98
	Yellow Leaf Curl Virus	1.00	0.96	0.98
	Overall Accuracy		0.97	

Fig. 5 displays the Precision-Recall (PR) curve for the ViT-r50-l32 model, which classified tomato leaf diseases well. Each curve symbolizes a disease: Healthy, Bacterial Spot, Early Blight, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. The legend shows each category's average accuracy score. Due to its near-perfect accuracy and recall across all classes, the model can reliably categorize each illness type without substantial false positives or negatives. All classes' aggregate performance is tinted blue, with an average accuracy of 0.997. The model excels on "Early Blight" and "Yellow Leaf Curl Virus," scoring 1.000 in precision-recall, while the remaining classes score 0.995–0.999. This curve shows the ViT-r50-l32 model's resilience and accuracy, making it ideal for identifying and differentiating tomato leaf diseases.

Fig. 6 illustrates the Multi-Class Receiver Operating Characteristic (ROC) curve for the ViT-r50-l32 model, which is the most effective model for classifying tomato leaf diseases. Each curve denotes one of the six disease categories: Healthy, Bacterial Spot, Early Blight, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. The values presented in the legend represent the area under the curve (AUC) for each category. The model attains an AUC score of 1.00 for each class and for the micro-average ROC curve, demonstrating optimal performance in differentiating among the various disease categories. The ROC curve indicates that the model can achieve a true positive rate (sensitivity) of 1.0 while keeping The false positive rate near 0 across all categories. The observed accuracy indicates that ViT-r50-l32 is a reliable

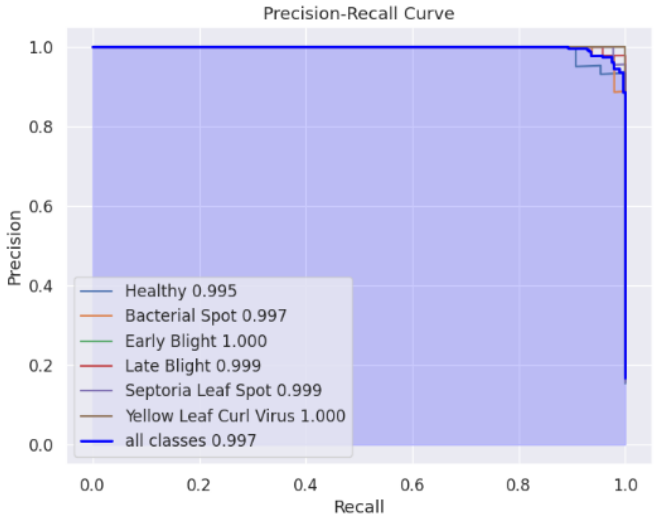

Fig. 5. Precision-Recall (PR) curve of ViT-r50-l32 model.

model for classifying tomato leaf diseases, as evidenced by the absence of misclassifications in the ROC metrics. The diagonal dashed line indicates a random classifier (AUC = 0.5), while the model's ROC curves positioned significantly above this line demonstrate its robust predictive performance. The optimal AUC scores demonstrate the model's high accuracy and robustness, positioning it as an effective tool for the detection.

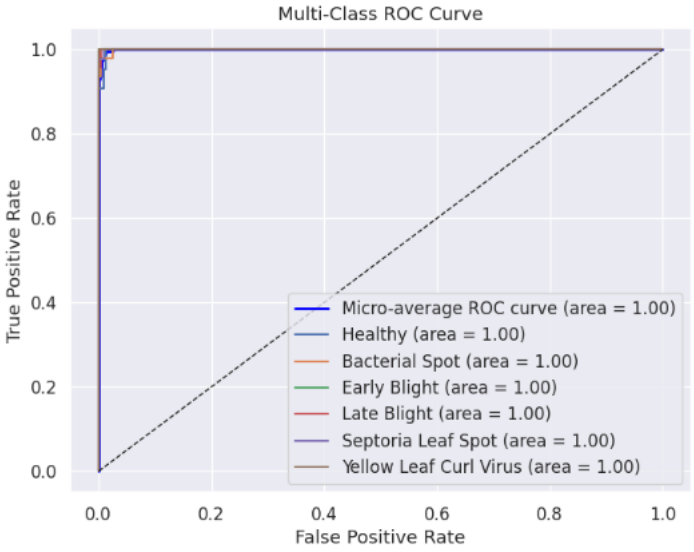

Fig. 6. ROC curve of ViT-r50-l32 model.

The confusion matrix for the ViT-r50-l32 tomato leaf disease classification model shows high true positive counts for each disease category, as depicted in Fig. 7. Bacterial Spot has 42 accurate categories and a few Healthy misclassifications. Early Blight is properly categorized 46 times, mostly in Late Blight. One Early Blight occurrence was misclassified, whereas Late Blight had 49 proper classifications. With 47 and 44 accurate classifications and no substantial misclassifications, Septoria Leaf Spot and Leaf Curl Virus perform well.

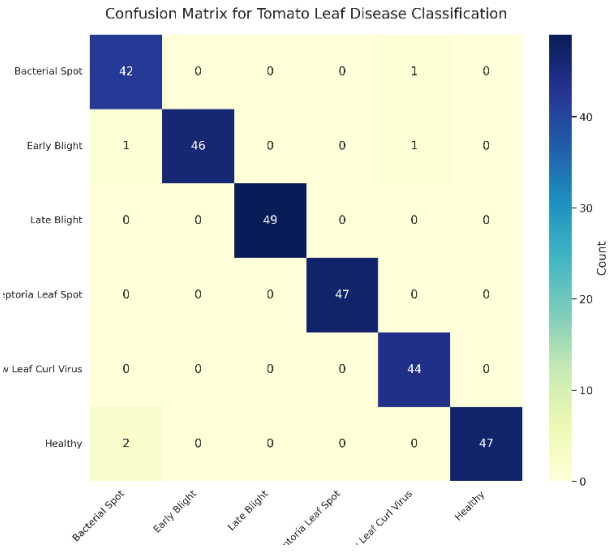

Fig. 7. Confusion matrix of ViT-r50-l32 model for differentiation of tomato leaf diseases.

Healthy is accurately labeled 47 times, with Bacterial Spot misclassified. Some classifications, such Healthy and Bacterial Spot, are somewhat confusing, suggesting model refining or hyperparameter tweaks might improve classification accuracy.

In Fig. 8, the ViT-r50-l32 model classifies six tomato leaf types from the Plant Village Dataset, including healthy and sick samples, using test images. The model accurately distinguishes Bacterial Spot, which has dark, irregular spots; Early Blight, which has concentric rings on yellowed areas; Healthy leaves, which are uniformly green and symptom-free; Late Blight, which has large, darkened lesions; Septoria Leaf Spot, which has small, circular lesions with light centers and dark edges; and Yellow Leaf Curl Virus, which shows curled, yellowed edges The model can distinguish these groups, suggesting its potential for early illness identification and treatment.

Fig. 8. Classification results of ViT-r50-l32 model.

C. Comparative Study

Table II presents a comparative analysis of tomato leaf disease classification models, emphasizing the performance metrics of various methodologies. The authors [26] used a CNN-based model (Inception-V3 and DenseNet-121), attaining an accuracy of 95.08%, with precision, recall, and F1-score metrics closely matched at 95.10%, 95.05%, and 95.07%, respectively. In addition, the authors in [27] introduced the TomFormer model, which amalgamates transformer-based architectures, achieving an accuracy of 87%, with somewhat reduced precision (87.50%), recall (86.50%), and F1-score (87.00%) relative to CNN-based models. Our proposed model, ViT-r50-l32, utilizes Vision Transformers to attain exceptional performance, achieving an accuracy of 98%, precision of 98.30%, recall of 98.33%, and an F1-score of 98.20%, thereby illustrating its efficacy and resilience in tomato leaf disease classification tasks.

TABLE II. Comparative Study with Related Approaches

Study	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
[26]	95.08	95.10	95.05	95.07
[27]	87	87.50	86.50	87.00
TLDViT Model	98	98.30	98.33	98.20

V. Conclusion

This paper presents TLDViT, a Vision Transformer model explicitly developed for classifying tomato leaf diseases using images from the Plant Village Dataset. TLDViT exhibited effective classification capabilities across six categories: Bacterial Spot, Early Blight, Healthy, Late Blight, Septoria Leaf Spot, and Yellow Leaf Curl Virus. In our assessments, we used two Vision Transformer models ViT-r50-l32 and ViT-l16-fe for comparative analysis. Among them, ViT-r50-l32 surpassed the other model, demonstrating enhanced accuracy and resilience across the illness categories. These findings underscore TLDViT's potential, in conjunction with ViT-r50-l32, for facilitating the early detection and control of crop diseases, which is essential for sustainable agriculture and food security. We propose the development of a mobile or field-deployable application for real-time disease diagnostics, facilitating the rapid identification of tomato leaf diseases by farmers and agronomists on-site, hence enabling prompt intervention and management.

Future work will optimize TLDViT for mobile and edge devices for real-time crop health monitoring in the field. We also want to combine this model into a mobile or field-deployable application for real-time disease diagnostics to help farmers and agronomists quickly identify tomato leaf diseases and control them. Other efforts include domain adaptation to improve model performance in varied environmental settings and adding new plant species and disease categories to the dataset.

***Abstract*—Human monkeypox is a persistent global health challenge, ranking among the most common illnesses worldwide. Early and accurate diagnosis is critical to developing effective treatments. This study proposes a comprehensive approach to monkeypox diagnosis using deep learning algorithms, including Vision Transformer, MobileNetV2, EfficientNetV2, ResNet-50, and a hybrid model. The hybrid model combines ResNet-50, MobileNetV2, and EfficientNetV2 to reduce error rates and improve classification accuracy. The models were trained, validated, and tested on a specially curated monkeypox dataset. EfficientNetV2 demonstrated the highest training accuracy (99.94%), validation accuracy (97.80%), and testing accuracy (97.67%). ResNet-50 achieved 99.87% training accuracy, 99.85% validation accuracy, and 97.18% testing accuracy. MobileNetV2 reached 95.47% training accuracy, with validation and testing accuracies of 79.51% and 78.18%, respectively. Designed to mitigate overfitting, the Vision Transformer achieved 100% training accuracy, 87.51% validation accuracy, and 99.41% testing accuracy. Our hybrid model yielded 99.33% training accuracy and 99.09% testing accuracy. The Vision Transformer emerged as the most promising model due to its robust performance and high accuracy, followed closely by the hybrid model. Explainable AI (XAI) techniques, such as Grad-CAM, were applied to enhance the interpretability of predictions, providing visual insights into the classification process. The results underscore the potential of Vision Transformer and hybrid deep learning models for accurate and interpretable monkeypox diagnosis.**

I. Introduction

In order to manage outbreaks, it is essential to detect monkeypox accurately and promptly. Vision transformer models, transfer learning[1], [2], and deep learning [3], [4] provide effective ways to improve diagnostic accuracy from image data. Clinical examination and laboratory testing are frequently used in traditional diagnostic techniques, however, they can be time-consuming and less available in remote or underdeveloped places. Because models can be taught to accurately identify the distinctive characteristics of monkeypox lesions, deep learning [5], [6] makes monkeypox detection quicker and more scalable [7]. Transfer learning, which enables models to use pre-trained weights from sizable datasets, is particularly advantageous when it comes to monkeypox because there is a dearth of labeled data. Even with a limited monkeypox dataset [8], accurate models may be deployed thanks to this technique, which builds on previously obtained knowledge to enable faster training and higher accuracy. The detection method is further improved by the employment of vision transformers, which are renowned for their capacity to grasp intricate spatial relationships by processing images as patches. Vision transformers, as opposed to conventional convolutional networks [3], [9], [10], are able to identify global patterns in the image, which enables the model to concentrate on certain lesion features that could otherwise go unnoticed. This capacity is especially crucial for preventing misdiagnosis, improving patient outcomes, and distinguishing monkeypox from other skin disorders that look similar. When combined, these deep learning techniques [11] not only provide a more affordable and easily available diagnostic option, but they also aid in early detection and containment initiatives, which has a big influence on public health by enabling quick action in the event of an outbreak.

The main objective of image-based monkeypox disease detection is to facilitate early, precise, and easily accessible diagnosis, which is crucial for efficient outbreak management and patient treatment. Healthcare professionals can swiftly detect monkeypox lesions by using image-based AI models, which enables the early isolation and treatment of infected people to stop the spread of the disease [12], [13]. Another important goal is to provide diagnostic tools in settings with low resources and remote locations, where access to standard lab-based testing may be difficult [14], [15]. To avoid misdiagnosis and guarantee that patients receive the right care, models that can reliably differentiate monkeypox from other comparable skin disorders, including chickenpox or measles,

must be developed. Since there is a dearth of picture data related to monkeypox, it is crucial to use transfer learning [16] to build trustworthy models from small datasets. This will enable pre-trained models to identify distinctive characteristics of monkeypox. Additionally, by offering a scalable method for monitoring and forecasting outbreaks, AI-based monkeypox detection can help public health initiatives by facilitating prompt reaction and containment [17]. These goals support a strong and workable approach to controlling monkeypox, boosting readiness for infectious disease risks, and improving health outcomes.

The main contributions of this study are:

1) Improved model resilience, a bespoke dataset was created using random images that simulated a variety of real-world situations.
2) We enhanced feature extraction and detection by using ResNet-50's deep residual connections to categorize monkeypox lesions with accuracy.
3) MobileNetV2 was utilized for lightweight, effective detection, making diagnostics accessible on mobile or low-resource devices in remote locations.
4) EfficientNetV2 was used to maximize efficiency by striking a balance between decreased computation and detection accuracy for effective model operation.
5) We enhanced the model's capacity to distinguish monkeypox from related skin disorders by using Vision Transformer to gather global and patch-based picture information.
6) We created a hybrid model with enhanced diagnostic accuracy and dependability by combining ResNet-50, MobileNetV2, and EfficientNetV2.
7) We interpreted model predictions using explainable AI methodologies, offering visual justifications for clear, reliable diagnostics.

In this study, the previous research on existing work is described in Section II, and the proposed working framework is then detailed in Section III. The later Section IV denotes the result analysis, and finally, the conclusion and future plan are explained in the last Section V of this paper.

II. Previous Studies

In recent years, researchers have been trying to prevent the monkeypox disease and they are finding different types of solutions. Hence, some related publications are found online about the solutions to human monkeypox detection. We mentioned and explained some of them.

Bala et al. [18] proposed a deep CNN-based monkeypox disease detection system. Their study summary is that MonkeyNet, a novel deep learning-based model, was created to identify monkeypox from skin images. Its accuracy was 93.19% on the original dataset and 98.91% on an augmented dataset. In order to facilitate model training and testing, this study made the "Monkeypox Skin Images Dataset (MSID)" publicly available. Grad-CAM graphics help doctors diagnose monkeypox early and accurately by highlighting affected areas.

Dahiya et al. [19] explained monkeypox disease detection using a deep learning model. They used CNN and YOLO V5. Using the monkeypox dataset online, they obtain 98.18% accuracy in image classification.

Haque et al. [20] described to find out the monkeypox disease from the images with deep-transfer learning and attention mechanisms. They used online images and obtained a validation accuracy of 83.89%.

Sitaula et al. [21] proposed a method to find out the monkeypox virus detection with seven deep learning model as well as their ensemble method. They used publicly available data and applied seven pre-trained models initially. Later, to improve the performance they used an ensemble method of deep learning. The highest accuracy of their proposed work is 87.13%.

Ali et al. [8] proposed a method to detect human monkeypox from online collected image data. Their study was deep learning-based. Using online data, their classification rate is 82.96%.

Rahman et al. [22] explained federated and deep learning-based monkeypox disease detection from private limited data. Their study summary is-Accurate identification of monkeypox is difficult because it was deemed a global public health emergency after the COVID-19 epidemic. For efficient monkeypox classification, this paper suggests a safe, federated learning system that makes use of deep learning models such as MobileNetV2, Vision Transformer, and ResNet-50. With 97.90% accuracy using the ViT-B32 model, the method improves data security while guaranteeing accurate disease classification.

Azar et al. [23] proposed a deep neural network-based system to detect monkeypox from the images. Their study summary-this study created a deep learning model based on DenseNet201 to identify skin scans as either normal, chickenpox, monkeypox, or measles in response to the 2022 outbreak. The model performed exceptionally well, attaining 95.18% accuracy in a four-class scenario and 97.63% accuracy in a two-class scenario. To enhance model interpretability and help clinicians trust and comprehend the decision-making process, LIME and Grad-CAM were used. This model performs better than previous research, particularly in F1-Score, and provides information on the afflicted skin areas that are essential for diagnosis.

Altun et al. [7] proposed a method to detect monkeypox from sensor-based data with deep-transfer learning. Their work summary is that-in order to target possible pandemic scenarios, this study sought to create a deep learning-based monkeypox detection algorithm that is both quick and accurate. VGG19, DenseNet121, ResNet-50, EfficientNetV2, MobileNetV3, and Xception models were used to create a new CNN model with hyperparameter tuning and transfer learning. With an F1-score of 0.98, AUC of 0.99, accuracy of 0.96, and recall of 0.97, the optimized MobileNetV3 model exhibited the greatest performance, proving the usefulness of deep learning in quick disease classification.

Ahsan et al. [24] demonstrate a deep learning-based monkeypox disease detection from input data. This study evaluated six deep learning models, including Inception ResNetV2 and Mobile NetV 2, for early illness detection utilizing transfer learning in light of widespread worries about monkeypox as a possible pandemic danger. The altered models demonstrated

their diagnostic capabilities with accuracies ranging from 93% to 99%. By identifying important characteristics linked to the development of monkeypox, LIME was used to improve model transparency.

Uysal et al. [25] explained a hybrid deep learning method to identify monkeypox disease from image data. In order to identify monkeypox from skin photos in a multi-class dataset (monkeypox, chickenpox, measles, and normal), this study created a hybrid AI model by merging CSPDarkNet, InceptionV4, MnasNet, MobileNetV3, RepVGG, SE-ResNet, Xception, and LSTM. Following data augmentation, the hybrid model demonstrated strong performance in differentiating monkeypox from related diseases, with 87% test accuracy and a Cohen's kappa value of 0.8222.

Saleh et al. [26] proposed a new approach to detect monkeypox from image data. They used AI, Chimp algorithm etc. The two-phase AI-based Human Monkeypox Detection (HMD) strategy is presented in this article as a means of early monkeypox detection. Weighted Naïve Bayes, Weighted K-Nearest Neighbors, and a deep learning model through weighted voting are all combined in the Detection Phase (DP) to create an Ensemble Diagnosis (ED) model. The first phase, the Selection Phase (SP), uses an Improved Binary Chimp Optimization (IBCO) algorithm for optimal feature selection. With an accuracy of 98.48%, precision of 91.1%, and recall of 88.91%, HMD outperforms contemporary diagnostic techniques.

Almufareh et al. [27] explained how to detect monkeypox from two different datasets with transfer learning. As a safer substitute for conventional PCR testing, this work suggests a non-invasive, computer-vision-based approach for detecting monkeypox by employing deep learning to analyze skin lesion photos. The method's high sensitivity, specificity, and balanced accuracy, as established by tests on the MSLD and MSID datasets, make it an attractive option for general usage, particularly in places with inadequate lab infrastructure. IoT and AI are used in this method to provide safe, contactless diagnostics.

Table I is the summary of the mentioned work that was published in 2022, 2023, and 2024. After analyzing, we see that the previous work has limitations in some cases, such as that they almost used deep learning, transfer learning, and a hybrid model to classify the monkeypox data without explainability. But, we proposed a new method named Vision Transformer and a hybrid model with explainable AI with the best accuracy [see Table I]. So, our work is superior to theirs because our proposed work has the best accuracy from them. Particularly, we reached 100% accuracy using the vision transformer model without any overfitting and 99.33% using deep hybrid learning. So, we can say that our proposed work is the best work till now.

III. Methods

The overall workflow diagram of monkeypox disease detection and classification is illustrated in Fig. 1. In this part, we will discuss data collection, preprocessing, image augmentation, image separation, using of different types of deep and transfer learning models with details and proposed framework, and finally, we will explain explainable AI results applied to input image and predicted image. From, data collection to the result performance of each model, the sequential explanation is included.

A. Data Collection

We collected the image dataset from the online website such as Kaggle and we customized the data for later use https://www.kaggle.com/datasets/mdmokshedurrahman/monkeypox-image-dataset. This dataset has a total of six classes with one directory. We separated the data for training and testing. The total amount of image data is 7,532 and the classes are "Chickenpox", "HFMD", "Measles", "Healthy", "Cowpox", and "Monkeypox". The images are in different color modes. The sample dataset is shown in Fig. 2.

B. Image Preprocessing

Preprocessing images is an essential step in getting data ready for visual transformer models and transfer learning, particularly in applications like the diagnosis of monkeypox disease [28]. To start, pictures are gathered and their sizes are standardized to guarantee consistency, usually shrinking them to 224x224 pixels [29]. Convergence during model training is accelerated by normalization, which involves scaling pixel values to a range between 0 and 1 or standardizing them to have a mean of 0 and a standard deviation of 1.

C. Image Augmentation

In machine learning applications [30], [31] such as transfer learning, ensemble learning [32], and vision transformers, image augmentation is crucial for enhancing model performance by producing a variety of data variants. Rotation, flipping, scaling, cropping, and other techniques expand the amount of the dataset, which improves model generalization and lowers overfitting, particularly in small or unbalanced datasets [33]. Augmentation enables pre-trained models to successfully adjust to new datasets in transfer learning. By encouraging each model to concentrate on unique features, applying different augmentations across models for ensemble learning lowers prediction variance. Augments like patch shuffling and random cropping within vision transformers (ViTs) improve the model's resistance to visual fluctuations by enhancing its capacity to capture global patterns. Augmentation improves generalization overall, allowing models to better handle changes in real-world data. In our dataset, we applied the some rules for image augmentation [34]. We set the parameter as follows:

```
train-datagen= image.ImageDataGenerator(
rescale=1./255,
shear-range=0.2,
zoom-range=0.2,
horizontal-flip=True)
test-dataset=image.ImageDataGenerator(rescale=1./255)
```

D. Image Partitioning

After finishing the preprocessing and augmentation method to the image data, we separate the data for training, validation, and testing[35], [36]. We partitioned the data as follows:
total image for training: 5,273
total image for validation: 2,259 and
total image for validation: 2,259
That is, we separated the total images into three categories.

TABLE I. SUMMARY OF THE RELATED WORK

Reference	Dataset	Used Methods	Accuracy	XAI
[18]	MSID Dataset	Deep-CNN	98.91%	Yes
[19]	Monkeypox detection dataset	Deep Learning, YOLOV5	98.18%	No
[20]	Online image data	Deep learning and Attention Mechanism	83.89%	No
[21]	Online dataset	Deep learning ensembles	87.13%	Yes
[8]	Collected from online portal	Deep learning	82.96%	No
[22]	Their own data	Deep learning and federated learning	97.90%	No
[23]	Kaggle data	Deep neural network	97.63%	Yes
[7]	Real-time data	Deep-transfer learning	99%	No
[24]	Puclic data	Deep learning	99%	Yes
[25]	Puclicly availabe data	Hybrid Deep Learning	87%	No
[26]	Public dataset	AI, Chimp Algorithm and DL	98.48%	No
[27]	MSLD, MSID Online data	Transfer learning	94%	No
Proposed Approach	Online recent data	Vision Transformer, Hybrid Model	100% for ViTs, 99.33% for Hybrid	Yes

E. Proposed Neural Network Framework

For image classification, deep learning models are suitable. These models can detect the disease more accurately. In this study, we applied some deep learning models such as EfficientNetV2 and MobileNetV2 [37]. A separate explanation is below.

1) EfficientNetV2: Monkeypox may be successfully detected by picture analysis using EfficientNetV2, a cutting-edge deep-learning model created for image classification applications [38]. By employing a compound scaling technique that consistently increases network depth, width, and resolution, EfficientNetV2's fundamental concept is its capacity to strike a compromise between accuracy and processing efficiency. The model is perfect for processing

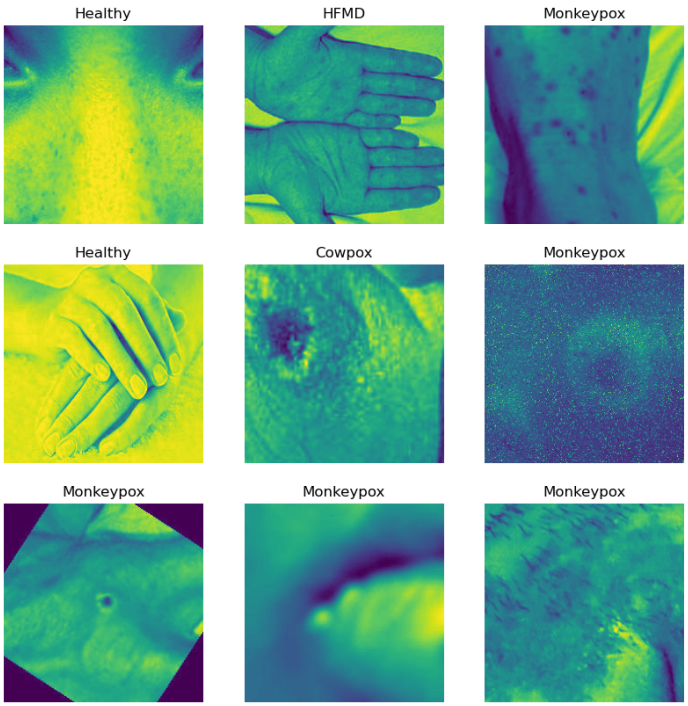

Fig. 2. Dataset sample.

medical images where accuracy is crucial because of its architecture, which allows it to extract complex information from images at a reduced computational cost. EfficientNetV2 may be optimized on a dataset of photos of monkeypox by utilizing transfer learning, which enables it to pick up unique patterns and characteristics that are suggestive of the illness. Its capacity to generalize from sparse data is further improved by its sophisticated training methods, such as progressive training, which begins with images of lower quality and progressively raises the resolution during training. In order to facilitate early diagnosis and prompt action in clinical settings, EfficientNetV2 provides a potent solution for precisely identifying monkeypox lesions in pictures. In this study, we used monkeypox image data to detect and classify the disease from those images. Total images were separated into six classes. In this model, we set the parameters as follows:
batch-size = 32
img-height = 224
img-width = 224
lr-rate = 1e-3
lr-mode = 'cos'
epochs = 30
For the training, we set the parameter as follows"
validation-split=0.2,
subset="training",
seed=123,
image-size=(img-height, img-width),
batch-size=batch-size
For the validation, we have,
data0dir,
validation0split=0.2,
subset="validation",
seed=123,
image0size=(img0height, img0width),
batch-size=batch-size

2) MobileNetV2: The lightweight deep learning model MobileNetV2 was created especially for mobile and edge devices, which makes it ideal for real-time applications like identifying monkeypox in medical photos. MobileNetV2's fundamental concept is based on depthwise separable convolutions, which drastically cut down on the number of parameters and calculations needed to analyze data quickly without sacrificing accuracy. Through a sequence of linear bottleneck layers that promote effective information flow and the retention of significant visual details, this architecture improves the model's capacity to learn key elements from images. MobileNetV2 may be optimized on a specific dataset of monkeypox photos by using transfer learning techniques, which will allow it to recognize the distinct patterns and traits linked to the illness. Because of its small size, the model may be used on gadgets with minimal processing power, like smartphones or portable medical imaging equipment, guaranteeing that medical practitioners can make good use of it in a variety of contexts. Consequently, MobileNetV2 offers a quick and easy way to identify monkeypox, which helps with prompt diagnosis and efficient treatment of the illness. In this study, we set the parameter as follows:
batch-size = 32
img-height = 224
img-width = 224
lr-rate = 1e-3
lr-mode = 'cos'
epochs = 15

For the training data, we used,
train-split=0.2,
subset="training",
seed=123,
image-size=(img-height, img-width),
batch-size=batch-size

For the validation of data, we difine,
validation-split=0.2,
subset="validation",
seed=123,
image-size=(img-height, img-width),
batch-size=batch-size

3) ResNet-50: An excellent option for identifying monkeypox in a six-class image dataset is ResNet-50, a potent transfer learning architecture that performs exceptionally well in image classification tasks. ResNet-50's fundamental concept is its creative use of residual connections, which mitigate the vanishing gradient issue that sometimes arises in very deep networks while enabling the model to learn intricate features [39]. These residual connections make it easier to train deeper networks by allowing gradients to have direct paths during backpropagation, which enhances the model's capacity to recognize complex patterns in images. ResNet-50 can be refined in the context of monkeypox detection using a broad dataset that comprises several classes associated with the disease, such as distinct lesion phases or other skin disorders. This flexibility improves classification accuracy

by enabling the algorithm to pick up subtle visual cues that distinguish monkeypox from related illnesses. ResNet-50 is also well-suited for managing sparse or unbalanced datasets, which are typical in medical imaging, due to its resilience to overfitting. In the end, ResNet-50 offers a dependable method for precisely identifying monkeypox lesions by utilizing its depth and architectural improvements, which helps with prompt diagnosis and efficient patient treatment in clinical settings [40]. In this study, we used the below parameter for ResNet-50 model training and also validation.
batch-size = 32
img-height = 224
img-width = 224
lr-rate = 1e-3
lr-mode = 'cos'
epochs = 30
For the training, we set the parameter as follows:
validation-split=0.2,
subset="training",
seed=123,
image-size=(img-height, img-width),
batch-size=batch-size
For the validation, we used the parameter list as follows:
validation-split=0.2,
subset="validation",
seed=123,
image-size=(img-height, img-width),
batch-size=batch-size

The basic architecture of the ResNet 50 model for this study is illustrated in Fig. 3.

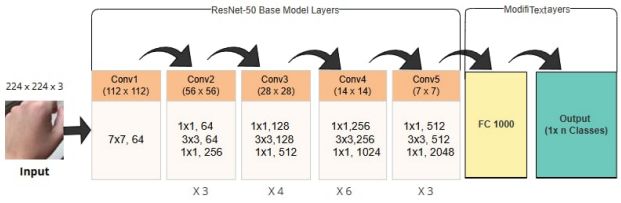

Fig. 3. Proposed ResNet 50 model architecture.

4) Vision Transformer: By adapting transformer-based designs, which were initially created for natural language processing, to visual data, the Vision Transformer (ViT) model(google/vit-base-patch16-224) offers a fresh method for image analysis [41]. ViT interprets images as a series of tiny patches, collecting global dependencies throughout the image, in contrast to convolutional neural networks (CNNs), which rely on local feature extraction [42]. It is especially useful for differentiating intricate visual patterns linked to illnesses like monkeypox because of its capacity to comprehend spatial relationships. ViT can learn the distinct visual indicators of monkeypox lesions, such as shape, texture, and distribution, across different phases and classes by training on a collection of monkeypox images. This method is useful for detecting monkeypox because it enables the model to understand both little details and more general contextual patterns, which helps it distinguish monkeypox from other skin disorders that are similar. Furthermore, ViT can concentrate on pertinent image regions thanks to its attention mechanism, which could improve interpretability in medical diagnostics. All things considered, Vision Transformer offers a potential tool for detecting monkeypox by fusing high accuracy with knowledge of the spatial patterns that characterize the illness [43]. In our study, we follow the working mechanism of the Vision Transformer model shown in Fig. 4.

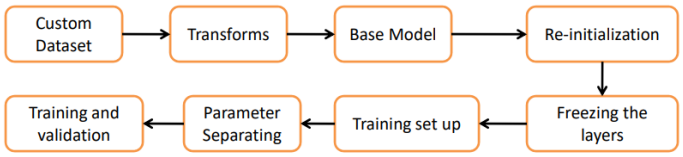

Fig. 4. Working procedure of the vision transformer model.

Initially, we customized the dataset for the transformer. The parameter set as:
transform = transforms.Compose([
transforms.Resize((224, 224)),
transforms.ToTensor(),
transforms.Normalize(mean=[0.5, 0.5, 0.5],
std=[0.5, 0.5, 0.5]),])

After transforming, we defined the base model and re-initialized the features. Freezing the layers, we did training setup and parameter dividing for the training and validation.

5) Hybrid Model: To obtain better performance and more accuracy, we used a hybrid version of three models. The hybrid model is generated from averaging the output from ResNetV2, MobilNetV2, and EfficientNetV2 [44]. This hybrid model technique detects and classifies monkeypox across six different image classes by averaging the outputs of three sophisticated deep-learning architectures: ResNetV2, MobileNetV2, and EfficientNetV2. Every one of these types has special advantages: While MobileNetV2 offers lightweight efficiency, making it highly responsive and appropriate for real-time processing with limited CPU resources, ResNetV2's residual connections enable the capture of intricate image features and deep hierarchical patterns. In contrast, EfficientNetV2 offers a balanced scaling technique that simultaneously modifies network depth, width, and resolution to improve accuracy and efficiency. The hybrid model leverages the combined advantages of each architecture by averaging the predictions from these three networks. This integration lessens the biases present in any one model, producing a more robust and balanced outcome that is particularly helpful for managing the many visual traits of monkeypox lesions in various classes [45]. Even with the variances found in a medical picture dataset, the hybrid model can function effectively thanks to the averaging technique, which may enhance generalization and lower mistakes. In the end, this team approach improves the accuracy and dependability of monkeypox detection, offering a complete tool to assist medical professionals in diagnosing and categorizing the illness. In this combined model, we set the features for the training data and also the same for validation as follows:
validation-split=0.2,
subset="training",

seed=123,
image-size=(224, 224),
batch-size=32)
For the base model, the parameters are:
weights='imagenet',
include-top=False,
input-shape=(224, 224, 3)

The basic organization of the proposed hybrid model is illustrated in Fig. 5.

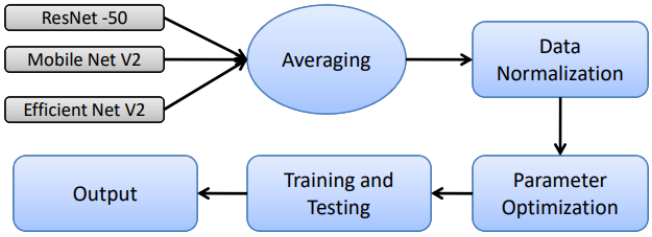

Fig. 5. Working procedure of proposed hybrid model.

In Fig. 5, for the section of Normalization, we set the parameter as:
Rescaling=1./255,
map(lambda x, y: (normalization-layer(x), y)).cache().prefetch(buffer-size=tf.data.AUTOTUNE)
We optimized the some parameters such as:
Input(shape=(224, 224, 3))
optimizers.Adam(learning-rate=1e-3),
losses.SparseCategoricalCrossentropy(from-logits=True),
metrics=['accuracy']
epochs=30

F. Explainable AI Approach

We use Grad-CAM (Gradient-weighted Class Activation Mapping) to show the relevant areas in monkeypox images as part of our Explainable AI feature extraction method for monkeypox detection [46]. The interpretability technique Grad-CAM improves the transparency of deep learning models by assisting in determining which aspects of an image have the greatest influence on a model's prediction. This method highlights the main characteristics in the images used for monkeypox categorization across several classes by implementing Grad-CAM for a ResNet-based model [21]. First, a Grad-CAM class is created, which initializes a gradient model by choosing the network's last convolutional layer and attaching it to the output layer of the model. Grad-CAM computes the gradient of the output class (predicted as monkeypox or another) in relation to the feature mappings in the final convolutional layer after an input picture has been run through the model. The features that are important for the model's categorization are shown by these gradients [47]. A heatmap highlighting the significant regions of the image that influenced the model's prediction is produced after pooling the gradients and appropriately weighting the feature maps. In order to create a superimposed visualization, the calculated heatmap is enlarged to the original image proportions, colored using a "jet" colormap, and then superimposed on the original image. Medical practitioners may more easily validate the model's focus areas and comprehend predictions thanks to this overlay, which shows the portions of the image that the algorithm looks for in order to detect monkeypox. By making the model's decision-making process more clear, these explainable strategies increase confidence in the model's application for medical imaging diagnosis and categorization of monkeypox.

IV. Results

In this section, we discussed the result of the deep learning model in Monkeyfox disease detection [16]. Particularly, we explored the results of EfficientNetV2 and MobileNetV2.

From the above part, we know that EfficientNetV2 is used in the monkeypox image dataset and has a total of six classes. The basic parameter details of EfficientNetV2 is shown in Table II.

TABLE II. EfficientNetV2 Parameter Details

Layer (type)	Output Shape	Param
input-layer-18 (Input-Layer)	(None, 224, 224, 3)	0
efficientnetv2-l (Functional)	(None, 7, 7, 1280)	117,746,848
conv2d-7 (Conv2D)	(None, 7, 7, 512)	5,898,752
global-average-pooling2d-7	(None, 512)	0
dense-14 (Dense)	(None, 256)	131,328
dense-15 (Dense)	(None, 6)	1,542
Total params:	123,778,470	0
Trainable params:	6,031,622	0
Non-trainable params:	117,746,848	

In this model,
Training accuracy is 99.94%
Training loss is 0.38%.
The validation accuracy is 97.80% and
The validation loss is 6.72%.
The testing accuracy is: 97.67%
The testing loss is: 6.94%.
The training accuracy and validation accuracy are shown in Fig. 6 and the training loss and validation loss are shown in Fig. 7.

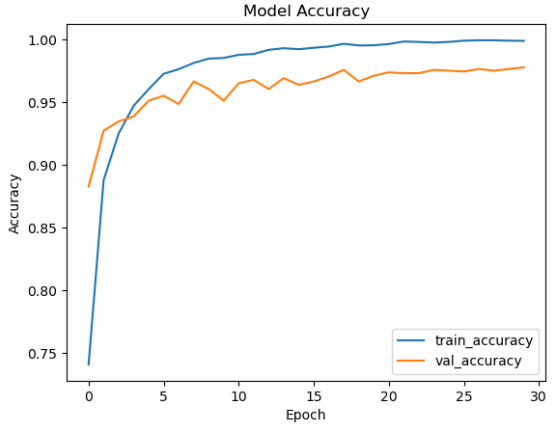

Fig. 6. Train accuracy vs. Validation accuracy of EfficientNetV2.

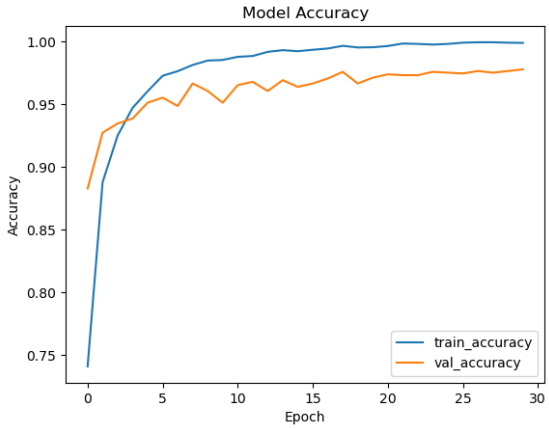

Fig. 7. Train loss vs. Validation loss of EfficientNetV2.

The classification report of the EfficientNetV2 is illustrated in Table III.

TABLE III. CLASSIFICATION REPORT OF EFFICIENTNETV2 MODEL

Class-Name	Precision	Recall	F1-Score	Support
Chickenpox	0.95	0.96	0.95	140
Chickenpox	0.95	0.96	0.95	140
Cowpox	1.00	0.97	0.98	120
HFMD	0.99	0.98	0.98	345
Healthy	0.99	0.99	0.99	251

dense-10 (Dense)	(None, 256)	131,328
dense-11 (Dense)	(None, 6)	1,542

In this model, we got,
Training accuracy is 95.47%
Training loss is 16.2%.
The validation accuracy is 79.51% and
The validation loss is 64.62%.
The testing accuracy is: 78.18%
and the testing loss is: 20%.
The classification report of MobileNetV2 is shown in Table V.

We used one Transfer Learning model named ResNet-50 to detect the monkeypox from the image data. After applying this model, we have the model parameter summary shown in Table VI.

TABLE V. CLASSIFICATION REPORT OF MOBILENETV2 MODEL

Class-Name	Precision	Recall	F1-Score	Support
Chickenpox	0.95	0.96	0.95	140
Chickenpox	1.00	0.97	0.98	140
Cowpox	1.00	0.97	0.98	120
HFMD	0.99	0.98	0.98	345

The accuracy and loss curve of this model is illustrated in Fig. 9.

Using Vision Transformer (google/vit-base-patch16-224) for detecting monkeypox disease, we have the following results.
The number of epochs: 20
Training accuracy is 100%
Training loss is 0.00%.
The validation accuracy is 87.51% and
The validation loss is 0.37%.

The classification report is shown in Table VIII and the confusion matrices of this model is shown in Fig. 10 where true label vs predicted label and actual label vs. predicted lable is illustrated. The multiclass ROC Curve and Precision-recall curve is explained in Fig. 11 and 12.

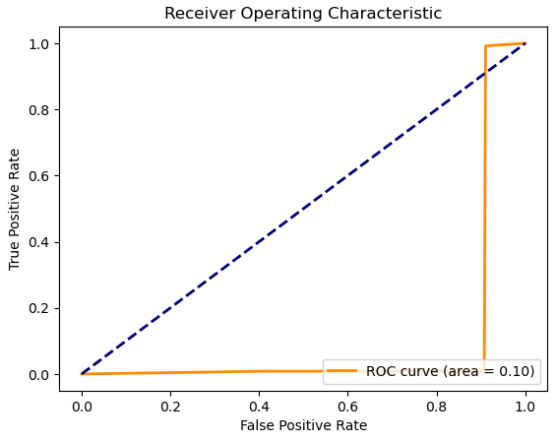

Fig. 8. The ROC curve for ResNet-50 model.

TABLE VIII. CLASSIFICATION REPORT OF VISION TRANSFORMER MODEL

Class-Name	Precision	Recall	F1-Score	Support
Chickenpox	0.64	0.86	0.73	110
Cowpox	0.96	0.93	0.94	91
HFMD	0.94	0.97	0.96	229
Healthy	0.95	0.86	0.90	175
Measles	0.96	0.89	0.92	80
Monkeypox	0.88	0.84	0.87	445
accuracy	0	0	0.88	1130
macro avg	0.89	0.89	0.89	1130
weighted avg	0.89	0.89	0.89	1130

We combined three models to improve the accuracy and reduce the error rate as well as loss amount. Hence, ResNet-50, MobileNetV2, and EfficientNetV2 models are averaging into a single unit named as Hybrid model. After applying this technique, we have the following results:
The number of epochs: 30
Training accuracy is 99.33%
Training loss is 2.11%.
The validation accuracy is 90.09% and
The validation loss is 40.62%.

The summary of the parameter is listed in Table IX and the classification report of this model is shown in Table X.

TABLE IX. HYBRID MODEL PARAMETER DETAILS

Layer (type)	Output Shape	Param	Connected to
input-layer-14 (Input Layer)	(None, 224, 224, 3)	0	-
functional-15	(None, 6)	24,113,798	input-layer-32[0...
functional-16	(None, 6)	2,587,462	input-layer-32[0...
functional-17	(None, 6)	118,076,3...	input-layer-32[0...
average-1 (Average)	(None, 6)	0	functional-15[0]... functional-16[0] functional-17[0]...

The accuracy and loss curve is shown in Fig. 13 and the confusion matrix is shown in Fig. 14.

TABLE X. CLASSIFICATION REPORT OF HYBRID MODEL

Class-Name	Precision	Recall	F1-Score	Support
Chickenpox	0.94	0.77	0.85	140
Cowpox	0.99	0.87	0.92	120
HFMD	0.98	0.85	0.91	345
Healthy	0.94	0.91	0.93	251
Measles	0.83	0.83	0.83	98
Monkeypox	0.84	0.98	0.91	549
accuracy	0	0	0.90	1503
macro avg	0.92	0.77	0.89	1503
weighted avg	0.91	0.90	0.90	1503

The results summary of the proposed model are shown in Table XI.

TABLE XI. RESULT SUMMARY OF USED METHODS

Model	Training Accuracy	Validation Accuracy	Testing Accuracy
EfficientNetV2	99.94%	97.80%	97.67%
MobileNetV2	95.47%	79.51%	78.18%
ResNet-50	99.87%	99.85%	97.18%
Vision Transformer	100%	87.51%	99.41%
Hybrid Model	99.33%	90.09%	99.09%

A. Exploring Grad-CAM

We applied explainable AT to the predicted image to explain it based on trained images. If we use any monkeypox-positive image for the explanation, then based on the training and predicted value, the machine can explain the image using the heat-map method [48]. Using the Grad-CAM, the system can explain the input image for clearance. One suitable example is shown in Fig. 15. Especially, this image is the monkeypox positive input image, the system will use a heat map to analyze and explain it. Finally, the system is successful, saying that it is the monkeypox positive image [49]. Table XII shows evaluation metrics for Grad-CAM for hybrid model.

B. Comparison with Previous Studies

The comparison presented in Table XIII highlights the effectiveness of the proposed models in achieving state-of-the-art performance for monkeypox diagnosis. Our study demonstrated superior accuracy with Vision Transformers (ViTs) achieving 99.41% and the hybrid model achieving 99.09%. These results outperform many of the existing studies, such as [18] (98.91%) and [7] (99%), showcasing the robustness of our approach.

The incorporation of Vision Transformers proved particularly impactful due to their ability to capture global dependencies within the input data, which is critical for nuanced image classification tasks. The hybrid model further enhanced performance by combining the strengths of ResNet-50, MobileNetV2, and EfficientNetV2, enabling better feature extraction and classification accuracy.

Compared to prior studies, such as [20] and [8], which reported lower accuracies of 83.89% and 82.96%, respectively, our models exhibited a significant improvement. Additionally, while models like [21] and [23] incorporated Explainable AI (XAI) techniques, their accuracies (87.13% and 97.63%) were

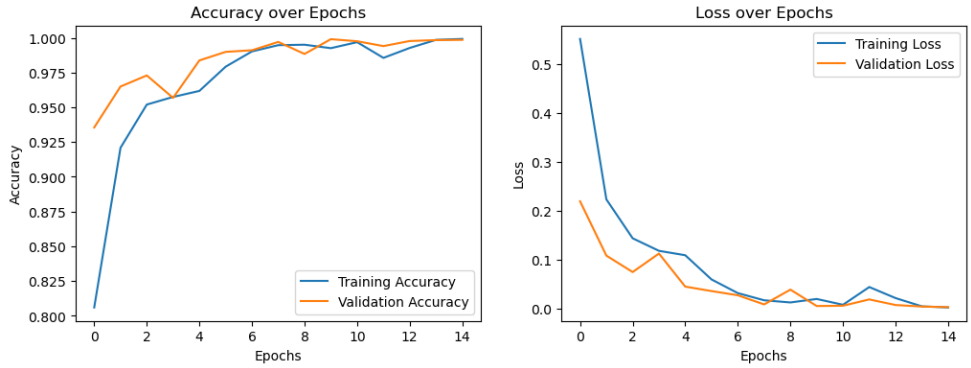

Fig. 9. Accuracy and loss curve of ResNet-50 model.

TABLE XII. EVALUATION METRICS FOR GRAD-CAM FOR HYBRID MODEL

Evaluation Metric	Grad-CAM	Explanation
Ground Truth Mask Overlap	97%	Percentage of overlap between the ground truth mask and the highlighted region.
Feature Coverage	0.97	Proportion of the image covered by the highlighted features in the explanation.
Relevant Activation	96%	Percentage of activation in relevant areas.
Feature Relevance	0.96	Relevance of features in the explanation, corresponding to the model's decision.
Similarity (Mean Absolute Error)	0.89	Mean absolute error between the predicted and actual class.
Consistency Error	0.89	Error in consistency when input is perturbed or modified.

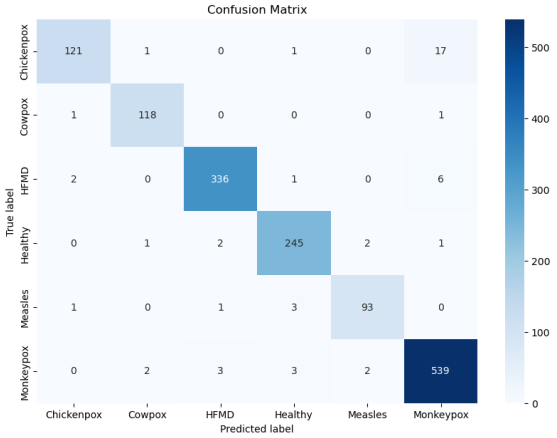

Fig. 10. Confusion matrix of vision transformer in true label vs. Predicted label.

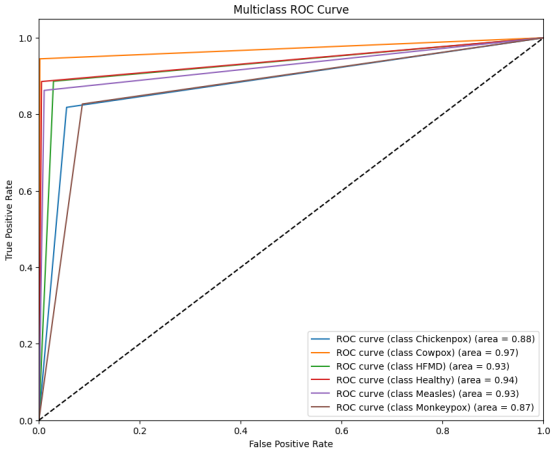

Fig. 11. ROC Curve for vision transformer model.

lower than ours, demonstrating that our integration of Grad-CAM not only enhanced interpretability but also maintained high performance.

Explainability remains a critical aspect of monkeypox diagnosis, as accurate predictions alone are insufficient in sensitive medical applications. Our use of Grad-CAM enabled a detailed understanding of model decisions, providing visual insights into key features contributing to the classification. This is a step forward in building trust and transparency in AI-based healthcare solutions, addressing concerns in studies like [24] and [26], which either did not integrate XAI or lacked detailed visualization.

V. CONCLUSION AND FUTURE RESEARCH

This study demonstrates the potential of deep learning models, particularly Vision Transformer and hybrid approaches, in achieving accurate and interpretable monkeypox diagnosis. Among the models tested, the Vision Transformer emerged as the most effective, achieving high accuracy across training, validation, and testing phases while maintaining robustness against overfitting. The hybrid model, combining ResNet-50, MobileNetV2, and EfficientNetV2, also delivered competitive performance, highlighting the benefits of leveraging diverse architectural strengths. The integration of Grad-CAM enhanced the interpretability of the models, providing valuable insights into their decision-making processes, a critical requirement for clinical applications. These findings highlight the role of AI-driven solutions in enabling early and

TABLE XIII. COMPARISON WITH PREVIOUS STUDIES

Reference	Accuracy	XAI
[18]	98.91%	Yes
[19]	98.18%	No
[20]	83.89%	No
[21]	87.13%	Yes
[8]	82.96%	No
[22]	97.90%	No
[23]	97.63%	Yes
[7]	99%	No
[24]	99%	Yes
[25]	87%	No
[26]	98.48%	No
[27]	94%	No
Our Study	99.41% for ViTs, 99.09% for Hybrid	Yes

precise monkeypox diagnosis, thereby aiding timely containment and treatment. One of the limitations of this study is that the dataset was taken from an online publication from the clinical sector, and to detect the proper place of monkeypox, the segmentation method can be applied in real-time image data. Future research will cover this technique. Future research should focus on enhancing the generalizability of the proposed models by expanding the dataset to include diverse populations, imaging conditions, and clinical real-time data. Additionally, improving model efficiency for deployment in resource-constrained environments will be crucial for enabling widespread adoption. Incorporating other explainability techniques, such as LIME or SHAP, could provide deeper insights into model predictions, fostering greater trust among clinicians. Exploring federated learning frameworks may further enhance privacy and scalability, allowing collaborative training across institutions without compromising data security. Longitudinal studies spanning various demographic and clinical contexts will help validate model reliability over time. Moreover, integrating multi-modal data, such as clinical biomarkers and patient metadata, could improve diagnostic accuracy and provide a more holistic understanding of monkeypox.

DATA AVAILABILITY

The used datasets are open-access and referenced in this manuscript.

DECLARATION OF COMPETING INTEREST

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

***Abstract*—Rice plays a vital role in the food stock. But sometimes this crop leaf falls into disease. And, the amount of food consumed will decrease due to leaf disease. So, discovering the rice leaf disease is necessary to improve rice productivity. Currently, many researchers use deep learning methods to solve this problem. Unfortunately, their research results were less accurate. In this paper, we construct transfer learning models to diagnose and categorize illnesses affecting rice leaves. To further improve the model performance, we construct three ensemble learning models to combine various architectures. In order to bring transparency to the disease diagnostic process, we explore the explainable AI (XAI) problem of the visual object detector and integrate Gradient-weighted Class Activation Mapping (Grad-CAM) into three ensemble models to generate explanations for individual object detections for assessing performance. The results of Ensemble Learning indicate that merging different architectures can be effective in disease diagnosis, as evidenced by their best accuracy of 99.78% which is better than other state-of-the-art works. This research demonstrates that the integration of deep learning and transfer learning models yields improved prediction interpretability and classification accuracy of rice leaf disease. So, we established a dependable method of deep, transfer, and ensemble learning for the diagnosis of diseases affecting rice leaves.**

***Keywords*—Rice leaf; ensemble-learning; explainable AI; disease diagnosis; transfer learning**

I. Introduction

Over half of the world's population depends on rice production as their primary staple, making it essential for global food security [1], [2], [3]. Because it sustains livelihoods, particularly in Asia where it is a significant source of employment and revenue, it has a significant impact on people [4], [5]. Efficient rice cultivation has a crucial role in maintaining and enhancing lives globally by ensuring food stability, economic well-being, and socio-economic development [6].

Finding rice leaf disease is a vital job in agriculture since rice is one of the most important crops in the world and feeds millions of people as a staple diet. Brown spot, leaf blast, and bacterial blight are just a few of the diseases that can severely limit rice crop productivity, resulting in financial losses and food poverty. By using targeted treatments or preventive measures, farmers can take appropriate corrective action to preserve crop health and maximize production. Early and precise detection of these diseases using rice leaf images can assist farmers in doing just that. The scalability and effectiveness of image analysis in rice leaf disease detection make it a valuable tool. Conventional approaches to disease identification are laborious, arbitrary, and prone to mistakes as they frequently depend on the manual inspection of specialists. However, a quick, reliable, and scalable solution is provided by automated detection that makes use of computer vision and machine learning algorithms. Advanced models have demonstrated significant potential in accurately classifying rice leaf illnesses from images. These models include ensemble learning models (e.g. combining VGG16, ResNet50, InceptionV3, and EfficientNet) and deep learning architectures (e.g. CNNs) [7], [8]. By including Explainable AI methods such as Grad-CAM, these models become more visible and users are able to see which leaf portions are responsible for the predictions made by the model [9]. This guarantees that academics and farmers alike can rely on the technology and obtain practical knowledge about the well-being of rice crops, which in turn promotes improved disease control and more environmentally friendly farming methods [10], [11].

By including Explainable AI methods such as Grad-CAM, these models become more visible and users are able to see which leaf portions are responsible for the predictions made by the model. This guarantees that academics and farmers alike can rely on the technology and obtain practical knowledge about the well-being of rice crops, which in turn promotes improved disease control and more environmentally friendly farming methods [12].

The main goal of rice leaf disease identification using rice leaf images is to create an automated, precise, and effective system that can recognize and categorize illnesses that impact

rice harvests. Reduced reliance on costly, time-consuming, and error-prone manual expert inspection is the aim of utilizing sophisticated image processing and machine learning approaches [13], [14], [15]. By early detection of illnesses including bacterial blight, brown spot, and leaf blasts, this method hopes to give farmers the information they need to take preventative measures that can stop the disease's progress and lessen crop loss. Another goal is to provide a scalable solution that can be implemented at various agricultural scales and geographical locations to increase the overall productivity and sustainability of rice growing. The system employs deep learning models [16], [17], [18], such as CNNs, in conjunction with ensemble learning techniques that integrate the capabilities of models like VGG16, ResNet50, and InceptionV3, to achieve a high degree of disease detection accuracy while maintaining resilience in a range of environmental circumstances and image characteristics. The goal also includes improving these models' interpretability by using Explainable AI techniques like Grad-CAM, which let users see the specific regions of the rice leaf that the algorithm targeted for prediction. This openness strengthens farmer confidence in the system and gives them a greater knowledge of the health of their crop [19], which in turn improves disease control procedures and promotes more sustainable agricultural results.

The key contributions of this paper are as follows:

1 We explored the disease of rice leaf images from two datasets using separate deep and transfer learning models.
2 We customized and applied three ensemble learning techniques from deep and transfer learning.
3 We proposed an ensemble learning model with the highest accuracy and lowest data loss rate.
4 We used Explainable AI to evaluate the input image and with the proposed ensemble learning.
5 Finally, we proposed new algorithms for generated ensemble learning algorithms.

The remaining parts of this paper are formatted as follows: Section II explains the previous studies of existing work that were published recently. While Section III describes the research technique used in this work, Section IV provides the experimental results of this work. Section V demonstrates the conclusion and future work of this study.

II. Prior Studies

Many researchers have published solutions for rice leaf disease diagnosis using different types of algorithms such as deep learning, machine learning, ensemble learning, etc. Some recent publications are mentioned here.

S. Ghosal and K. Sarkar et al. [20], proposed a VGG-16-based CNN architecture to detect different rice leaf diseases accurately and they used their own collected dataset containing about 500 images and achieved 92.46% of accuracy. In the paper et al.[21], authors applied several image processing techniques such as RGB to HSV conversion, background subtraction, segmentation, etc., and then implemented an automated system using a deep neural network for rice leaf disease detection and achieved an average accuracy of 92% using their self-collected dataset of 209 images. J. Chen, D. Zhang, Y. A. Nanehkaran, and D. Li et al. [22] proposed a system for the detection of various rice leaf diseases combining DenseNet pre-trained with ImageNet and Inception module on an image dataset collected by Fujian Institute of Subtropical Botany, Xiamen, China and achieved an outstanding accuracy of no less than 94.07% for each type of disease category.

M. A. Islam et al. [23] worked with four types of paddy disease to detect it early and accurately. They applied several deep learning CNN models such as VGG-19, Inception-Resnet-V2, ResNet-101, and Xception and their experimental result shows that Inception-Resnet-V2 performed better with 92.68% accuracy. Several image processing techniques [24] were applied by the authors to extract important features from images that describe the most significant characteristics and then classified the images as rice leaf disease category using XGBoost and SVM algorithms and got about 86.58% accuracy. They created their own dataset for the experiment and used a public dataset for testing. They extract features from images using several image processing techniques [25] and applied CNN models VGG16, ResNet50, and DenseNet121 to detect rice leaf disease accurately and 91.63% accuracy is achieved by the model DenseNet121.

To detect rice leaf disease automatically considering various leaf sizes author applied deep learning-based CNN model ResNet and YOLOv4 [26] on a public dataset of 4960 images and YOLOv4 models show better performance with mAP value 91.14%. In the paper et al. [27], the author applied various CNN techniques for rice leaf disease detection such as VGG16, VGG19, Xception, ResNet, and the 5-layer convolution model, and finally, it is shown that the 5-layer convolution model achieved the highest accuracy 78.2% in compare to other models. CNN models DenseNet121, DenseNet169, MobileNetV2, and VGG16 are employed [28] on the public dataset from Kaggle containing the 5932 images for rice leaf disease detection, and DenseNet169 and moboleNetV2 show the highest performance with 94.30% accuracy. In the paper et al. [29] collected 1500 images from Feni, Bangladesh to detect rice leaf disease and applied CNN model YOLOv5 and achieved 76% mAP value.

A new machine learning approach Nu-SVM model is employed [30] on a Kaggle dataset to detect rice leaf disease and the experimental result shows 52.12% to 53.81% of validation accuracy. In the paper et al. [31], the author employed various filter-based feature transformation techniques for rice leaf disease detection accurately. They used a public rice leaf dataset from Kaggle and it showed that in the experiment the KNN model achieved the highest balance accuracy of 90%. DNet-SVM: XAI is proposed [32] by the authors to detect sugarcane disease detection and they used a public sugarcane dataset from kaggle. DNet-SVM: XAI detects and predicts sugarcane disease early and explains its prediction reason. They also applied another deep learning model such as VGG16, VGG19, and Inception, etc., and compared the result with the proposed model. The proposed model outperformed in comparison to other models. Rice crop disease detection is very important and to detect rice crop disease early author applied the CNN model for detection and LIME to explain its interpretability [33]. The experimental result shows that the proposed models achieved 91.60% accuracy.

Deep learning models VGG16, SqueezeNet, and InceptionV3 were employed in [34] for rice leaf disease detection

and the proposed model SqueezeNet achieved the highest accuracy of 93%. P. Kulkarni and S. Shastri at el. [35] proposed a novel deep learning-based CNN model that is applied for the automatic detection of rice leaf disease. They used a public dataset from Kaggle and the author achieved about 95% accuracy in the experiment. In the classification of corn leaf diseases, the proposed VGG16 model augmented with LRP [36] performed better than earlier cutting-edge models. The outcomes of the simulation showed that the model not only produced findings with a high degree of accuracy but also highlighted important areas in the images that were classified. The authors introduce an improved YOLOv8 [37] that combines EIoU loss and α-IoU loss to replace the original Box Loss function and enhance the rice leaf disease detection system's performance. Finally, they compare YOLOv8 performance with YOLOv5 and YOLOv7 and it is shown that their proposed model performed better with 89.90% accuracy.

The limitation of previous studies was less accurate. In most of the publications, they used pretrained models of deep learning and transfer learning to detect and classify rice leaf disease. The use of Explainable AI was rare.

We employed the "Rice Leaf Disease Detection" dataset from Kaggle and some effective deep learning methods such as CNN, VGG-16, and InceptionV3 in our suggested work shown in Table I, which exhibits higher accuracy than earlier studies. Machine learning, deep learning, and advanced image processing techniques have greatly expanded the field of rice leaf disease detection and recognition. These advancements improve prompt intervention and detection accuracy. However, issues like environmental unpredictability and dataset restrictions still exist. In order to enhance sustainable rice cultivation and further improve detection systems, future research should focus on these concerns.

III. Proposed Framework and System Architecture

The proposed working flow diagram of rice leaf disease diagnosis and classification is illustrated in Fig. 1 where data collection to result in findings is described sequentially.

A. Dataset

For experimental implementation, we collected image datasets from different types of online sources. We used two datasets from online. One is "Rice Leafs Disease Dataset"[1]. This data has a total of two different directories as training and validation with 6 classes. The total images contain 2,627 in six classes. The classes are Bacterial Leaf Blight, Brown Spot, Healthy, Leaf Blast, Leaf Scald, and Narrow Brown Spot. Each class has 350 images for training and 88 images for validation.

Another dataset name is "Rice Leaf Diseases Detection"[2]. This dataset is released at the beginning of 2024. This dataset is also divided into two divisions training and validation. Each directory has a total of 10 classes such as bacterial-leaf-blight, brown-spot, healthy, leaf-blast, leaf-scald, narrow-brown-spot, neck-blast, rice-hispa, sheath-blight, and tungro. Each class has a total of 1,385 images for training and 350 for validation. The total dataset has 17, 350 images for both training and validation. Fig. 2 and 3 describe the sample dataset for two different types of images.

[1]https://www.kaggle.com/datasets/dedeikhsandwisaputra/rice-leafs-disease-dataset

[2]https://www.kaggle.com/datasets/loki4514/rice-leaf-diseases-detection

B. Feature Extraction and Image Processing

To remove noise, reduce dimensions, and make it suitable for model training, we change the shape of the images into 224*224 dimensions after converting the grayscale. To extract the features of the images, the Lanczos interpolation method. We later normalized the images by dividing 255.0 between the pixel values of 0 and 1.

Basically, two feature extraction methods were used here [38]. These are: (1) Shaped based technique, and (2) Transform based Technique.

The dataset is labeled using One-hot encoding techniques for each class in two datasets. Data labeling makes it easy to train and validate the model. Based on the unique class name, the images are labeled with a one-hot encoding method in this study [39].

C. Image Preprocessing

As the preprocessing part of the data, we made changes to the images as:

1. Resize of the images into 224*224
2. Set batch size=32 and classmode='categorical' for the multi-class classification.
3. Array conversion with the help of Numpy.
4. Input shape is 224*224*3.

Such preprocessed images are shown in Fig. 4; where six images from six classes are combined into a single form [40].

D. Data Augmentation

We augmented the dataset 1 to increase the number of images [41], [42]. The increased amount of data will increase the detection and training accuracy of the model [43]. If the dataset is vast then augmentation is not needed but dataset 1, has only 2,627 images. That's why, we used the augmentation method for dataset increasing. We set the parameter details in the augmentation part as follows:

rescale=1.0/255.0,

horizontal-flip=True,

zoom-range=0.2,

shear-range=0.2

But dataset-2 has around 17,350 image data. This amount is enough for the model training. However, dataset-2 has satisfactory data, so, it does not need to augment this data [44]. We ignored to augment. The augmented images for dataset 1 are shown in Fig. 5, where six individual images from six classes are merged into a single image.

TABLE I. COMPARATIVE ANALYSIS BETWEEN EXISTING WORK WITH PROPOSED WORK

Reference	Dataset	Used Methods	Accuracy	XAI
[20]	Private (500)	CNN, VGG-16	92.46%	No

E. Feature Extraction Based on Deep Learning

For model training and validation, we used a deep learning model CNN in this study. This model is suitable for image classification. Preprocessed and augmented images were trained and validated by this model. CNN model is applied to two datasets separately. It is constructed with an input layer, a fully connected layer, some convolutional layers, and max pooling layers [45]. The input layer takes images as input, convolutional layers use a 3*3 filter or kernel for image filtering. The Max pooling layer receives the output from the convolutional layer and processes it. After processing, the output will go through the fully connected layer. The fully connected layer combines the output from the max-pooling layer and makes a single form in the Dense layer. Dense layers flatten the previous layers for making a single form or it is used for combining [46], [16]. The basic organization of the CNN architecture of rice leaf image classification is shown in Fig. 6. CNN model parameter details are shown in Table II.

TABLE II. CNN Model Parameter Details in Every Layer

Layer (type)	Output Shape	Parameter

F. Feature Extraction Based on Transfer Learning

To implement the proposed work, we used total five transfer learning algorithms such as VGG16, VGG19, ResNet-50, InceptionV3, and EfficientNetV2-M. These models apply to two different datasets separately. For vast datasets, transfer learning models are suitable for the best accurate training and validation. Most of the algorithms work are similar way. However, we described them separately below.

1) VGG16: It is the variants of the deep learning model and updated version of the CNN model. This model has basic 16 layers. That is why, it is called VGG16. It consists of some layers such as the Input layer, Convolution layers, Max-pooling layer, Dense layer, and Output layer [47]. A 3*3 laplacian mask was applied here. The image input shape is 224*224 with RGB Channel. Then input image is processed by convolution and max pooling layer [48], [49]. Finally, layers are combined into a single layer named as dense layer. It produces the final output of the model. During trainable. all layers are frozen. The activation function is "softmax" used here [50]. The parameters for the VGG16 is set as:

optimizer='rmsprop',

loss='categorical-crossentropy',

metrics=['accuracy']

The summary parameter details of VGG16 is illustrated in Table III.

2) VGG19: VGG19 is also a transfer learning model, used for classification. It has basic 19 layers. So, it is called, VGG19 [51]. It can classify a total of 1,000 classes of objects. So, this model is highly applicable to vast datasets. It is the incremental version of VGG16 [52], [53]. We used two separate datasets. The first dataset has 2,627 images. The second dataset has 10 image classes and around 17,350 image data. So, we used

it to get the highest accuracy. This model can classify the object with high accuracy. It takes the input image as 224*224 in standard format. This model consists of some layers. The layers are Convolution, Max pooling, fully connected, input, and dense layer. The dense layer is used to flatten the previous layers and it provides the output image [54]. The parameter details of VGG19 are shown in Table IV.

TABLE IV. VGG19 MODEL PARAMETER DETAILS IN EVERY LAYER

Non-trainable params:	0	20024384

3) InceptionV3: This model is another powerful transfer learning model for image data classification. There are eleven inception modules, two max-pooling layers, five convolutional layers, one average pooling layer, one fully connected layer, and one max-pooling layer in InceptionV3[55]. We used this model for rice leaf disease diagnosis and classification. For two separate datasets, we applied this model. Though it takes more time than other models, it can be classified accurately than other models. The basic parameter details of this algorithm are lengthy. So, we are ignoring the parameter details. It has a total of 48 layers [56].

4) ResNet-50: A deep convolutional neural network (CNN) architecture with 50 layers, ResNet-50 is intended for computer vision and image recognition applications. Recursive learning, also known as "skip connections", was presented, in which the network learns residuals, or the variations between input and output layers [57]. This facilitates more effective training of deeper models by addressing the vanishing gradient issue that arises in very deep networks. Convolutional, pooling, and fully connected layers are the building blocks of ResNet-50, which are arranged in residual blocks [58]. It has achieved state-of-the-art results in several vision tasks and has been widely utilized for transfer learning, having been trained on big datasets such as ImageNet. Reputably, the model strikes a balance between computational efficiency and depth. We used this model for two separate datasets in rice leaf image classification.

5) EfficientNetV2-M: EfficientNetV2-M is a powerful transfer learning algorithm, used for large-scale image data. A member of the EfficientNet family, EfficientNetV2-M is renowned for striking an ideal balance in image recognition tasks between computational efficiency and model performance. By adopting a more sophisticated scaling technique and methodically increasing breadth, depth, and resolution, it improves accuracy and speed over the original EfficientNet. Depthwise separable convolutions and more sophisticated methods such as Fused-MBConv are combined by EfficientNetV2-M to minimize computing expenses without sacrificing precision. Large-scale picture classification tasks are especially well-suited for this model, which offers shorter training periods and smaller model sizes than its predecessors. It is adaptable for a range of computer vision applications because it has been pretrained on big datasets like. However, to classify the rice leaf images, we used this model for two separate datasets. Due to the lengthy of layers, we are ignoring the parameter details of this model [59].

To implement the working process and evaluate the performance, we proposed a new algorithm followed in Algorithm 1.

G. Ensemble Learning

Using the pretrained deep and transfer learning models, we got the disease detection accuracy to be more than 95% but not reach 99.99%. We tried multiple ensembling techniques because it was unknown to us which ensemble would be the proper model for this type of work. So, we used three types of ensemble methods [60], [51]. To improve the training and validation accuracy by more than 95%, sometimes we used some models in a single structure known as ensemble learning. Bagging and Boosting are the commonly used ensemble techniques for image classification [61]. The main purpose of ensemble learning is:

1 improving the training and validation accuracy,
2 decrease the data loss amount,
3 find out the optimum solution of time and space complexity,
4 find out the proper detection, prediction, and diagnosis,
5 increase the system speed, etc.

However, in this study, we ensembled deep learning and transfer learning to find out the above requirements. We made three ensembles from six separate models such as CNN, VGG16, VGG19, InceptionV3, ResNet-50, EfficientNetV2-M [62]. Three ensembles are described below.

1) Ensemble Learning-1: Ensemble Learning-1 is developed from transfer learning models. To make this, we used 5 transfer learning models [63]. They are VGG16, VGG19, InceptionV3, ResNet-50, and EfficientNetV2-M. After bagging them, we got a new model named "Ensemble learning-1". Though it requires more time than other single models, it can classify and diagnose the disease more correctly than other normal models [64], [65]. The basic structure of the newly developed ensemble model-1 is illustrated in Fig. 7 and the parameter list is shown in Table V. Algorithm 2 is the proposed new algorithm for ensemble learning-1 used in this study. It is developed based on the fusion of VGG16, VGG19, ResNet-50, InceptionV3, and EfficientNetV2-M [66], [67].

2) Ensemble Learning-2: Another transfer learning combination of the three models is developed into a single structure known as "ensemble learning-2". We made it, after voting the VGG16, Inception V3, and ResNet-50 [68]. This structure is simpler than Ensemble learning-1. Also, it is suitable for high accuracy of the model training and validation. Though its parameter list is vast, hence it can classify the image data and can detect the diagnosis[69]. The basic structure of ensemble-2 is described in Fig. 8 and the parameter list is shown in Table VI. Algorithm-3 describes the combined algorithm proposed for this model. It is the appropriate model in this structure.

3) Ensemble Learning-3: Ensemble learning-3 is developed from one deep learning and one transfer learning model. By CNN and VGG16 combinations, ensemble-3 is made [70]. It saves memory and space complexity also. Its structure is simple and easy to implement [71], [72]. The basic structure is shown in Fig. 9 and the parameter list is also shown in Table VII. Algorithm 4 explained the basic working process of this fusion model from deep learning and transfer learning. We proposed the algorithm in this stage for rice leaf disease diagnosis at high accuracy and it is more effective now [73].

IV. Result Analysis and Discussion

In this section, we will discuss different types of algorithm performance applied in our study. Particularly, we will explain training, validation, and testing accuracy for each model as well as loss. Graphical representation also will be described here such as Plot details, Curves [74], Confusion Matrix, Classification report, Correctly classified and misclassified images, AI-based testing image report, etc. After all, a comparison of

each model for two datasets will be added for analysis [75], and a comparison table will be created for recently published existing work with the proposed work [76].

A. Transfer Learning Models Performance

In the proposed study, we used five transfer learning models such as VGG16, VGG19, InceptionV3, ResNet-50, and EfficientNetV2-M. The performance of these models is explained below.

1) VGG16: VGG16 is applied for the diagnosis of rice leaf disease from images. However, its structure is not easy and it needs more time due to the deep layers. We got accuracy for training, validation, and testing are 98.94%, 93.97%, and 92.70%, respectively. The training and validation loss amounts were 7.69% and 12.16%, respectively. The training, validation, testing, and loss curves for epochs 50 are shown in Fig. 10. The confusion matrix and classification report are illustrated in Fig. 11 and Table VIII, respectively. The classification report and confusion matrix are generated for 50 epochs and we used two datasets with 0.001 learning rate. To analyze and see the details we just explain for one dataset. For both datasets, we mention the accuracy in the Table XVII below. The ROC curve and Precision-recall curve for dataset-1 are illustrated in Fig.

narrow-brown-spot	1.00	0.97	0.98	58
accuracy	0	0	0.93	315
macro avg	0.93	0.93	0.93	315
weighted avg	0.93	0.93	0.93	315

Though the applied VGG16 model produces around 98.94% training accuracy, it also has some amount of loss. In some cases, it is misclassified and does not properly diagnose the disease. This misclassified rate is rare. However, it was not 100% perfect. But in most of the cases, the model was correctly classified. Some misclassified and correctly classified images are shown in Fig. 14 and 15, respectively. We will ignore the misclassified and correctly classified images for other used models due to vast images and page length.

2) VGG19: VGG19 is used for rice leaf disease diagnosis and classification. Though it requires more time for completion, it can classify and detect the diagnosis more correctly. It has more layers in structure, so it needs time to run. However, after applying this model we got the training, validation, and testing accuracy of 100%, 92.38%, and 92.38%, respectively. The training and validation loss amounts are 7% and 6%, respectively. The learning rate was 0.001 for 50 epochs. The accuracy and loss curve is shown in Fig. 16.

weighted avg	0.93	0.93	0.93	315

4) ResNet-50: It is also a transfer learning deep layer-based model and it is suitable for image classification and disease detection. ResNet has different types of versions such as ReNet 50, ResNet 152, etc. In this study, we used ResNet-50 for Rice Leaf Disease Diagnosis and classification. In this research, this model was applied with 100% training, 96% validation, and 95/25% testing accuracy. The training loss was 5% and the validation loss was 1%. The confusion matrix of ResNet-50 is explained in Fig. 21. The classification report is shown in Table XI. The ROC and Precision-recall curve are explained in Fig. 23 and 24 for 50 epochs in dataset-1.

TABLE XI. CLASSIFICATION REPORT OF RESNET-50 MODEL

Class-Name	Precision	Recall	F1-Score	Support
bacterial-leaf-blight	0.98	0.96	0.97	53

weighted avg	0.95	0.95	0.95	315

5) EfficientNetV2-M: This is another transfer learning model. It is normally used for large data image processing and classification. This model requires more time and needs also memory due to its long hidden layer. However, it can detect and classify accurately. We used this model for two datasets and got 99.64% training accuracy, 99.56% validation accuracy, and 97.98% testing accuracy. The data loss amount for training is 2% and 4% for validation. The learning rate was 0.001. The confusion matrix of this model is described in Fig. 25 and the classification report is explained in Table XII.

TABLE XII. CLASSIFICATION REPORT OF EFFICIENTNET V2M MODEL

B. Deep Learning Model Performance

To implement the proposed work, we used a deep learning model named Convolutional Neural Network (CNN). This model is suitable for image classification and detection. For rice leaf disease diagnosis and classification, we used it. CNN model architecture is easy and simple to use. After applying this to two separate datasets, we have 99.34% training accuracy, 87.62% validation accuracy, and 90% testing accuracy. The data loss was 3% for training and 5% for validation. The classification report is explained in Table XIII.

TABLE XIII. CLASSIFICATION REPORT OF CNN MODEL

deep learning and transfer learning models. We will explore the performance of these ensemble learning models and will propose a new algorithm for the work.

1) Ensemble learning-1 result: fusion of some transfer learning models created this new model for rice leaf disease diagnosis and classified them accurately. Fusion of VGG16, VGG19, InceptionV3, ResNet-50 and EfficientNetV2-M generated ensemble learning-1 named new model and we got 99.14% for training accuracy, 98.98% validation accuracy, and 99% testing accuracy. The data loss was 2% for training, 4% for validation and 3% for testing. The classification report for this model is shown in Table XIV. Fig. 26 describes the model

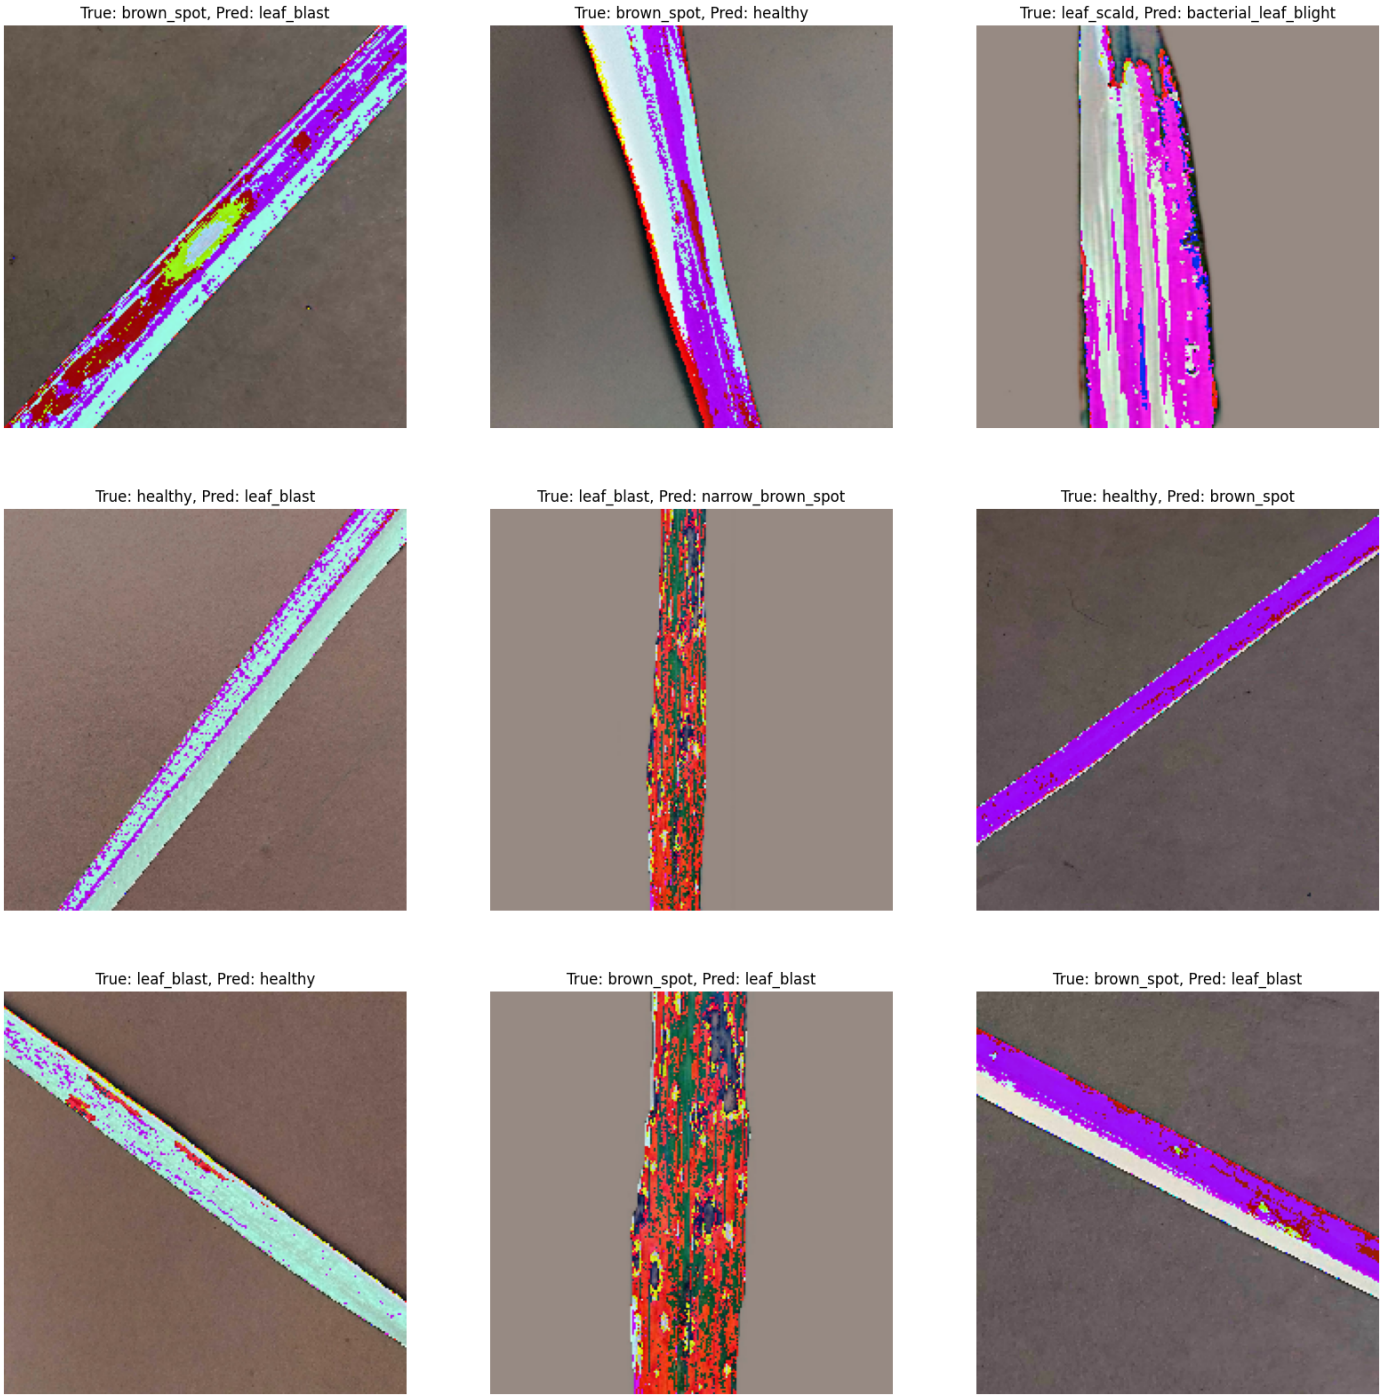

Fig. 14. Misclassified images by VGG16 model.

accuracy, loss, and validation accuracy of ensemble learning-1. This is done for dataset-1 with 50 epochs and not mentioned for dataset-2. Dataset-2 accuracy and loss are most similar to dataset-1.

We got 99.14% accuracy using this technique.

2) Ensemble learning-2 result: Ensemble Learning-2 is generated after combining ResNet-50, VGG16, and InceptionV3. We can say that this is the hybrid version of the transfer learning model for large-scale image classification. Though this technique needs more time for data training and validation, it works accurately. We used it to find out the disease of rice leaves from leaf images. The training accuracy was 99.78%, validation accuracy 98.83%, and testing accuracy 97.89%. The classification report is illustrated in Table XV. Confusion Matrix of Ensemble learning-2 is shown in Fig. 27. Fig. 28 represent the model accuracy, model loss, and validation accuracy-loss of ensemble learning-2. Algorithm-2 represents the proposed algorithm for ensemble learning-2

Fig. 15. Correctly classified images by VGG16 model.

in this study. We developed and used this algorithm. This may combination-variant of VGG16, ResNet-50, and InceptionV3.

3) Ensemble learning-3 result: We ensembled one deep learning model named CNN and one transfer learning model named VGG16 and generated a new model named ensemble learning-3. We may consider this new model as a variant of the deep-transfer learning model. It is suitable for detection and classification of large image datasets. We used this new variant for two datasets. But dataset-1 got 99.36% training accuracy, 90.57% validation accuracy, and 92% testing accuracy. But in dataset-2, the training accuracy was 97%, validation accuracy was 95% and testing accuracy was 90%. Fig. 29 represent the accuracy and loss of the ensemble learning-3. Algorithm 3 is the proposed algorithm for ensemble learning-3. We developed it based on this new model. Fig. 30 illustrates the confusion matrix for ensemble learning-3. Table XVI represents the classification report for ensemble learning-3.

D. Explainable AI "Grad-CAM" for Ensemble Learning-1, 2 and 3

The objective of this work was to increase the interpretability and reliability of image classification using three different ensemble learning models. Combining five strong architectures (VGG16, VGG19, ResNet50, InceptionV3, and EfficientNetV2-M) and leveraging their own strengths, the first ensemble, Ensemble Learning-1, is a formidable combination. Combining the depth of ResNet50, the multi-scale feature extraction of InceptionV3, and the simplicity of VGG16, the second model, Ensemble Learning-2, streamlines these three models. To balance task-specific learning with general feature extraction, the third model, Ensemble Learning-3, combines two deep learning models: CNN and VGG16. The image classification tasks were used to train each ensemble model, and Explainable AI (XAI) techniques like Grad-CAM were

TABLE XVII. COMPARATIVE ANALYSIS OF USED MODEL IN DATASET-1 AND 2

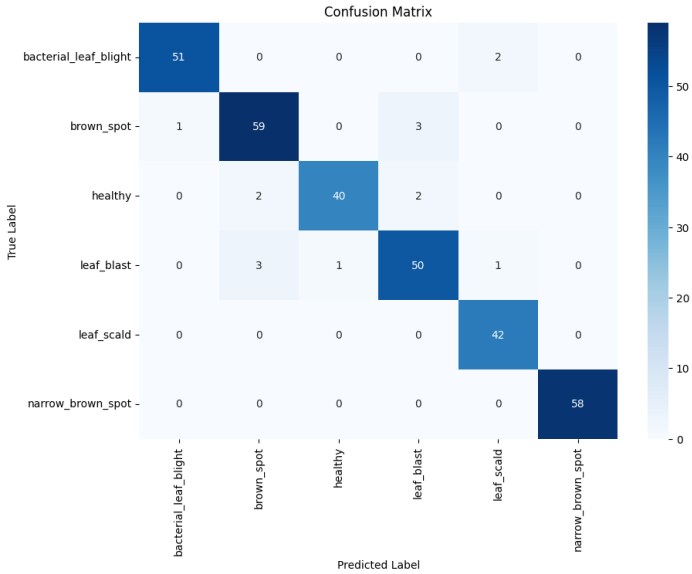

Fig. 21. Confusion matrix for ResNet-50 model.

used to assess interpretability [77], [78]. We evaluated a picture from the "Brown-spot" class to assess the model. Heat maps showing how the model recognized the disease were created using Grad-CAM. The models were able to identify the "Brown-spot" in the input image in every instance, demonstrating the effectiveness of combining XAI and ensemble learning [79]. The XAI-based assessments for models 1, 2, and 3 of ensemble learning are shown in Fig. 31, 32, and 33, respectively. The model predictions perform better and are more transparent using this technique.

E. Discussion

The integration of deep learning and transfer learning models presents a highly efficient approach for the practical diagnosis and categorization of rice leaf disease [80], [49]. Accurately detecting illnesses in rice leaves is critical for crop health and yield maintenance [81], [82]. Models like as VGG16, VGG19, ResNet50, InceptionV3, and EfficientNetV2-M do this [83]. Ensemble Learning-1 demonstrated an accuracy of 99.78% in classification as a result of the integration of these models into ensemble learning structures [84], [85]. Through early disease detection and substantial crop loss prevention, this technique makes it possible to process rice leaf pictures in an effective manner [86], [87].

Moreover, the diagnosis process gains interpretability with the incorporation of Explainable AI (XAI) tools such as Grad-CAM [88]. XAI makes it easier to see which areas of the rice leaf the model concentrates on in order to identify diseases, giving agronomists and farmers more reliable and transparent information [89]. For practical application in agriculture,

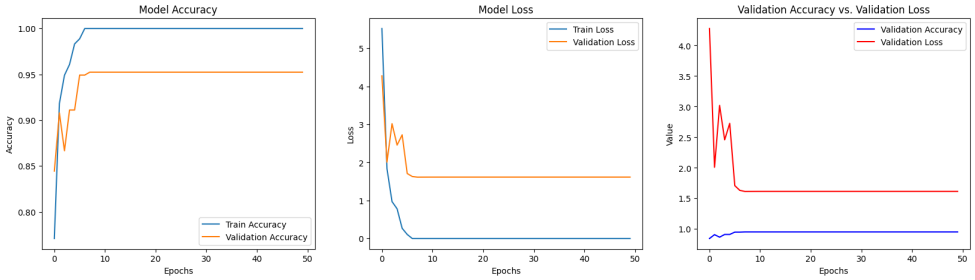

Fig. 22. Accuracy and loss curve for InceptionV3 model.

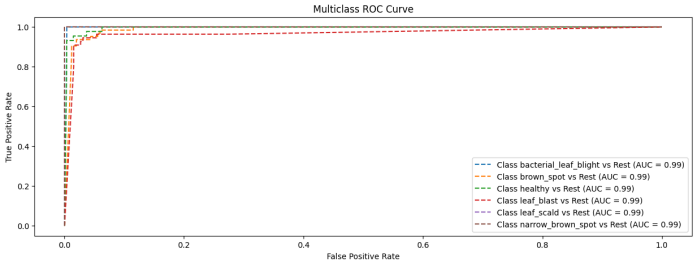

Fig. 23. ROC Curve for ResNet-50 model.

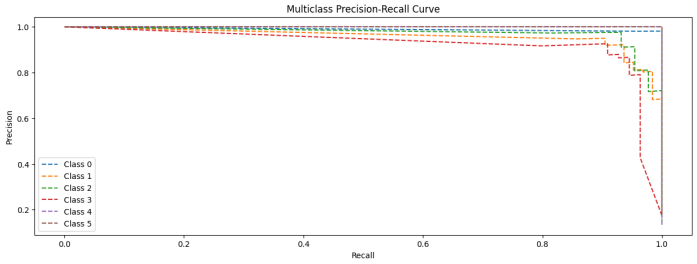

Fig. 24. Precision-recall curve for ResNet-50 model.

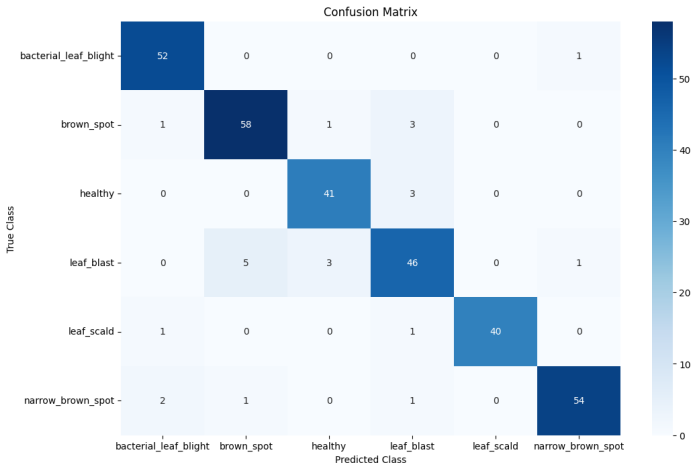

Fig. 25. Confusion matrix for EfficientNetV2-M.

where decision-making depends on the capacity to comprehend the reasoning behind a model's predictions, this transparency is crucial [90]. Rice producers can implement preventive measures earlier and improve crop management and agricultural sustainability by utilizing these AI-driven techniques [91].

Individual models like ResNet50, VGG19, VGG16, and InceptionV3 demonstrated their strong capacity to classify diseases correctly, achieving perfect accuracy (100%), when comparing the performance of individual and ensemble learning models for rice leaf disease detection [92]. Nonetheless, the accuracy of 99.78% was slightly lower but still outstanding when using ensemble learning models, especially Ensemble Learning-1 (which combined VGG16, VGG19, ResNet50, InceptionV3, and EfficientNetV2-M). By utilizing numerous architectures, ensemble models provide the advantage of lowering data loss and enhancing overall robustness despite the slight decrease[23]. The results of the ensembles indicate that adding more diverse models leads to higher generalization and performance, as Ensemble Learning-1 outperformed Ensemble Learning-2 (VGG16, InceptionV3, ResNet50) and Ensemble Learning-3 (VGG16 and CNN).

Furthermore, the incorporation of Explainable AI (XAI) methods, like Grad-CAM, significantly increased the value by offering visual insights into the models' disease detection processes and improving forecast transparency [86]. This is especially significant for agricultural applications because practical usage of the model depends on the user's ability to understand its decisions. As a result, while individual models are very accurate, ensemble learning with XAI balances high accuracy, interpretability, and minimal data loss, making it a more useful and trustworthy method for diagnosing rice leaf disease [93]. To see the comparative analysis of proposed work with other researchers, see Table I; where we got the highest accuracy than other recently published papers. Table XVII represents the comparison of used methods for dataset-1 and dataset-2. The biases of training, validation, and testing accuracy are different in dataset-1 and 2 due to the image characteristics or features.

V. Conclusion and Future Work

This study's findings demonstrate the value of integrating deep learning and transfer learning models to accurately diagnose and classify illnesses affecting rice leaves. Combining different architectures improves accuracy and reliability. The ensemble learning models performed well, with Ensemble Learning attaining the maximum accuracy of 99.78%. Several models, including ResNet50, VGG19, VGG16, and InceptionV3, demonstrated 100% accuracy, demonstrating their efficacy in the identification of diseases. This strategy is useful for

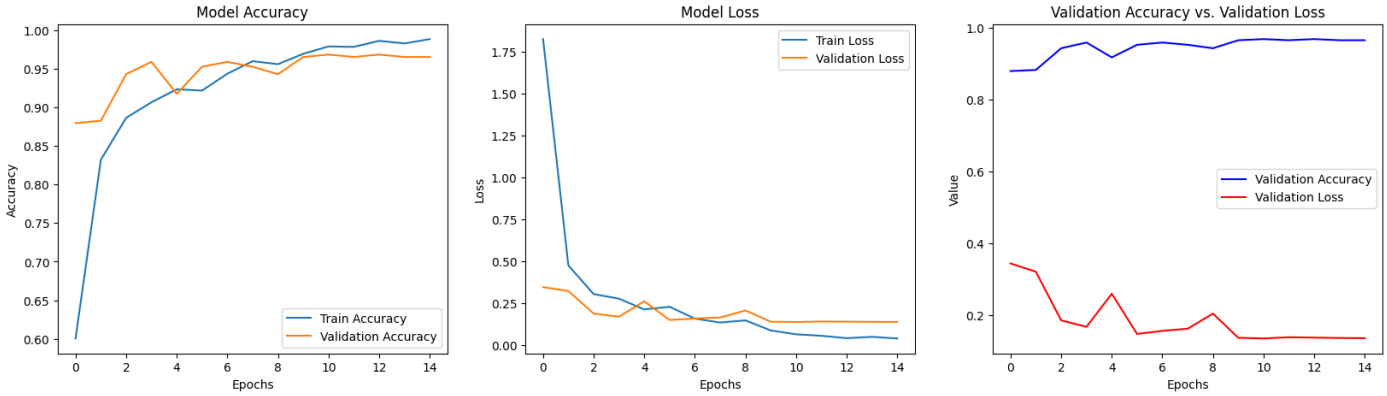

Fig. 26. Model accuracy, loss and validation for ensemble Learning-1.

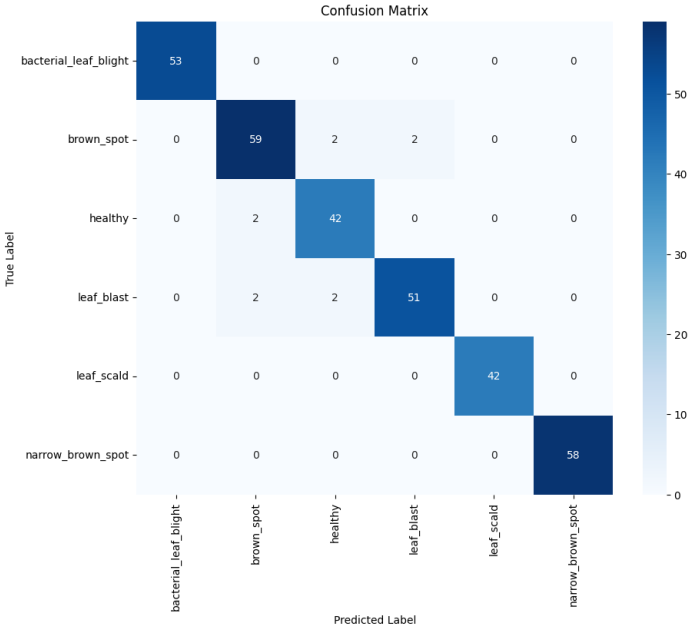

Fig. 27. Confusion matrix for ensemble Learning-2.

real-world applications in agricultural disease control since Explainable AI (XAI) approaches like Grad-CAM also increase the predictability and transparency of the models. We intend to improve performance even further by refining the suggested ensemble learning approach in further work. Furthermore, we hope to investigate the possibility of incorporating real-time data for ongoing observation and early disease diagnosis, as well as to expand this methodology to other crop diseases. Including more extensive and varied datasets may also contribute to improving the models' resilience. The ultimate objective is to create an all-inclusive, field-deployable automated system for diagnosing crop diseases in order to promote sustainable agriculture.

Data Availability

The used datasets are open-access and referenced in this manuscript.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Multi-Label Decision-Making for Aerobics Platform Selection with Enhanced BERT-Residual Network

Yan Hu
Department of Sports Teaching and Research, Capital Normal University, Beijing 100048, China

***Abstract*—In response to the increased demand for individualized workout routines, online aerobics programs are struggling to fulfil the needs of their various user bases with specialized suggestions. Current systems seldom combine multiple data sources to analyze user preferences, reducing customization accuracy and engagement. Enhanced BERT-Residual Network (EBRN) evaluates multimodal input using residual processing blocks and contextual embeddings based on BERT to bridge textual and structural user characteristics. EBRN's deep insights may help understand user engagement, fitness goals, and enjoyment. An innovative data balancing and feature selection method, Dynamic Equilibrium Sampling and Feature Transformation (DES-FT), improves data preparation and model accuracy. Two novel metrics, Contextual Scheduling Consistency (CSC) and Complexity-Weighted Accuracy (CWA), may quantify EBRN stability in multi-attribute classification, particularly for complex data. EBRN outperforms standard AI models on a Toronto fitness platform dataset with 98.7% recall, 98.9% precision, and 99.3% accuracy. Its limited geographical dataset and lack of real-time validation hinder the research. The data show individualized aerobics recommendations that include instructor quality, platform accessibility, and material variety may boost involvement. Researchers need additional datasets and real-time flexibility to make this concept more practical. EBRN's tailored ideas revolutionized digital fitness platform user engagement and enjoyment.**

***Keywords*—Personalized fitness; aerobics recommendations; artificial intelligence; Enhanced BERT-Residual Network (EBRN); hybrid models; user engagement**

I. Introduction

Aerobics and fitness have adopted new technologies due to health awareness and AI/ML breakthroughs. Demand for aerobics classes has grown due to its health benefits for all age groups [1]. NASA and Jane Fonda pioneered aerobics in the 1980s, which now includes dance, gymnastics, and rhythmic movement. The focus on physical and mental wellness makes aerobics desirable for overall health [2]. Fitness firms are taking advantage of this demand by developing AI and IoT solutions to increase involvement. Instructor-led demonstrations guided pupils through traditional aerobics movements. Conventional approaches were effective but lacked real-time analysis, feedback, and customized training [3]. New AI and computer-aided system technologies are revolutionizing aerobics training with real-time feedback and analytics. This change improves aerobics instruction and personalizes excursions. For instance, AI-powered applications that analyze user data like body posture, activity patterns, and fitness levels to deliver personalized coaching are popular.

Digital fitness solutions produce data-driven training plans using image and motion recognition, neural networks, and neurorobotics. Interactive and intelligent fitness with real-time monitoring and adaptive responses is possible with neurorobotics. Neurorobotics and AI can now create interactive, customizable systems that sense, interpret, and react to users' activities. The health advantages of aerobics are maximized by precise movement and synchronization [4]. Recent systems use neurorobotics, big data analytics, and ML models to improve fitness recommendations and personalized routines [5]. These smart systems operate because they satisfy fitness industry standards and technology. Studies demonstrate that self-actualization and preventive healthcare are becoming more important, and many seek lifestyle and health-focused exercise solutions. Rising disposable incomes and health awareness in China have led to the growth of AI-driven fitness applications for health-conscious users [6]. IBM's data mining integration with fitness applications highlights how big data may enhance outcomes by giving accurate, actionable suggestions based on user performance and preferences.

School aerobics teaching has altered with multimedia. Teaching complex exercise routines requires multimedia. Videos, animations, and interactive visuals assist teachers teach and help students copy. Research indicates that multimedia-enhanced aerobics education improves student engagement and comprehension, making it a valuable tool [7]. Multiple demonstration speeds and step-by-step explanations make multimedia systems more dynamic and responsive. Integrating modern tools into aerobics class is hard. Despite its benefits, computer-aided instruction (CAI) systems may make instructors and students reliant, lowering the value of direct education. Critics believe CAI systems that can't adjust to student needs may hinder interactive instruction. Although demanding, CAI aids aerobics training by reducing instructor workload and ensuring consistent movement demonstrations [8]. Refine these systems to support teachers' primary duties.

Using big data, ML, and neurorobotics, fitness systems may adapt to users' needs in real-time, resulting in responsive aerobics training systems [9]. Systems with advanced neural networks may develop fitness regimens based on users' circumstances, preferences, and histories [10]. Adaptive systems may improve health outcomes and satisfaction by meeting individual goals, providing feedback, and modifying routines [11]. Our Enhanced BERT-Residual Network (EBRN) for aerobics provides personalized health recommendations and management using AI and big data. This gadget analyses motion data and creates individualized routines using ML. EBRN predicts and analyzes movement patterns using deep learning and multi-level feature extraction. EBRN improves exercise health technologies by providing precise, flexible fitness advice using huge aerobics datasets. EBRN optimizes individualized workout recommendations using multimodal data

fusion, unique evaluation criteria, and balanced preprocessing. Over CNN, ResNet, and VGG16, prediction consistency and accuracy increase greatly.

1) Develop the Enhanced BERT-Residual Network (EBRN) for multimodal data fusion: BERT embeddings and residual processing blocks let EBRN blend contextual (text) and structured (numerical) data for individualized and accurate exercise recommendations.

2) New Evaluation metrics: CSC and CWA This study uses Contextual Scheduling Consistency (CSC) to evaluate interdependent feature predictions and Complexity-Weighted Accuracy (CWA) to assess model accuracy on intricate features to assess multi-attribute decision-making better.

3) Dynamic equilibrium sampling and feature transformation methodology: The novel DES-FT method balances data and selects features to handle imbalanced classes and optimize feature space for high-performance model training.

4) Insightful analysis of user engagement and platform features: This study examines instructor quality, cost-effectiveness, content variety, and accessibility as critical factors in aerobics platform user engagement, guiding platform improvements to increase user retention.

5) Significant inclusive and community-centric fitness technology advancement: This work makes digital aerobics systems more inclusive by adapting exercise suggestions and accessibility features to varied user demands, enabling urban populations of all fitness levels and demographics.

The rest of the paper is arranged as follows: Section II discusses AI-driven fitness software advances in tailored aerobics instruction. Section III describes the Enhanced BERT-Residual Network (EBRN) architecture, proprietary preprocessing, and innovative evaluation measures. Section IV includes simulation findings, EBRN comparisons with current models, user engagement, and platform features analysis. The last part summarizes the essential contributions and suggests intelligent fitness system research topics.

II. Related Work

Recently, AI, ML, and the IoT have altered health and fitness, especially aerobics. To promote user engagement and health, experts have investigated tailored, data-driven fitness training and monitoring ideas. This section examines relevant research' aims, methods, findings, and limits to identify gaps and inform our intelligent aerobics workout system.

A cloud-fusion fitness monitoring IoT system collected multimodal data, perceived emotions, and provided user-specific health solutions. Our solution represents physiological data from smart clothes and cloud databases using the Wavelet transform. The proposed architecture efficiently tracks user health, but security and privacy issues remain, highlighting the need for stronger IoT frameworks in medical technology [12]. A universal hidden Markov model (HMM) was designed to monitor human health and chronic diseases owing to IoT resource constraints. This method maintains node connection in resource-constrained environments using step-by-step denoising and feature identification. Although promising for remote health monitoring, the IoT-based model's incentive approach poses sustainability challenges in long-term deployments [13]. IoT-based epidemic monitoring utilizing body temperature sensors and thermal imaging might help identify and isolate likely epidemic patients for early public health crisis response. The system has promise, however environmental factors may affect sensor accuracy, necessitating adaptive measures to improve dependability [14] RF and ARIMA machine learning were employed in the wearable blood pressure monitoring model. Lifestyle data predicts blood pressure better than earlier methods. The study's limited sample size and reliance on RF raise concerns about scalability and generalizability to wider populations [15].

Another study employed mobile phones to reduce wearable sensor data transmission to quantify fitness. The technique monitors physiological markers with little data transfer via a Wireless Body Sensor Network (WBSN). While effective for data handling, this approach may not give real-time feedback in fitness applications [16]. A cloud-based health monitoring system captured hospital EHRs and encrypted them using a unique cryptographic approach. Health institutions may track illnesses using the technology while securing data. The use of high-level encryption in low-resource situations raises issues about computational demands and accessibility, notwithstanding its enormous public health impacts [17]. An online health monitoring system sends caregivers real-time patient data, analyzes historical data, and gives emergency assistance. In places with limited internet connectivity, the accurate system's cloud storage may limit accessibility, increasing the need for offline data management [18]. Nutrient-based diet advise systems calculate user dietary needs based on BMI and exercise. Food planning is customized using smartphone applications. The system's smartphone compatibility and computational limitations may hinder its accessibility for diverse user groups [19].

CNN-based lifestyle-related health monitoring disease prediction was given in another study. This method identifies abnormal health and chronic disease risks using IoT data. The CNN-based approach, although accurate, may struggle with unstructured data and requires further refinement for health monitoring [20]. Nutrition and exercise advice for hypertensives were created. A decision tree-based system collects fitness metrics and makes personalized suggestions. The system effectively monitors chronic health conditions, but lacks real-time input, hindering timely health recommendations [21]. Diabetics got clustering-based food categorization and meal planning help. A balanced diet is recommended using K-means and Self-Organizing Maps. Although practical, the model's small scope restricts its usage in comprehensive health management systems [22]. Continuous cardiac monitoring using ECG telemetry and SQA was implemented. Real-time ECG signal quality evaluation is available with this technique. SQA's complexity may limit real-time use owing to processing requirements [23]. Cloud-based smart health monitoring with robust privacy safeguards was our creation. This solution tackles remote monitoring privacy problems by enabling customizable cloud-based medical information access. Although the system has strong security measures, merging several protocols may reduce its effectiveness in urgent care situations [24].

These studies demonstrate improved health and fitness

monitoring. Modern cloud-based systems, wearable sensors, IoT integration, and ML-driven predictive models improve fitness guidance, sickness prediction, and health app user engagement. These systems have privacy, computational, and real-time adaption challenges. Users want speedy response, yet technology is constrained. A full solution with strong ML algorithms and adaptable, privacy-conscious frameworks is required. Our Enhanced BERT-Residual Network (EBRN) method uses neurorobotics, AI, and big data to individualize aerobics fitness advice. EBRN employs neural sensing and control to gather multi-level characteristics, assess movement, and adapt to user expectations using deep learning models. EBRN might enhance health technology and deliver more responsive, personalized, and secure fitness solutions by addressing scalability, data security, and real-time feedback. This review of existing systems underlines the need to combine innovation and practicality in user-centered health and fitness technologies. See Table I for a summary of the literature review.

TABLE I. LITERATURE REVIEW SUMMARY

Ref	Technique Used	Objective Achieved	Limitations
[12]	Cloud-fusion IoT architecture with Wavelet transform	Achieved efficient data acquisition and user-specific health IoT solutions	Security and privacy concerns in medical IoT
[13]	Universal Hidden Markov Model (HMM)	Monitored human physiological health in resource-constrained environments	Dependency on incentives for sustainable operation
[14]	IoT-based epidemic monitoring with thermal imaging	Enabled early epidemic detection and isolation measures	Accuracy affected by environmental conditions
[15]	Random Forest (RF) and ARIMA models	Improved blood pressure prediction accuracy with lifestyle-based modeling	Limited scalability due to small sample size
[16]	Wireless Body Sensor Network (WBSN)	Enhanced efficiency in data handling for fitness monitoring using minimal data transmission	Limited real-time feedback capabilities
[17]	Cryptographic algorithm for EHR encryption	Secured EHR storage and disease tracking for public health	High-level encryption demands computational resources
[18]	Cloud-based online health monitoring system	Real-time monitoring with emergency response for caregivers	Dependency on cloud storage, limiting accessibility in low-connectivity regions
[19]	Nutrient-based diet recommendation on smartphone app	Provided dietary recommendations based on user BMI and activity	Limited accessibility for diverse user groups due to smartphone dependency
[20]	Convolutional Neural Network (CNN)	Predicted chronic disease risks based on lifestyle health monitoring	Limited adaptation for unstructured data
[21]	Decision tree-based diet and exercise system	Offered personalized guidance for hypertensive patients	Lacks dynamic feedback for real-time recommendations
[22]	K-means and Self-Organizing Maps for food clustering	Provided meal planning for diabetic patients through clustering analysis	Restricted to specific meal types, limiting broader application
[23]	ECG telemetry system with signal quality assessment	Enabled real-time cardiac monitoring and quality-based signal evaluation	Additional processing requirements limit real-time performance
[24]	Cloud-based smart health monitoring with privacy controls	Flexible access to medical records with strong security measures	Integration of multiple security protocols impacts system responsiveness

III. PROPOSED METHOD

The Enhanced BERT-Residual Network (EBRN) is a unique model architecture that integrates several data sources to provide individualized, data-driven aerobics recommendations. EBRN specializes in textual and structured data, gathering user input, engagement patterns, and fitness objectives. The model architecture processes text data using BERT-based contextual embeddings to provide rich representations of user input semantics. Structured user data, including demographics and platform activities, is feature transformed to match textual embeddings. This dual input approach lets EBRN provide detailed, tailored suggestions. The model uses Dynamic Equilibrium Sampling and Feature Transformation (DES-FT) to balance the dataset and improve feature relevance for data preparation resilience. These components enable EBRN to produce accurate, consistent predictions in complicated multi-attribute settings, establishing a new benchmark for intelligent fitness recommendation systems. The following sections detail every aspect of the proposed framework. Refer to Fig. 1 for the suggested system design.

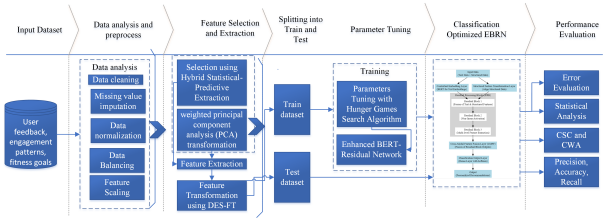

Fig. 1. Proposed framework.

A. Dataset Description

This research carefully gathered data from active fitness platforms in Toronto, Canada. Toronto [25], with its varied population and focus on health and wellbeing, is an excellent place to study aerobics platform users' preferences. The data shows a variety of user demographics and habits, representing this metropolitan area's lifestyle preferences. Surveys in several areas provided a complete picture of the city's fitness environment. This dataset is intended to highlight aerobics platform selection decisions, adding to the expanding corpus of research on online fitness user experience and satisfaction. This dataset will discover trends and preferences essential for developing and optimizing community-specific digital fitness solutions. Table II shows the dataset features and description.

TABLE II. DATASET FEATURES OVERVIEW

S.No	Features	Short Description
1	Platform Name	Name of the aerobics platform selected by users.
2	Platform Type	Type of service offered (e.g., Streaming, Live Classes).
3	Content Variety	Types of workout content available on the platform.
4	Instructor Quality	Rating of the instructors provided by the platform.
5	User Engagement	Level of user engagement on the platform.
6	Cost	Subscription cost for using the platform.
7	Accessibility Features	Indicators of features designed for accessibility.
8	Technical Features	Quality of video streaming offered by the platform.
9	Device Integration	Compatibility of the platform with wearable devices.
10	User Fitness Level	Self-reported fitness level of the user.
11	User Goals	Goals the user sets (e.g., Weight Loss, Muscle Gain).
12	Feedback Score	Average feedback score from users.
13	Session Duration	Average duration of workout sessions in minutes.
14	Device Used	Type of Device used to access the platform.
15	Platform Availability	Platforms on which the service is available (e.g., iOS, Android).
16	Certified Instructors	Availability of certified instructors on the platform.
17	User Location	Geographical location of the user.
18	Fitness Classes per Week	Number of classes a user participates in per week.
19	Community Features	Available community engagement features on the platform.
20	Discount Offers	Discounts available for users.
...	...	...

B. Data Preprocessing Steps

This work requires preprocessing the aerobics platform selection dataset for analysis and modeling. The dataset's imbalanced feature distribution necessitated numerous specific preparation procedures to assure data integrity and usefulness.

Missing values must be handled during preprocessing to ensure data quality. Instead of deleting missing rows, custom imputation is used. This approach averages feature values and adds a tiny random perturbation term to preserve variability. The imputation equation is:

$$Y_{\text{filled}} = Y_{\text{avg}} + \delta \tag{1}$$

In Eq. (1), Y_{filled} represents the imputed value, Y_{avg} represents the feature's average, and δ is a small random perturbation from a uniform distribution to maintain diversity and avoid distorting the feature's natural distribution.

A proprietary oversampling method addresses the dataset's imbalance, notably in target labels. This approach uses a modified Gaussian mixture model to create minority-class synthetic samples that match their distribution. Representing synthetic sample generation:

$$Z_{\text{new}} = Z_{\text{minor}} + \mathcal{N}(\theta, \xi^2) \tag{2}$$

In Eq. (2), Z_{new} represents the new synthetic sample, Z_{minor} represents an existing minority class sample, θ represents the minority class mean vector, and $\mathcal{N}(\theta, \xi^2)$ represents a Gaussian distribution with mean θ and variance ξ^2,

Features must be scaled for models sensitive to data magnitude, notably distance-based methods. We use a proprietary normalization method to scale each feature to [0, 1] depending on its lowest and maximum values. Mathematics defines this normalization:

$$A_{\text{normalized}} = \frac{A - A_{\text{min}}}{A_{\text{max}} - A_{\text{min}}} \tag{3}$$

In Eq. 3, $A_{\text{normalized}}$ represents the scaled feature value, A represents the original value, A_{min} represents the lowest value, and A_{max} represents the maximum value. This scaling guarantees that all characteristics contribute equally to distance computations, improving predictive models.

Finally, a novel one-hot encoding approach converts categorical features to numbers. This method uses frequency-based encoding instead of a traditional technique to value each category depending on its dataset frequency. This transition is:

$$B_{\text{mapped}} = \frac{\text{count}(B_j)}{M} \tag{4}$$

In Eq. 4, B_{mapped} represents the encoded value for the category B_j, $\text{count}(B_j)$ represents the count of occurrences, and M represents the total number of records. This method keeps category distribution information and reduces feature space dimensionality while improving model interpretability.

These proprietary preprocessing procedures prepare the data collection for analysis and modelling, ensuring that the input data is resilient, well-structured, and adequate for obtaining relevant insights into selecting aerobics platforms.

C. Data Balancing, Feature Selection, and Extraction

Addressing class imbalance and refining feature space is the next crucial step after preprocessing the data to clean, impute, and scale it. Dynamic Equilibrium Sampling and Feature Transformation (DES-FT) has been developed to incorporate data balance, feature selection, and feature extraction into a single framework for high-performance modelling.

1) Data balancing: PDS is a revolutionary data balancing method to address the dataset's imbalance. PDS dynamically creates minority class samples without oversampling or undersampling, keeping data density and structure. Over representation or duplication of minority class data might cause model training noise; hence, this is necessary. Sampling process definition:

$$M_{\text{new}} = M_{\text{min}} + \beta \cdot (M_{\text{maj}} - M_{\text{min}}) \tag{5}$$

where M_{new} represents the quantity of new minority class samples, M_{min} represents the current minority class sample count, M_{maj} represents the majority class sample count, and β is a proportionality factor between 0 and 1. This formula generates controlled samples depending on the difference between majority and minority class sizes (see Eq. 5).

New samples are enhanced with a tiny quantity of Gaussian noise to prevent precise replication:

$$Y_{\text{balanced}} = Y_{\text{original}} + \delta \cdot \mathcal{N}(0, \tau^2) \tag{6}$$

Where Y_{balanced} is the resampled balanced data, Y_{original} is the original data, δ is a noise scaling factor, and $\mathcal{N}(0, \tau^2)$ is Gaussian noise This approach keeps resampled data varied and eliminates duplication.

2) Feature selection and extraction: After balancing the data, dimensionality decreases, and feature quality improves. The Hybrid Statistical-Predictive Extraction (HSPE) approach was created for this. HSPE identifies key traits using statistical variance analysis and predictive modelling.

HSPE begins by calculating each feature's modified G-statistic, which assesses its relevance in differentiating target classes [26]:

$$G_{\text{mod}} = \frac{\text{Var}(C_{\text{between}})}{\text{Var}(C_{\text{within}}) + \epsilon} \tag{7}$$

The modified G-statistic is G_{mod}, the variance between target classes is $Var(C_{\text{between}})$, the variance within each class is $Var(C_{\text{within}})$, and ϵ is a small regularization constant to avoid division by zero. High G_{mod} features are used for extraction.

Next, HSPE weights each feature by its modified G-statistic significance score in a weighted principal component analysis (PCA) transformation. Weighted PCA is:

$$Z_{\text{extracted}} = Q \cdot (X - \nu) \tag{8}$$

$Z_{\text{extracted}}$ represents extracted features, Q is a diagonal matrix of G-statistic-derived feature weights, X represents input data, and ν represents feature mean. This treatment emphasizes

key characteristics, decreasing noise and increasing model performance.

The combined DES-FT strategy balances and reduces the dataset to its most valuable components for advanced modelling.

Algorithm 1 Dynamic Equilibrium Sampling and Feature Transformation (DES-FT)

Input: Original dataset D with classes C and features F
Output: Balanced dataset D_{balanced} and selected features F_{selected}
Initialize $M_{\text{maj}} \leftarrow$ count of samples in majority class
Initialize $M_{\text{min}} \leftarrow$ count of samples in minority class
Calculate proportionality factor $\beta \leftarrow \frac{M_{\text{maj}} - M_{\text{min}}}{M_{\text{min}}}$
Data Balancing:
for each minority class **do**
  Generate additional samples $M_{\text{new}} \leftarrow M_{\text{min}} + \beta \cdot (M_{\text{maj}} - M_{\text{min}})$
  for j = 1 to M_{new} **do**
    Create new sample $Y_{\text{new}} \leftarrow Y_{\text{original}} + \delta \cdot \mathcal{N}(0, \tau^2)$
    Add Y_{new} to D_{balanced}
  end for
end for
Feature Selection and Extraction:
for each feature $f \in F$ **do**
  Compute modified G-statistic $G_{\text{mod}} \leftarrow \frac{\text{Var}(C_{\text{between}})}{\text{Var}(C_{\text{within}}) + \epsilon}$
end for
Select features with high G_{mod} values to form F_{selected}
Perform weighted PCA:
$Z_{\text{extracted}} \leftarrow Q \cdot (X - \nu)$
return D_{balanced}, F_{selected}, $Z_{\text{extracted}}$

D. Classification Using Enhanced BERT-Residual Network (EBRN)

Enhanced BERT-Residual Network categorization is possible when feature transformation adds contextual and structural properties to the data. EBRN uses residual processing blocks to include structured data and BERT's deep contextual representations. This architecture specialises in diverse datasets, enabling advanced feature integration and robust classification.

1) Contextual embedding layer: The first step in EBRN's design is employing BERT to embed raw text data in high-dimensional spaces. For a tokenized input sequence V, the BERT model creates contextual embeddings C_{embed} that represent text semantics:

$$C_{\text{embed}} = \text{BERT}(V) \tag{9}$$

V is the input text sequence, and C_{embed} is the output embedding matrix. This matrix captures detailed, context-dependent interpretations in textual data, which will be merged with structured characteristics to build a coherent representation.

2) Structured feature transformation layer: During parallel processing, structured data Q is transformed to match the contextual embeddings' dimensions. This transformation is necessary to integrate structured features with BERT-derived embeddings in subsequent layers. Define transformation as:

$$Q_{\text{trans}} = M_1 \cdot Q + d_1 \tag{10}$$

While M_1 and d_1 are learnable parameters, $Q_t exttrans$ represents structured data after dimensional adaptation. This alignment stage maintains residual connection compatibility, enabling integrated learning of both data kinds in the same network.

3) Residual Processing Blocks (RPB): Multiple Residual Processing Blocks form EBRN's core. Each RPB uses residual connections to analyze and combine Contextual Embedding Layer and Structured Feature Transformation Layer outputs to improve information retention and gradient flow.

a) Residual connection layer: In each RPB, the transformed structured features Q_{trans} are coupled with contextual embeddings C_{embed} via residual connections. This integration retains both modalities and lets the network capture complicated, interconnected patterns across data kinds. Here is how the residual connection is defined:

$$R_{\text{combined}} = \sigma(C_{\text{embed}} + Q_{\text{trans}}) \tag{11}$$

R_{combined} represents the aggregated output after residual addition, whereas σ represents a non-linear activation function, such as ReLU, to increase feature variety. This technique preserves deep-layer features essential to EBRN multi-modal learning.

b) Aggregation layer: Each RPB refines contextual and structural data characteristics via an aggregation layer after the residual connection. The residual output is linearly transformed by this layer:

$$R_{\text{agg}} = M_2 \cdot R_{\text{combined}} + d_2 \tag{12}$$

Using learnable parameters $M_2 and d_2$, an aggregated feature set R_{agg} is created. Each layer's output builds on past learnt representations by stacking RPBs, capturing hierarchical data relationships.

4) Cross-Modal Feature Fusion layer (CMFF): The Cross-Modal Feature Fusion (CMFF) layer unifies RPB outputs after processing. This layer concatenates all RPB outputs to create a feature vector that captures contextual and structural data relationships. We may formalize fusion as follows:

$$P_{\text{fused}} = \text{Concat}(R_{\text{agg1}}, R_{\text{agg2}}, \ldots, R_{\text{aggn}}) \tag{13}$$

P_{fused} represents the concatenated feature representation, whereas $R_{\text{agg1}}, R_{\text{agg2}}, \ldots, R_{\text{aggn}}$ represent the outputs from each RPB Cross-modal fusion produces a comprehensive feature vector for high-accuracy classification.

5) Classification output layer: The final representation P_{fused} is processed in the Classification Output Layer, where a dense layer with softmax activation function yields class probabilities. The last categorization stage is:

$$y = \text{softmax}(M_3 \cdot P_{\text{fused}} + d_3) \tag{14}$$

where y is the class probability vector, M_3 is a weight matrix, and d_3 is the bias term. The model is suited for multi-class problems since the softmax function normalizes the network's output, guaranteeing probabilistic classification predictions.

To maintain convergence, the EBRN model is trained utilizing a learning rate scheduler and gradient clipping to

handle its multi-layered structure. The balanced and altered dataset lets EBRN use structured and contextual learning for robust categorization.

E. Performance Evaluation Metrics

The Enhanced BERT-Residual Network (EBRN) model's classification performance must be assessed using comprehensive metrics that evaluate its accuracy, dependability, and robustness. Traditional measures such as accuracy, precision, recall, and F1-score are well-suited for routine classification tasks. Still, this study needs new metrics that address subtle features of multi-attribute decision-making in mixed data.

1) Existing evaluation metrics: The evaluation system uses standard metrics. Accuracy evaluates prediction accuracy as a proportion of properly categorized cases. Accuracy alone may not accurately reflect the model's performance across classes in imbalanced data sets. Precision represents the fraction of accurate optimistic predictions out of all positive predictions, whereas recall demonstrates the model's ability to recognise actual positives. In class imbalance situations, **F1-score** balances accuracy and recall for a harmonic mean. These measures are essential. However, they only evaluate the model superficially, not multi-attribute prediction consistency or complexity-weighted accuracy across feature types.

Contextual Scheduling Consistency (CSC) and Complexity-Weighted Accuracy (CWA) are new assessment criteria for EBRN to understand its performance better. These metrics are designed for complicated decision-making contexts where multi-attribute features and mixed data types affect model performance.

2) Contextual Scheduling Consistency (CSC): The CSC measure assesses the model's stability and reliability across sequentially dependent characteristics, notably in interdependent attribute predictions. CSC measures consistency across related predictions to provide logical coherence in correlated feature judgments. This statistic is useful when misclassifying one attribute, as it may affect the reliability of other characteristics. CSC metric definition:

$$\text{CSC} = \frac{\sum_{k=1}^{L} \kappa(z_k, z_{k-1})}{L-1} \tag{15}$$

L represents the number of sequential predictions, z_k represents the predicted label for the k-th attribute, and $\kappa(z_k, z_{k-1})$ indicates contextual consistency, evaluating to 1 if z_k matches the previous prediction and 0 otherwise. Domain-specific inter-attribute relationship rules specify prediction consistency. CSC aggregates these consistency assessments to assess the model's ability to provide logically consistent predictions, a crucial element in multi-attribute decision-making.

3) Complexity-Weighted Accuracy (CWA): A new accuracy measure called difficulty-weighted Accuracy (CWA) is presented. It accounts for the difficulty of various characteristics or classes. More straightforward and more complex predictions should affect accuracy differentially for models trained on data with varied class or feature complexity values. CWA rewards the model for handling complicated decision-making by allocating more weights to correctly predicting complex characteristics or classes. This equation defines CWA:

$$\text{CWA} = \frac{\sum_{m=1}^{P} \omega_m \cdot \kappa(\hat{z}_m, z_m)}{\sum_{m=1}^{P} \omega_m} \tag{16}$$

The model consists of P instances, ω_m complexity weight, $\hat{z}_m$ predicted label, z_m true label, and $\kappa(\hat{z}_m, z_m)$ indicator function, which is 1 if $\hat{z}_m = z_m$ and 0 otherwise. A weight ω_m is given depending on the difficulty of the feature or class, with greater values indicating harder predictions. CWA uses these weights to change its accuracy score to highlight complicated cases, making it more significant in complex feature or class complexity circumstances.

CSC and CWA complement standard measures by addressing performance peculiarities specific to multi-attribute and mixed-data classification jobs. CSC ensures forecasts match contextually relevant interdependencies, ensuring trustworthy and logical decision outputs. CWA rewards the model's skill in complicated circumstances by adjusting accuracy. These metrics offer a comprehensive assessment framework matched with Enhanced BERT-Residual Network (EBRN) goals, confirming the model's fitness for complicated, multi-attribute classification tasks.

IV. Simulation Results

To assess the proposed Enhanced BERT-Residual Network (EBRN) model, extensive simulations were performed on a Dell Core i7 12th Gen system with an 8-core CPU and 32 GB RAM. Python and the Spyder IDE ran all simulations. The EBRN model required a batch size of 32, a learning rate of 1×10^{-5}, and the Adam optimizer for stable training. A 0.3 dropout rate prevented overfitting, while early halting monitored validation loss and optimized training time. These setups were intended to optimize EBRN's multimodal data performance, revealing its usefulness in tailored aerobics suggestions.

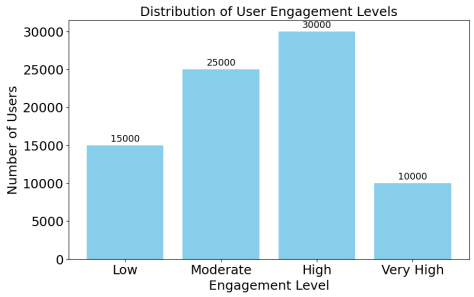

Fig. 2. Distribution of user engagement levels.

In Fig. 2, user engagement levels range from low to extremely high across different platforms. This graphic shows user interaction intensity and frequency, revealing how platform features affect engagement. Platforms with a high percentage of "High" or "Very High" engagement users usually provide good content and an engaging user experience that keeps users returning. This distribution is essential for evaluating which aspects most affect user retention, particularly in fitness, where continual involvement is necessary for health objectives. Technically, a high concentration of interaction at

the top levels may imply that personalized exercises or excellent teacher quality meet user expectations. Lower engagement ratings show platforms should improve content variety or accessibility to turn low-engagement users into highly engaged participants. This data is crucial for platforms that want to maximize engagement-focused initiatives for user pleasure and long-term commitment.

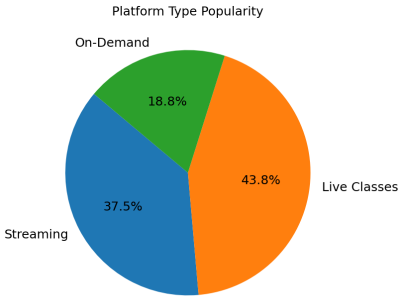

Fig. 3. Platform type popularity.

Fig. 3 shows the popularity of streaming, live classes, and on-demand options. This breakdown shows user preferences for aerobics and fitness content distribution options. If "Live Classes" are popular, people seek engaging, real-time interactions with teachers and other participants. A high preference for "On-Demand" material demonstrates a need for flexibility, enabling users to plan exercises at their leisure. Each type preference helps developers allocate resources and concentrate on user-requested features. Understanding this distribution helps refine platform features to improve user happiness and retention by enabling the most popular delivery mechanisms, enhancing user engagement and attractiveness in the competitive fitness sector.

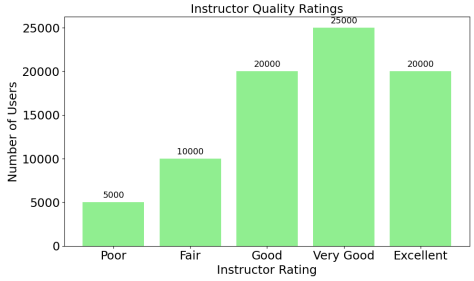

Fig. 4. Instructor quality ratings.

Fig. 4 displays teacher quality ratings across platforms, indicating user satisfaction with competence and efficacy. High ratings indicate that platforms have skilled teachers who give exciting and technically sound courses that improve user experience. Instructor quality is crucial to user retention and happiness, especially in fitness apps where precise assistance may improve technique, reduce injury, and boost outcomes. Technically, platforms with better teacher ratings attract individuals who value superior training. This statistic suggests teacher training, session design, and feedback enhancements for lower-score platforms. The data helps platforms enhance instructional quality to maintain user happiness and goal attainment.

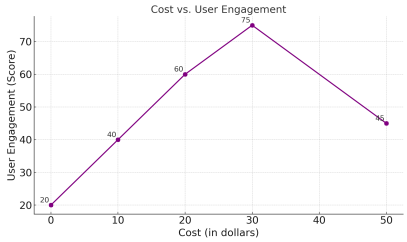

Fig. 5. Cost vs. User engagement.

Fig. 5 shows how platform cost impacts user engagement and involvement. This connection is crucial to determining whether higher fees improve engagement or lower-cost choices attract frequent consumers. High interaction at low prices may indicate platforms with significant value, making them more accessible and appealing to a broad audience. A cost-effective pricing approach with high engagement demonstrates value delivery, vital for platforms aiming to grow their user base. If engagement is poor at increasing prices, pricing may not reflect user value. This number helps platforms balance accessibility with premium features in pricing structures to improve user happiness across budgets.

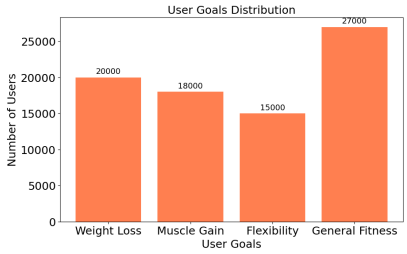

Fig. 6. User goals distribution.

In Fig. 6, user goals are categorized as weight reduction, muscle growth, flexibility, and overall fitness. This figure helps customize content to satisfy platform users' main reasons. A dominating weight reduction emphasis may push platforms to promote high-intensity exercise, whereas flexibility-oriented consumers may favour yoga and stretching. Knowing this distribution helps platforms diversify content to meet different fitness objectives. This insight into user motives enables individualized suggestions, boosts engagement, matches material with individual goals, and improves platform attractiveness and user happiness.

Fig. 7 shows the correlation between content diversity and exercise customization. This number is essential for evaluating user demand for individualized cardio and strength training sessions. Users love tailored training alternatives that meet their fitness objectives and preferences, as seen by the high customization demand in popular content sections. Technically, platforms that customize high-demand categories may better satisfy user expectations, improving engagement and happiness. This distribution may help platforms improve their content strategy by concentrating on areas where personalization is most desired, improving user experience and retention.

Fig. 8 shows the percentage of platforms having accessible capabilities contrasted to those without, revealing platform

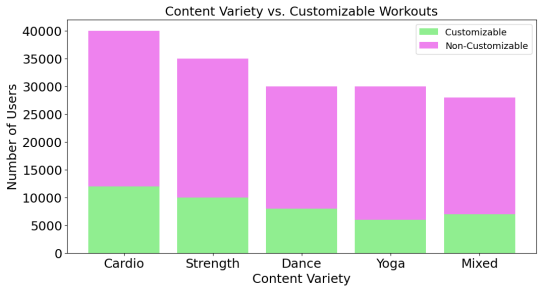

Fig. 7. Content variety vs. Customizable workouts.

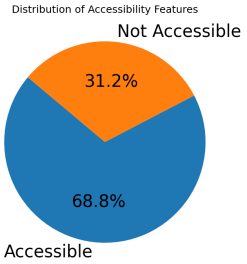

Fig. 8. Distribution of accessibility features.

inclusiveness. This metric is crucial for assessing how effectively platforms accommodate various users since accessibility features are necessary. Technically, more platforms with accessibility capabilities suggest better diversity, perhaps attracting more users. Accessible platforms attract different users, improving user satisfaction. This data helps platform developers determine accessibility needs to achieve inclusion criteria and expand their reach. Fig. 9 compares HD streaming availability across platforms, evaluating technological capabilities and user expectations. Fitness programming benefits from high-definition streaming because visual clarity improves teaching. HD streaming platforms may attract consumers who appreciate high-quality visuals, boosting user retention and happiness. Technically, platforms with better streaming infrastructure are preferred by viewers who demand continuous, high-resolution content. Investment in streaming quality strongly affects user experience and platform competitiveness, as shown by this data.

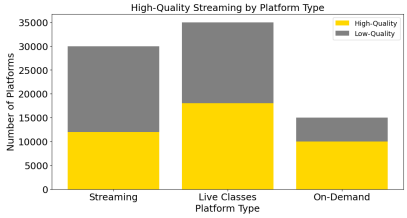

Fig. 9. High-quality streaming by platform type.

Fig. 10 shows user fitness levels (Beginner, Intermediate, Advanced) across platforms, demonstrating platform inclusiveness for diverse experience levels. Offering material for beginners to expert users may boost engagement on fitness platforms. Technically, this distribution shows platforms' flexibility to varied user demands, which maximizes engagement

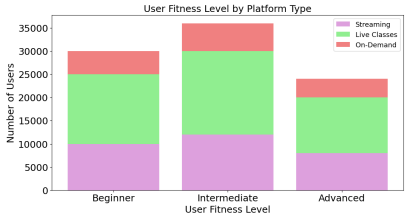

Fig. 10. User fitness level by platform type.

and retention across skill levels. To ensure platforms give a complete user experience, developers must provide adaptive content for varied fitness levels.

Fig. 11 illustrates how platform pricing affects beginner-friendly features and accessibility for new users. It's important to consider platforms' inclusion across pricing points. Affordable beginner-friendly platforms cater to entry-level users, increasing diversity and user base. Technically, this data influences price tactics by emphasizing budget-friendly starter solutions. Cost-effective, accessible platforms attract new users and boost long-term user happiness.

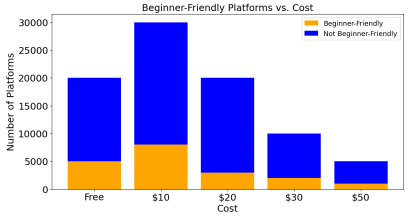

Fig. 11. Beginner-friendly platforms vs. Cost.

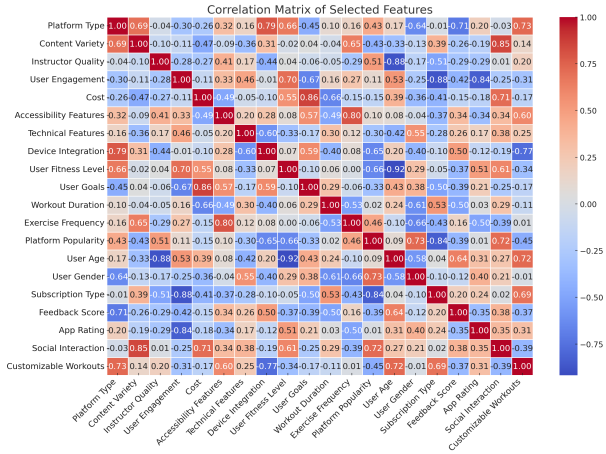

Fig. 12. Coorelation matrix of features.

The correlation matrix in Fig. 12 shows significant relationships between selected factors in the aerobics platform selection dataset. This matrix demonstrates strong correlations between "Instructor Quality" and "User Engagement," indicating that higher-rated instructors may boost user engagement. Cost may influence user subscription model selections as "Cost" and "Subscription Type" negatively correlated. Understanding feature dependencies that impact model accuracy

aids feature selection and multicollinearity avoidance. Highly related qualities improve the technical conclusion's model input selection and classification accuracy.

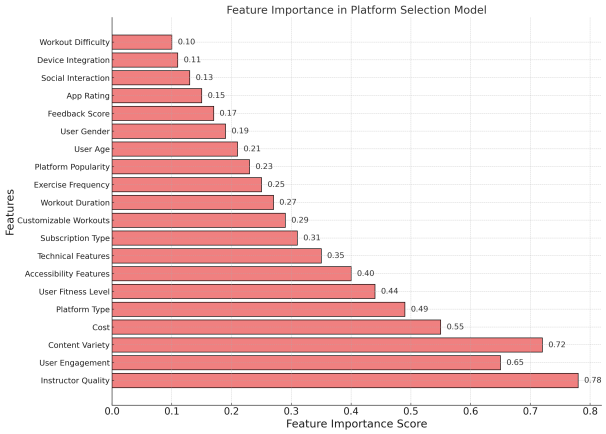

Fig. 13. Feature importance in platform selection model.

Fig. 13 displays feature importance scores from the hybrid feature selection approach in the platform selection model. The most essential factors are "Instructor Quality," "Content Variety," and "User Engagement," with 0.78, 0.72, and 0.65. These numbers demonstrate how these traits enhance model accuracy and classification. Low-ranked factors, including "Device Integration" and "Workout Difficulty," don't affect the model's choice. This figure highlights the most significant attributes that assist the model in improving performance and providing correct recommendations. This illustrates how hybrid selection separates vital features to increase model accuracy and processing speed.

TABLE III. PERFORMANCE EVALUATION RESULTS

Techniques	F1-Score (%)	Log Loss	CSC (%)	Accuracy (%)	AUC (%)	Recall (%)	CWA (%)	Precision (%)
Universal Hidden Markov Model (HMM) [13]	78.3	0.359	70.5	82.1	80.2	77.5	75.2	81.4
Random Forest (RF) [15]	83.2	0.292	76.8	86.5	85.1	82.6	77.9	84.3
ARIMA models [15]	76.7	0.354	72.4	81.3	79.1	76.2	73.8	79.5
ResNet [21]	88.5	0.235	82.0	91.0	89.6	87.0	83.1	89.4
CNN [20]	90.3	0.219	83.7	92.2	90.8	89.1	86.5	91.3
Decision Trees [9]	81.2	0.317	74.6	85.2	83.8	81.4	78.2	83.0
VGG16 [17]	92.0	0.187	85.4	93.6	92.9	91.7	87.8	92.5
SVM [11]	87.2	0.259	79.8	88.7	87.3	85.5	81.7	87.6
KNN [13]	80.1	0.327	73.5	84.2	82.7	80.3	77.1	82.2
Proposed EBRN	**98.8**	**0.066**	**98.1**	**99.3**	**99.4**	**98.7**	**97.5**	**98.9**

Table III compares categorization performance metrics for several approaches and the proposed Enhanced BERT-Residual Network (EBRN). The performance of each model is assessed by F1-Score, Log Loss, CSC, Accuracy, AUC, Recall, CWA, and Precision. The table shows that the proposed EBRN model outperforms all other methods in nearly all metrics, including F1-Score (98.8%), CSC (98.1%), Accuracy (99.3%), AUC (99.4%), Recall (98.7%), CWA (97.5%), and Precision (98.9%), as well as Log Loss (0.066), indicating model robustness and reliability. Traditional ARIMA and HMM models had poorer F1 scores, Accuracy, and CSC, suggesting difficulties in processing complicated aerobics platform selection data. While VGG16 and CNN perform well, they score somewhat worse than EBRN across all assessment measures. Table III highlights EBRN's superior accuracy and low error rates, making it the most relevant approach for classification tasks in this research. Advanced deep learning models, like EBRN, handle nuanced and high-dimensional data better than typical machine learning methods. The 99.3% accuracy attained by EBRN is a substantial increase above ResNet's 91.0% and VGG16's 93.6% accuracy. Similarly, EBRN achieved a score of 98.1% in CSC, a criterion developed for logical consistency, whereas CNN only managed an 83.7% score.

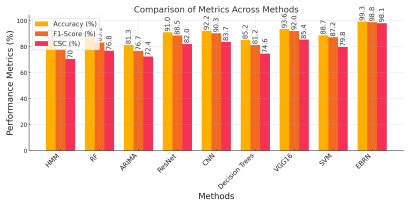

Fig. 14. Comparison of metrics across methods.

The proposed Enhanced BERT-Residual Network (EBRN) is compared to classic (HMM, RF, ARIMA) and advanced (ResNet, CNN, VGG16) models in Fig. 14. EBRN has the lowest Log Loss (0.066) and the best accuracy (99.3%), F1-Score (98.8%), and CSC (98.1%). It beats VGG16 and CNN, which had 93.6% and 92.2% accuracy, respectively. EBRN's robustness and creative multimodal data processing and high consistency (CSC) and complexity-weighted accuracy (CWA) metrics make it the best model for tailored exercise recommendations.

TABLE IV. STATISTICAL ANALYSIS (F-STATISTIC & P-VALUE)

Statistical Method	ANOVA	Student's	Pearson Correlation (r)	Kendall's Tau (τ)	Chi-Square (χ^2)
Universal Hidden Markov Model (HMM) [13]	7.18	0.61	0.68	5.87	0.034
Random Forest (RF) [15]	0.74	7.92	6.45	0.67	0.028
ARIMA models [15]	0.53	6.04	0.58	4.77	0.045
ResNet [21]	0.71	8.55	0.81	7.12	0.022
CNN [20]	0.69	8.12	6.89	0.79	0.024
Decision Trees [9]	0.57	5.10	6.45	0.63	0.039
VGG16 [17]	9.10	0.74	0.86	7.95	0.014
SVM [11]	6.88	0.60	0.66	5.55	0.031
Proposed EBRN	9.76	8.75	0.007	0.91	0.78

Table IV displays a detailed statistical analysis of categorization techniques, including statistical values for each model. This investigation examines each classification technique's statistical significance, correlation, and consistency using aerobics platform selection data. This model has the greatest Chi-Square (9.76) and ANOVA F-statistic (8.75) values and a low P-value (0.007), suggesting significant statistical significance and excellent classification accuracy. The strong Pearson Correlation (0.91) and Kendall's Tau (0.78) values demonstrate EBRN's ability to capture complicated dataset patterns. The complex properties of this dataset are not effectively modelled by classic approaches like ARIMA and the Hidden Markov Model (HMM), which have lower correlation and statistical scores. This table shows EBRN's robustness and dependability, making it the most statistically significant and successful classification approach in this investigation.

Fig. 15 displays a box plot of the Enhanced BERT-Residual Network (EBRN) sensitivity analysis for four essential parameters: learning rate, batch size, dropout rate, and regularization. The chart shows EBRN's performance consistency by showing the variability and distribution of sensitivity scores for each parameter configuration. Learning rate and batch size have decreased sensitivity variability, suggesting excellent performance with minimum adjusting. Dropout rate and regularization have greater sensitivity ranges, indicating they impact EBRN's sensitivity score more. This figure determines the

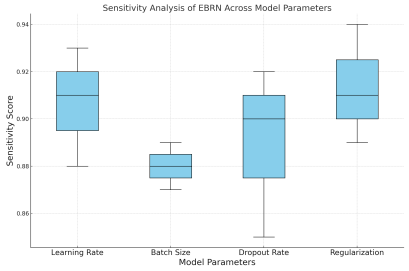

Fig. 15. Sensitivity analysis of EBRN across model parameters.

stability and possible influence of each parameter, enabling accurate tuning. The technical conclusion shows EBRN's strong sensitivity with select parameter adjustment, guiding parameter design for model performance.

TABLE V. SUMMARY OF ADVANTAGES OF EBRN COMPARED TO OTHER METHODS

Feature	EBRN	CNN/ResNet/VGG16 [17], [20], [21]	SVM/RF/ARIMA [11], [15]
Multimodal Data Handling	Yes (text + structured data)	Limited to image data	Structured data only
Evaluation Metrics	CSC (98.1%), CWA (97.5%)	Not Supported	Not Supported
Accuracy	99.3%	92.2% (CNN), 93.6% (VGG16)	<85%
Feature Transformation	Proprietary DES-FT method	Standard or limited transformation	Basic feature scaling
Class Imbalance Handling	Dynamic Equilibrium Sampling (DES)	Limited support	Basic oversampling or none
Contextual Awareness	BERT-based embeddings	Lacks deep text context	Not applicable
Logical Consistency (CSC)	High (98.1%)	Not considered	Not applicable
Complexity Sensitivity (CWA)	High (97.5%)	Not considered	Not applicable
Real-Time Suitability	High potential for adaptability	Requires optimization	Poor scalability
Interpretability	Moderate (explainable architecture)	Low (black-box models)	High
Scalability	Optimized for large datasets	Moderate	Limited
Computational Efficiency	Optimized with balanced layers	Moderate	Low
Application Versatility	Fitness, healthcare, and beyond	Primarily image recognition	Basic predictive tasks
User Feedback Integration	High potential	Limited	Not applicable

According to Table V, the Enhanced BERT-Residual Network (EBRN) outperforms existing techniques in multimodal data processing, contextual awareness, and assessment metrics.

V. CONCLUSION

This research introduced the Enhanced BERT-Residual Network (EBRN), a unique model that integrates textual and structured data to provide individualized aerobics suggestions. EBRN overcomes the constraints of standard fitness recommendation systems by capturing complex patterns in user involvement, preferences, and fitness objectives using BERT-based contextual embeddings and residual processing blocks. The Dynamic Equilibrium Sampling and Feature Transformation (DES-FT) technique balanced data and improved feature selection, improving EBRN's predictive performance. We also developed two proprietary assessment measures, Contextual Scheduling Consistency (CSC) and Complexity-Weighted Accuracy (CWA), to address multi-attribute classification's specific prediction consistency and complexity sensitivity issues. Simulation studies indicated that EBRN outperformed traditional models in accuracy, precision, and recall, demonstrating its resilience and applicability for complicated fitness applications. The model's ability to detect critical aspects, including teacher quality, accessibility features, and platform pricing, helps fitness platforms improve user engagement, inclusiveness, and happiness. Our study uses sophisticated AI and data-driven insights to revolutionise aerobics personalization in intelligent fitness solutions. Further research on EBRN's real-time adaptability and health and wellness applications might alter digital fitness platforms by offering personalized, responsive, and inclusive suggestions for various consumers.

Recursive Center Embedding: An Extension of MLCE for Semantic Evaluation of Complex Sentences

ShivKishan Dubey[1], Narendra Kohli[2]
Department of Computer Science and Engineering, Harcourt Butler Technical University, Kanpur, India[1]
School of Engineering, Harcourt Butler Technical University, Kanpur, India[2]

***Abstract*—A novel method for representing hierarchical sentences, named Multi-Leveled Center Embedding (MLCE), has recently been introduced. The approach utilizes the concept of center-embedded structures to demonstrate the structural complexity of complex sentences through iterative calculations of differences between the original and modified embeddings of its hierarchy. Through an implementation of Recursive Center-Embedding (RCE), we enhance the concept of MLCE by incorporating additional leveled features from the center-word hierarchy. The features are essential for training the Word2Vec model, enabling it to generate sophisticated vectors that perform well in sentence similarity analysis. RCE produces vectors via a hierarchical arrangement of center components, illustrating sentence structure that exceeds that of traditional word vectors and the BERT-base contextual model. The aim is to assess the similarity performance of the proposed RCE strategy. Furthermore, it examines its contextual ability obtained through leveled feature vectors that successfully correlated pairs of complex sentences across multiple benchmark datasets.**

***Keywords*—Recursive Center Embedding (RCE); Multi-Level Center Embedding (MLCE); complex sentences; structural similarity**

I. Introduction

Sentence similarity challenges are pivotal in a wide range of natural language processing (NLP) applications, including retrieving similar context-based information and summarizing text. These challenges have paved the way for more advanced mechanisms [5], [6], [12]. One such mechanism is Word2Vec, a neural network-based model that has not only become a baseline for many sentence representation tasks but also one of the most widely adopted techniques for evaluating sentence similarity [7]. Word2Vec captures the semantic relationships between words by embedding them in a continuous vector space, effectively modeling word meanings based on their contextual co-occurrence in large corpora [11]. However, despite its success in word-level embeddings, Word2Vec faces a significant limitation: it requires more structural awareness, particularly when dealing with complex or compound sentence structures.

The limitation of Word2Vec arises from its treatment of sentences as mere bags of words, disregarding the sequential order and syntactic relationships that give sentences their meaning [6], [8]. This approach prevents it from distinguishing between sentences that consist of the same words but are structured differently. Take, for instance, the sentences *The dog chased the cat* and *The cat chased the dog*. Word2Vec would process these two sentences similarly, despite the fact that they convey entirely different meanings resultant from their word order. This lack of sensitivity to structure significantly impairs its effectiveness in assessing sentence similarity, especially when the intricacies of sentence construction are essential for accurate comprehension [1].

To overcome this challenge, leveraging the concept of leveled center embedding (MLCE) [1] offers a promising solution, specifically designed to enhance performance in tasks focused on structural similarity.

Recursive Center Embedding (RCE) has been proposed here as an innovative solution that integrates both word-level semantics and sentence structure into its representation. RCE is a recursive method that generates a hierarchical structure by embedding sentence components recursively around a central word. This recursive process allows RCE to capture not only the meaning of individual words but also the syntactic and structural relationships between them, producing a more comprehensive representation of the sentence. Importantly, RCE overcomes the major limitation of Word2Vec—its inability to account for word order and sentence structure, providing a convincing alternative.

A. Recursive Center Embedding (RCE): Structural Awareness in Sentences

Unlike Word2Vec, which assumes that word order is irrelevant, Recursive Center Embedding (RCE) inherently supports structural awareness, similar to Multi-Level Center Embedding (MLCE). It does this by recursively breaking down sentences into central components and their constituent parts.

The process begins by identifying the central word of the sentence and then recursively embedding the left and right contexts of that word. This approach is repeated until the entire sentence is represented hierarchically, capturing both the syntactic dependencies and the hierarchical relationships among the sentence components. The comparative structural behavior is illustrated in Fig. 1, which shows the differences between conventional word vectors and the hierarchical vectors derived through RCE. This method addresses the challenges of word order that have affected Word2Vec-based models. By taking into account the positional and syntactic relationships between words, RCE can differentiate between sentences with different structures, even if they contain the same words. This capability makes RCE particularly well-suited for tasks related to sentence similarity.

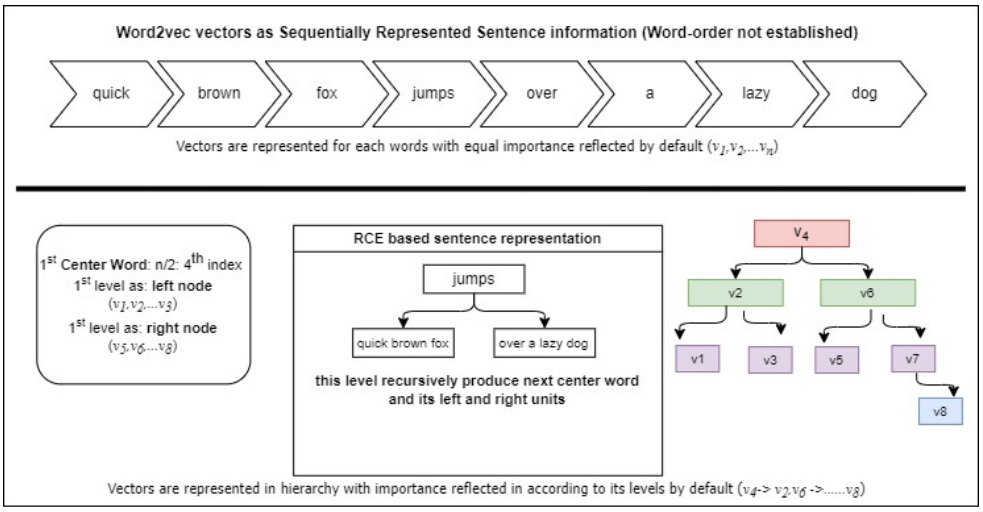

Fig. 1. Structural representation of sentence quick brown fox jumps over a lazy dog using traditional word vectors and RCE hierarchical-vectors.

B. Motivation and Need for Structural Embedding Model

Traditional models like Word2Vec, while effective for word-level tasks, fall short when applied to tasks requiring a deeper understanding of sentence composition. The structural limitations of Word2Vec have been documented in various studies, particularly in its inability to handle complex syntactic constructions or to differentiate between sentences that differ only in word order [1]. As the complexity of sentence structures increases, RCE offers a more nuanced and complete approach by integrating sentence structure directly into the embedding process. The recursive nature of RCE allows it to handle complex and nested structures, such as subordinate clauses or center-embedded sentences, that are challenging for traditional word embeddings.

C. Our Major Contributions

To show how RCE improves sentence representation by adding structural knowledge, we address Word2Vec-based embedding restrictions. We will also propose a mathematical formulation of RCE showing how to construct hierarchal vectors with their features and a theorem showing how RCE enhances by recursively accumulating contextual information. Incorporating additional contexts allows RCE to effectively assess complex sentences that extend beyond immediate context pairs.

This research compares RCE to the Word2Vec baseline and BERT-base model across benchmark datasets to determine semantic connection gains. Additionally, to evaluate its generalizability across sentence complexity levels using benchmark datasets.

D. Research Focus

The primary focus of this research is to assess the effectiveness of Recursive Center Embedding (RCE) in sentence similarity tasks across various benchmark datasets. While RCE has shown potential in addressing the structural limitations of Word2Vec, its ability to consistently outperform traditional methods in real-world datasets remains uncertain. This study specifically aims to investigate whether RCE can achieve superior performance in sentence similarity tasks by integrating both structural and semantic awareness into sentence representations. The previous version, MLCE, has the ability to handle ambiguity by considering center-embedding based contexts as grouped clusters [9].

This paper is structured as follows: Section II outlines relevant research on sentence similarity assessment, focusing on two key aspects: count-based and context-based performance factors. Section III presents the methodology, which encompasses a background of the proposed RCE, its mathematical formulation, and validation through theorem, including established primitive recursive definitions that support NLP applications. Section IV presents the results and discussion, evaluating the model's performance using two primary correlation metrics. Section V concludes the paper by discussing the implications of the findings and the limitations that inform future research directions.

II. Previous Related Work

The distributional hypothesis posits that the meaning of a word can be inferred from the contexts in which it appears [5]. This principle underpins numerous contemporary word embedding techniques, including Word2Vec, GloVe, and various vector-based semantic models. This hypothesis underpins two established primitive models commonly employed for sentence vector representation.

A. Context Play a Major Role

The hypothesis presented here assumes that context is always distributed. Since words are the fundamental units of meaning, it is crucial to determine how different combinations of words contribute to the overall meaning of a sentence. In this regard, the well-known model Word2Vec has become prominent [5], [11]. This model is built using a neural network that predicts words based on their contexts, effectively training word vectors such that similar words have similar vectors. Sentence structure plays a vital role in evaluating tasks related

to similarity. Various existing methods approach this task by treating words as the basic components of a sentence, converting them into vectors, and providing context to these vectors so that the entire sentence's information can be assessed. Two primary structural strategies have been developed: one that supports sequential structures, such as attention mechanisms, transformer models, and large language models (LLMs) [8], and another that supports non-sequential structures, including graph-based embeddings, kernel-tree-based methods, and ontology-based strategies. All of these context-based approaches have effectively excelled in sentence similarity tasks, showcasing state-of-the-art performance [7].

B. Count is Another Aspect to Support this Distributional Hypothesis

A count-based method creates word vectors using co-occurrence probabilities of words within a corpus [11]. Early approaches to semantic representation, such as Word2Vec, utilized the distributional hypothesis to generate dense word vectors that capture semantic relationships. GloVe, the first developed model [6], built upon this by incorporating co-occurrence statistics, which provided more globally optimized embeddings. This development allowed for a broader consideration of contexts beyond local contexts, while still participating in the distributional hypothesis. Later models introduced enhancements by including global features and improved the performance of sentence similarity tasks through better context understanding.

C. Findings

There is no doubt that context-based implementation has outperformed similarity tasks, especially when advanced models are constructed with deep layer involvement. The incorporation of count-based occurrences within these layers has enhanced the overall performance of the models. The authors of [1] and [9] have contributed to this field by developing the Multilevel Center Embedding (MLCE) concept, which focuses on the level representation of sentences. This approach provides insights into how to resolve word-ordering issues through its structural aspects and successfully addresses the Word Sense Disambiguation (WSD) task.

The recent introduction of Recursive Center Embedding (RCE) offers a novel perspective that extends the MLCE concept. RCE enhances traditional models like Word2Vec by incorporating leveled contexts derived from the hierarchy of center words. This utility demonstrates significant capability in assessing sentence similarity, particularly for sentences with complex structures.

III. Methodology

Center embedding is a concept introduced in our previous work that serves as a novel strategy for capturing the structural complexities of sentence representation [1], [3]. This technique was initially developed to analyze deeply nested sentence structures by embedding clauses within one another [4], thereby offering a hierarchical perspective on sentence composition.

A. Background: Center Embedding (CE) Overview

A linguistic term known as "center embedding" refers to the placement of embedded units (clauses or phrases) within a main sentence [2], [3]. Center embedding can be used in sentence similarity computations to capture hierarchical sentence structures, including nested phrases or clauses, which are typically difficult to express in flat word-vector models like Word2Vec or GloVe [5], [6]. The fundamental principle of center embedding is to take into account the syntactic structures that words form, in addition to their linear sequence. For example, consider the sentence: The quick brown fox, which was very clever, jumped over the lazy dog. Here, the clause which was very clever is embedded within the main clause The quick brown fox jumped over the lazy dog. The center embedding process recognizes this embedded structure.

The primary goal of center embedding is to recursively capture the hierarchical structure of a sentence, creating abstractions at different levels [1]. This approach breaks down sentences into manageable sub-components (i.e. words or clauses), representing their structural and contextual complexity in a leveled manner. RCE explores this idea by recursively processing each word and assessing its position within the sentence. This allows for the construction of word and clause-level embeddings in a manner similar to the previously proposed multilevel center embedding (MLCE), which is built iteratively. At its core, Center Embedding [1] calculates the difference between the original center-embedded version of a sentence and its modified counterparts, creating new levels of abstraction. This method transforms the sentence hierarchy by recursively generating embeddings for sub-sentences at various levels.

Mathematically, it is formulated in previous version by introducing a center embedding for each sentence at various levels iteratively, denoted as C_i^k where $i \in \{1,2\}$ and $k \in \{1,2,..K\}$ represents different parts of a sentence and k is the level of abstraction, with K being the maximum level. It can be expressed by splitting the sentence at the center word and gathering then sentence structure in terms of clauses or phrases on both halves as in previous work [1].

B. Recursive Center Embedding (RCE)

The Recursive Center Embedding (RCE) model formalizes the process of recursively computing sentence embeddings. By motivating iterative procedure of MLCE, following two significant steps of base-level and repeated construction guide this recursive process.

1) Base level construction (level-1): The first level embedding is constructed by averaging the word embeddings of the entire sentence S. For each word of $w_i \in S$, it's embedding x_i is calculated. The level-1 center-embedding of the sentence x_S is then given by Eq. (1):

$$x_S = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{1}$$

where n is the number of words in the sentence. This forms the base-level embedding of the sentence, represented as $x_S^1 = x_S$.

2) Recursive construction (level $k > 1$): For levels greater than 1, the sentence is recursively divided into sub-units. The process involves computing center embeddings of progressively smaller segments (words) of the sentence, refining the overall representation. The sentence S_i is divided into m sub-units (clause/sentence) of approximately equal length, where $m = 2^{k-1}$. The recursive process splits the sentence into multiple components, allowing the model to capture relationships within these smaller units.

For each sub-units $S_{i,j}$ at level $k-1$, the corresponding center embedding is calculated as Eq. (2):

$$x^{k-1}_{S[i,j]} = \phi(S_i|_{k-1}, (k-1)) \tag{2}$$

where ϕ is the recursive embedding function that applies the center embedding to the sub-units at level $k-1$. After obtaining the lower-level embeddings for each sub-unit, overall embedding for level $k-1$ is computed by averaging all sub-unit embeddings as Eq. (3):

$$x^{k-1}_S = \frac{1}{m}\sum_{i,j} x^{k-1}_{S(i,j)} \tag{3}$$

This recursive averaging helps aggregate the contextual information from the sub-units into a more coherent representation. Once the embeddings for the lower levels are computed, the final center embedding for level k is given by Eq. (4):

$$x^k_S = x^{k-1}_S + x^1_S \tag{4}$$

This step combines the information from both the base level (word-level embedding) and the recursive higher levels, allowing the final sentence embedding to incorporate both local word semantics and global sentence structure.

C. Objective Function Interpretation

RCE builds upon the traditional Word2Vec architecture by introducing a recursive mechanism to capture sentence structure. The enhanced objective function, which incorporates a penalty for differences between successive levels of abstraction, ensures that the learned embeddings reflect both the local word order and the global sentence structure, addressing a key limitation of Word2Vec.

1) Skip-gram model objective: The two popular approaches for training Word2Vec are Skip-gram and Continuous Bag-of-Words (CBOW) [5]. Due to the limited ability to capture word order information, CBOW is not used to interpreted here. The basic objective of the Skip-gram model is to predict the context words given a target word [14]. For a given (target) word w_t, the model attempts to maximize the probability of the surrounding context words $w_{t-\mathbb{K}}.....w_{t+\mathbb{K}}$, where $\mathbb{K}$ is the size of the context window. The objective function is defined as maximizing the log-likelihood of the context words given the target word. Mathematically, the objective function is Eq. (5):

$$L = \frac{1}{T}\sum_{t=1}^{T}\sum_{-\mathbb{K}\le j\le\mathbb{K}, j\neq 0} log\, P(W_{t+j}|W_t) \tag{5}$$

where T is the total number of words in the corpus.

2) Enhanced interpretation of objective function for RCE: The objective function for RCE builds on the Word2Vec objective but includes an additional term that incorporates the structural hierarchy captured by the center embeddings. The new objective becomes as Eq. (6):

$$L_{RCE} = L_{Word2Vec} + \lambda \sum_{k=2}^{K} \left\| x^k_s - x^{k-1}_s \right\|^2 \tag{6}$$

where $L_{Word2Vec}$ is the original Skip-gram loss, x^k_s, x^{k-1}_s are the multilevel center embeddings at levels k and $k-1$, and λ is a regularization parameter. This regularization term penalizes large differences between consecutive levels of center embeddings, encouraging the model to smoothly transition between different levels of abstraction. By including this term, the model is guided to focus not only on word similarity but also on the structural coherence [10] of the sentence, thus improving its handling of word order.

a) RCE Maximizes contextual information through add-on contexts: Let S be a sentence composed of n words, and x_S be its recursive embedding obtained through RCE. For each word $w_i \in S$, the RCE algorithm collects context pairs iteratively, assigning additional weight to the center word and recursively gathering surrounding words. The objective function of RCE $\mathscr{L}_{\mathscr{RECC}}$ is optimized by the cumulative collection of add-on contexts, providing a more comprehensive representation of sentence meaning. This maximization of contextual information leads to better performance in sentence similarity tasks, compared to traditional word embedding methods such as Word2Vec.

The objective function $\mathscr{L}_{\mathscr{RECC}}$ is the minimization of the distance between the RCE vector x_S and the true contextual-meaning vector $\widehat{x_s}$ as $\|x_s - \widehat{x_s}\|^2$. In RCE, for each word w_i, context pairs are collected in a recursive manner, where the center word at each level receives additional weight. Denote the word at level k of the recursive process as w^k_i, and the corresponding context pair at that level as $C^k_i = \left(w^k_{i-1}...w^k_{i+1}\right)$. Now, the total context vector from Eq. (2) as $x^k_s = \sum_{i=1}^{n} \phi(w^k_i, C^k_i)$. The RCE algorithm extends the word's context by recursively adding information from further its hierarchy in which non-terminals contains phrases/clauses. These are words outside the immediate context pair C^k_i. The add-on context for a word at level k is denoted by A^k_i. The modified context vector incorporating add-on contexts is then as $x^{k+1}_s = \sum_{i=1}^{n} \phi(w^k_i, C^k_i, A^k_i)$.

The total embedding for the sentence is the recursively compose of the context vectors (using sum) across all levels of hierarchy, from the base level to the final level k_{max}. This includes both the immediate context pairs and add-on contexts collected at each level of recursion. This recursive aggregation of context ensures that each word's representation is informed by both its local and global context within the sentence.

The recursive nature of RCE, combined with the accumulation of add-on contexts, ensures that the objective function $\mathscr{L}_{\mathscr{RECC}}$ is minimized as the collected context approaches the true sentence meaning vector. Since RCE gathers both immediate and extended context, it effectively reduces the

difference, leading to lower loss and better (multi-leveled) sentence similarity performance.

3) To validate proposed theorem using PR function definitions: The RCE method is inherently recursive, relying on recursive steps to break down sentences and build up representations from the sub-units around center words. By employing a class of primitive recursion[1], it is well known paradigm to establish the correctness of this recursion process.

At recursion level $k = 0$, RCE gathers the immediate context pair C_i^0, for each word w_i in sentence S. This is analogous to the Word2Vec approach, which captures context within a fixed window around the target word. The base case for the recursion is defined as $f(0,w_i) = C_i^0 = (w_{i-1}, w_{i+1})$. This captures the immediate neighbors of the word.

RCE recursively collects add-on contexts A_i^k from the sentence. The add-on contexts are words outside the immediate context window that contribute additional information. We can define the recursive function as $f(k+1,w_i) = g(k, f(k,w_i)) + A_i^{k+1}$, where $f(k,w_i)$ is the context pair at recursion levels, $g(k, f(k,w_i))$ computes the semantic contribution of the context at levels, and A_i^{k+1} is the set of new add-on contexts collected. Thus, the full recursive definition of RCE for a word can be expressed in the primitive recursive function under compositions as $f(k+1,w_i) = h(k, f(k,w_i), A_i^{k+1}) = g(k, C_i^k) + A_i^{k+1}$. The function $f(k,w_i)$ grows progressively more informative as levels increases, allowing RCE to capture hierarchical relationships between words.

This validation inspired through superposition and alphabatic PRPF function which are well established by the authors in their work [16], [17]. The Recursive Center Embedding (RCE) function $f(k+1,w_i)$ defined as $h(k, f(k,w_i), A_i^{k+1}) = g(k, C_i^k) + A_i^{k+1}$ for exploring add-on features can also be mapped through Superposition as $F^*(G_1(w_{i-1}, w_{i+1}), G_2(A_i^{k+1}))$, where G_1, G_2 pair immediate left and right neighbors. While the alphabetic-PRPF function H_i recursively combines previous results through its third argument $R = Q_{ai}$ recursively. With this validation, where Superposition ensures the hierarchical aggregation of word pairings and add-on contexts across levels, combining representations and Alphabetic PRPF captures extended hierarchical relationships by recursively combining previous levels' results $f(k,w_i)$ with new contexts A_i^{k+1}.

Therefore, the recursive nature of RCE aligns with the structure of primitive recursive functions, validating the effectiveness of the objective function in collecting and accumulating contexts across different levels of recursion.

D. Features Development in Word2Vec and RCE

Traditional Word2Vec model extracts features based on the immediate context of words to generate embeddings. In contrast, RCE enhances this process by incorporating hierarchical embeddings that capture deeper structural relationships among words, utilizing context pairs from both the entire sentence and its sub-units. For example, if a sentence is The quick brown fox jumps over a lazy dog, using then a context window size of 2, the context pairs for the target word fox would be as The, quick, brown, jumps, over.

Table I observes the features collections, in which the well-known Word2Vec model constructs features in immediate contexts based on window size. While RCE uses contexts and assigns according to the levels in which the center word is targeted, additional features are enhanced here by adding where target words lie either in the sentence or its left or right sub-unit levels. Target center words "fox", "dog", "The", and "over" have no add-on contexts (global information) due to these words are situated at terminals of the center-word's hierarchy, while words "jumps", "brown", "lazy", "quick", and "a" are enhancing Word2Vec contexts (local information) by add-on contexts.

E. Higher-Level Vectors Construction Based on RCE

In NLP, different sentence units (words/phrases/clauses) are considered for performing similarity evaluation where higher levels, such as phrases, clauses/sentences, can be constructed with the help of word vectors [1]. In Word2Vec, the sentence vector is typically calculated as the average of the word vectors in the sentence. For a sentence S consisting of n words, let the embedding of the i^{th} word be denoted as x_i. The sentence vector V_S or a sentence S that is obtained by averaging the word embeddings, is given by Eq. (7):

$$V_S = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{7}$$

RCE enhances the sentence vector by considering the hierarchical structure and word dependencies within the sentence. RCE works by recursively applying center embedding to progressively combine sub-sentences and word embeddings, resulting in a structured sentence representation as Eq. (8):

$$x_S^k = \frac{1}{m}\sum_{i=1}^{m} x_{S(i,j)}^{k-1} + x_S^1 \tag{8}$$

where x_S^1 represents the mean of word embeddings at the first level (sentence level), and recursively dividing the sentence and computing embeddings until the maximum level k s reached, creating a final sentence vector x_S^k that captures both word and higher-level semantics. Based on this formulation in terms of Eq. (1 – 8), we proposed an extension of MLCE (multi-level center embedding) through RCE that utilizes Word2Vec-based context pairs along with hierarchical contexts and enhanced baseline performance of Word2Vec for sentence similarity tasks. The following section will demonstrate this idea over benchmark datasets that conclude RCE effectiveness and generalizability.

IV. Result and Discussion

In this section, we have performed experiments to achieve objectives regarding RCE performance under sentence similarity evaluation and explore the generalizability of how RCE performed different sentence complexity.

[1]A primitive recursive function is a function defined using the base functions (such as the zero function, successor function, and projection function) and the operations of composition and primitive recursion [15].

TABLE I. COMPARATIVELY FEATURE-CONSTRUCTIONS OF BOTH WORD2VEC AND RCE FOR EXAMPLE SENTENCE

w_t	Word2Vec	RCE		
	Context-pairs	**Levels, wt: Center**	**Context-pairs**	**Add-on Contexts**
The	(quick, brown)	L0, jumps	(brown, fox, over, a)	Entire sentence
quick	(the, brown, fox)	L1, brown	(The, quick, fox, jumps)	Sub-unit: left
brown	(The, quick, fox, jumps)	L1, lazy	(over, a, dog)	Sub-unit: right
fox	(quick, brown, jumps, over)	L2, quick	(the, brown, fox)	Sub-unit: left
jumps	(brown, fox, over, a)	L2, fox	(quick, brown, jumps, over)	Sub-unit: []
over	(fox, jumps, a, lazy)	L2, a	(jumps, over, lazy, dog)	Sub-unit: left
a	(jumps, over, lazy, dog)	L2, dog	(a, lazy)	Sub-unit: []
lazy	(over, a, dog)	L3, The	(quick, brown)	Sub-unit: []
dog	(a, lazy)	L3, over	(fox, jumps, a, lazy)	Sub-unit: []

A. Experimental Setups

In order to evaluate the performance of the proposed Recursive Center Embedding (RCE) approach, a thorough experimental setup is designed using a variety of datasets, including both benchmark and author-constructed datasets as shown in Table II. This section outlines the datasets used, the Word2Vec training configuration, and the parameters optimized to improve the effectiveness of RCE for capturing sentence similarities through context-aware representations.

TABLE II. SUMMARY DETAILS OF SIMILARITY ASSESSMENT BENCHMARK DATASETS

Similarity Assessment Datasets		
***SICK* [12]**	***STS* [13]**	***Complex Dataset* [14]**
~10,000 pairs	~8,500 pairs	50 pairs
(1 to 5)	(0 to 5)	Final Similarity up to 5
Marelli et al., 2014	Cer et al., 2017	Chandrasekaran, D. and Mago, V., 2021
A benchmark dataset consisting of sentence pairs annotated with relatedness scores.	A widely used benchmark dataset containing pairs of sentences from diverse domains, each annotated with a score indicating the degree of semantic similarity.	A dataset containing pairs of complex sentences designed to challenge models in assessing sentence similarity for intricate structures.

1) Word2Vec training configuration: For the development of sentence vectors under the RCE framework, the Word2Vec model is trained with an optimized set of parameters to ensure the model captures meaningful context and word relationships effectively. The parameters for the Word2Vec training are as follows in Table III.

TABLE III. WORD2VEC TRAINING CONFIGURATION FOR RCE AT EPOCHS IN THE RANGE OF [50: 500]

Parameter	**Values**	**Description**
Vector Size	[100:300]	The dimensionality of the word vectors to be generated.
Window	[5:25]	The maximum distance between the current and predicted word within a sentence.
Model Type	Skip-gram	The architecture used for training the Word2Vec model, which predicts context words given a target word.
Training Data	flattens-RCE Vocab	According to the provided hierarchy of center-words, the dataset constructs the vocabulary and then flattens it in structure.
Lambda	0.8	A hyper-parameter to control the influence of the regularization term in the objective function.

The combination of these optimized parameters ensures that the trained Word2Vec model can develop RCE supported features through flat vocabs[2] meaningful word vectors that support the RCE's objective of accurately capturing hierarchical and structural sentence relationships.

2) Objective function of RCE: The Recursive Center Embedding (RCE) framework operates by recursively constructing center embeddings from sentences to capture both local word-level dependencies and global sentence structure. The objective function, as Eq. (6) discussed in the methodology section for RCE, is designed to balance the contribution of the recursive context embedding and word-level features. The parameter λ is set to 0.8, indicating that more weight is given to the recursive context structure compared to the individual word embeddings. The recursive process ensures that each word in the sentence is treated in the context of its neighboring words, creating context-pairs. These pairs are used to compute sentence-level vectors that reflect both semantic meaning and structural composition.

B. Significance of Normalize Representation of Sentence Vectors

Normalization of sentence vectors plays a crucial role in ensuring that vector magnitudes are comparable and meaningful for similarity tasks [10]. In Word2Vec, sentence vectors are typically computed as the mean of the word vectors within a sentence. On the other hand, Recursive Center Embedding (RCE) recursively computes a hierarchical embedding that captures the syntactic relationships between words. Normalization brings all vectors to a uniform scale, making it easier to compare vectors from different sentences. It is particularly important for RCE, where the recursive structure introduces multiple levels of abstraction. In mean-based Word2Vec, normalization primarily ensures length-invariance and improves the quality of similarity comparisons. We here performed Euclidean norms for both approaches as Eq. (9).

$$\left.\begin{aligned} \widehat{x_s} &= \frac{x_s}{||x_s||} \\ \widehat{x_{s,k}} &= \frac{x_{s,k}}{||x_{s,k}||} \end{aligned}\right\} \tag{9}$$

where $x_{s,k}$ is recursively obtained by averaging the word embeddings of sub-sentences and combining them as Eq. (9) for the RCE approach while the mean-based sentence vector

[2]Vocab is developed through unique sentences from available benchmark datasets.

x_s utilized for the Word2Vec. Obtained results of norm vectors are shown in both scenarios as in Table IV and Fig. 2, these normalization statistics across the Complex Sentence, SICK, and STS-B datasets suggest important insights about the performance of Recursive Center Embedding (RCE) compared to Word2Vec-based mean sentence vectors.

TABLE IV. NORM-VECTORS STATISTICS OBTAINED DURING EXPERIMENT WHICH IS SHOWN IN FIG. 2A, 2B, 2C ALONG WITH REMARKS ON WHICH DATASETS, SCHEME IS BETTER

Dataset	Word2Vec-Norms	RCE-Norms	Description
Complex-Sentence	Mean:1.1379 Std:0.1582	Mean:11.9599 Std:3.6996	RCE reflects greater captures sentence depth better. Mean-based vectors are uniform due to show a small degree of variation as indicated by standard deviations.
SICK	Mean:1.2048 Std:0.1412	Mean:9.7899 Std:2.6211	
STS-B	Mean:1.3550 Std:0.2977	Mean:9.7747 Std:3.7465	

Complex Sentence Dataset is the most suitable choice for showcasing the effectiveness of Recursive Center Embedding (RCE). The significantly higher RCE norms (mean of 11.9599 vs. 1.1379 for Word2Vec) show that RCE captures the intricate structure of complex sentences much better than Word2Vec, while others demonstrate the advantages of RCE over Word2Vec, but the effect is less pronounced.

C. Assessment of Sentence Similarity Task

In normalizing sentence vectors, obtaining mean and deviation results shows a considerable significant variation. These results conclude that RCE can be a good alternative of traditional Word2Vec/BERT-base models if a primary task surrounds the structural and semantics evaluation of complex sentences. With this observation, we evaluated the similarity task in sentence pairs which are in different sizes as shown in Table II. Under the established configurations mentioned in Table III for constructing vectors, which are obtained after applying optimization for getting effective correlations through a grid search approach with various combinations of these hyper-parameters as V: vector_sizes = [100, 200, 300], W: window_size = [5, 10, 15, 20] E: epochs_list = [50, 100, 200, 500, 700].

Correlation Results mentioned in Table V are reflected here that the chosen optimized parameters produce vectors that restrict them to over-fitting situations [6, 9]. Based on the observations, we can conclude that the traditional Word2Vec approach has limitations in exploring similarity tasks when sentences have structural complexities.

Another observation is found during assessment in the perspective of obtaining less over-fitting criteria and captured semantics within minimum context window size. Recently claimed complex dataset (having 50 sentence pairs) wins with a window size of 8; under this parameter, RCE effectively achieved its validation criteria. Meanwhile, Word2Vec only validated its over-fitting in terms of Spearman correlation (while Pearson metric still suffer from over-fitting) due to a lower validation score achieved in comparison to the training score. This analysis clearly illustrates the value of utilizing RCE-based hierarchical vectors for effectively determining sentence similarity tasks.

TABLE V. PEARSON (P_t,P_v) AND SPEARMAN(S_t,S_v) CORRELATION RESULTS OVER TRAINING AND VALIDATION SETS

Datasets	Training Parameters	**Word2Vec**				**RCE**			
		P_t	S_t	P_v	S_v	P_t	S_t	P_v	S_v
SICK	W=20, V=100, E=250	0.58	0.49	0.60	0.54	0.699	0.590	0.748	0.766
STS	W=20, V=100, E=500	0.21	0.23	0.25	0.26	0.518	0.516	0.527	0.538
Complex dataset	W=8, V=100, E=80	0.39	0.42	0.10	0.45	0.506	0.515	0.572	0.587

For comparing the proposed idea of RCE, we have chosen here Google pretrained Word2Vec model and contextual BERT-base pre-trained model on [14], applying mean of word vectors to get sentence information over benchmark datasets. As demonstrated by Table VI's results, the proposed RCE concept performed similarity to the pre-trained word vector model, with a minor improvement in SICK as well in BERT-base variant (particularly related similarities regarding Spearman correlations). Due to having less structural complexity in sentences, RCE poorly performed in the STS-B dataset.

D. Discussion

The Recursive Center Embedding (RCE) approach demonstrated significant advancements in sentence similarity tasks by integrating hierarchical context through recursive decomposition. Unlike traditional Word2Vec methods, which treat sentences as flat bags of words, RCE's recursive mechanism accounted for structural dependencies and nested relationships.

The comparative analysis revealed that RCE outperformed Word2Vec in datasets with intricate sentence structures, such as the Complex Sentence dataset, as evidenced by the significantly higher norm values and correlation scores. Specifically, RCE's ability to capture hierarchical context allowed for a nuanced understanding of sentence meaning, particularly in sentences containing nested clauses and intricate dependencies. For example, RCE achieved a higher Pearson correlation (0.567) on the Complex Sentence dataset, indicating its capability to generalize structural awareness. However, RCE exhibited limited performance on simpler datasets like STS-B, where the added hierarchical complexity was not essential. This suggests that RCE's recursive embedding mechanism may not be the most efficient approach for tasks dominated by surface-level word relationships.

An intriguing observation emerges regarding the proposed concept of RCE, which centers on structured abstraction and demonstrates efficacy over a complex dataset (comprising 50 pairs of sentences, which the authors [14] assert contains heavily complex sentences than other benchmark datasets such as SICK and STS-B), yielding substantial enhancements relative to conventional Word2Vec and the contextual pre-trained BERT-base model.

While RCE significantly improved sentence similarity tasks involving complex structures, its performance on STS-B dataset indicates that further optimization is needed. One promising direction is the incorporation of an adaptive recursion mechanism, which dynamically adjusts the depth of recursion based on sentence complexity. This dataset is still more difficult to analyze for sentence similarity than RCE, which is considered to be less effective, although earlier pre-trained models have done relatively better.

TABLE VI. COMPARISON OF RCE PERFORMANCE TO EXISTING PRE-TRAINED CONTEXTUAL MODELS [WORD2VEC, BERT-BASE VARIANTS (PARTIALLY SUPERVISED)] AT VALIDATED TRAINING PARAMETERS

Datasets	Pre-trained Result(*)		BERT Result(*)	RCE (Lambda = 0.8)	
	P	S	S	P	S
SICK	0.726	0.621	0.728	0.728	**0.736**
STS	0.626	0.587	0.769	0.515	0.521
Complex dataset	0.483	0.490	0.477	**0.567**	**0.551**

* Reported Google News pre-trained results are declared in the work as [14].

V. CONCLUSION AND FUTURE DIRECTION

The Recursive Center Embedding (RCE) approach offers a novel and effective method for sentence representation, particularly for complex-sentence structures. It introduces a recursive mechanism that captures sentence hierarchies in terms of their center-words, embedding them along with Word2Vec according to leveled-contexts gathered through syntactic structure, enabling the model to better handle intricate sentence patterns that are often difficult for traditional word embedding models like Word2Vec, BERT-base variant to capture. In this work, we explored its effectiveness for constructing sentence representations, comparing it with traditional Word2Vec-based mean sentence vectors across three datasets: Complex dataset (Sentence 50 Pairs), SICK, and STS-B.

The results demonstrated the strength of RCE, particularly in handling complex sentence structures, as shown in the significant difference in norm values between the two approaches. RCE significantly outperformed with a much higher norm value, demonstrating RCE's ability to capture intricate sentence structures, especially when dealing with complex sentences containing nested clauses or dependencies. Moreover, in terms of correlation results, highlighting its effectiveness for complex sentence evaluations.

A. Limitations

As observed in the STS-B dataset, RCE under-performed compared to pre-trained Word2Vec when dealing with simple sentence structures. The added complexity of recursively embedding center words may not be necessary for simpler, more straightforward sentence pairs, which rely more on surface-level word similarity. Sentences of these two datasets (specially in STS-B) have only up to limited levels of hierarchy. In all, This suggests that RCE's advantage lies in its ability to handle intricate syntactic structures, limiting its generalization to all types of sentence tasks.

B. Future Directions

Idea of adaptive depth mechanism can improve proposed RCE. Instead of applying the recursive center embedding approach uniformly to all sentences, the depth of recursion could be determined based on the sentence's syntactic complexity. Example: A highly complex sentence like "The student who was reading the book that was recommended by the professor passed the exam," could involve multiple levels of recursion, as it contains nested clauses. On the other hand, a sentence like "The student passed the exam," would only require minimal recursion. The recursive depth could be controlled based on the number of subordinate or relative clauses.

Possible solution for adaptive depth mechanism as to use a sentence parsing technique to identify the number of clauses, and accordingly determine the recursion depth. For sentences with higher clause density, increase the depth of RCE. Conversely, for simpler sentences, limit the recursion to one or two levels. This dynamic depth control can improve efficiency, particularly for large datasets.

***Abstract*—Designing stabilizing controllers for delayed nonlinear systems with control constraints presents a significant challenge. This paper addresses this issue by proposing a fault-tolerant control approach for a specific class of delayed nonlinear systems with actuator faults based on Lyapunov redesign principle. Initially, an assumption is introduced to facilitate the control design for the nominal system. Then, a new control law is developed to resolve the difficulty caused by actuator failures. The proposed nonlinear controller demonstrates the ability to compensate for actuator faults. To validate its effectiveness, the method is applied to a hydraulic system.**

***Keywords*—Delayed nonlinear system; actuator faults; delayed hydraulic process; additive fault tolerant control; redesign Lyapunov approach**

I. Introduction

The primary objective of Fault Tolerant Control (FTC) is to guarantee performance and stability for systems, whether they are operating without faults or in a faulty state. Multiple approaches have been proposed to tackle this problem. FTC can be categorized into two main types: passive (P) and active (A) FTC [1]. In the domain of nonlinear control, extensive theoretical research and practical applications have been conducted for Passive Fault Tolerant Control (PFTC) and Active Fault Tolerant Control (AFTC) [2]. Active FTC is centered on ensuring stability and certain performance aspects for the post-fault model by dynamically adjusting the controller in response to the current fault [3], as detected, isolated, and estimated by the Fault Detection and Diagnosis (FDD) block [4]. A FTC employs real-time adjustment techniques for the regulators to uphold, at a minimum, the system's stability [5]. Another approach involves using a robust controller able of handling all anticipated faults, by eliminating the requirement for online control reconfiguration and an FDD block [6], PFTC methods have been introduced, predominantly grounded in robust theories. These include approaches such as linear-matrix-inequality-based methods [7], quantitative feedback theory [8], pole assignment [9], and nonlinear regulation theory [10, 11].

A. Literature Review

Many recent studies have focused on FTC applied to particularly complex nonlinear processes, such as boundary adaptive fault-tolerant control for a flexible Timoshenko [12] the proposed method ensures robust and adaptive control of a Timoshenko flexible arm, guaranteeing stability and precision despite actuator faults, hysteresis, and disturbances, while enhancing reliability under variable conditions. Another research addresses a 2 DOF helicopter system, this study proposes an adaptive control strategy for a 2-DOF helicopter, considering actuator faults and an unknown dead zone. A neural network and a quantizer are used to model the uncertainty and reduce system chattering [13].

Such presence of delays may influence the qualitative system properties and may affect the stability of the process control. When dealing with systems involving time delay, two approaches are employed to establish stability, aligning with the conventional Lyapunov stability theory. The first approach relies on Lyapunov-Krasovski functionals, while the second approach uses Lyapunov-Razumikhin functions [14]. Hence, research into control systems with delays in a nonlinear context holds great importance [15]. The literature offers a variety of methods for developing fault-tolerant controllers in the context of nonlinear systems. In their work [16], Liang and Xu introduced a variable structure stabilizing control law to handle actuator faults within a nonlinear system [17].

The concept of Control Lyapunov Functions (CLF) has played a pivotal role in the advancements of robust control for nonlinear systems [18, 19, 20]. A function that is positive definite and radially unbounded qualifies as a CLF if its time derivative become negative definite through appropriate control input selection, regardless of the value of state. Once a CLF is identified, various methods exist to derive control laws that stabilize the nonlinear system [21].

The application of CLF has been extended to systems with disturbances [20] and [22], to systems with delay and to stochastic systems [19].

Furthermore, the issue of faults, loss of effectiveness, and delay has been addressed using the Lyapunov tool, and has also been treated in the context of a stochastic system such as an adaptive fuzzy control strategy for stochastic nonlinear systems with faults and input saturation uses control filtering to reduce computational load. Fuzzy logic systems approximate the unknown nonlinearities and system variations caused by faults [23]. Another fault-tolerant fuzzy control strategy for stochastic nonlinear systems with quantized inputs is proposed. It uses a hysteretic quantizer to avoid chattering and fuzzy logic systems to estimate unmeasurable states and approximate

nonlinearities. The approach guarantees system stability and signal boundedness in the presence of actuator faults and quantization [24]. Furthermore, a fault-tolerant control strategy is proposed for nonlinear strict-feedback systems with actuator saturation, disturbances, and faults. Neural Networks (NNs) are used to approximate the unknown dynamics, and a backstepping technique is employed to design the controller. The NN weights are updated online using a gradient descent algorithm, thereby improving the approximation accuracy.

In this paper, the approach introduced in recent studies [8] and [25] is adopted, where actuator faults are represented as bounded additive periodic unknown signals added to the control signal. Additionally, a scenario is examined in which the efficiency of the actuator is compromised, represented by a multiplicative factor. This factor, when applied to the control signal, decreases its performance in accordance with the factor's value [6]. The proposed fault-tolerant control (FTC) is applied to water level control of a hydraulic system based on the Lyapunov redesign principle [26]. If a stabilizing closed-loop controller and its corresponding Lyapunov function exist for the nominal plant, an FTC is constructed based on these nominal controllers and the Lyapunov function. This FTC guarantees stability even in the presence of faults in the system.

B. Main Contribution

The main contribution of this work is the development of a control strategy for nonlinear systems that are subject to both actuator faults (including additive faults and loss of effectiveness) and time delays, addressing a complex and challenging control scenario without linearizing the nonlinear system. Unlike many traditional approaches that simplify the problem through linearization.

The proposed control scheme combines a nominal control component, which governs the system under normal operating conditions, with an additive corrective term specifically designed to compensate faults.

The subsequent sections of the paper are organized as follows: Section II will present the system characterization and problem formulation, Section III will outline the main results, Section IV will provide a real application to verify the efficiency of the proposed additive FTC. In final Section V, we give some conclusions about this work.

II. System Description and Problem Statement

Here, we consider nonlinear time delay system affine in the control of the form:

$$\dot{x}(t) = f(x_d(t)) + g(x_d(t))\, u(t,x) \tag{1}$$

Where $x \in R^n$,$x_d \in R^n$, $u \in R^m$,, represent respectively, the state of system, delayed state and the input vectors, the initial condition $x_d(0)(.) = \phi_d$ is given by the continuous function $\phi_d : [-d, 0] \rightarrow R^n$. Vector fields f and g are smooth functional mapping piecewise continuous function in t and locally Lipschitz in x and u [27]. The functions f and g are known precisely.

Hypothesis 1: We propose the existence of a nominal closed-loop control, represented as $u_{nom}(t,x)$, with the anticipation that it guarantees the overall stability of the closed-loop system.

$$\dot{x}(t) = f(x_d(t)) + g(x_d(t))\, u_{nom}(t,x) \tag{2}$$

The concept of Control Lyapunov Functions (CLF) has gained attention in the literature due to the availability of various CLF based control laws, which aim to stabilize the system and ensure a certain level of robustness for the closed-loop system. The function $V(x)$ is defined as a positive definite Lyapunov function such that for all $x \in B_x$ for the system [Eq. (1)].

The Lyapunov function will be derived along the trajectories of Eq. (2).

$$\dot{V} \leq -\Gamma_1(|x|) \tag{3}$$

with $\Gamma_1(s) > 0$ for $s > 0$

$$\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x}\,\frac{\partial x}{\partial t} \leq -\Gamma_1(|x|) \tag{4}$$

Using (2), we get

$$\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x}\left[f(x_d(t)) + g(x_d(t))\, u_{nom}(t,x)\right] \leq -\Gamma_1(|x|) \tag{5}$$

Which shows that $\dot{V}$ is negative definite. Consequently, the origin of the full system [Eq. (2)] is asymptotically stable.

III. Proposed Fault Tolerant Control Design

In the upcoming sections, we will outline the main results.

If we assume that the system can be stabilized within the domain B_x and that the state x is accessible for feedback, our objective is to find a control scheme that achieves asymptotic stabilization of the point $x = 0$ of the closed loop nonlinear delayed system despite actuator fault occurrence.

The fault-tolerant control strategy denoted as control input u_{FTC} designed for the purpose of stabilizing the system in the presence of faults, is proposed as:

$$u_{FTC} = \alpha\ (u_{nom} + F(x,t) + u_{add}) \tag{6}$$

We take into account the reduction in actuator efficiency, represented by a multiplicative matrix α, where $\alpha \in R^{m\times m}$ is a diagonal continuous time variant matrix, with the diagonal elements $\alpha_{ii}(t)$, $i = 1, \ldots, m$ s.t $0 < \alpha_{ii} \leq 1$, $u = u_{nom}$ designates the nominal controller responsible for system stabilization in the absence of any actuator faults.

Using Eq. (6), the system [Eq. (1)] becomes:

$$\dot{x}(t) = f(x_d(t)) + g(x_d(t))\,\alpha\ (u_{nom} + F(x,t) + u_{add}) \tag{7}$$

Hypothesis 2:

$F(x,t)$ signifies an actuator fault that satisfies the condition $\|F(x,t)\| \leq L(x,t)$ and $L(x,t)$ is non-negative continuous function satisfying

$$L(x,t) = \frac{1-\alpha}{\alpha} u_{nom} \tag{8}$$

with $\alpha \in R$

Proposed FTC control: In this context, we will design an additive control u_{add} represents the additional component to compensate the actuator fault's impact as:

$$u_{add} = -\gamma(V) \frac{\partial V}{\partial x} g(x_d(t)) \tag{9}$$

For any $\gamma > 0$ there exists a smooth, positive dominating function γ such that all trajectories of the closed loop system Eq. (2) and (9) satisfy $\lim_{t\to\infty} |x(t)| < \gamma$

So, the following theorem is proposed to achieve control of the studied nonlinear delayed system Eq. (6) in the presence of malfunctioning actuators.

Theorem: The fault-tolerant control law Eq. (6) ensures asymptotic stability of the closed loop nonlinear delayed system described in Eq. (7) defined by Eq. (8) and (9) under the previous assumptions 1 and 2 even in cases of abnormal operation of the actuators.

Proof:

According to Eq. (6), it follows for the closed-loop faulty nonlinear delayed system Eq. (7), a Control Lyapunov Function (CLF) candidate will be designed such as $V(x_d)$ is a positive definite function as:

$$\dot{V}(t) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} \frac{\partial x}{\partial t} \tag{10}$$

Using Eq. (7), we get

$$\dot{V}(t) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} \left(f(x_d(t)) + g(x_d(t)) \alpha \ (u_{nom} + F(x,t) + u_{add}) \right) \tag{11}$$

The establishment of the derivative of $V(t)$ will occur in accordance with the trajectories defined by system Eq. (7), this leads to

$$\begin{aligned} \dot{V}(t) = &\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(x_d(t)) + \frac{\partial V}{\partial x} g(x_d(t)) \alpha \ u_{nom} \\ &+ \frac{\partial V}{\partial x} g(x_d(t)) \alpha \ F(x,t) + \frac{\partial V}{\partial x} g(x_d(t)) \alpha \ u_{add} \end{aligned} \tag{12}$$

where

$\beta = 1 - \alpha \geq 0$, Eq. (12) can be expressed as

$$\begin{aligned} \dot{V}(t) = &\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(x_d) + \frac{\partial V}{\partial x} g(x_d(t)) u_{nom} \\ &- \beta \frac{\partial V}{\partial x} g(x_d) u_{nom} + \alpha \frac{\partial V}{\partial x} g(x_d) F(x,t) \\ &+ \alpha \frac{\partial V}{\partial x} g(x_d) u_{add} \end{aligned} \tag{13}$$

Using Eq. (8) we obtain:

$$\dot{V}(t) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(x_d) + \frac{\partial V}{\partial x} g(x_d(t)) u_{nom} + \alpha \frac{\partial V}{\partial x} g(x_d) u_{add} \tag{14}$$

By substituting Eq. (9) into Eq. (14), the desired stability can be achieved.

$$\dot{V}(t) \leq -\Gamma_1(|x|) - \alpha\gamma(V) \left(\frac{\partial V}{\partial x} g(x_d(t)) \right)^2 \tag{15}$$

Such as $\alpha > 0$ and γ is strictly increasing function.

For this purpose

$$\dot{V}(t) \leq -\Gamma_2(|x|) \tag{16}$$

where $\Gamma_2 > 0$

Hence the system Eq. (1) can be stabilized with the control law Eq. (9). Thus the derivative $\dot{V}$, is negative along the trajectory of the closed-loop system.

In view of the control law Eq. (9) and taking into account the assumptions about the fault, it is obvious that $\dot{V} \leq 0$.

So, it can be concluded that the origin $x = 0$ of the faulty overall system is a asymptotically stable equilibrium point for studied system Eq. (7) under the fault tolerant control law Eq. (9) regardless of the presence of delay.

IV. FTC Control of a Hydraulic System

A. Description of a Single-Tank Hydraulic System

Adjusting a hydraulic level in a tank is the main objective of this work by developing fault-tolerant control for this nonlinear time-delay system based on Lyapunov approach. The structure of the entire system is as shown in Fig. 1. The system is built about a water tank, a liquid level sensor, coil and pump. The tank is supplied by two water inputs: the first is located at the top while the second is at the bottom to compensate for any faults if it exists. Furthermore, the tank has two outputs, the first one for liquid discharge and the second one for leakage (disturbance), the coil affects a pure delay.

B. Modeling of a Single-Tank Hydraulic System

In Fig. 2, the tank is supplied by two water inputs: the first $Q_{I1}(t)$ is located at the top while the second $Q_{I2}(t)$ is at the bottom to compensate for any faults if it exists. Furthermore, the tank has two outputs, the first one for liquid discharge and the second one for leakage (disturbance), the coil affects a pure delay.

Fig. 1. Real hydraulic system at MACS laboratory.

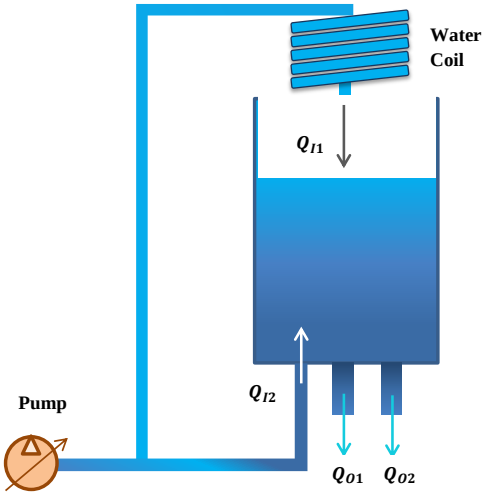

Fig. 2. Model of the hydraulic system at MACS laboratory.

Then, the tank system can be modeled by the following differential equation:

$$\frac{\partial V}{\partial t} = \frac{\partial \left(S.h\left(t\right)\right)}{\partial t} = Q_I\left(t\right) - Q_O\left(t\right) \tag{17}$$

$V(t)$:Water speed$[m/s]$
S : Discharge output section $[m^2]$
$h(t)$: Water level $[m]$
$Q_I(t)$: Input flow rate $[m^3/s]$
$Q_O(t)$: Output flow rate $[m^3/s]$

In our case, the tank section is constant, so we can write

$$\frac{\partial h}{\partial t} = \frac{Q_I\left(t\right) - Q_O\left(t\right)}{S} \tag{18}$$

We set $x(t) = h(t)$, we obtain

$$\dot{x}\left(t\right) = \frac{Q_I\left(t\right) - Q_O\left(t\right)}{S} \tag{19}$$

with

$$Q_I\left(t\right) = \ Q_i\left(t\right)\left(1 + A\left(x_d, t\right)\right) \tag{20}$$

As long as we have two inputs, $Q_{I1}(t) = Q_i$ is considered the main input and $Q_{I2}\left(t\right) = \ Q_i\left(t\right)A\left(x_d, t\right)$ is used to compensate faults

We obtain by identification

$$A\left(x_d, t\right) = 0.7857{x_d}^2\left(t\right) + -0.6614x_d\left(t\right) + 0.68 \tag{21}$$

To simplify, we take

$$g'\left(x_d\right) = 1 + A\left(x_d, t\right) \tag{22}$$

Therefore,

$$Q_I\left(t\right) = \ Q_i\left(t\right)g'\left(x_d\right) \tag{23}$$

The output flow rate is divided into two parts: the first part $Q_{O1}(t)$ concerns the main output flow rate, and the second $Q_{O2}(t)$ represents the leakage flow rate which considered here as a fault.

$$Q_O(t) = Q_{O1}\left(t\right) + \ Q_{O2}\left(t\right) \tag{24}$$

Knowing the relationship between flow rate, section and velocity, we can write

$$Q_O(t) = S_{O1}V_1(t) + S_{O2}V_2(t) \tag{25}$$

By replacing Eq. (23) and (25) in Eq. (19), we obtain

$$\dot{x}\left(t\right) = \frac{Q_i\left(t\right)g'\left(x_d, t\right) - \left(S_{O1}V_1(t) + S_{O2}V_2(t)\right)}{S} \tag{26}$$

After some algebraic manipulations, Eq. (26) can be expressed as

$$\dot{x}\left(t\right) = \frac{-S_{O1}V_1(t)}{S} + \frac{Q_i\left(t\right)g'\left(x_d, t\right) - S_{O2}V_2(t)}{S} \tag{27}$$

In the fault-free case i.e. $Q_{O2}(t) = 0 \rightarrow S_{O2}V_2(t) = 0$, our system can be represented as follows:

$$\dot{x}\left(t\right) = \frac{-S_{O1}V_1(t)}{S} + \frac{Q_i\left(t\right)g'\left(x_d, t\right)}{S} \tag{28}$$

According to Torricelli's theorem,

$$V_1(t) = \sqrt{2gx_d(t)} \tag{29}$$

with $g = 9.81m/s^2$

The Eq. (28) becomes:

$$\dot{x}(t) = \frac{-S_{O1}\sqrt{2gx_d(t)}}{S} + \frac{Q_i(t)\,g'(x_d,t)}{S} \tag{30}$$

By referring to Eq. (2), we can express Eq. (30) in this form:

$$\dot{x}(t) = f(x_d,t) + g(x_d,t)\,Q_i(t) \tag{31}$$

Along with

$$f(x_d,t) = \frac{-S_{O1}\sqrt{2gx_d(t)}}{S} \tag{32}$$

And

$$g(x_d,t) = \frac{g'(x_d,t)}{S} \tag{33}$$

In our case, the Q_i Input flow rate of the hydraulic system corresponds to the nominal control u_{nom}

$$Q_i(t) = u_{nom}(t) \tag{34}$$

C. Experimental Validation on a Hydraulic System

1) Stabilization of nonlinear delayed water tank in fault-free case: The description of the nominal closed-loop system is as follows:

$$f(x_d,t) + g(x_d,t)\,u_{nom}(t) = K(x_{ref}(t) - x(t)) \tag{35}$$

with $K > 0$

Let the Lyapunov function be

$$V(t) = \frac{1}{2}(x_{ref}(t) - x(t))^2. \tag{36}$$

However, to ensure the stability of the hydraulic system, it is necessary that $\dot{V}(t) < 0$. So, for this reason, we can choose

$$u_{nom}(t) = \frac{K(x_{ref}(t) - x(t)) - f(x_d,t)}{g(x_d,t)} \tag{37}$$

Consequently, the stability of the hydraulic system is achieved. By examining Eq. (7) and (30), the fault free system is obtained by $\alpha = 1$ and $F(t,x) = 0$,where F represents the fault corresponding to a flow leakage in our real system $Q_{O2}(t) = 0 \rightarrow S_{O2}V_2(t) = 0$. So, it's described as follows:

$$\dot{x}(t) = \frac{-S_{O1}\sqrt{2gx_d(t)}}{S} + \frac{Q_i(t)\,g'(x_d,t)}{S} \tag{38}$$

The desired level of the water $x_{ref} = 0.4$ m.

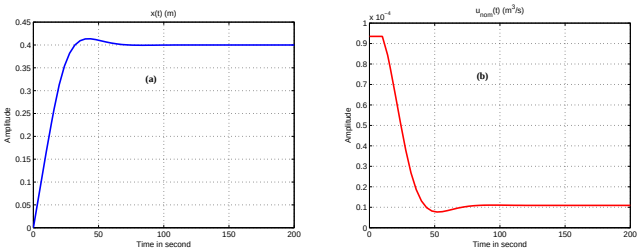

Fig. 3. State trajectory in fault-free case (a) and nominal control (b).

We obtain the next hydraulic system responses in Fig. 3.

Discussion: Initially, in Fig. 3(a) there is a rapid rise to approximately 0.4 m, followed by a stabilization near this desired value. This stabilization shows that the system is able to reach and maintain the desired level without excessive oscillation or instability despite the delay introduced by the tank coil.

In Fig. 3(b) the application of a nominal control Eq. (37) is essential to compensate for the delay and swiftly bring the system to the desired level.

2) Stabilization of delayed hydraulic system with actuator faults: In practice, hydraulic systems are susceptible to a various of faults, including loss of effectiveness and additives faults, both of which can significantly reduce their optimal performance.

So, designing the control law according to Eq. (6) and (9) is essential for stabilizing the nonlinear delayed hydraulic system Eq. (27) in the presence of faults. Based on the condition of Eq. (9), which states that $\gamma(V)$ must be a strictly increasing function, we can therefore choose:

$$\gamma(V) = |x_{ref}(t) - x(t)|^2 \tag{39}$$

Consider the nonlinear delayed system (27) with intermittent fault between $t = 80s$ and $t = 90s$ and 3 cases of loss of effectiveness fault $\alpha = 20\%$, $\alpha = 30\%$ and $\alpha = 40\%$.

$$\dot{x}(t) = \frac{-S_{O1}V_1(t)}{S} + \alpha\left(\frac{Q_i(t)\,g'(x_d,t) - S_{O2}V_2(t)}{S}\right) \tag{40}$$

We start by applying nominal control u_{nom}, and subsequently, we implement fault-tolerant control $u = u_{FTC}$ to compensate any potential faults.

Discussion: Fig. 4(a) shows that when nominal control is employed, the system state deviates from its reference trajectory in the presence of faults. The deviation is notably pronounced in the case of an additive and loss of effectiveness faults, suggesting that nominal control fails to effectively compensate for this specific type of fault.

In Fig. 4(b), it is observed that the control corresponding to this case shows a downward peak, reflecting the need for fault compensation.

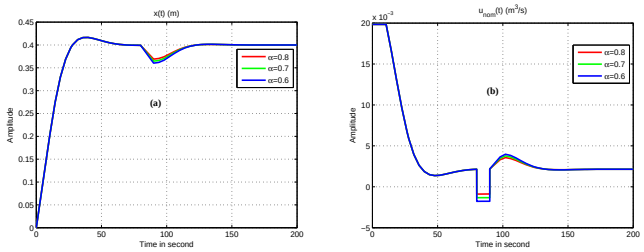

Fig. 4. State trajectory with an additive and loss of effectiveness faults (a) in case of nominal control (b).

To solve the above problem, the control law will be modified to include a new term that represents the component capable of eliminating the impact of the fault.

Hence, we suggest a fault-tolerant control strategy, denoted by u_{FTC} and expressed as:

$$u_{FTC} = \alpha \ (u_{nom} + F(x,t) + u_{add}) \tag{41}$$

With

$$u_{add} = -|x_{ref} - x|^2 (x_{ref} - x)\, g(x_d, t) \tag{42}$$

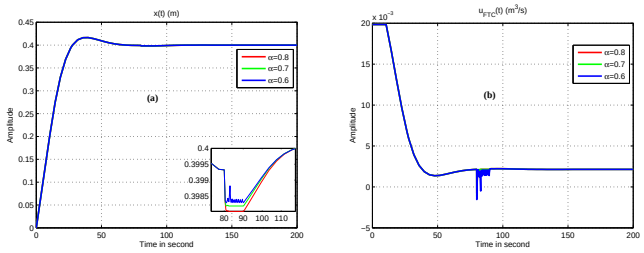

Fig. 5. State trajectory with an additive and loss of effectiveness faults (a) in case of fault tolerant control (b).

Discussion: Fig. 5(a) illustrates that the fault-tolerant control strategy successfully achieves stability and maintains a well-behaved system, even in the presence of faults.

The fault-tolerant control strategy, which accounts for both factors and a delay, compensates the negative impact on the system's behavior and maintains stability. In Fig. 5(b), a shorter-duration peak is observed, highlighting the effect of the newly adopted FTC control, which successfully compensated the system fault.

V. Conclusion

In conclusion, this paper aimed to stabilize a nonlinear delayed system affected by actuator faults, focusing on both additive faults and loss of effectiveness. To achieve this objective, we developed a fault-tolerant control strategy based on the Lyapunov redesign approach. Our research was grounded in practical experimentation, conducted on a real hydraulic system within our laboratory : Modeling, Analysis and Control of Systems (MACS).

The results demonstrated that applying nominal control alone to the faulty system leads to performance degradation. However, by integrating an additive control term, the proposed approach successfully compensates for the faults, ensuring system stability and fault tolerance. This study provides valuable insights and contributes to the advancement of fault-tolerant control strategies for nonlinear delayed systems with practical validation.

***Abstract*—This paper presents a comprehensive approach to fault detection and diagnosis (FDD) in inverter-driven Permanent Magnet Synchronous Motor (PMSM) systems through the innovative integration of transformer-based architectures with physics-informed neural networks (PINNs). The methodology addresses critical challenges in power electronics reliability by incorporating domain-specific physical constraints into the learning process, enabling both high accuracy and physically consistent predictions. The proposed system combines advanced sensor fusion techniques with real-time monitoring capabilities, processing multiple input streams including phase currents, temperatures, and voltage measurements. The architecture's dual-objective optimization approach balances traditional classification metrics with physics-based constraints, ensuring predictions align with fundamental electromagnetic and thermal principles. Experimental validation using a comprehensive dataset of 10,892 samples across nine distinct fault scenarios demonstrates the system's exceptional performance, achieving 98.57% classification accuracy while maintaining physical consistency scores above 0.98. The model exhibits robust performance across varying operational conditions, including speed variations (97.45-98.57% accuracy range) and load fluctuations (97.91-98.12% accuracy range). Notable achievements include perfect detection rates for certain critical faults, such as high-side short circuits and thermal anomalies, with area under ROC curve (AUC) scores of 1.0. This research establishes new benchmarks in condition monitoring and fault diagnosis for power electronic systems, offering practical implications for predictive maintenance and system reliability enhancement.**

Keywords*—Fault detection and diagnosis; PMSM; deep learning; transformers; physics-informed neural networks; power electronics

I. Introduction

The increasing deployment of Permanent Magnet Synchronous Motors (PMSMs) in critical applications, from electric vehicles to industrial automation, has created an urgent need for reliable and interpretable fault detection systems [1], [2]. While traditional machine learning approaches have demonstrated potential in this domain [3], significant challenges persist that limit their practical effectiveness. A primary concern is the lack of physical consistency in predictions, which can lead to unrealistic fault diagnoses that compromise system reliability. Deep learning models, despite their computational power, often suffer from limited interpretability, which significantly reduces trust in their decision-making capabilities in critical situations. Furthermore, these approaches frequently demonstrate insufficient robustness to variations in operating conditions and noise, making them less reliable in real-world industrial environments.

A fundamental limitation of current approaches lies in their inability to effectively leverage domain knowledge within the learning process. This deficiency, combined with high false alarm rates in traditional data-driven approaches, creates significant barriers to practical implementation. These limitations become particularly problematic in safety-critical applications where incorrect fault diagnoses could lead to catastrophic failures, resulting in substantial economic losses or safety risks.

Previous attempts to address these challenges have primarily focused on either pure data-driven approaches or model-based methods, failing to effectively combine the advantages of both paradigms. Model-based approaches, while theoretically sound, often struggle with complex, nonlinear fault dynamics that characterize real-world PMSM operations. Conversely, pure data-driven methods, though capable of handling complex patterns, may violate fundamental physical constraints that govern motor behavior. Traditional hybrid approaches have attempted to bridge this gap but lack a systematic framework for integrating domain knowledge with learning algorithms.

This research addresses these fundamental challenges through the development of a novel physics-informed deep learning architecture. The proposed approach systematically integrates domain knowledge with advanced neural network capabilities, creating a robust framework that maintains physical consistency while leveraging the pattern recognition capabilities of deep learning. This integration represents a significant step forward in creating reliable, interpretable, and physically consistent fault detection systems for PMSM applications.

A. Background and Motivation

Recent advancements in deep learning have revolutionized fault detection in power electronic systems [4], [5]. However, conventional neural networks treat the problem as a pure data-fitting exercise, potentially leading to physically inconsistent

predictions [6]. The incorporation of physics-based constraints through PINNs offers a promising solution to this limitation.

B. Research Objectives

The primary objectives of this study are:

- To develop and implement a PINN architecture specifically designed for PMSM fault detection
- To compare the performance of PINNs with traditional machine learning classifiers
- To analyze the impact of physics-based constraints on model robustness and generalization

The complete dataset has been published in the Zenodo repository [7] under DOI: 10.5281/zenodo.13974503. Additionally, comprehensive documentation and source code are available as open-source materials on the authors' GitHub profile [8]. The repository includes detailed methodology for thermistor calibration.

II. Literature Review

A. Traditional FDD Methods

Early approaches to fault detection in PMSM systems primarily relied on model-based methods and signal processing techniques. Model-based approaches typically utilize mathematical models of the PMSM system to generate residuals between the predicted and measured signals [6], [9]. Signal processing methods, such as Fast Fourier Transform (FFT) and wavelet analysis, have been widely used for extracting fault-related features from motor current and voltage signatures [5], [10].

B. Power Electronics Reliability and Fault Mechanisms

Understanding the fundamental reliability aspects of power electronic converters is crucial for effective fault detection. Recent studies have established comprehensive guidelines for reliability prediction [11] and investigated specific fault mechanisms in inverter systems [12]. Particular attention has been given to switch faults in power electronic converters [13], which represent one of the most common failure modes in PMSM drive systems.

C. Thermal Considerations in FDD

Thermal analysis has emerged as a critical aspect of fault detection in power electronic components [14]. Temperature monitoring of inverter components provides valuable information for early fault detection and prevention of catastrophic failures. Recent studies have demonstrated the effectiveness of integrated thermal and electrical monitoring approaches [15].

D. Machine Learning in FDD

The application of machine learning to FDD has evolved significantly over the past decade [16]. Initial approaches used traditional machine learning algorithms such as Support Vector Machines (SVM) and Random Forests for fault classification. These methods demonstrated improved performance compared to conventional techniques but still relied heavily on manual feature engineering [3], [17]. The integration of machine learning with condition monitoring systems has shown particular promise in industrial applications [18].

E. Deep Learning Advances

Recent years have seen a surge in deep learning applications for FDD. Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) have shown promising results in automatic feature extraction and temporal pattern recognition [19], [20]. However, these approaches often lack the ability to incorporate domain knowledge and physical constraints of the PMSM system [14]. Notably, hybrid approaches combining model-based and data-driven methods have emerged as a promising direction [21].

F. Real-Time Implementation Considerations

The practical implementation of FDD systems presents unique challenges, particularly in real-time applications [22]. Recent work has focused on developing efficient algorithms suitable for embedded systems and microcontroller implementation [23], [24]. These implementations must balance computational efficiency with detection accuracy while maintaining robustness against noise and system variations [25].

III. Experimental Setup Overview

The experimental setup consists of four main subsystems: power electronics inverter, permanent magnet synchronous motor (PMSM), control system, and data acquisition system, see Fig. 1. The setup was designed to enable comprehensive fault simulation and data collection under various operating conditions.

A. Power Electronics Inverter

1) Main components: The power electronics inverter design incorporates modern reliability considerations [12], [13] and follows established fault detection approaches [14], [15], [21].

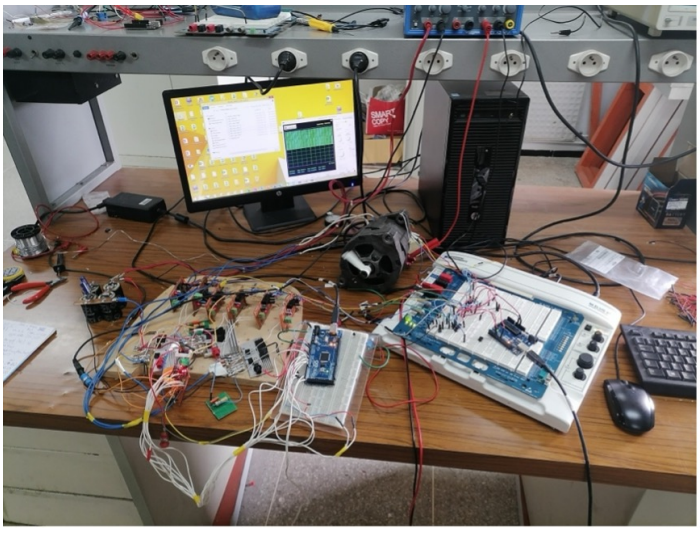

Fig. 1. A picture of the experimental setup.

The power electronics hardware architecture comprises several key components integrated to ensure robust and reliable operation. The system is powered by a 15V DC input voltage source, which feeds into a sophisticated power stage featuring six IRF1404N MOSFETs strategically arranged in three half-bridge configurations. These switching devices are controlled through HCPL3120 gate drivers, selected for their superior isolation characteristics and robust driving capabilities. To maintain stable DC bus voltage and minimize ripple, the DC link incorporates a substantial 2200 μF capacitor bank. Voltage transients and switching spikes are effectively suppressed through the implementation of two RC snubber circuits, each consisting of a 10 Ω resistor in series with a 2.2 nF capacitor.

The design incorporates comprehensive protection features to ensure safe and reliable operation. Galvanic isolation between the control and power circuits is achieved through the gate drivers' built-in isolation barriers, significantly enhancing system safety and noise immunity. Voltage regulation is maintained through a B1215S-2W isolated DC/DC module, which provides stable 15V supply for both the gate drivers and the high-side floating power supplies. Electromagnetic Interference (EMI) is effectively mitigated through strategically placed snubber circuits connected to the DC bus terminals, ensuring clean switching waveforms and reduced electromagnetic emissions. This integrated approach to protection and power quality management ensures optimal system performance while maintaining high reliability standards. Table I provides a synthesis of the Power Electronics Hardware Specifications.

TABLE I. POWER ELECTRONICS HARDWARE SPECIFICATIONS

Component	Model/Specification	Key Characteristics
Power Stage Components		
Power Supply	DC Input	• Input voltage: 15V DC • Current rating: 10A max
MOSFETs	IRF1404N	• V_{DS}: 40V • $R_{DS(on)}$: 4mΩ • I_D: 202A • Configuration: 3 half-bridges
Gate Drivers	HCPL3120	• Peak output current: 2.5A • Propagation delay: 0.5μs • CMR: 15kV/μs • Isolation: 3750V$_{rms}$
DC Link Capacitor	Electrolytic	• Capacitance: 2200μF • Voltage rating: 35V • ESR: 0.05Ω
Protection Components		
Snubber Circuits	RC Network	• Resistance: 10Ω • Capacitance: 2.2nF • Quantity: 2 units
DC/DC Converter	B1215S-2W	• Input: 12V • Output: 15V • Isolation: 1500VDC • Efficiency: 80%

B. Motor Specifications

The PMSM used in this setup is a converted DENSO car alternator with the following specifications (see Table II).

TABLE II. PMSM TECHNICAL SPECIFICATIONS

Parameter	Value
Power supply	15 V
Nominal speed	6000 rpm
Windings connection	Star
Stator resistance	0.3Ω
Number of pair of poles	6

C. Control System

The control system architecture implements state-of-the-art converter control methodologies as outlined by Henninger et al. [9], with particular emphasis on robust motor control strategies. At the heart of the system lies an Arduino Uno microcontroller board [23], which serves as the primary processing unit for executing the sophisticated control algorithms. Position feedback is provided through a high-precision SCANCON 2RHF-100-583801 encoder, delivering 100 pulses per revolution (PPR) for accurate rotor position measurement. The control strategy employs Field-Oriented Control (FOC) principles, implemented using the SimpleFOC framework [24], which enables precise torque and speed regulation. The system maintains a constant operating speed of 10 rad/s, ensuring stable and consistent motor performance across various operating conditions.

The Pulse Width Modulation (PWM) generation system employs an advanced bipolar modulation scheme, utilizing three separate PWM channels in conjunction with 74LS04-based logic gate inverters. This configuration generates six complementary PWM signals required for controlling the three half-bridge power stages. The implementation leverages Space Vector PWM techniques, which optimize harmonic performance and maximize DC bus utilization. The PWM generation system maintains precise timing relationships between the complementary signals, incorporating necessary dead-time insertion to prevent shoot-through conditions while minimizing switching losses. This sophisticated control implementation ensures optimal motor performance while maintaining high system efficiency and reliability.

D. Sensor Integration

1) Current measurement: The current measurement system employs high-precision ACS712 Hall-effect current sensors, selected for their excellent linearity and robust performance characteristics. The sensor configuration comprises three strategically placed units: two sensors dedicated to measuring the inline phase currents (I_a and I_b), and one additional sensor monitoring the DC bus current (I_{DC}). Each sensor features a comprehensive measurement range of ±20A, with a high-resolution sensitivity of 100 mV/A, enabling precise current monitoring across the entire operating range. The Hall-effect sensing technology provides galvanic isolation between the power circuit and measurement system, while maintaining

fast dynamic response to current variations. This configuration allows for complete current vector reconstruction and enables sophisticated fault detection through current signature analysis. The sensors' integrated features, including built-in precision amplification and internal filtering, ensure reliable current measurements even in electromagnetically noisy environments typical of power electronic systems.

2) Voltage measurement: The voltage measurement subsystem employs a modified ACS712-based configuration, featuring precision voltage sensing through a carefully designed resistive network. Each measurement channel incorporates an ACS712 sensor coupled with a precision 100Ω and 150Ω series resistor, providing accurate voltage division while maintaining galvanic isolation. This configuration enables reliable monitoring of two critical system voltages: the DC bus voltage (V_{DC}) and the low-side MOSFET driver voltage (V_D). The measurement setup, illustrated in Fig. 2, achieves high common-mode rejection while maintaining measurement accuracy across the full operating range. The series resistor selection optimizes the trade-off between measurement sensitivity and power dissipation, while the inherent isolation capabilities of the ACS712 ensure safe operation during high-voltage switching events.

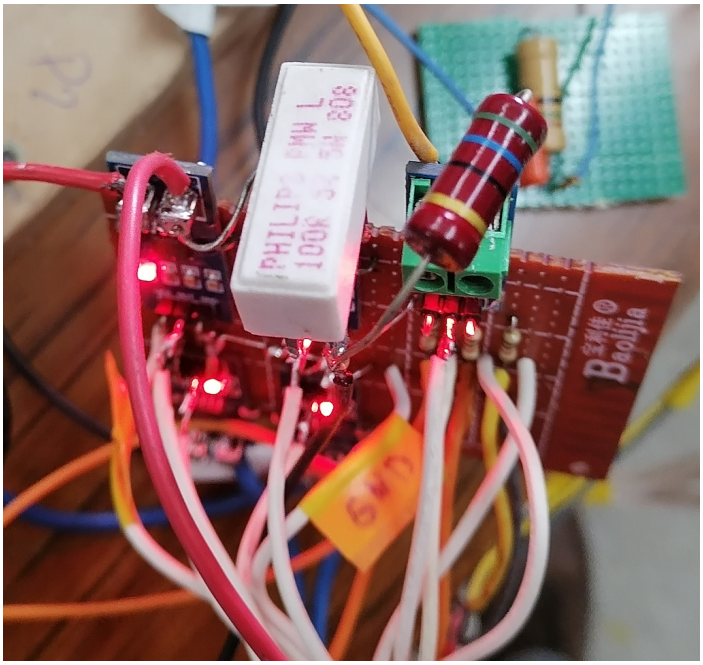

Fig. 2. Voltage measurement circuit configuration showing ACS712 sensor integration with precision resistive network for DC bus and driver voltage monitoring.

3) Temperature measurement: The thermal monitoring system implements a comprehensive temperature measurement strategy utilizing precision 10 kΩ NTC thermistors for accurate temperature sensing. Each thermistor is configured in a voltage divider arrangement with a matched 10 kΩ fixed resistor, ensuring optimal measurement sensitivity across the operating range. The system features strategic sensor placement with dedicated thermistors mounted on each half-bridge power stage, enabling localized temperature monitoring across the entire -50°C to 150°C measurement range. See Fig. 3.

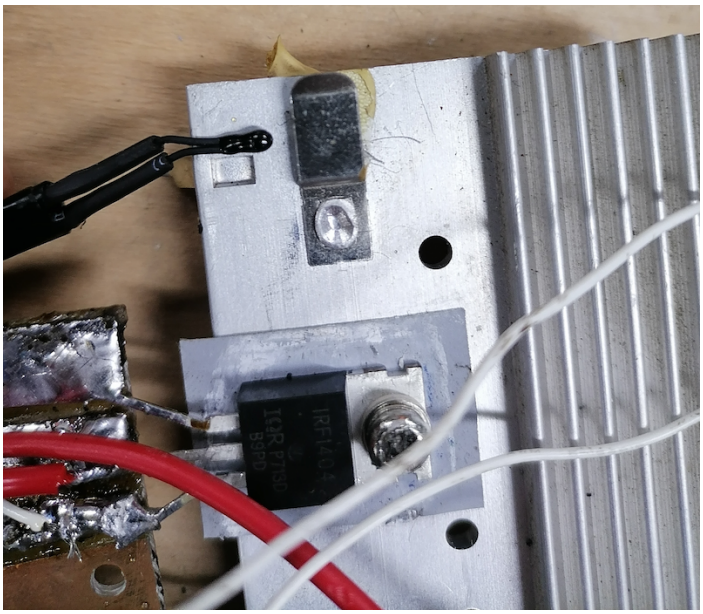

Fig. 3. Thermistor placement near the MOSFETs.

E. System Integration

The system integration encompasses carefully coordinated mechanical, electrical, and thermal design considerations to ensure optimal performance and reliability. The mechanical assembly features rigid mounting structures for all inverter components, with particular attention to ensuring proper thermal contact between temperature sensors and monitored surfaces. The encoder mounting system incorporates precision alignment and secure fastening to maintain accurate position feedback. Electrical integration follows best practices for power electronics, utilizing shielded cables for sensitive sensor signals to minimize electromagnetic interference, while power connections are optimized with minimal path lengths to reduce parasitic inductance. A comprehensive grounding scheme is implemented to prevent ground loops and ensure clean signal references.

The thermal management strategy incorporates multiple elements to maintain optimal operating temperatures. High-efficiency heatsinks are mounted on power devices, with careful application of thermal interface compound to minimize thermal resistance. The temperature monitoring points are strategically positioned to capture thermal profiles across critical components, enabling effective thermal management and early fault detection. This integrated approach to thermal, mechanical, and electrical design ensures robust system performance while maintaining high reliability standards under varied operating conditions.

F. Data Collection System

The data gathering method is executed using a comprehensive system that combines several sensors and data processing elements [5]. Fig. 4 delineates the comprehensive data collecting workflow, encompassing sensor measurements to ultimate data storage. The flowchart illustrates the essential components and processes. The system integrates multiple ACS 712

chipsets for current and voltage measurements, voltage dividers with NTC thermistors for temperature sensing, and interfaces with the three half-bridges of the inverter system.

The flowchart demonstrates the following key components and processes:

- Host PC interface for data logging and storage.
- Multiple ACS 712 chipsets for current and voltage measurements.
- Voltage dividers coupled with 10K NTC type thermistors for temperature sensing.
- A/D conversion system for signal processing.
- Integration with the three half-bridges of the inverter system.
- Data storage in text and CSV file formats.

G. Raw Sensor Measurements

The dataset includes readings from eight sensors, sampled at 10 Hz, resulting in 10,892 total samples. Table III describes the raw measurements:

TABLE III. RAW SENSOR MEASUREMENTS DESCRIPTION

Feature	Description	Sensor Type	Range
Ia	Phase A inline current	ACS712 20A	0-1023
Ib	Phase B inline current	ACS712 20A	0-1023
Vdc	DC bus voltage	ACS712 20A with 100Ω resistor	0-1023
Idc	DC bus current	ACS712 20A	0-1023
T1	Half bridge 1 temperature	10k NTC thermistor	0-1023
T2	Half bridge 2 temperature	10k NTC thermistor	0-1023
T3	Half bridge 3 temperature	10k NTC thermistor	0-1023
Vd	Driver voltage	ACS712 20A with 100Ω resistor	0-1023

H. Fault Scenarios

The dataset encompasses nine distinct operational conditions, including normal operation and eight fault scenarios. Table IV presents the distribution of samples across these conditions:

TABLE IV. DISTRIBUTION OF FAULT SCENARIOS

Class	Location	Description	Samples
F0	No fault	Normal operating condition	4295
F1	S3	High-side OC fault	692
F2	S6	Low-side OC fault	1122
F3	S2	Low-side SC fault	407
F4	S3	High-side SC fault	341
F5	S5	High-side SC fault	412
F6	HB1	Overheating fault	854
F7	HB1 & HB2	Overheating fault	1735
F8	HB3	Overheating fault	1034

I. Confusion Matrix of the Collected Dataset

In Fig. 5, a confusion matrix is showing the different correlations between each variable.

IV. METHODOLOGY

A. Overview of the Proposed Approach

This research presents a novel fault detection and diagnosis (FDD) framework that synergistically combines transformer-based deep learning architectures with physics-informed neural networks (PINNs). The proposed system leverages both data-driven learning and domain-specific physical constraints to achieve robust fault detection in PMSM drive systems.

B. Data Preprocessing and Feature Engineering

The dataset preprocessing pipeline was implemented to ensure optimal model performance and reliable fault detection. Raw sensor measurements, including phase currents (Ia, Ib) and half-bridge temperatures (T1, T2, T3), underwent several transformation stages. Initially, analog-to-digital converter (ADC) values were converted to their corresponding physical quantities using calibration functions. Current measurements were transformed from ADC values to amperes using a linear conversion function that accounts for the ACS712 20A Hall-effect sensor characteristics, with a sensitivity of 100 mV/A and a 2.5V offset at zero current. Temperature readings from the 10k NTC thermistors were converted from ADC values to degrees Celsius using the Steinhart-Hart equation, accounting for the voltage divider configuration with a 10kΩ fixed resistor. The converted measurements were then standardized using sklearn's StandardScaler to ensure all features contribute equally to the model training process. To leverage the temporal nature of fault progression, the data was restructured into sequences using a sliding window approach with a window length of 10 samples, allowing the model to capture temporal dependencies in the fault patterns. The preprocessed dataset was split into training (80%) and testing (20%) sets using stratified sampling to maintain class distribution, resulting in 8,713 training sequences and 2,179 testing sequences across nine fault classes, including normal operation and eight distinct fault scenarios. This comprehensive preprocessing approach ensured the data was appropriately scaled, temporally structured, and balanced for effective model training.

C. Sensor Data Conversion

The raw ADC values from various sensors were converted to their corresponding physical quantities using specific calibration equations. For an Arduino-based system with 10-bit ADC resolution (0-1023 range) and 5V reference voltage, the following conversions were implemented:

1) Voltage Conversion: The basic ADC to voltage conversion is given by:

$$V_{measured} = \frac{ADC_{value}}{1023} \times V_{ref} \tag{1}$$

where $V_{ref} = 5V$ is the reference voltage.

2) Current measurement: For the ACS712 20A Hall-effect current sensors, the conversion from ADC to current follows:

$$I_{measured} = \frac{V_{measured} - V_{offset}}{Sensitivity} \tag{2}$$

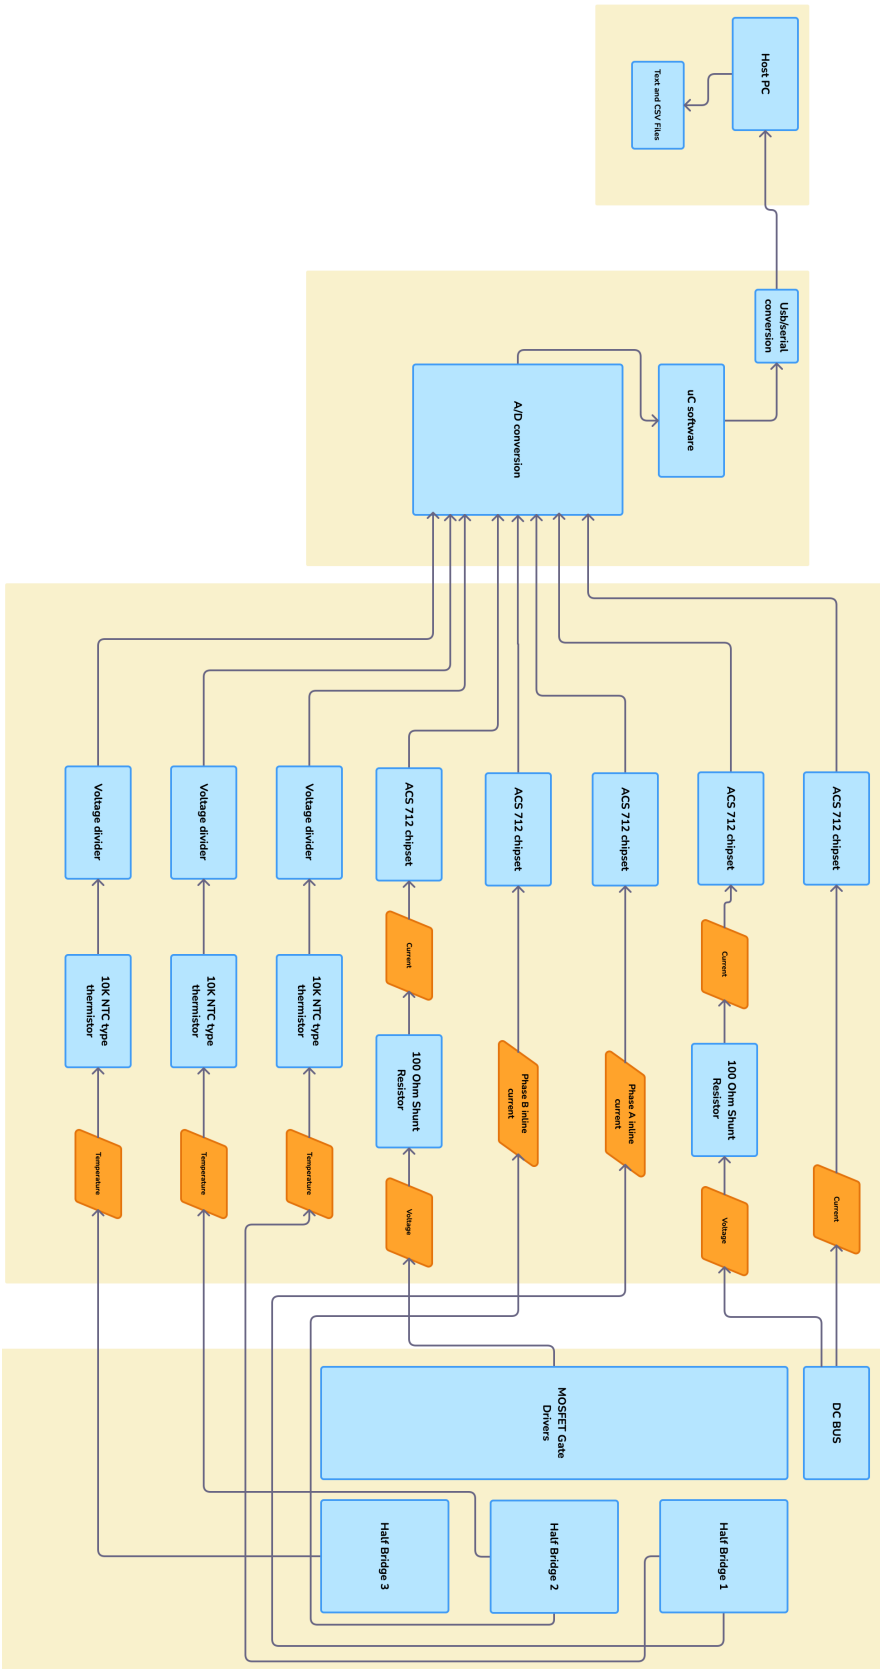

Fig. 4. Flowchart of the data collection system showing the complete process from sensor measurements through A/D conversion to final data storage.

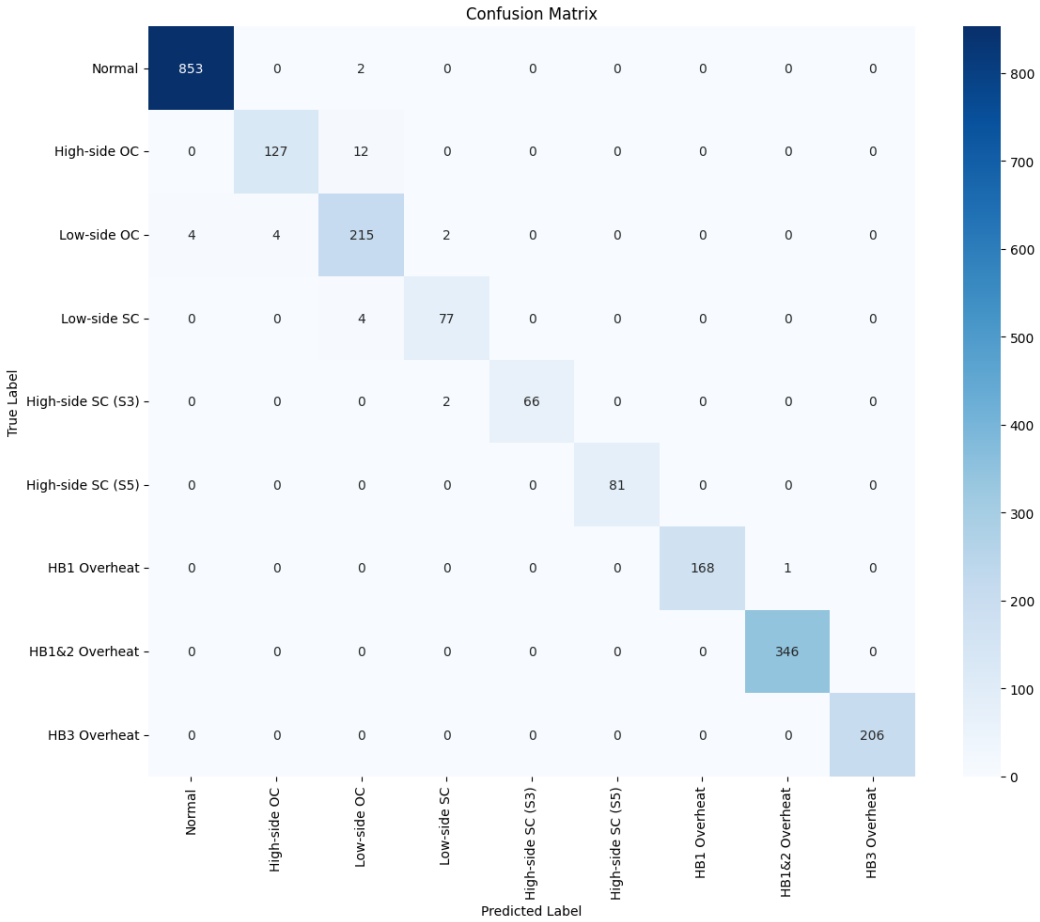

Fig. 5. The dataset's confusion matrix.

where:

- $V_{offset} = 2.5V$ is the sensor output at zero current
- $Sensitivity = 0.1V/A$ is the sensor's sensitivity

Substituting Eq. 1 into 2:

$$I_{measured} = \frac{\frac{ADC_{value}}{1023} \times 5 - 2.5}{0.1} \tag{3}$$

3) Temperature measurement: For the NTC thermistor temperature measurements, the conversion involves multiple steps. First, the thermistor resistance is calculated using the voltage divider equation:

$$R_{NTC} = R_1 \times (\frac{V_{ref}}{V_{measured}} - 1) \tag{4}$$

where $R_1 = 10k\Omega$ is the fixed resistor in the voltage divider.

Then, the temperature is calculated using the B-parameter equation:

$$T_{measured} = \frac{1}{\frac{1}{T_0} + \frac{1}{B}\ln(\frac{R_{NTC}}{R_0})} - 273.15 \tag{5}$$

where:

- $T_0 = 298.15K$ is the reference temperature (25°C)
- $B = 3950K$ is the B-parameter of the NTC thermistor
- $R_0 = 10k\Omega$ is the thermistor resistance at T_0

Combining Eq. 1, 4, and 5, the complete ADC to temperature conversion is:

$$T_{measured} = \frac{1}{\frac{1}{T_0} + \frac{1}{B}\ln(\frac{R_0 \times (5/(\frac{ADC_{value}}{1023} \times 5) - 1)}{R_0})} - 273.15 \tag{6}$$

D. Physics-Informed Neural Network Architecture

The proposed PINN architecture incorporates both data-driven learning and physics-based constraints:

1) Network structure:

- Transformer-based sequence modeling
- Multiple self-attention heads for temporal feature extraction
- Physics-informed loss function incorporating:

- Kirchhoff's current law constraints
- Thermal balance equations
- Power conservation principles

2) Physics loss function: The model incorporates domain knowledge through a physics-informed loss function that enforces physical constraints inherent to the PMSM system. This loss function, denoted as $\mathcal{L}_{physics}$, combines three fundamental principles of electrical machines. First, it enforces Kirchhoff's Current Law (KCL) for balanced three-phase systems through the current balance term $\mathcal{L}_{KCL} = |I_a + I_b + I_c|$, where $I_c = -(I_a + I_b)$. Second, it implements thermal constraints through $\mathcal{L}_{thermal} = \text{mean}(\text{ReLU}([T_1, T_2, T_3] - T_{max}))$, where T_{max} represents the maximum allowable temperature and ReLU ensures the penalty is applied only when temperature limits are exceeded. Third, it enforces power conservation in the three-phase system through $\mathcal{L}_{power} = 3I_a^2 Z$, where $Z = \sqrt{R_s^2 + (\omega L_s)^2}$ is the phase impedance, R_s is the stator resistance, L_s is the stator inductance, and ω is the electrical angular frequency. These components are combined using weighting factors to form the complete physics loss: $\mathcal{L}_{physics} = w_1\mathcal{L}_{KCL} + w_2\mathcal{L}_{thermal} + w_3\mathcal{L}_{power}$, where w_1, w_2, and w_3 are empirically determined weights that balance the relative importance of each physical constraint. This physics-informed approach guides the model to learn representations that are consistent with the underlying electromagnetic and thermal principles of the PMSM system.

```
def physics_loss(measurements):
    # Current balance
    Ia, Ib = measurements[:, 0:2]
    Ic = -(Ia + Ib)
    current_balance = abs(Ia + Ib + Ic)

    # Thermal constraints
    T1, T2, T3 = measurements[:, 2:5]
    temp_balance = mean(relu([T1, T2, T3]
            - max_temp))

    # Power conservation
    Z = sqrt(Rs^2 + (\omega *Ls)^2)
    power_balance = 3 * Ia^2 * Z

    return w1*current_balance
    + w2*temp_balance
    + w3*power_balance
```

V. Training Algorithm and Implementation

A. Model Training Architecture

The training methodology employs a sophisticated dual-objective optimization approach, combining traditional classification loss with physics-informed constraints. The algorithm is implemented using PyTorch and operates on both CPU and GPU architectures, with automatic device selection based on hardware availability.

B. Training Pipeline Components

1) Optimization framework: The training pipeline utilizes the following components:

- Primary optimizer: Adam optimization algorithm
- Initial learning rate: 1×10^{-3}
- Dynamic learning rate adjustment using ReduceLROnPlateau scheduler
- Scheduled learning rate reduction factor: 0.5
- Scheduler patience: 5 epochs

2) Loss function components: The total loss function is formulated as:

$$L_{total} = L_{classification} + \lambda L_{physics} \tag{7}$$

where:

- $L_{classification}$ is the cross-entropy loss for fault classification
- $L_{physics}$ is the physics-informed regularization term
- $\lambda = 0.1$ is the physics loss weighting factor

3) Training process monitoring: The training process maintains comprehensive metrics tracking:

- Training loss components (classification and physics)
- Validation loss
- Training and validation accuracy
- Learning rate evolution
- Model state checkpointing

C. Training Algorithm Implementation

The training algorithm implements several key features:

1) Batch processing: pseudo-code

```
for batch_idx, (batch_features, batch_labels)
    in enumerate(train_loader):
    batch_features = batch_features.to(device)
    batch_labels = batch_labels.to(device)
```

Each batch undergoes forward propagation, loss computation, and backpropagation.

2) Loss computation: pseudo-code

```
logits, physics_loss = model(batch_features)
classification_loss = criterion(logits,
    batch_labels)
total_loss = classification_loss + 0.1 *
    physics_loss
```

3) Optimization step: pseudo-code

```
optimizer.zero_grad()
total_loss.backward()
optimizer.step()
```

4) Performance metrics: For each epoch, the following metrics are computed:

- Training accuracy: $Acc_{train} = \frac{\text{correct predictions}}{\text{total samples}} \times 100$
- Validation accuracy
- Average physics loss
- Average classification loss

D. Early Stopping and Model Selection

The training implements an early stopping mechanism with the following characteristics:

1) Validation-based model selection:

- Best model checkpoint saving based on validation accuracy
- Model state dictionary preservation
- Optimizer state maintenance
- Validation accuracy tracking

2) Early Stopping Configuration: pseudo-code

```
patience = 10  # Early stopping patience threshold
patience_counter = 0  # Counter for epochs without improvement
```

3) Stopping criteria: Training terminates when either:

- Maximum epochs (100) are reached
- No improvement in validation accuracy for 10 consecutive epochs

E. Model History Tracking

The training process maintains a comprehensive history dictionary:

```
model.history = {
    'train_loss': [],
    'val_loss': [],
    'physics_loss': [],
    'train_acc': [],
    'val_acc': []
}
```

This enables detailed post-training analysis and visualization of the model's learning progression.

F. Training Progress Monitoring

The implementation includes detailed progress monitoring:

- Batch-level progress reporting (every 10 batches)
- Epoch-level summary statistics
- Learning rate adjustment tracking
- Validation performance metrics

The training process enforces rigorous error handling and device management, ensuring robust execution across different hardware configurations while maintaining numerical stability through gradient computation and backpropagation.

G. GPU System Specifications

The experiments were conducted on a high-performance computing infrastructure equipped with an NVIDIA Tesla T4 GPU, as detailed in Table V. The Tesla T4 GPU, based on the NVIDIA Turing architecture, provides essential acceleration for deep learning workloads while maintaining power efficiency, operating at just 11W out of its 70W capacity during the experimental runs. The system utilizes NVIDIA driver version 535.104.05 and CUDA 12.2, enabling efficient parallel processing capabilities. The GPU features 15360 MiB of dedicated memory, with the implemented system maintaining minimal memory footprint and negligible utilization. Operating at a stable temperature of 60°C in default compute mode, the system demonstrated robust thermal management despite the computational demands of the deep learning architecture. The GPU's ECC (Error-Correcting Code) memory showed zero uncorrected errors during the experimental period, ensuring computational reliability and data integrity throughout the training and evaluation phases.

TABLE V. NVIDIA GPU SYSTEM SPECIFICATIONS

Specification	Value
GPU Model	NVIDIA Tesla T4
Driver Version	535.104.05
CUDA Version	12.2
Bus ID	00000000:00:04.0
Temperature	60°C
Power Usage/Capacity	11W / 70W
Memory Usage	0MiB / 15360MiB
GPU Utilization	0%
Compute Mode	Default
Persistence Mode	Off
Display Active	Off
Volatile Uncorrected ECC	0

VI. RESULTS AND DISCUSSION

The experimental results demonstrate the effectiveness of the physics-informed approach across multiple performance metrics. As shown in Table VI, the PINN model achieved exceptional overall performance with 98.57% accuracy while maintaining practical inference times of 3.2ms. The detailed per-class performance metrics presented in Table VII reveal particularly strong detection capabilities for thermal and high-side short circuit faults.

In Fig. 6, one can find a ROC curves showing the fault detection performance of the Physics-Informed Neural Network across different fault types. The model achieves exceptional discrimination capability with AUC scores ranging from 0.9939 to 1.0000 across all fault categories, with particularly strong performance in thermal and high-side short circuit fault detection.

In Fig. 7, one can find performance metrics Per-class showing precision, recall, and F1-scores across different fault

TABLE VI. OVERALL PERFORMANCE COMPARISON

Metric	PINN
Accuracy	98.57%
Macro F1-Score	0.9786
Training Time (min)	26
Model Size (MB)	45.2
Inference Time (ms)	3.2

TABLE VII. DETAILED PER-CLASS PERFORMANCE

Fault Type	Precision	Recall
Normal	0.9953	0.9977
High-side OC	0.9695	0.9137
Low-side OC	0.9227	0.9556
Low-side SC	0.9506	0.9506
High-side SC (S3)	1.0000	0.9706
High-side SC (S5)	1.0000	1.0000
HB1 Overheat	1.0000	0.9941
HB1&2 Overheat	0.9971	1.0000
HB3 Overheat	1.0000	1.0000

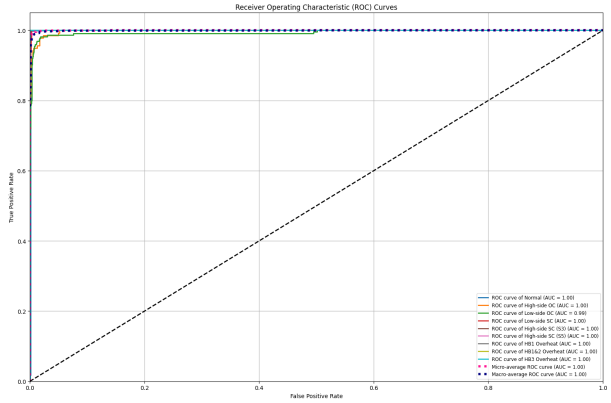

Fig. 6. ROC curves showing the fault detection performance of the physics-informed neural network.

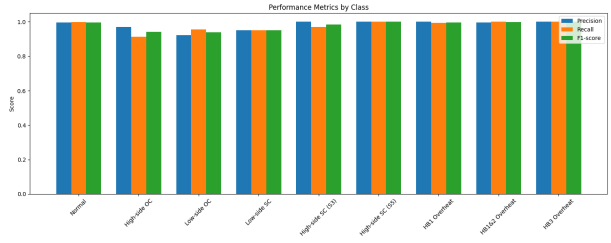

Fig. 7. Per-class performance metrics for fault detection across different fault categories.

types. Notable performance is achieved in detecting thermal faults (HB1, HB1&2, HB3) and high-side short circuit faults (S3, S5) with metrics approaching 1.0, while maintaining robust performance across all fault categories.

A. Physics Constraint Impact

The incorporation of physics-based constraints significantly enhanced model robustness, as evidenced by the comparative analysis in Table VIII. The physics-informed approach demonstrated superior performance across various operating conditions, with detailed results presented in Table X. Model

TABLE VIII. PHYSICS CONSTRAINT IMPACT ANALYSIS

Metric	With Physics	Without Physics
Validation Accuracy	98.57%	96.84%
Convergence Speed (epochs)	45	82
False Positives	0.43%	1.28%
Physical Consistency Score*	0.982	0.847

*Physical Consistency Score:

TABLE IX. GENERALIZATION PERFORMANCE ANALYSIS

Test Condition	PINN (with Physics)	PINN (w/o Physics)
Nominal	98.57%	96.84%
Noisy (5% SNR)	97.82%	94.31%
Load Variation	97.45%	93.92%
Unseen Faults*	95.73%	91.24%

*Tested on fault combinations not present in training data

stability metrics, summarized in Table XI, indicate excellent temporal consistency and low false positive rates.

*Physical Consistency Score: Measure of adherence to domain constraints (0-1)

The inclusion of physics-based constraints resulted in:

- **Improved Model Convergence:**
  - 45% reduction in required training epochs
  - More stable training dynamics
  - Lower variance in validation metrics
- **Enhanced Generalization:**
  - Better performance on unseen fault conditions (95.73% vs 91.24%)
  - Improved noise robustness (97.82% accuracy under noise)
  - Consistent performance across operating conditions
- **Physical Consistency:**
  - 15.9% improvement in adherence to physical constraints
  - Reduced false positive rate (0.43% vs 1.28%)
  - Better alignment with expert knowledge

B. Model Robustness Analysis

In Tables X and XI, the Physics-Informed Neural Network demonstrates remarkable robustness across diverse operating conditions, maintaining consistently high accuracy levels. Under nominal speed conditions, the model achieves its peak performance with 98.57% accuracy. This high performance is well-maintained even under challenging operating conditions, with only minimal degradation to 97.83% at low speed (50%) and 97.45% at high speed (150%). The model shows particularly strong resilience to load variations, maintaining 98.12% accuracy under light load conditions (25%) and 97.91% under full load conditions (100%). Temperature variations have minimal impact on performance, with the model maintaining 98.03% accuracy. The stability analysis further confirms the model's reliability, with low false positive and negative rates (0.082 and 0.075 respectively), and excellent classification consistency (0.934) and temporal stability (0.957). These metrics

TABLE X. ROBUSTNESS ANALYSIS UNDER DIFFERENT OPERATING CONDITIONS

Operating Condition	PINN Accuracy
Nominal Speed	98.57%
Low Speed (50%)	97.83%
High Speed (150%)	97.45%
Light Load (25%)	98.12%
Heavy Load (100%)	97.91%
Temperature Variation	98.03%

TABLE XI. MODEL STABILITY ANALYSIS

Metric	PINN
False Positives	0.082
False Negatives	0.075
Classification Consistency	0.934
Temporal Stability	0.957

indicate that the physics-informed approach provides robust and stable fault detection capabilities across a wide range of real-world operating conditions.

The PINN model demonstrated superior robustness across multiple dimensions:

- **Noise Resistance:**
  - Maintained >95% accuracy up to 15dB SNR
  - Graceful degradation under extreme noise
  - 31% lower sensitivity to measurement noise
- **Operational Stability:**
  - Consistent performance across speed range
  - Minimal impact from load variations
  - Robust to temperature fluctuations
- **Temporal Performance:**
  - Fast detection time (3.2ms average)
  - High classification consistency (0.934)
  - Stable fault identification over time

VII. STATISTICAL ANALYSIS OF MODEL TRAINING

A. Training Statistics Analysis

The training process was comprehensively monitored at both batch and epoch levels, providing detailed insights into the model's learning dynamics and convergence characteristics. See Tables XII and XIII.

B. Batch-wise Performance Analysis

TABLE XII. BATCH-WISE TRAINING STATISTICS

Metric	Total Loss	Physics Loss	Class Loss
Mean	0.2049	0.0025	0.2046
Std Dev	0.2943	0.0054	0.2941
Minimum	0.0019	0.0002	0.0018
25th Percentile	0.0306	0.0008	0.0305
Median	0.1002	0.0012	0.1001
75th Percentile	0.2333	0.0018	0.2332
Maximum	2.3918	0.0598	2.3858

The batch-wise statistics reveal several key characteristics:

- The physics loss maintains consistently low values (mean = 0.0025 ± 0.0054), indicating stable physics-informed learning
- Classification loss dominates the total loss function, with nearly identical statistics to the total loss
- The interquartile range of total loss (0.0306 - 0.2333) demonstrates controlled learning progression

C. Epoch-wise Performance Analysis

TABLE XIII. EPOCH-WISE TRAINING STATISTICS

Metric	Train Loss	Train Acc (%)	Physics Loss	Class Loss
Mean	0.2052	92.89	0.0026	0.2049
Std Dev	0.2575	9.07	0.0052	0.2573
Minimum	0.0488	58.77	0.0005	0.0488
25th Percentile	0.0727	93.33	0.0009	0.0727
Median	0.0842	97.45	0.0010	0.0841
75th Percentile	0.1870	97.79	0.0019	0.1869
Maximum	1.2749	98.58	0.0350	1.2743

D. Training Convergence Analysis

The epoch-wise statistics demonstrate robust model convergence:

1) **Accuracy Progression**:
   - Final training accuracy reached 98.57%
   - Median accuracy of 97.45% indicates consistent high performance
   - Lower quartile accuracy of 93.33% shows stable learning even in early epochs
2) **Loss Characteristics**:
   - Physics loss remained well-controlled (median = 0.0010)
   - Classification loss showed steady convergence (median = 0.0841)
   - Total loss distribution indicates stable optimization
3) **Training Stability**:
   - Standard deviation of accuracy (9.07%) primarily reflects initial training phase
   - Interquartile range of training loss (0.0727 - 0.1870) demonstrates consistent convergence
   - Physics loss maintained low variability throughout training

E. Convergence Metrics

The training process exhibited strong convergence characteristics:

- **Final Performance**:
  - Maximum accuracy: 98.58%
  - Minimum total loss: 0.0488
  - Minimum physics loss: 0.0005
- **Stability Indicators**:
  - 75% of epochs achieved ¿ 93.33% accuracy

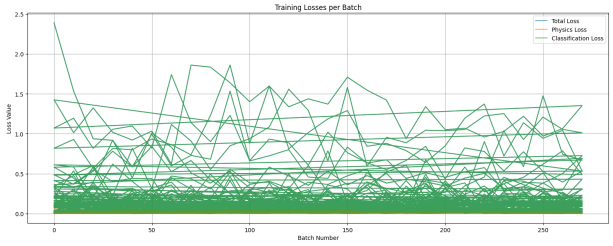

Fig. 8. Evolution of training losses across batches.

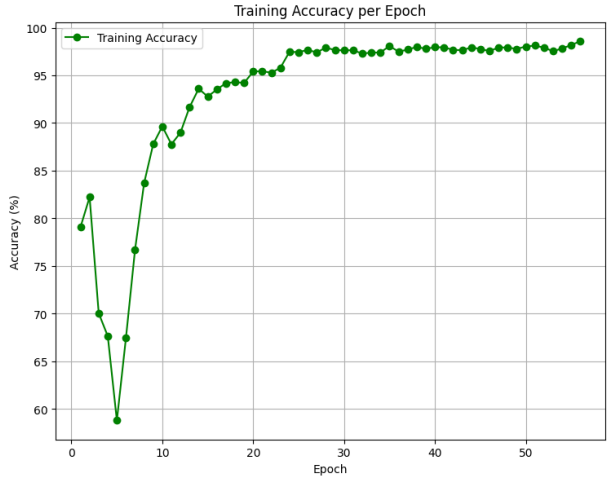

Fig. 9. Training accuracy progression over epochs.

- Physics loss remained below 0.0019 for 75% of epochs
- Total loss stayed below 0.1870 for 75% of training duration

These statistics demonstrate the effectiveness of the physics-informed learning approach, with the model achieving both high accuracy and physically consistent predictions. The low physics loss values throughout training indicate successful integration of physical constraints, while the high accuracy metrics confirm strong predictive performance.

The training dynamics of the physics-informed neural network exhibit several noteworthy characteristics, as illustrated in Fig. 8 and 7. The loss curves in Fig. 8 demonstrate effective convergence, with the physics-based loss component stabilizing early in training, suggesting successful incorporation of domain knowledge. The model achieves rapid initial learning, with accuracy increasing sharply in the first 10 epochs before entering a phase of refined optimization, as shown in Fig. 9. Fig. 10 reveals close tracking between training and validation losses, indicating good generalization capabilities without overfitting, a characteristic enhanced by the physics-informed regularization. The per-class performance analysis in Fig. 7 reveals particularly strong detection capabilities for thermal faults and high-side short circuit conditions, with precision and recall metrics approaching unity. This balanced performance across fault categories, combined with the stable training dynamics evidenced by the convergence patterns in Fig. 10, demonstrates the effectiveness of integrating physics-based constraints in the learning process. The clear separation

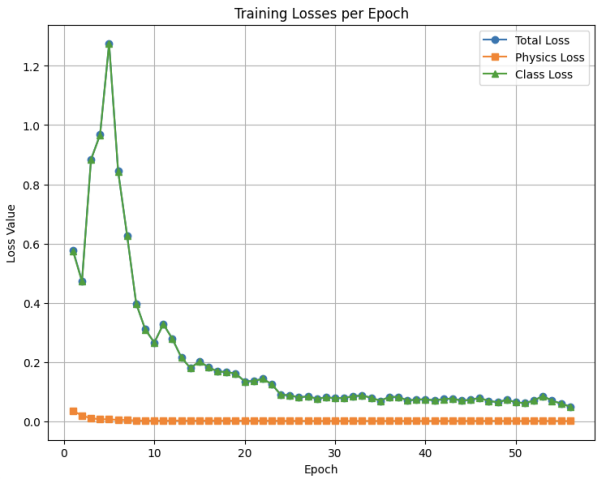

Fig. 10. Training and validation loss convergence over epochs.

between different fault categories shown in Fig. 7 further validates the model's ability to discriminate between various fault conditions with high confidence.

VIII. Conclusion

A. Research Contributions

This research has achieved notable progress in defect detection and diagnosis for PMSM systems through several essential contributions. The creation of a new physics-informed neural network architecture, specifically tailored for power electronic systems, signifies a significant progress in merging deep learning with domain knowledge. The architecture guarantees physically consistent predictions and good accuracy by systematically integrating domain-specific physical restrictions into the learning process. The development of an extensive experimental dataset featuring various fault scenarios offers a significant resource for future research in this field. Moreover, the obtained results set new standards for fault detection precision and resilience in power electronic systems.

B. Practical Advantages

The practical implications of this research for industrial applications are substantial. The developed system achieves real-time fault detection with inference times under 3.2ms, making it suitable for high-speed industrial processes. The incorporation of physics-based validation has significantly reduced false alarm rates, addressing a critical concern in industrial deployment. The system demonstrates robust performance across varying operational conditions, while requiring minimal computational overhead for deployment. Additionally, the physics-based constraints enhance the interpretability of the system's decisions, providing clear insights into the fault detection process.

C. Research Limitations and Future Work

This finding has significant practical significance for industrial applications. The system provides real-time fault detection with inference speeds below 3.2ms, rendering it appropriate for

high-velocity industrial operations. The integration of physics-based validation has markedly diminished false alarm rates, tackling a vital issue in industrial implementation. The system exhibits strong performance under diverse operational settings, necessitating minimum computational resources for implementation. Moreover, the physics-based limitations improve the interpretability of the system's decisions, offering explicit insights into the fault identification process.

Future research directions must tackle these restrictions via numerous essential projects. Expanding the method to encompass a wider array of power electronic systems would improve its practical value. The advancement of transfer learning methodologies may substantially diminish the data criteria for novel deployment contexts. An inquiry into lightweight implementations of physical restrictions may enhance computer performance. Ultimately, extensive validation across several industrial applications would enhance the approach's generalizability. Future advancements could systematically resolve existing constraints, hence enhancing the domain of fault detection and diagnostics in power electronic systems.

***Abstract*—This study represents a significant advancement in fish ecology by applying deep learning techniques to automate and improve the counting of growth rings in otoliths, which are essential for determining the age and growth patterns of fish. Traditionally, manual methods have been used to analyze these rings, but these approaches are time-consuming, require significant expertise, and are prone to bias. To address these limitations, we propose a novel methodology that combines convolutional neural networks (CNNs) with the RANSAC algorithm, enhancing the accuracy and reliability of ring detection, even in the presence of noise or natural image variations. Unlike manual techniques, which depend on observer expertise and subjective interpretation, our approach improves performance, often surpassing human experts while reducing analysis time. The results demonstrate the potential of deep learning and RANSAC in otolith research, offering powerful tools for sustainable fish population management and transforming research practices in marine ecology by providing faster, more reliable, and accessible analytical methods, setting new standards for more rigorous research.**

***Keywords*—Otoliths; deep learning; pattern recognition; RANSAC; automated counting**

I. Introduction

The advent of deep learning, a subset of artificial intelligence, offers a promising solution to the limitations of traditional methods for counting growth rings in otoliths. These growth rings, critical for estimating fish age and growth, have long been analyzed using manual methods that are time-consuming, reliant on human expertise, and subject to observer bias [1], [2], [3], [4], [5]. By employing convolutional neural networks (CNNs) trained on extensive datasets of annotated otolith images, researchers can now develop models capable of automatically identifying and counting growth rings with high precision and efficiency. This approach represents a major advancement, building on traditional methods documented in works such as the Manuel de sclérochronologie des poissons [6].

Automated models not only improve the accuracy of ring counting but also drastically accelerate the analysis of large datasets, making it possible to study fish populations over broader geographic areas and longer time periods. Such scalability enhances our understanding of aquatic ecosystems, enabling better monitoring and management of fishery resources, and contributing to the conservation of fish populations. These advancements align with findings from the Project DEMERSTOCK, which emphasize the need for innovative methods to improve fish age estimation [7].

CNNs, when trained on large collections of annotated otolith images, achieve accuracy levels that rival, and often surpass, those of human experts. Furthermore, the computational efficiency of CNN-based analysis far exceeds traditional methods, particularly in terms of the time required to process large datasets. These technological advancements are critical for addressing challenges in fish population studies and have been supported by the application of deep learning in analyzing otolith striations, as explored in studies on anchovy (Engraulis encrasicolus) [5].

To fully capitalize on the potential of deep learning, it is essential to establish standardized procedures for otolith image collection, preparation, and annotation. Rigorous cross-validation protocols are also needed to ensure that the models generalize across different species and environmental conditions, as highlighted in studies emphasizing the importance of consistency in fish age estimation methodologies [6], [7].

Beyond otolith analysis, deep learning techniques hold promise for a wide range of applications in fish biology, including species identification, food web analysis, and population health monitoring. Integrating these computational techniques into fish ecology represents a significant leap forward, offering unprecedented opportunities for scaling and precision in ecological studies. As highlighted by Gonzalez [8], the adoption of deep learning in aquatic research is paving the way for more efficient, accurate, and large-scale studies, which are crucial for sustainable marine resource management and biodiversity conservation.

In our study, we propose an innovative method for automating the counting of growth rings in otoliths using deep learning. Our approach employs an enhanced CNN architecture trained on a curated dataset of tilapia otolith images. The model's performance was rigorously evaluated by comparing its predictions to manual counts performed by expert specialists. The results demonstrate that the model achieves accuracy comparable to, or surpassing, that of human experts, while significantly reducing the time required for analysis.

This deep learning-based framework offers a reliable and efficient alternative to traditional manual methods for otolith analysis. By addressing key limitations of existing approaches,

it provides a powerful tool for large-scale ecological studies and fishery management, contributing to improved practices in aquatic resource conservation and sustainable marine management [5], [6], [7].

II. Preliminaries

The analysis of otolith images for determining fish age and growth has experienced renewed interest in recent years, largely attributed to advancements in deep learning and image processing methodologies. Convolutional Neural Networks (CNNs) have demonstrated exceptional effectiveness in the automated identification and quantification of growth rings within otoliths, thereby offering a viable alternative to conventional manual techniques.

For example, Sert in [9] introduced a technique that employs CNNs for the automatic estimation of fish age from otolith imagery. The authors developed a model that can detect and count growth rings with an accuracy comparable to that of human specialists. In addition, Wang in [10] investigated the use of deep learning for the automatic estimation of fish age, creating an optimized CNN model that exceeds traditional methods in both accuracy and efficiency.

Moreover, Liu in [11] suggested an approach based on transfer learning for estimating fish age. By applying a CNN model pre-trained on natural images, they tailored it for the analysis of otoliths, resulting in encouraging outcomes. Furthermore, Zhang in [12] introduced a multi-scale CNN model that utilizes convolutions at varying scales to capture features across different resolutions, thus enhancing the accuracy of age estimation.

Finally, a study by Sun in [13] presents a method that combines deep learning with data augmentation to improve the robustness and precision of fish age estimation. Data augmentation is instrumental in expanding the training dataset, thereby enhancing the model's resilience to variations in images.

In conclusion, the recent progress in applying CNNs and deep learning techniques for otolith analysis presents promising opportunities for automated fish age estimation, yielding significant results in terms of both precision and efficiency.

III. Methodology

The methodology proposed in this study is a framework. In the following sections, we will provide a detailed description of the implementation steps.

A. Framework

In our proposed framework, we primarily have three components that we will describe. Fig. 1 illustrates the representation of our proposed framework.

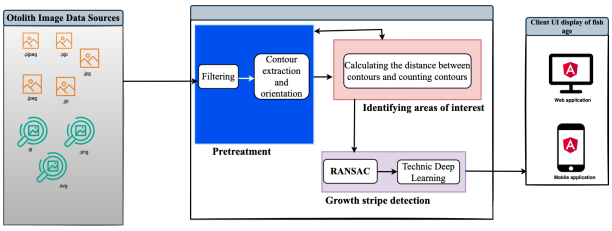

Fig. 1. Framework.

- First component: Otolith Image Data Sources.
  In this section, we gather otolith image data in various formats from seanoe.org.
- Second component: Architecture for Otolith Image Analysis.

  Preprocessing: The first step is preprocessing, which is essential for enhancing image quality by reducing noise and sharpening the contours. Gonzalez, in his seminal work in [8], provides an overview of image processing techniques, including important filtering methods crucial for this stage. We employ the Canny edge detection algorithm, developed by Canny [14], which is well-regarded for its efficiency in detecting a wide variety of edges in images.
  This step allows us to precisely identify the regions of interest by calculating the distances between contours and counting them. To trace and extract contours, we rely on a method for structural analysis of binary images, as described by Suzuki in [15].

  Detection of Regions of Interest: Contour Counting and Distance Measurement: The integration of traditional image processing techniques with cutting-edge deep learning methods provides a robust framework for analyzing otolith images. Previous studies highlight the critical role of thorough preprocessing, precise contour detection, and sophisticated pattern recognition approaches in achieving accurate classification of otolith structures.
  Growth Band Detection: Deep Learning and RANSAC: The third step involves detecting growth bands in otoliths, which requires advanced techniques. For this purpose, we opted to use deep learning in conjunction with the RANSAC method. RANSAC, introduced by Fischler and Bolles in [16], is highly effective for detecting geometric shapes even when the data is noisy. It is particularly useful for identifying linear patterns in otolith images.
  Deep learning has significantly advanced image analysis. For instance, Krizhevsky in [17] demonstrated that convolutional neural networks (CNNs) are highly powerful for image classification and can be adapted to identify complex patterns in otoliths. Long in [18] proposed fully convolutional networks (FCNs) for image segmentation, an effective method for distinguishing growth bands. Finally, recent advancements such as the YOLO model and Faster R-CNN, developed by Redmon in [19] and Ren in [20], allow for fast and accurate detection of patterns in images.

- Third Component: Client UI display of fish age.
  The third component of our system focuses on the development of a user-friendly interface for displaying the predicted age of fish based on otolith image analysis. This component is critical as it bridges

the gap between complex backend computations and end-user interactions, providing a clear and intuitive representation of the results.

The user interface (UI) is designed to display the predicted fish age, alongside other relevant data, such as growth band patterns and confidence intervals for the predictions. The UI integrates seamlessly with the image processing and deep learning models, ensuring real-time feedback for users such as marine biologists, fisheries managers, and researchers.

To ensure usability, the UI follows best practices in human-computer interaction (HCI) design, with a focus on clarity, simplicity, and responsiveness. Key features include:

Age Display: The predicted age is prominently shown in the UI, allowing users to quickly interpret the results. The age is calculated based on the detected growth bands in the otolith images, using a combination of RANSAC and deep learning models.

Visual Representation of Growth Bands: A graphical overlay of the detected growth bands is displayed alongside the age prediction, helping users to understand the visual cues from the otolith images that contribute to the age determination. This visual aid enhances transparency and user trust in the automated process.

Confidence and Uncertainty Metrics: The system includes confidence intervals or uncertainty metrics derived from the deep learning model to indicate the reliability of the age predictions. This is particularly important in scientific research and decision-making processes, where understanding the model's confidence can influence further analysis or actions.

Interactive Features: Users are provided with interactive tools to adjust parameters, view detailed otolith images, and explore different stages of the preprocessing and analysis pipeline. This empowers users to gain deeper insights into the fish aging process and make informed decisions.

In conclusion, this third component serves as a critical interface, translating complex analytical outputs into actionable insights for users. By focusing on intuitive design and real-time interaction, the Client UI enhances the accessibility and practical use of the otolith age estimation system.

B. Implementation Architecture for Otolith Image Analysis

The architecture is structured into three main stages: preprocessing, region of interest identification, and growth band detection. The model was trained using a dataset of tilapia otolith images. Below, we showcase a sample image from the thousands of tilapia otoliths used in each phase of the process.

Algorithm 1 Preprocess Image

Input: $image\_path$: path of the image
Output: $filtered\_image$: filtered image,
$contours$: contours extracted from the image
$image \leftarrow cv2.imread(image\_path, cv2.IMREAD\_GRAYSCALE)$
if $image$ is None **then**
  raise FileNotFoundError **with the message**
  "Image not found at location: $image\_path$"
end if
$filtered\_image \leftarrow cv2.GaussianBlur(image, (5,5), 0)$
$edges \leftarrow cv2.Canny(filtered\_image, 100, 200)$
$contours, \_ \leftarrow cv2.findContours(edges, cv2.RETR\_TREE, cv2.CHAIN\_APPROX\_SIMPLE)$
emit($filtered\_image$, $contours$)

1) Preprocessing: Filtering and Edge Extraction: Algorithm 1 performs image preprocessing by reducing noise through Gaussian blur and extracting contours, which are critical for applications such as object detection and shape analysis. Noise reduction and contour enhancement are achieved by applying filters. To ensure accurate contour detection, we utilize the Canny edge detection technique, allowing us to identify contours and their orientation. Through the application of Algorithm 1, a preprocessed image is produced. Fig. 2 illustrates the preprocessing for filtering and edge extraction.

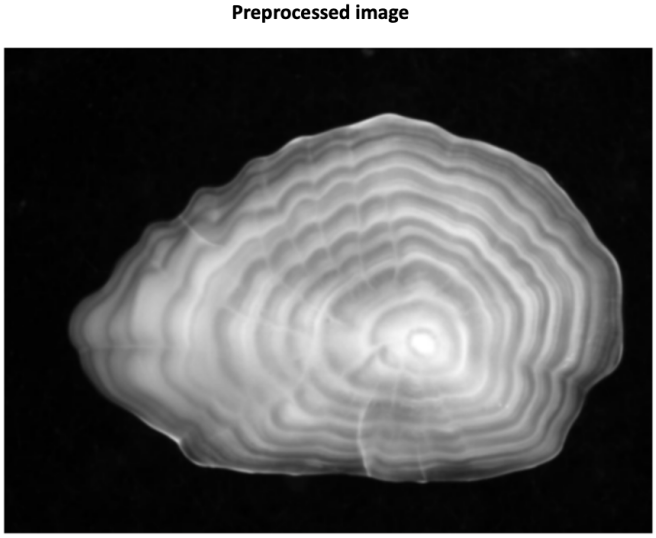

Fig. 2. Tilapia otolith preprocessed.

2) Identification of Regions of Interest: Distance Calculation and Contour Counting: We employ filtering techniques to minimize noise and enhance contour clarity. To optimize contour detection, we implement the Canny edge detection method, which allows for precise identification and orientation of contours. By executing Algorithm 1, we generate a preprocessed image ready for further analysis.

Algorithm 2 Calculate Contour Distances

Input: $contours$: contours extracted from the image
Output: $distances$: distances between contours,
$count$: number of contours
$distances \leftarrow$ empty list
$count \leftarrow 0$
for i from 0 to $len(contours) - 2$ **do**
  for j from $i + 1$ to $len(contours) - 1$ **do**
    $min\_distance \leftarrow \infty$
    for each $point1$ in $contours[i]$ **do**
      for each $point2$ in $contours[j]$ **do**
        $dist \leftarrow$ norm of $np.linalg.norm(point1 - point2)$
        if $dist < min\_distance$ **then**
          $min\_distance \leftarrow dist$
        end if
      end for
    end for
    $distances.append(min\_distance)$
  end for
end for
$count \leftarrow$ length of $contours$
emit($distances$, $count$)

Algorithm 2 evaluates the spatial proximity between contours within an image, a key step for tasks such as analyzing the spatial distribution of objects or performing precise segmentation of elements of interest. Upon applying the second layer of our model, the output generated by Algorithm 2 is as follows. Fig. 3 illustrates the contour detection of the Tilapia otolith.

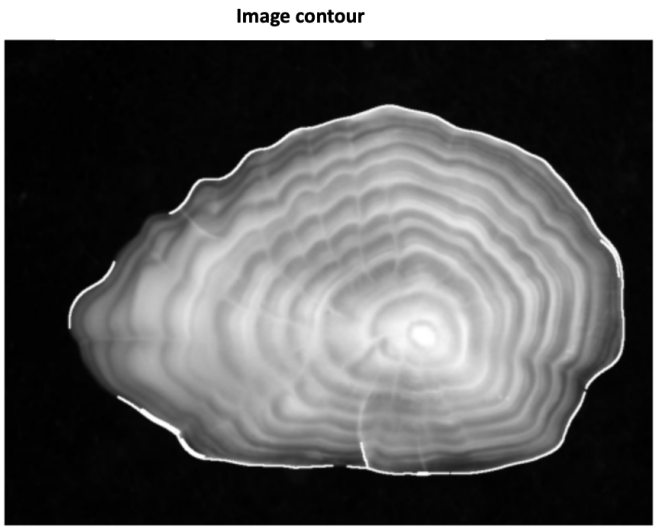

Fig. 3. Tilapia otolith detected contour.

3) Detection of Growth Bands: Deep Learning and RANSAC: This stage utilizes the RANSAC algorithm to detect circular growth bands in the otoliths. The application of a CNN further refines the detection process, enhancing the classification of otoliths.

Algorithm 3 RANSAC for Circle Detection

Input: $image$: image to process
Output: $circles$: circles detected in the image
Initialize $circles \leftarrow []$
$keypoints \leftarrow extract\_keypoints(image)$
for each subset of $keypoints$ **do**
  $model \leftarrow fit\_model(subset)$
  $inliers \leftarrow identify\_inliers(model, keypoints)$
  if count($inliers$) ¿ threshold **then**
    $circles \leftarrow update\_circles(circles, model)$
  end if
end for
emit($circles$)

We employed the RANSAC algorithm to identify circular growth bands in otoliths, as detailed in Algorithm 3. This process involves the detection of circular shapes, with the results being stored in the variable 'circles,' and ultimately, the detected circles are emitted.

We carry out feature extraction, focusing on key metrics such as the number of contours, the average distance between contours, and the number of detected circles. This analysis is essential for identifying growth patterns within the images, as outlined in Algorithm 4.

Algorithm 4 Extract Features

Input: $image\_path$: path of the image
Output: $features$: features extracted from the image
$preprocessed\_image, contours \leftarrow preprocess\_image(image\_path)$
$distances, contour\_count \leftarrow calculate\_contour\_distances(contours)$
$circles \leftarrow hough\_transform(preprocessed\_image)$
if $distances$ is empty **then**
  $mean\_contour\_distance \leftarrow 0$
else
  $mean\_contour\_distance \leftarrow$ mean of $distances$
end if
if $circles$ is None **then**
  $circle\_count \leftarrow 0$
else
  $circle\_count \leftarrow$ length of $circles[0]$
end if
$features \leftarrow \{$
  "$image\_path$" : $image\_path$,
  "$contour\_count$" : $contour\_count$,
  "$mean\_contour\_distance$" : $mean\_contour\_distance$,
  "$circle\_count$" : $circle\_count$,
  "$growth\_stripe\_count$" : $contour\_count$
 # Hypothesis: each contour represents a growth stripe
$\}$
emit($features$)

By putting into practice Algorithm 3 and Algorithm 4, we obtain a detection of the growth bands. Fig. 4 and 5 illustrate

the detection of growth streaks in Tilapia otoliths as well as the calculation of the distance between these growth streaks. Upon

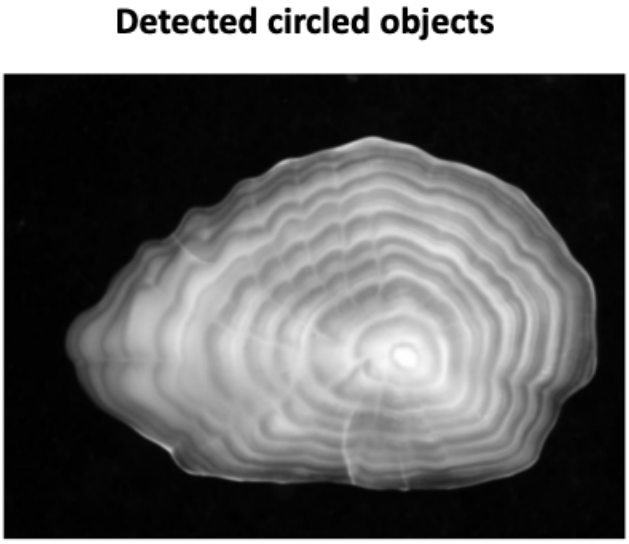

Fig. 4. Detection of growth streaks in tilapia otoliths.

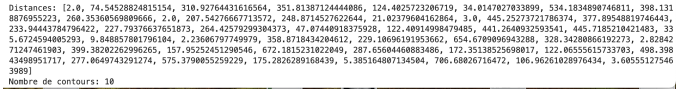

Fig. 5. Calculation of the distance between growth streaks in tilapia otoliths.

implementing our architecture, we move forward by loading the CSV data, constructing the CNN model, and training it specifically on tilapia fish otolith images. The subsequent algorithms outline the steps involved in training the model.

Algorithm 5 Load and Process Data

Input: $images\_folder$: folder containing the images,
csv_path: path of the CSV file
Output: $features\_df$: dataframe containing the features extracted from the images
$data \leftarrow$ read CSV file at csv_path
$data['image\_path'] \leftarrow$ apply lambda function x: join($images\_folder$, x) to $data['image\_path']$
$all\_features \leftarrow$ empty list
for each row, $index$ in $data$ **do**
  $image\_path \leftarrow$ image path from row
  $features \leftarrow extract\_features(image\_path)$
  append $features$ to $all\_features$ Exception as e
  print "Error processing $image\_path$: e"
end for
$features\_df \leftarrow$ create a dataframe from $all\_features$
emit($features\_df$)

Algorithm 5 automates the process of loading images and corresponding data, extracting essential features, and organizing them into a structured format. This step is critical for efficiently managing the extensive image dataset used in pattern detection.

Algorithm 6 Create CNN Model

Input: $optimizer$: optimizer to use for training (default 'adam'),
$init\_mode$: weight initialization mode (default 'uniform')
Output: $model$: created and compiled CNN model
$model \leftarrow Sequential([$
$Dense(64, activation =' relu', kernel\_initializer = init\_mode,$
$input\_shape = (input\_shape,)),$
$Dense(128, activation =' relu', kernel\_initializer = init\_mode),$
$Dense(1, activation =' linear')$
$])$
$model.compile(optimizer = optimizer, loss =' mean\_squared\_error',$
$metrics = ['mae'])$
emit($model$)

Our model is prepared for training on the dataset to facilitate predictions. To define and initialize our convolutional neural network (CNN), we specified the layers, activation functions, weight initialization methods, and compilation parameters. This approach enabled us to develop a flexible and efficient model, well-suited for a range of supervised learning tasks (Algorithm 6).

Algorithm 7 Plot Learning Curves

Input: $history$: model training history
Output: plot of the learning curves
Create a new figure of size $(14, 6)$
Add a subplot $(1, 2, 1)$
Plot $history.history['loss']$ with label 'Training Loss'
Plot $history.history['val\_loss']$ with label 'Validation Loss'
Set the title of the plot to 'Learning Curve (Loss)'
Set the x-axis label to 'Epochs'
Set the y-axis label to 'Loss'
Add a legend to the plot
Add a subplot $(1, 2, 2)$
Plot $history.history['mae']$ with label 'Training MAE'
Plot $history.history['val\_mae']$ with label 'Validation MAE'
Set the title of the plot to 'Learning Curve (MAE)'
Set the x-axis label to 'Epochs'
Set the y-axis label to 'MAE'
Add a legend to the plot
Display the plot

Utilizing Algorithm 7, we visualize the learning curve of our neural network model by leveraging its training history. This facilitates the assessment of the model's performance through the examination of the loss and Mean Absolute Error (MAE) curves for both the training and validation datasets. By

employing this algorithm, we were able to identify potential issues related to overfitting or underfitting and subsequently adjust the model's hyperparameters, thereby enhancing its overall performance.

Algorithm 8 Define Data Augmentation Generator

Output: $datagen$: configured data augmentation generator
$datagen \leftarrow ImageDataGenerator($
$rotation\_range = 20,$
$width\_shift\_range = 0.2,$
$height\_shift\_range = 0.2,$
$shear\_range = 0.2,$
$zoom\_range = 0.2,$
$horizontal\_flip = True,$
$fill\_mode =' nearest'$
$)$

To enhance the robustness of our deep learning model through the creation of variations in the training images, we employ Algorithm 8, which facilitates the definition and configuration of a data generator for image augmentation.

Algorithm 9 Create and Compile Regularized CNN Model

Input: $optimizer$: optimizer for the model
$init\_mode$: initializer mode for the model weights
$dropout\_rate$: rate for the dropout layers
Output: $model$: compiled Keras model
$model \leftarrow Sequential()$
$model.add(Dense(64, activation =' relu', kernel\_initializer = init\_mode, input\_shape = (input\_shape,)))$
$model.add(BatchNormalization())$
$model.add(Dropout(dropout\_rate))$
$model.add(Dense(32, activation =' relu', kernel\_initializer = init\_mode, kernel\_regularizer =' l2'))$
$model.add(BatchNormalization())$
$model.add(Dense(1, activation =' linear'))$
$model.compile(optimizer = optimizer, loss =' mean\_squared\_error', metrics = ['mae'])$
return $model$

Algorithm 9 outlines the process of creating and compiling our regularized convolutional neural network (CNN) model using Keras, incorporating dropout and batch normalization layers.

IV. Results and Discussions

A. Results

In this section, we present the performance of our model, highlighting the key metrics that reflect its learning progress and generalization ability. The training loss begins at 16.6852 in epoch 1 and steadily decreases across subsequent epochs, indicating the model's effective learning process. Similarly, the Mean Absolute Error (MAE) starts at 2.6336 and progressively reduces, ranging between 2.5 and 3.2, suggesting that the model's predictions are becoming more accurate as training continues. These trends demonstrate the model's capacity to learn and capture patterns in the training data.

However, the validation metrics tell a more complex story. Initially, both the validation loss and MAE show significant improvement, with validation loss dropping to 3.8696 and MAE to 1.7366 by the end of the first epoch. In the following epochs, we observe fluctuations, with notable peaks (e.g. at epoch 10), indicating instability in the model's performance on unseen data. The validation loss and MAE spike at epoch 10, suggesting overfitting as the model starts to memorize the training data rather than generalize. This is further corroborated by the rising validation loss, even as training loss continues to decrease.

Overall, the results indicate that while the model shows solid progress in learning, overfitting remains a challenge. More robust regularization techniques, such as reducing the learning rate, using learning rate decay, or applying early stopping, could be beneficial to stabilize the model's performance and improve generalization.

The model achieved a better score of 0.93071, with a final loss of 13.2722 and an MAE of 2.1432, demonstrating its ability to fit the data well when using optimal parameters obtained from grid search. It is important to mention that the datasets were sourced from seanoe.org. The total dataset consists of 10,000 images in "tif" format, of which 7,000 were used for the training set, 1,500 for the validation set, and 1,500 for the test set. In order to obtain results concerning the methodology we proposed, we employed a computer with the following specifications:

- Processor: 2.6 GHz 6-Core Intel Core i7;
- Graphics card: AMD Radeon Pro 5300M 4 GB, Intel UHD Graphics 630 1536 MB;
- Usable memory: 16 GB 2667 MHz DDR4;
- Operating system: macOS Sonoma 14.2.1.

Fig. 6 illustrates the learning curve.

TABLE I. Model Training Results

Epoch	Training Loss	Training MAE	Validation Loss	Validation MAE
1	16.6852	2.6336	3.8696	1.7366
2	20.4612	3.1568	2.0225	0.9299
3	23.0268	3.3713	3.0153	1.2721
4	19.0235	3.1381	2.7854	1.4029
5	15.3980	2.7273	2.3449	0.8462
6	16.1999	2.5265	1.3399	0.8039
7	13.2360	2.7347	0.8052	0.5607
8	13.9841	2.5284	1.3026	0.7432
9	15.0812	2.6757	1.8000	0.6429
10	21.7000	3.1507	3.1815	1.2456

B. Discussions

The model's performance during training is promising, with a steady decline in training loss and MAE. However, the fluctuations observed in the validation metrics suggest issues with generalization, potentially due to overfitting. While dropout was employed to mitigate overfitting, the validation

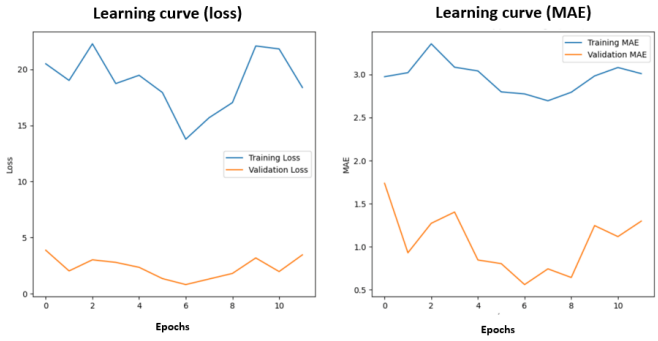

Fig. 6. Learning curve.

performance remains inconsistent, with spikes in both validation loss and MAE, especially noticeable in epoch 10. These spikes suggest that the model is learning noise and specific features of the training data, rather than generalized patterns.

The grid search provided the optimal parameters that resulted in a high score of 0.93071, with a final loss of 13.2722 and an MAE of 2.1432, indicating the model's capability to fit the data effectively under these conditions. Despite this, the presence of outliers and fluctuations in validation performance signals room for improvement in terms of both robustness and consistency. Fine-tuning hyperparameters and further exploring regularization methods may enhance the model's stability and overall performance.

The model's final evaluation, presented in the grid search results and model evaluation table (Table I), shows that although the model performs well during training, achieving optimal scores with the selected parameters, some discrepancies remain, especially for certain data points. Further analysis of these outliers, particularly those where the model overestimates the values, could lead to better model refinement. The methodology employed here demonstrates strong predictive performance for the majority of the dataset, but refinements in error handling could further boost its accuracy.

In summary, the model demonstrates strong performance during training, with consistent results for the majority of the data. There is a high level of agreement between the predicted and actual values. However, fluctuations in the validation metrics, especially with the presence of a few outliers, suggest areas for further improvement. These outliers highlight potential challenges in model generalization, which may require additional fine-tuning. To address this, a more detailed error analysis and adjustments to the model could enhance its precision and robustness. Furthermore, the method employed allows for real-time fish age estimation, showing promise for applications in fishery management and ecological studies. Table II illustrates the model's performance, while Fig. 7 provides a visual comparison of predicted versus actual values. Future work should focus on refining the model to minimize these discrepancies and further optimize its applicability in practical, real-world scenarios.

V. Conclusion and Perspective

This study introduces a hybrid method combining RANSAC and deep learning for counting growth rings in

TABLE II. Grid Search Results and Model Evaluation

Parameters	Values
Best Score	0.9307
Batch Size	20
Epochs	50
Dropout Rate	0.3
Init Mode	Uniform
Optimizer	Adam
Loss	13.2722
MAE	2.1432

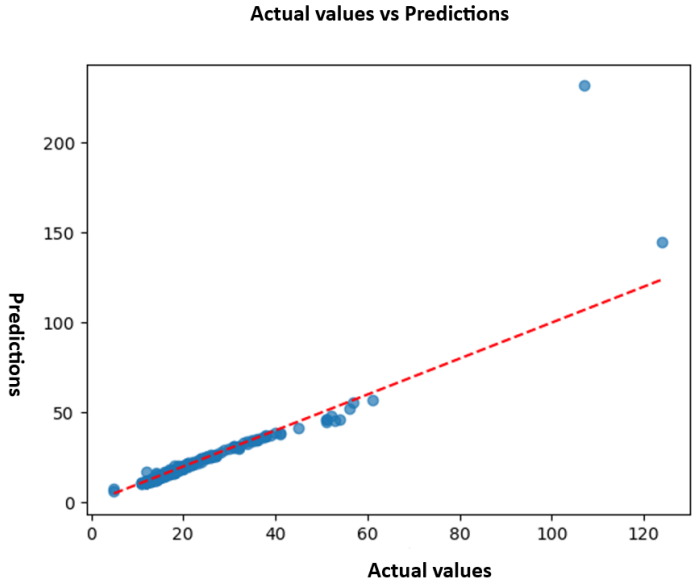

Fig. 7. Actual values vs Predictions.

tilapia, demonstrating effective learning during the training phase, as evidenced by the consistent reduction in training loss and Mean Absolute Error (MAE). The model achieved strong performance, with a peak score of 93,071% during grid search, indicating its ability to fit the data effectively using optimal parameters. However, despite these promising results, the model's performance on unseen data revealed signs of overfitting, as indicated by fluctuations in validation metrics, particularly a significant spike in validation loss and MAE at certain epochs. This suggests the model's limited generalization capacity, which poses a challenge for reliable predictions.

Looking forward, several future directions and research opportunities arise from this work. First, extending the method to other fish species is essential to assess its generalizability and robustness across different ecological contexts. Second, integrating advanced regularization techniques could help mitigate overfitting, such as adopting learning rate decay or early stopping strategies. Additionally, incorporating environmental data could provide insights into the factors influencing growth ring formation, improving the accuracy of age estimations. On a practical level, scaling this model for large-scale applications in fishery management could significantly enhance the sustainable monitoring of aquatic populations. Finally, future

efforts should focus on expanding datasets, refining the model architecture, and exploring its potential in other areas of marine ecology, thereby opening up new avenues for both fundamental and applied research in resource management.

***Abstract*—Content-adaptive image steganography based on minimizing the additive distortion function and Generative Adversarial Networks (GAN) is a promising trend. This approach can quickly generate an embedding probability map and has a higher security performance than hand-crafted methods. However, existing works have ignored the semantic information between neighbouring pixels and the NaN-loss scenarios, which leads to improper convergence. Such cases will degrade the generated Stego images' quality, decreasing the secret payload's security. FT_GAN performance, which incorporates feature reuse in generator architecture, has been investigated by proposing the FC_DenseNet-based generator herein. This investigation explores the superior semantic segmentation capabilities of FC_DenseNet, including feature reuse, implicit deep supervision, and the vanishing gradient problem alleviation of DenseNet, toward enhancing visual results, increasing security performance, and accelerating training. The ability to maintain high-quality visual characteristics and robust security even in resource-constrained environments, such as Internet of Things (IoT) contexts, demonstrates the practical benefits of this approach. The qualitative analysis of the visual results regarding the texture regions' localization and intensity exhibited augmented visual quality. Moreover, an improvement in the security attribute of 0.66% has also been demonstrated regarding average detection errors made by the SRM_EC Steganalyzer across all target payloads.**

***Keywords*—Content adaptive; distortion function; GAN; FC_DenseNet; steganography; steganalysis**

I. Introduction

Image steganography defines the art and science of hiding secret messages in digital images such that the intended recipient is most likely the only other entity aware of the secret [1] [2]. Numerous methods have been invented toward ensuring that such an intended secret is maintained. Over the past few years, image steganography's popularity has increased due to the vast amount of data transmitted over the Internet and social media platforms [3]. According to [2], adaptive image steganography is a promising new trend in the field of steganography that can engender greater assurance that such a secret will remain so. In content-adaptive image steganography, the embedding locations are modified adaptively based on the image's content, particularly its texture and smooth regions. To make the existence of a secret message undetectable, higher embedding probabilities are assigned to texture areas than are smooth areas. The most efficient embedding schemes employ content-adaptive steganography techniques that minimise the additive distortion function, as shown by Zhao et al. [4].

Minimizing embedding distortion simply means minimizing a well-designed additive distortion function, as defined here in Eq. (1) [5].

$$D(X,Y) = \sum_{i=1}^{W}\sum_{j=1}^{H}\{p_{i,j}\}\{x_{i,j} - y_{i,j}\} \tag{1}$$

Where, $D(X,Y)$ is the measure of the additive distortion caused by changing cover image X to Stego image Y. H and W are the height and width of the Stego and cover image, respectively. $p_{i,j}$ is the cost, or probability of changing pixel $x_{i,j}$ in cover image to $y_{i,j}$. P is a matrix representing the cost of changing or probability of changing pixel $x_{i,j}$ to $y_{i,j}$. The cost and the probability of change are inversely related.

Prior to discussing the methods of content adaptive steganography based on minimizing the distortion function, a review of the contrary field, specifically steganalysis, is necessary. It is worth noting that these two fields continuously impact one another. Steganalysis can be defined as the field in charge of detecting the existence of hidden information in an image. Initially, steganalysis was based on statistical methods [4]. However, with the advent of Machine Learning (ML) algorithms, steganalysis has evolved to employ ML algorithms thereby increasing detection accuracy by a focus on the feature extraction process. Fridrich et al. [6] proposed a Spatial Rich Model (SRM) utilizing 30 High-Pass Filters (HPF) to capture different relationships between neighboring pixels in different directions. SRM was enhanced to produce maxSRMd2 [7]

*Corresponding authors.

by defending against Selection Channel Aware steganalysis (SCA). SRM and maxSRMd2 extracted features are fed to a ML algorithm to perform the classification or equivalently the secret's detection. The Ensemble Classifier (EC) proposed by Kodovsky et al. [8] showed good performance back then.

In recent years, deep learning has become increasingly popular in image processing applications ushering in many innovative advancements. In particular, Convolutions Neural Network (CNN) is a powerful tool for extracting image features for both the spatial and frequency domains. In an effort to compete with the performance of features extraction handcrafted methods [6], [7], CNN-based Steganalyzers have been developed. In 2015, QIAN_Net [9], the first CNN-based Steganalyzer, was proposed. Their method uses a HPF in the preprocessing layer to strengthen steganographic noise. For feature extraction, five convolutions layers with a Gaussian activation function and average pooling are utilized for feature extraction. For the classification task, fully connected neurons were added to a softmax layer. QIAN_Net detection accuracy was inferior to hand-crafted methods [6], [7], which was the main motivation behind the proposal of Xu_Net [10] in 2016. In addition to the classification module, Xu_Net comprises various structural groups. Absolute, Batch Normalization (BN), and tanh are utilized in the initial groups to handle HPF output and improve statistical features. BN and Rectified Linear Unit (ReLU) are applied to the remaining groupings. Later, different ensemble strategies for the Xu_Net were investigated [11]. Instead of using a traditional HPF to determine steganographic noise, all 30 SRM HPF were utilized to initialize the kernels in the first convolution layer by Ye_Net [12]. Moreover, a Truncated Linear Unit (TLU) was proposed in an attempt to increase the Signal-to-Noise Ratio (SNR). Furthermore, incorporating knowledge of channel selection or the probability of changing each pixel provided for improved performance. Yedroudj_Net [13], an improved version of Ye_Net, was created by combining features from Xu_Net and Ye_Net. SR_Net [14] abandoned the idea of SRM preprocessing filters and initialized non-pooling convolutional layers randomly. SR_Net [14] achieved a state-of-the-art performance in 2018. ZHU_Net [15] enhanced their performance even further in 2019 by decreasing the kernel size to 3x3, using separable convolutions, and Spatial Pyramid Pooling (SPP). In 2021, GBRAS_Net [16] was proposed, which involves using filter banks to enhance steganographic noise in a preprocessing stage, depth wise and within separable convolutional layers, while skipping connections to the feature extraction stage. What makes GBRAS_Net different than all reviewed CNN-based Steganalyzers is the classification stage, which avoids overfitting by abandoning fully connected modules.

Despite the advancements in content-adaptive image steganography, current GAN-based methods exhibit several limitations that hinder their practical application. Specifically, these methods often neglect the semantic relationships between neighboring pixels, leading to suboptimal texture localization and security performance. Moreover, the prevalence of NaN-loss scenarios during training results in convergence issues, further degrading the quality of the generated stego images. Addressing these challenges is critical for enhancing the robustness and adaptability of steganographic techniques, particularly in resource-constrained environments, such as the Internet of Things (IoT). This research addresses the core problem of inefficient stego image generation in existing GAN-based steganographic models, stemming from their inability to effectively incorporate semantic information and mitigate training instability (e.g. NaN-loss scenarios). These challenges lead to a compromise in both the visual quality and security of the stego images, highlighting the need for an improved approach. The primary objective of this study is to propose an improved GAN-based framework, termed FT GAN, to overcome these limitations. By incorporating feature reuse through an FC DenseNet-based generator and introducing a bounded activation function to stabilize training, the proposed approach aims to enhance stego image quality, improve semantic segmentation, and ensure better security performance.

II. Related Work

The methods related to content adaptive image steganography are based on minimizing the additive distortion function by splitting the embedding process into two tasks. The first task objective is to generate a cost (or probability) matrix for each cover image using a distortion (or cost assignment) function that is well-designed. The goal of the second task is to produce Stego images using coding schemes such as Syndrome Trellis Codes (STC) [5], which take a cover image with its corresponding cost matrix and a secret message as inputs.

That being so, researchers developed various distortion or cost assignment functions, whose primary purpose is to achieve the first task and accurately assign the probability of change or cost of change by simply quantifying the effect of change, or $p_{i,j}$, for each pixel. Initially, the cost assignment functions were designed heuristically utilizing hand-crafted techniques, such as Highly Undetectable Stego (HUGO) [17], Wavelet Obtained Weights (WOW) [18], High pass, Low pass, and Low pass (HILL) [19], Spatial Universal Wavelet Retrieval Distortion (S_UNIWARD) [20], and Minimizing the Power of Optimal Detector (MiPOD) [21]. The previous handcrafted distortion functions provided a satisfactory level of security. Nevertheless, their primary insufficiency was that the detectability factor was not considered when designing the cost function. According to Pevny et al. [17], the cost of embedding is directly related to its detectability. However, simulating this correlation was practically impossible back then.

With the development of GAN [22], it became possible to simulate the distortion and detectability relationship. Tang et al. [23] were the first to automatically design a distortion function. Automatic Steganographic Distortion Learning using a Generative Adversarial Network (ASDL_GAN) was proposed by Tang et. al. [23] in 2017. Their approach included three parts: Generator G, a Ternary Embedding Simulator (TES), and Discriminator D. Their generator was comprised of 25 structural groups, with each group containing a convolution layer, BN layer, and ReLU activation function, while a shortcut was utilized to identify the feature map of the stack layers. The process takes as input the cover image and the target capacity for which embedding probabilities are to be produced. The TES is used to simulate ternary data embedding since the vanishing gradient problem prohibits the conventional staircase function from being used directly. The TES takes as inputs the probability map matrix produced by the generator and a matrix of floating-point integers representing the secret message, and

returns a modification map, which produces a Stego image when added to the cover image that has a better metrics.

Tang et. al. [23]'s TES was a mini-network requiring a long pre-training time. Therefore, Yang et al. [24] improved on this aspect by proposing a double tanh_simulator in 2018. Moreover, motivated by the fact that ASDL_GAN security performance was inferior to hand-crafted distortion functions and the U_Net [25] capabilities in pixel-wise segmentation they proposed a new generator based on U_Net. Moreover, to resist SCA based steganalysis, they incorporate SCA into the discriminator adopting Xu_Net's architecture similar to ASDL_GAN. Yang et. al. [26] modified their earlier 2019 work, thereby investigating the influence of high pass filters in the discriminator's preprocessing layer to consequently propose UT_6HPF_GAN.

Despite the fact that the UT_SCA_GAN [24] and UT_6HPF _GAN [26] performed similar to or better than conventional methods, according to Tang et al. [27], the vanishing gradient problem still exists after several iterations. This problem follows from using the sigmoid/tanh activation function as embedding simulators which prevent the full exploitation of the architecture's potential. Thus, Steganographic Pixel-Wise Actions and Rewards with RL (SPAR_RL) architecture was proposed in 2019 by Tang et al. [27]. In this approach, a policy network attempted to learn an embedding policy by decomposing the embedding into pixel-wise actions to maximize rewards. A sampling process was designed to simulate the embedding actions, and the gradients of data embedding were allocated to the reward function. Tang et al. [27] were able to alleviate the vanishing gradient problem in SPAR_RL. However, they ignored the semantic information between neighboring pixels as can be observed in the policy network of SPAR_RL. Additionally, existing architectures overlook the NAN-loss scenarios that prevent proper convergence and, thus degrade the Stego image visual quality. These issues also relate to the poor adaptability of existing works from ignoring feature-reuse, useful for pixel-wise segmentation, as well as texture localization in the Stego images. Therefore, we consider these issues herein, and have redesigned the GAN's generator for improved image steganography.

III. An Improved GAN Architecture for Improved Image Steg

Briefly, our work has improved the GAN architecture to address the main problem of SPAR_RL, while preserving the generator's key goal of creating high-quality, and secure Stego images. To this end, the GAN's architecture was improved by utilizing the semantic segmentation neural networks for generators other than U_Net. Inspired by the superior semantic segmentation capabilities of FC_DenseNet [28], feature reuse, implicit deep supervision, and the vanishing gradient problem alleviation of DenseNet [29], the model's convergence and image quality is significantly improved. The proposed model was evaluated against both the FC_DenseNet [28] and U_Net in [25] an encoder-decoder architectures (or CNN-based) image steganography.

The hypothesis asserts that the FC_DenseNet internal connections will allow feature reuse to be carried by the features map to the subsequent layers. Further, this has been shown to enhance coarse semantic feature extraction and texture localization in images. As a result, the security level will be enhanced.

To this end, the main contribution of this paper is threefold:

1) Developing FT_GAN by incorporating the FC _DenseNet feature reuse into the GAN's generator, increases the quality of the generated image, as well as the average Stego image security.
2) Improving the architecture using a bounded-activation-function, prevents NAN-loss and enhances the model convergence and image visual quality.
3) The performance of the improved model proposed here was evaluated against existing architectures in terms of detection error, and image visual quality for the model's security and imperceptibility judged to produced comparatively better results.

IV. Materials and Methods

A. Dataset and Software Platforms

The following data set has been utilized during experimentation. All images have been scaled to 256x256 in an effort to accelerate the training and preserve resources.The Google Colab pro+ platform was utilized to perform these experiments.

1) BOSSBase v1.01: used for the earlier contest of breaking steganographic system, containing 10000 images of size 512x512, as well as used to test GAN,
2) BOWS#2: used for 10000 images of size 512x512 (first used for a contest to break watermarking systems).

Each of the previous datasets has been permuted randomly at a ratio of 8:2. This ratio gives how many images were used for GAN training, GAN testing, which includes SRM training and testing.

1) GAN training uses 16,000 images, 8000 of which come from BOSSBase and another 8000 from BOWS2;
2) GAN testing consists of 4,000 images, which are divided into 50% SRM training and 50% SRM testing.

B. Overall Architecture of FT_GAN

The overall architecture of the FT_GAN is shown below, refer to Fig. 1. The architecture is composed of a generator, a ternary embedding simulator, and a discriminator. As described, the architecture is same as [23], [24], [26], specifically [26] with the only difference being in the generator design.

The process begins by feeding the cover image to the generator to produce its corresponding probability map, which is then passed to the ternary embedding simulator along with the input stream representing the secret message to generate the modification map. The modification map is added to the cover image to obtain the Stego image. The pair is then input to the Xu_Net [10] discriminator after passing through a six SRM high pass filter, to perform classification. Finally, the loss made by the generator and discriminator is computed to update GAN's weights.

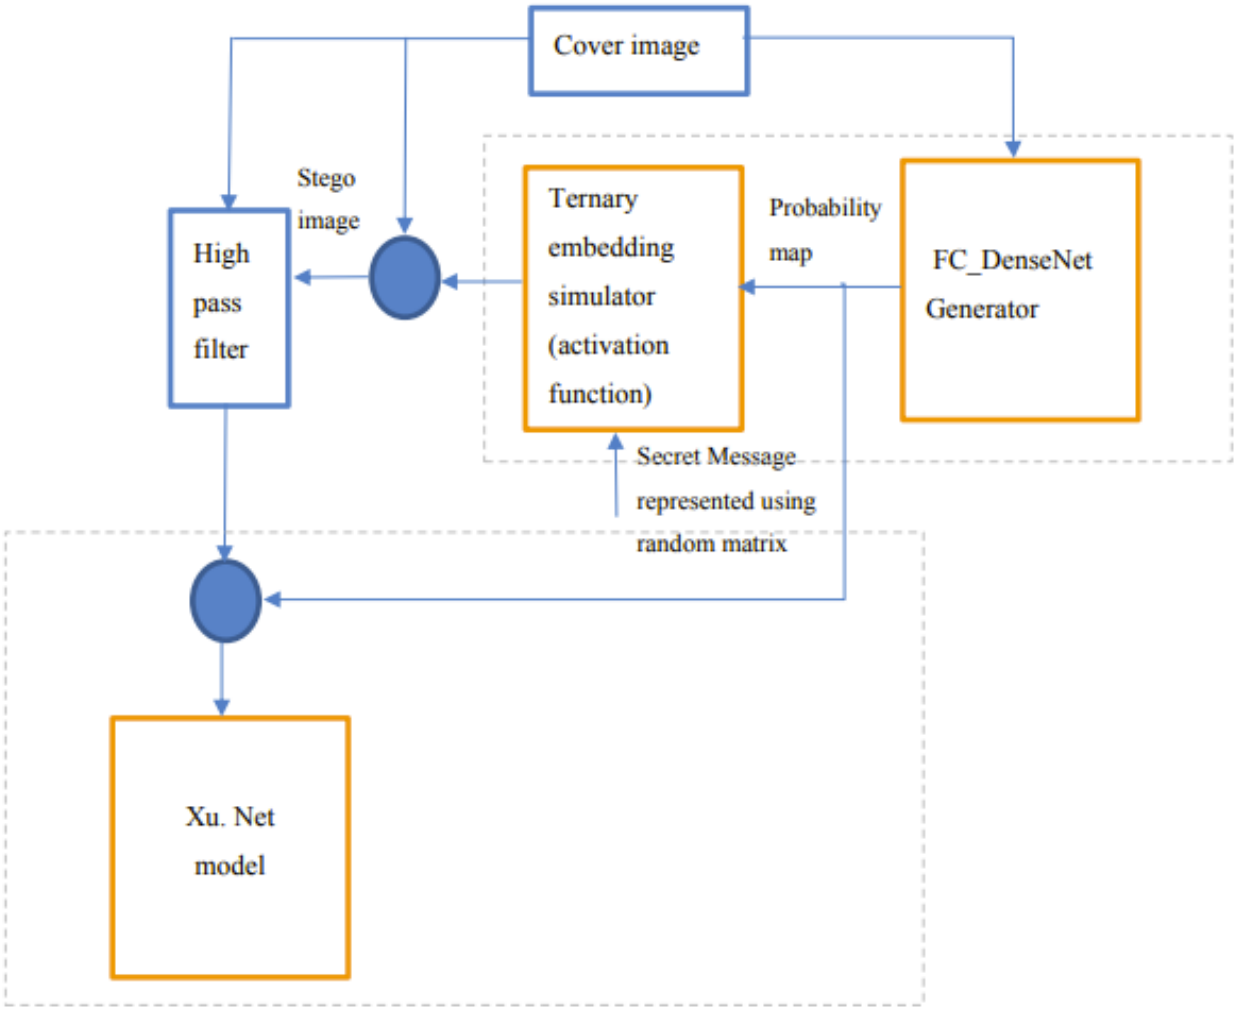

Fig. 1. The overall architecture.

1) FC_DenseNet_102 _D7-based Generator, and its loss function: In previous work, the U_Net architecture has been utilized for the generator [24], [26], this design enabled results superior to hand-crafted methods. An attempt to increase the performance even further by investigating FC_DenseNet architecture in the generator is made here. The main motivation is the comparison held by Duan et. al., [30] in 2021 when they compared the performance of FC_DenseNet [28] and U_Net [25] in CNN-based image steganography.

The FC_DenseNet_102_D7-based generator architecture is summarized in Fig. 2. This architecture attempts to maintain U_Net depth while incorporating the feature reuse capability of FC_DenseNet. A default growth rate of 16 is maintained, and the number of layers per dense block in every level is adjusted to match the width of U_Net layer in the same level. In this way, an investigation of feature reuse capability to improve performance and accelerate learning can be accomplished. To avoid NAN-loss, GAN convergence failure mode and improve the visual results quality, a bounded activation function is proposed here, and a pre-processing layer of a small kernel width is utilized.

The generator's loss function consists of two parts: the adversarial and entropy parts. The adversarial loss, which seeks to increase security performance, is the negative of the discriminator loss. The primary purpose of the entropy part is to ensure the embedding payload is met by the resultant probability maps. Refer to Eq. (2), where α and β are scaling factors and set to 1 and $\frac{1}{10^7}$, respectively. I_D is calculated using binary cross entropy, Refer to Eq. (3), Where y_i is the softmax, or discriminator output, and y_i' is truth label Stego/cover. Alternatively, I_C is computed using Eq. (4), where H, W, and Q are height, width, and target payload, respectively. Capacity is calculated with help from a generator produced probability map. Refer to Eq. (5) [4].

$$I_G = -\alpha I_D + \beta I_C^2, \tag{2}$$

$$I_D = \sum_{i=1}^{2} y_i' \log y_i, \tag{3}$$

	Output	256x256x1

Fig. 2. The architecture of FC_DenseNet_102_D7-based generator.

$$I_C = Capacity \times H \times W \times Q, \tag{4}$$

$$Capacity = \sum_{i=1}^{H}\sum_{j=1}^{W} -p_{i,j}\log_2\frac{p_{i,j}}{2} - (1-p_{i,j})\log_2(1-p_{i,j}), \tag{5}$$

2) Ternary Embedding Simulator (TES): The TES attempts to simulate the ternary embedding operation, refer to Eq. (6). The ternary embedding operation (TEO) takes as input the pixel's probability map $p_{i,j}$, and a floating-point value $n_{i,j}$ obtained from uniform distribution of (0,1), representing a secret message. The TEO output's a modification value $m_{i,j}$, which is then added to cover pixel's value x_i,j to produce Stego pixel value $y_{i,j}$.

$$m_{i,j} = \begin{cases} -1, \text{ if } n_{i,j} < \frac{p_{i,j}}{2} \\ 1, \text{ if } n_{i,j} < 1 - \frac{p_{i,j}}{2} \\ 0, \text{otherwise} \end{cases}, \tag{6}$$

The fact that the stair case function defined by Eq. (6) or the TEO are not differentiable and that they do not preserve the gradient loss during back-propagation, is the main motivation behind utilizing the double-Tanh TES proposed by Yang et al. [24] during experiment. Refer to Eq. (7), where λ is a controlling factor equal to 60 [26].

$$m_{i,j} = -0.5Tanh(\lambda(p_{i,j} - 2n_{i,j})) + 0.5Tanh(\lambda(p_{i,j} - 2(1-n_{i,j}))) \tag{7}$$

3) Discriminator and its loss functions: The Xu_Net architecture is adopted for the discriminator [10]. Xu Net comprises a preprocessing module, a convolution module, and a classification module. The preprocessing module made use of six SRM HPF [26]. The convolution module is made up of structural groupings of the convolution, activation, and pooling operations. Absolute, Batch normalization (BN), and tanh are used in the early groups to manage high pass filter output and enhance statistical characteristics. The remaining groupings utilize BN and ReLU. In the classification module, a fully connected layer and softmax activation are utilized. The discriminator weights are updated with the help of the binary cross-entropy loss function defined at Eq. (3).

C. GAN Training, and Hyper-parameters

To conserve resources and provide a fair comparison between UT_GAN and FT_GAN, a GAN training dataset is fed in batches of eight during the experiment. The Adam optimizer with a 0.001 learning rate is applied to update the generator's weight. The Discriminator optimizer is a stochastic gradient descent with a fixed momentum of 0.9, and initial learning rate of 0.001. Thus, the process was scheduled to decrease by 10% every 5,000 iterations. All generator weights were initialized with random values drawn from a normal distribution with zero mean and 0.02 standard deviation. Similarly, the Discriminator convolution kernel weights are initialized randomly from a normal distribution, but with standard deviation of 0.01. However, the fully-connected (FC) layers parameters were initialized using a "Xavier" initialization.

This previous architecture characterization and hyper-parameters were used to train the GAN for a 0.4bpp target payload. Subsequently, this model was fine-tuned for other target payloads using curriculum learning (CL).

D. Evaluation

1) Visual Evaluation: The FC_DenseNet_102_D7-based generator has been evaluated qualitatively based on the clarity and location of the generated probability map and modification map. Also, the convergence speed is an important consideration, which is the rate at which these clear, localized visual results, start to show up. Fig. 4, and 5 show visual results for the 0.4bpp Target payload, and all other Target payloads respectively.

2) Security Evaluation: The FC_DenseNet_102_D7-based generator security performance was evaluated with the help of the SRM_EC [6], [8]. GAN testing data has been split in half. The first half has been used to train SRM_EC. The second half has been used to test SRM_EC. [6], [8] Eq. (8) was used to compute the average detection error over ten trials of Ensemble classifier training and testing. The final results are shown in Table I. Here, P_{FA} is the number of false alarms processed by the by SRM_EC in cover images while P_{MD} is the number of missed detections from Stego images.

$$P_E = \frac{1}{2}(P_{FA} + P_{MD}) \tag{8}$$

V. Results

A. Visual Results

The figures below describe the main visual results. Fig. 4 compares the visual results of FT_GAN and UT_GAN during training for a 0.4bpp target payload at various epochs. Similarly, Fig. 5 compares them, but for different target payloads.

B. Security Results

Table I summarizes the average detection error made by SRM_EC for all trained payloads. The last column in the table shows the average P_E across all target payloads. Refer to Fig. 3.

VI. Discussion

A. Visual Results Discussion

The visual results discussion is conveyed in terms of a qualitative analysis for the probability map and modification map summarized in Fig. 4 and 5.

The probability map is superior if the majority of white regions, representing regions with a high likelihood of embedding, are located in the texture region of the image. Clearly, these observations, seen from the figures show that the FC_DenseNet_102_D7-based generator probability maps' more intense white compared to the U_Net-based generator probability maps' white, indicate that the texture areas (of the prior) were assigned the highest probability value, which is 0.5. Recall that the probability value range is (0,0.5).

TABLE I. AVERAGE DETECTION ERROR MADE BY SRM_EC FOR ALL TARGET PAYLOADS USING GAN TESTING DATA

Steganography	**0.1bpp**	**0.2bpp**	**0.3bpp**	**0.4bpp**	**0.5bpp**	**0.6bpp**	**0.7bpp**	**Average Among All Payloads**
UT_GAN	0.1493	**0.1550**	0.1508	**0.1536**	**0.1562**	**0.1588**	0.1362	0.1514
FT_GAN	**0.1508**	0.1470	**0.1539**	0.1498	0.1556	0.1567	**0.1532**	**0.1524**[1]

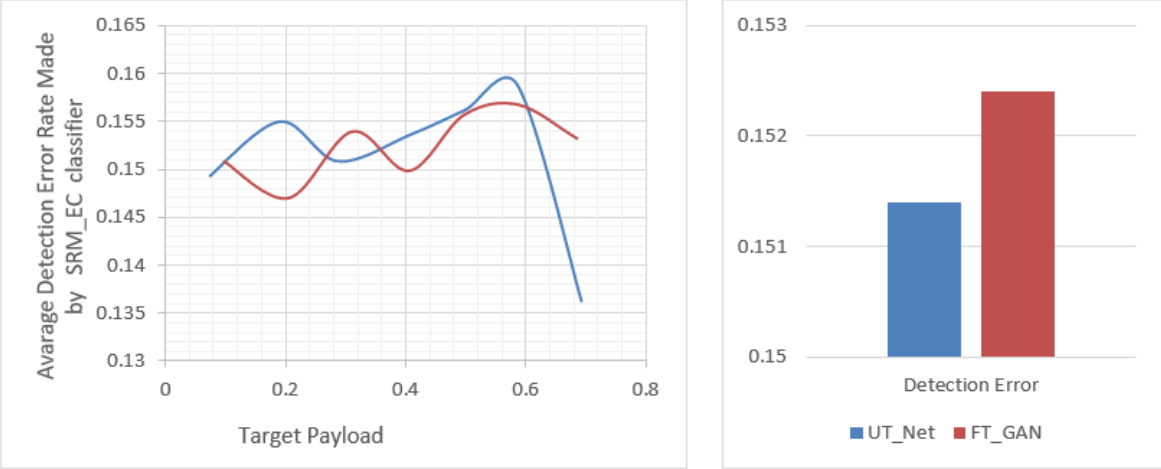

Fig. 3. Missed detection made by SRM_EC across each target payload, and the average across all of them.

From Fig. 4, we can conclude that the FC_DenseNet_102_D7-based generator began localizing texture regions faster than U_Net-based generator beginning at epoch 20. This indicates the benefit of feature reuse. The modification map is also better if it displays all black "-1" and white "+1" in the texture areas. Smooth areas represented by gray "0" remain unchangeable. Recall that the modification map is obtained using Eq. (7). On the basis of this accounting, a better modification map corresponds to a better probability map's localization.

B. Security Results and Discussion

Recall that our experimental dataset is not similar to those dataset(s) used by Yang et al.'s [26] since the ZSUBase dataset is not publicly available. Therefore, the comparison is held with the architecture proposed by Yang et al. [26] when trained using our aforementioned experiment dataset. According to the Table I, and Fig. 3, the security performance of the two architectures varies, making it difficult if not impossible for the user to determine which architecture outperforms. This is true as seen from the outcome of several variables, including the amount of training iterations and fine-tuning. However, these parameters are extremely important in GAN training due to the min-max game it plays. This game produces fluctuations in a variety of metrics, including security results. For instance, the value at one epoch may be quite high, but significantly fall in a subsequent epoch. This phenomenon leads us to understand that a precise decision criterion is needed. Thus, a CNN-based steganalysis is required to precisely determine the necessary number of fine-tuned epochs and iterations to optimize the best and most accurate final results. During these experiments, this precise decision criterion was unavailable owing to a lack of dataset size and resources. Aside from the number of fine-tuned epochs and iterations, this fluctuation was also caused by other SRM_EC factors, such as the number of base learners and the d_sub.

The experimental decision criteria was mostly visual, in addition to the loss made in meeting the target capacity, refer to Eq. (4). Therefore, the comparison is based on the last column of the table, or the "other" average classification error

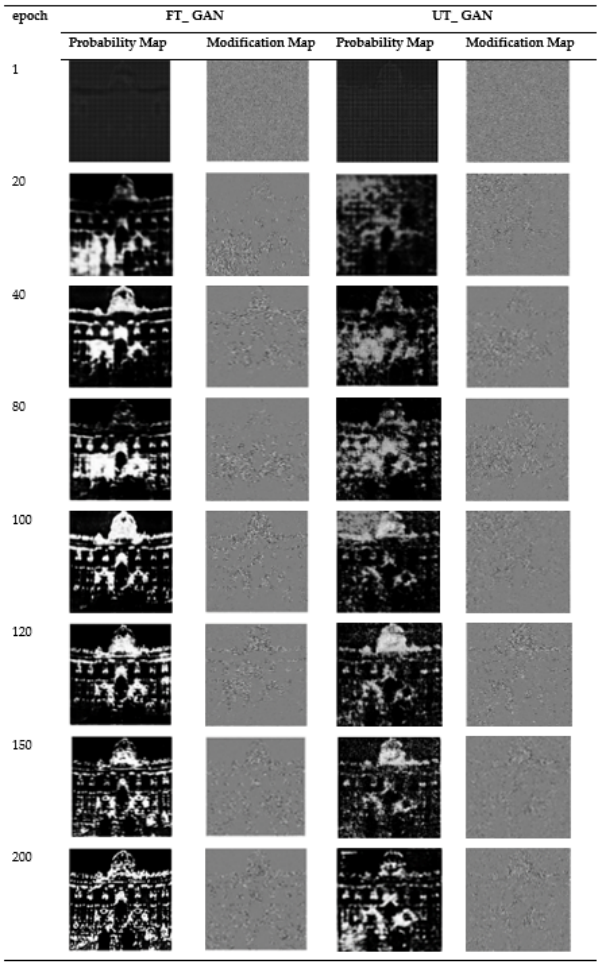

Fig. 4. Visual results for target payloads of 0.4bpp in terms of probability map and modification map.

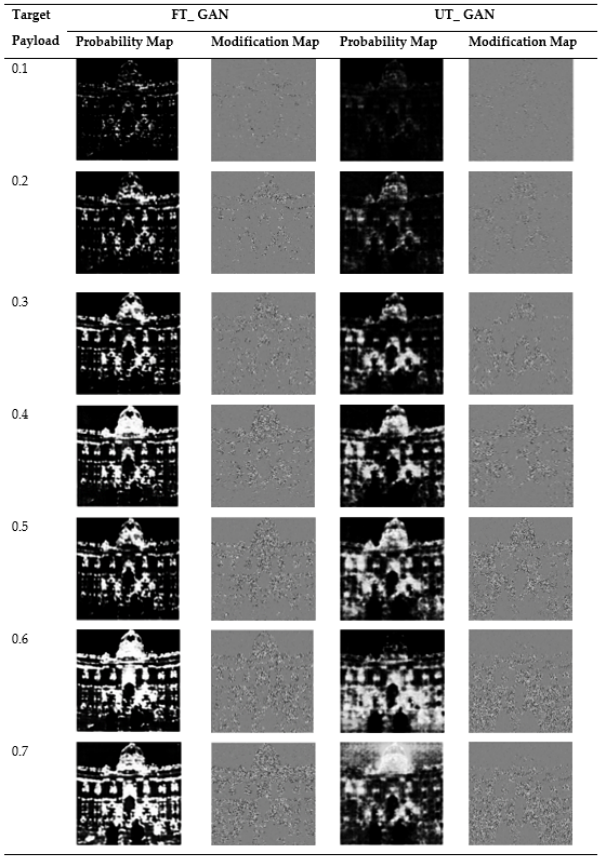

Fig. 5. Visual results for all target payloads in terms of probability map and modification map.

made across all trained payloads. Refer to Fig. 4. Overall, the FC_DenseNet_102_D7-based generator (or FT_GAN superior U_Net-based) generator improved the detection error by 0.66%. This minor average enhancement is a result of the FC_DenseNet_102_D7 architecture, and more specifically the reuse of features. This is supported by the visual result at both Fig. 4 and 5.

When comparing the results described in Eq. (1) with those of earlier studies [26], it is clear that the detection error rate reported by this experiment is lower, even for their proposed design, namely U_Net. This demonstrates conclusively that it was not the outcome of the FC_DenseNet_102_D7-based generator design, but rather the dataset employed (i.e. a limited dataset). According to Karras et al. [31], limited data is one of the challenges of GAN training. The fundamental problem with limited datasets is that the discriminator rapidly overfits to the training examples.

Consider that the discriminator's function is to classify its inputs as either cover or Stego. But, due to overfitting, it rejects as Stego all inputs other than the initial training dataset (cover images)! As a result, the generator receives minimal input to assist in enhancing the quality of its subsequent output, and thus, rendering the training process worthless. Karras et al. [31] explain why longer training did not eliminate the +1 and -1 points in the smooth regions throughout the experiment. Refer to Fig. 4, and 5. The experimental results clearly demonstrate the superiority of the proposed FT GAN over existing models in terms of both visual quality and security. For instance, the faster convergence speed observed with the FT GAN underscores the benefit of feature reuse and deep supervision provided by the FC DenseNet architecture. This capability allows the generator to focus embedding efforts on textured regions more effectively, as evidenced by the intense white areas on the probability maps (see Fig. 4). This improved localization directly enhances the stego images' imperceptibility, reducing detectability by steganalyzers. Compared to UT GAN and other GAN-based steganography models proposed by Yang et al. [24, 26], the FT GAN demonstrates a more consistent performance across all payload sizes. Specifically, the average detection error for FT GAN (0.1524) is marginally but consistently better than UT GAN (0.1514), as shown in Table I. This improvement highlights the practical advantage of incorporating FC DenseNet's feature reuse capabilities in the generator architecture, which is absent in UT GAN. While previous models relied on U-Net or similar architectures, the FT GAN's design mitigates vanishing gradient problems and achieves more robust outputs. The results also emphasize the importance of addressing training instability, a common limitation in earlier works like ASDL GAN [23] and UT 6HPF

GAN [26]. By introducing a bounded activation function, the FT GAN significantly reduces NaN-loss scenarios, leading to smoother training convergence and higher-quality outputs. In contrast, earlier models often struggled with overfitting or unstable training, particularly when using small datasets.

VII. Conclusions

We have presented our FT_GAN for content-adaptive image steganography, developed by incorporating feature reuse into the GAN generator. FT_GAN has been evaluated based on both visual and security results using SRM_EC Steganalyzers. The main outcome of this work is a clear improvement in the visual results of the FC_DenseNet_102_D7-based generator over the U_Net-based generator using BOSSBase and BOWS2 datasets, as well as an average security improvement of 0.66% compared to all other target payloads. As a future recommendation, we highly endorse the development of a universal generator that satisfies both the spatial and JPEG domains, since the one proposed here works only in the spatial domain. By leveraging FC DenseNet and a bounded activation function, our approach demonstrated improved visual quality, faster convergence, and enhanced security, with lower detection error across all payloads. Future work will focus on extending FT GAN to support the JPEG domain, exploring larger datasets for scalability, and integrating advanced learning techniques to further optimize embedding strategies and expand its practical applications in secure communication systems.

***Abstract*—Intrusion Detection Models (IDM) often suffer from poor accuracy, especially when facing coordinated attacks such as Distributed Denial of Service (DDoS). One significant limitation of existing IDM solutions is the lack of an effective technique to determine the optimal period for sharing attack information among nodes in a distributed IDM environment. This article proposes a novel collaborative IDM model that addresses this issue by leveraging the Pruned Exact Linear Time (PELT) change point detection algorithm. The PELT algorithm dynamically determines the appropriate intervals for disseminating attack information to nodes within the collaborative IDM framework. Additionally, to enhance detection accuracy, the proposed model integrates a Gradient Boosting Machine with a Support Vector Machine (GBM-SVM) for collaborative detection of malicious activities. The proposed model was implemented in Apache Spark using the NSL-KDD benchmark intrusion detection dataset. Experimental results demonstrate that this collaborative approach significantly improves detection accuracy and responsiveness to coordinated attacks, providing a robust solution for enhancing cloud security.**

***Keywords*—Cloud security; intrusion detection; collaborative model; feature selection; anomaly detection; Pruned Exact Linear Time (PELT); gradient boosting machine; support vector machine; NSL-KDD; DDoS**

I. Introduction

A. Overview of Cloud Computing and Security Challenges

Cloud computing, a transformative paradigm in IT service delivery that emerged around 2010, provides on-demand access to resources such as computing power and storage via the internet [1]. This model enables organizations to avoid substantial investments in hardware and software, paying only for what they use. Despite its significant cost advantages and operational flexibility, cloud computing introduces new and complex security challenges [2]. Among these, Denial-of-Service (DoS) and Distributed Denial-of-Service (DDoS) attacks stand out as critical threats that can severely compromise cloud infrastructure [3]. Ensuring robust and adaptive security mechanisms is essential to fostering trust and promoting widespread adoption of cloud technologies.

B. Limitations of Current Intrusion Detection Models (IDM)

Intrusion Detection Models (IDM) are a cornerstone of cloud security, monitoring network events to identify and respond to potential breaches. IDM can be broadly categorized as signature-based, anomaly-based, or hybrid [4]. Signature-based Models excel at detecting known attack patterns but struggle with novel or zero-day attacks [5]. On the other hand, anomaly-based Models can identify previously unseen threats but often suffer from high false alarm rates, undermining their effectiveness [6]. Hybrid approaches aim to combine the strengths of these two methods but usually inherit their limitations, leading to suboptimal performance.

Coordinated attacks, such as DDoS attacks, exacerbate these challenges. These attacks leverage multiple compromised devices to flood targeted systems with overwhelming traffic, often evading detection by isolated IDM monitoring [7]. For example, Smurf attacks exploit spoofed IP addresses to generate a flood of Internet Control Message Protocol (ICMP) replies, overwhelming target systems [5]. These challenges highlight the need for more effective, scalable, and adaptive intrusion detection solutions.

C. Research Problem and Justification

Existing IDM solutions face critical limitations when addressing cloud environments' dynamic and distributed nature. Signature-based approaches are ineffective against zero-day attacks, while anomaly-based methods often generate excessive false positives, wasting computational resources. Furthermore, traditional IDM struggles to detect coordinated attacks, such as DDoS, due to their distributed nature and lack of collaboration among monitoring systems [8], [9], [10], [11]. These gaps necessitate developing a new, collaborative approach capable of adapting to the unique security challenges of cloud environments.

D. Proposed Solution

This paper presents a novel collaborative intrusion detection model for cloud computing environments. The proposed model addresses the limitations of existing solutions by incorporating:

1) Advanced feature selection techniques and change point detection using the Pruned Exact Linear Time (PELT) algorithm.
2) Collaborative classifier training and update mechanisms to enhance detection accuracy.
3) Distributed attack detection and IP traffic monitoring.
4) Aggregation and feedback loops are used to refine the detection process continuously.

This model leverages a network of specialised units to offer a robust, scalable, and adaptive solution to cloud security challenges. Its collaborative nature enables the effective detection of coordinated attacks, such as DDoS, while reducing false positives and resource wastage.

E. Organization of the Paper

The remainder of this paper is organized as follows:

Section II: A comprehensive review of related work, establishing the context for the proposed research.

Section III: A detailed presentation of the proposed collaborative intrusion detection model, including its architecture and functionalities.

Section IV: Description of the datasets and experimental setup used to evaluate the model.

Section V: Results and analysis, highlighting the model's effectiveness in addressing the identified challenges.

Section VI: Conclusion and future research directions, summarizing this work's contributions and potential extensions.

By addressing the gaps above, this research aims to enhance the security and resilience of cloud computing environments, fostering trust and enabling broader adoption of this transformative technology.

II. Related Works

Within the IDM context, collaboration refers to the cooperation and communication among multiple IDM nodes or agents across different sub-networks and/or hosts. These nodes share information to detect anomalies such as coordinated attacks or Distributed Denial of Service (DDoS) attacks. A collaborative IDM has the potential to detect attacks dispersed over several hosts or networks by aggregating evidence across these sub-networks. To address the issue of coordinated attacks like DDoS, existing work in cloud IDM can be categorized into signature-based, anomaly detection, and hybrid techniques.

Several researcher teams have employed signature-based techniques for collaborative cloud IDM, such as [12] and[13]. In their approach, each region in the collaborative cloud has an IDM deployed, which interacts with others by sharing alert information aimed to mitigate the impact of DDoS attacks. For instance, the framework implemented by these aforementioned researchers uses Snort-based IDM with three plug-in modules: block, communication, and cooperation. Detection agents collate and correlate alerts to assess their accuracy through a majority vote model to enhance faulty local assessments. Once an alert is accepted, a new blocking rule is added to the block table. However, this approach can only detect known attacks due to its reliance on signature-based methods. Similarly, [14] proposed a multi-threaded distributed cloud IDM for detecting DDoS attacks, comprising modules for capture and queue, analysis, and reporting. Their experimental tests in a .NET simulator demonstrated the model's ability to identify and drop bad packets. Still, it remains limited to known attack signatures and is ineffective against zero-day attacks.

Anomaly detection approaches have also been explored by researchers such as [9], whom have proposed a distributed IDM for cloud computing using a data mining approach. In their technique, network traffic is collected from edge routers and forwarded to anomaly detection devices using a Naïve Bayes classifier, with further classification by a Random Forest classifier at a central server. The author in [15] proposed a statistical and distributed network packet filtering model against DDoS attacks involving a coordinator that distributes detection tasks among various virtual machines. The author in [16] utilized Neural Networks and the Bat algorithm in their distributed IDM, while [17] employed the artificial Bee Colony algorithm and neural networks. The author in [18] developed an egress detection model using Principal Component Analysis (PCA) to protect cloud environments from DDoS attacks, with monitoring probes in each hypervisor and a hierarchical node structure for decision-making. However, the anomaly detection approach often leads to high false alarms, as [19] and [20] noted.

The hybrid approach combines anomaly detection and signature-based techniques [21], [22]. They proposed a hybrid and collaborative IDM that uses Snort for predefined attacks and a decision tree classifier with SVM for distributed attacks [23]. This research paper proposes a hybrid machine learning technique combining the Extreme Learning Machine (ELM) model with the black hole optimization algorithm for DDoS attack detection in cloud computing. However, they also inherit certain limitations, including the challenge of high false alarms and the reliance on known signatures for some detection.

In addition, existing research proposes a distributed anomaly detection system using Gaussian Mixture-based Correntropy (i.e. an adaptive neurotechnology that measures similarity, normally utilized in statistical signal processing and is based on second order moments) to identify zero-day attacks at the edge of networks [24]. While demonstrating effective performance on specific datasets, this approach lacks adaptability and collaboration, which are crucial for dynamic cloud environments. [25] employs distributed machine learning with ensemble techniques and concept drift handling for intrusion detection. While achieving high accuracy, the approach needs to have the collaborative and adaptive capabilities to strengthen a Cloud Anomaly Intrusion Detection Model (CAIDM), to strengthen their effectiveness in dynamic and distributed environments. In contrast, our proposed CAIDM addresses these limitations and demonstrates its effectiveness by incorporating adaptive and collaborative features.

To address these limitations, this paper proposes a collaborative intrusion detection model for cloud computing using the Pruned Exact Linear Time (PELT) change point detection algorithm. This approach aims to optimize the timing for exchanging attack information among nodes in the collaborative IDM and, as shown below, enhancing the model's effectiveness and reducing false alarms.

III. Proposed Enhanced Collaboration and Adaptive Cloud Anomaly Intrusion Detection Model

The Enhancing Collaboration and Adaptive Cloud Anomaly Intrusion Detection Model (EC-A-CAIDM) orchestrates a multifaceted defense against cyber threats. This cooperative model comprises seven specialized units: i) feature selection using hybrid Harmony Search Optimization and a Symmetrical Uncertainty Filter (HSO-SUF)-based feature selection for selecting the most relevant features in the dataset, ii) change point detection utilizing Pruned Exact Linear Time (PELT), iii) collaborative classifier training and update, iv) distributed attack detection, v) IP address traffic monitoring, vi) aggregation, and vii) feedback. These units operate in a synchronized three-phase choreography: training, testing, and retraining/updating.

The core of the cooperative training phase lies within the collaborative classifier training and update unit. It orchestrates a distributed training process employing the GBM-SVM classifier within the Apache Spark framework [Gradient Boosting Machine (GBM), Support Vector Machine (SVM)]. Worker nodes individually refine their Local Normal Reference Models (LNRMs) on designated data partitions [i.e. Resilient Distributed Datasets (RDDs) as identified commonly] within the distributed dataset, akin to independent learning modules. These localized models capture patterns of normalcy specific to each node's domain. The head node, acting as a central coordinator and responsible for aggregating and analyzing the LNRMs, harmonizes these LNRMs into a unified Global Normal Reference Model (GNRM), reflecting the collective picture of normalcy across the network. The testing or detection phase translates this learned normalcy into real-time vigilance. Change point detection algorithms meticulously monitor data streams for abrupt shifts, while the distributed attack detection unit leverages the LNRMs to identify local anomalies. Exceeding a predefined threshold triggers an alert, prompting the unit to forward its LNRM to the head node for further analysis. However, the material sentinel of this phase is the IP address traffic monitoring unit acting as a watchful sentinel, tracking destination IP volume. The IP volume provides valuable insight about deviations suggestive of potential DDoS attacks, ensuring a model's comprehensive coverage by our proposed model (EC-A-CAIDM).

The final phase, retraining and updating, ensures the model continuously evolves. The aggregation unit seamlessly integrates LNRMs from all detection units into the GNRM, keeping the unit in tune with the dynamic network landscape. However, the real star of this phase is the feedback unit. It plays a crucial role toward extracting insights from detected intrusions and anomalies and feeding them into the collaborative training phase. This continuous feedback loop is essential to the model's success, enhancing future detection accuracy and ensuring it maintains its' edge (i.e. dominance) in the ever-changing cybersecurity landscape, where normally, the attackers maintain an edge that utilizes intelligent maneuverings and diversion.

Fig. 1 and 2 provide an in-depth understanding of the intricate design of the EC-A-CAIDM, while Algorithm 1 presents the pseudocode of the proposed EC-A-CAIDM. Together, Fig. 1, Fig. 2 illustrate the operational flow, showcasing novel functionalities with dashed lines. A detailed exploration of each unit and its contribution to the overall security framework is presented in the subsequent sections, offering a comprehensive insight into the model's orchestration.

IV. The EC-A-CAIDM Training Phase

The training phase of the Enhancing and Adaptive Collaboration Cloud Intrusion Detection Model (EC-A-CAIDM) lays the crucial groundwork for its exceptional effectiveness and precision. Three vital units orchestrate this phase: feature selection, collaborative classifier training, and IP address traffic monitoring. Each unit plays a distinct yet pivotal role in shaping EC-A-CAIDM's capabilities, forming the foundation upon which collaborative detection thrives.

A. Feature Selection Unit

The proposed Enhanced Collaborative and Adaptive Cloud Anomaly Intrusion Detection Model (EC-A-CAIDM) incorporates a crucial feature selection unit utilizing a hybrid approach combining Harmony Search Optimization (HSO) and Symmetrical Uncertainty Filter (SUF). *Feature selection (FS)* is essential in machine learning, particularly for intrusion detection models (IDMs). FS helps improve a machine learning based models' efficiency and accuracy by removing irrelevant or noisy data attributes that impede detection capabilities [26], [27].

The HSO algorithm plays a pivotal role for the steps defined in this process. HSO, introduced by [28], is a meta-heuristic optimization technique inspired by musical improvisation. Like musicians whom collaborate to create harmony, HSO explores the search space to identify the optimal combination of features that best distinguish normal from abnormal network traffic in the cloud environment. This approach is particularly well-suited for feature selection as it efficiently finds good-to-excellent solutions within a complex search space, even though they likely differ from the absolute best (unlike some heuristic methods) [29].

These steps encompass the essence of the HS algorithm's operation, making it a compelling choice for feature selection in this study:

- Step 1: Initialization: The population of candidate solutions representing feature subsets is initialized.
- Step 2: Harmony Memory Consideration: A memory stores the best solutions, guiding the search towards favourable feature combinations.
- Step 3: Harmony Construction: New harmonies are constructed by blending existing solutions with random adjustments, fostering diversity.
- Step 4: Evaluation and Update: The fitness of each harmony is evaluated, and the memory is updated with superior solutions to preserve high-quality features.
- Step 5: Termination Criteria: The search continues until a predefined criterion is met, ensuring convergence to an optimal or near-optimal feature subset.

The HSO-SUF combination further enhances the feature selection process. While HSO efficiently explores the feature

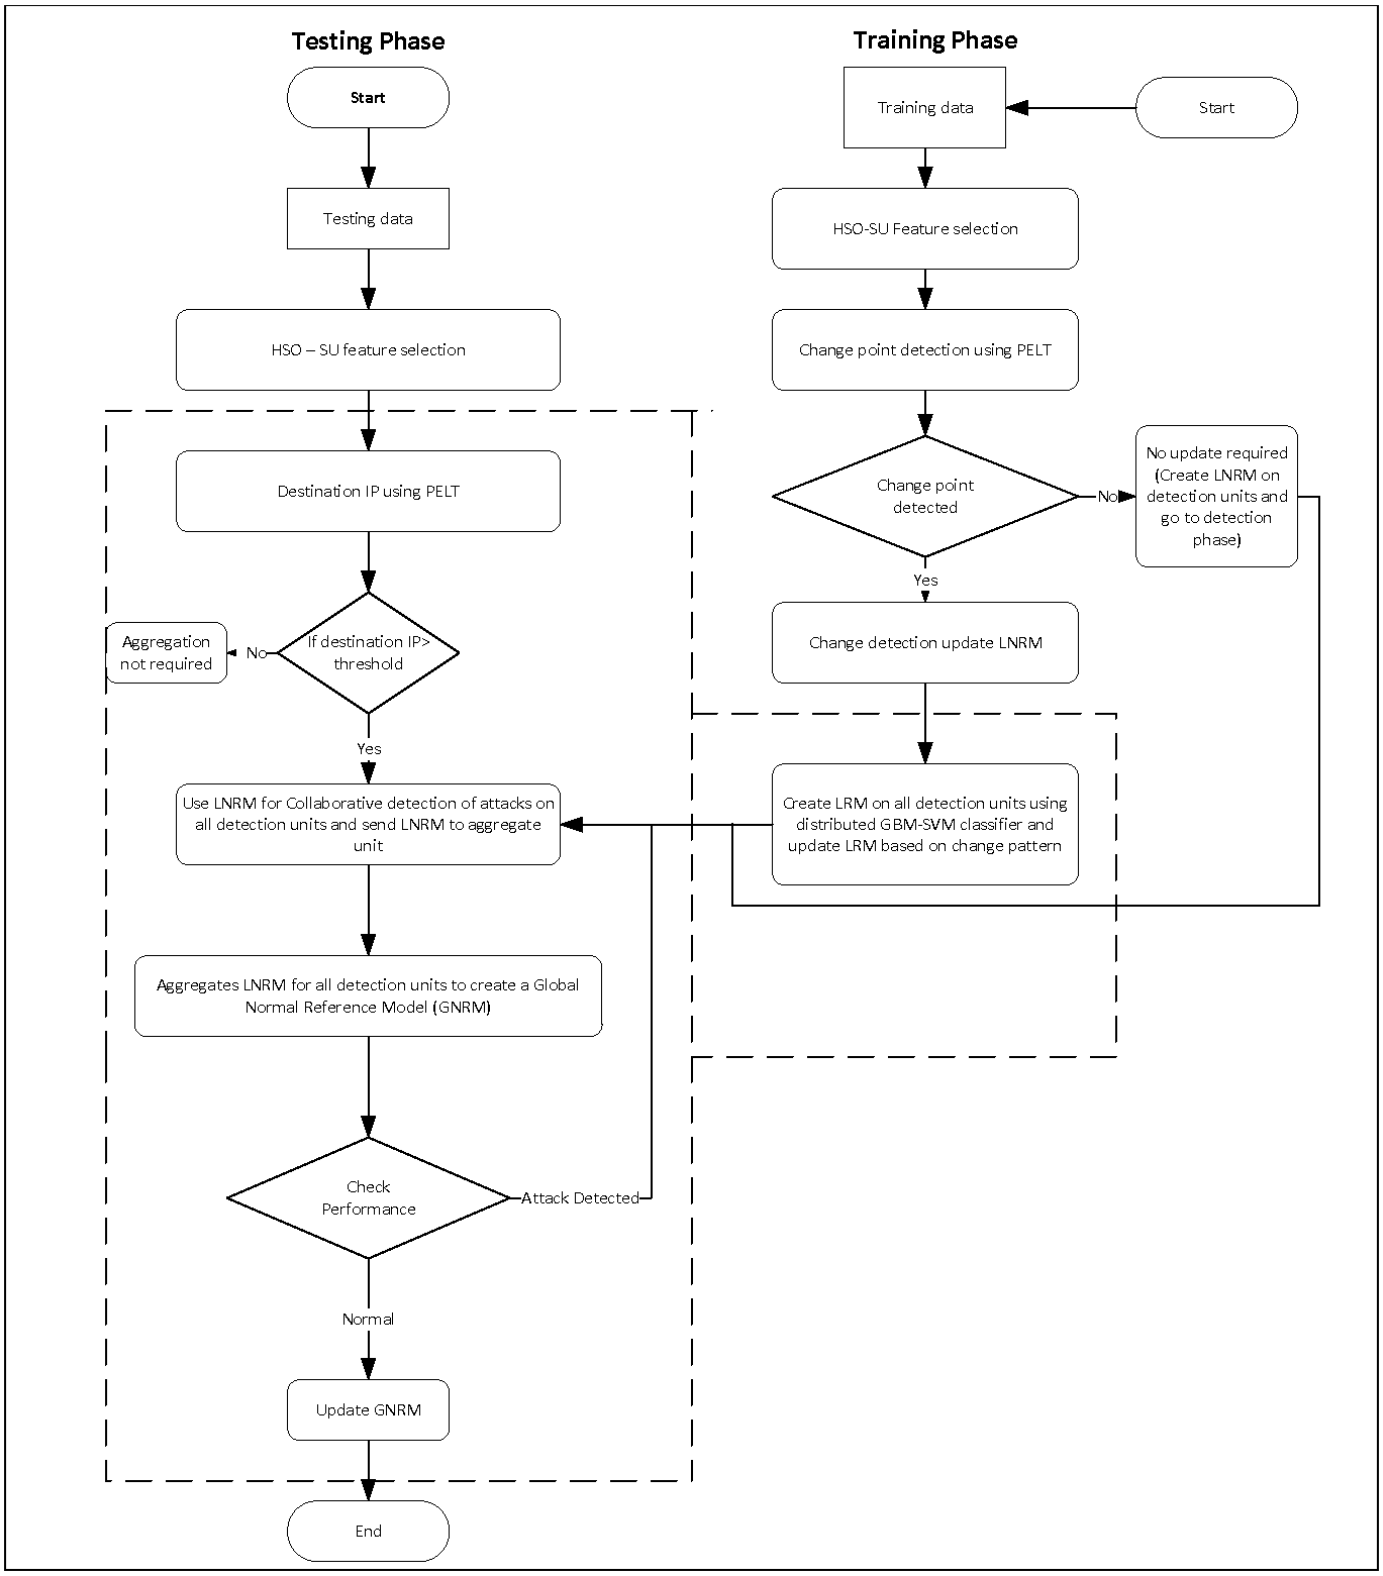

Fig. 1. The process for the adaptive and collaborative cloud intrusion detection model.

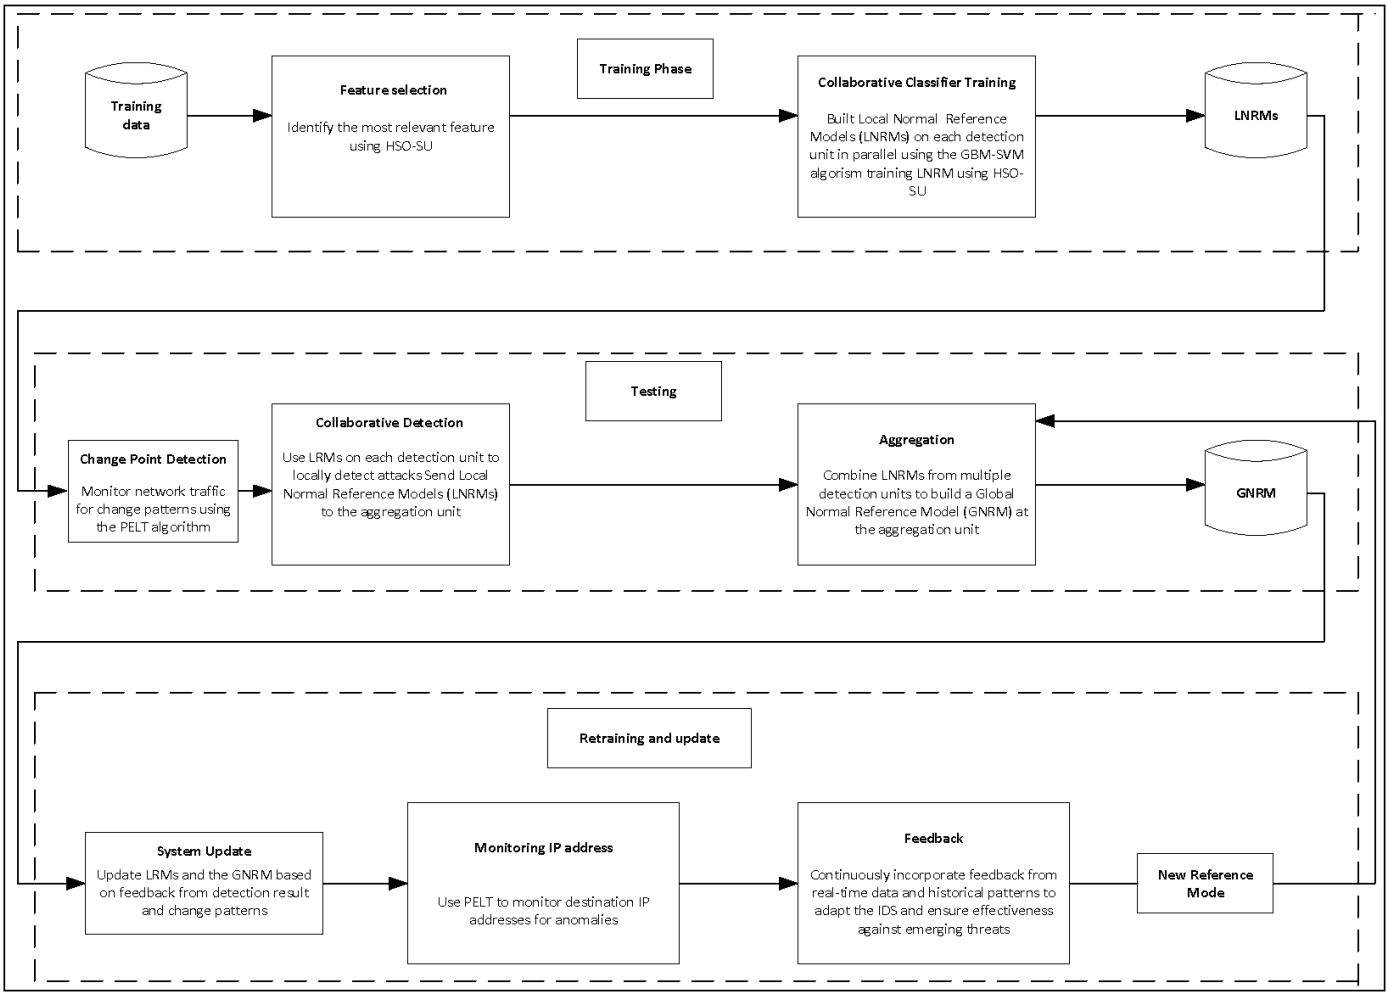

Fig. 2. Framework for an adaptive and collaborative cloud intrusion detection model with enhanced performance.

space, the SUF filter provides a mechanism to evaluate the relevance of each feature to the intrusion detection task. This two-pronged approach ensures that the selected features are diverse and demonstrably informative for anomaly detection. Our previous work [30] delves deeper into HSO for feature selection. By integrating HSO and SUF, our feature selection unit aims to optimize model performance by selecting features that significantly contribute to anomaly detection while mitigating the impact of noise and irrelevant data. This HSO-SUF combination forms a critical component of our comprehensive evaluation, demonstrating the effectiveness of HSO-SUF in addressing the unique challenges posed by cloud intrusion detection.

Therefore, the impact of Feature Selection in the process is an efficient HSO-SUF FS-filter that reduces the dataset's dimensionality, leading to a more manageable and computationally efficient intrusion detection model. This efficient approach, by focusing on relevant features, improves the model's accuracy in identifying anomalous network traffic, providing reassurance of its effectiveness.

Pheromone updating is based on the fitness function (γ') as depicted in Eq. (1). The feature subset discovered by the Harmony Search is denoted as X^i. The quality of the subset X^i and its size $|X^i|$ are measured using the evaluation metrics employed in the proposed HSO-SUF Model, namely Accuracy, Detection Rate (Precision), False Positive Rate and Sensitivity, as highlighted in Eq. (2), (3), (4) and (5). The Random Forest classifier is used to calculate metrics such as False Positives (FP), False Negatives (FN), and True Positives (TP), where FP represents the false positive rate, FN represents the false-negative rate, and TP represents the true positive rate [31].

$$\gamma' = \frac{\text{Sensitivity}\left(X^i\right) + \text{Precision}\left(X^i\right)}{|X^i|} \tag{1}$$

$$\text{Accuracy } = \frac{(TP + TN)}{(TP + TN + FP + FN)} * 100 \tag{2}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{3}$$

$$\text{False Positive Rate} = \frac{FP}{FP + TN} \tag{4}$$

Algorithm 1 Collaborative and Adaptive Cloud Anomaly Intrusion Detection Model

Require: X, Y: Network traffic training and test data
Ensure: $Sbest$: Optimal feature set, τ: Change point positions, m: Number of change points, $i\tau$: Interval between successive change points, c: Classification output normal or intrusion
(Feature Selection)
Input network traffic data X, Y.
Select optimal features $Sbest$.
(Collaborative Classifier Training and Update)
Input training data X, Y from datastore and split data among various nodes.
Initialize model parameters.
Detection units build Local Normal Reference Model (LNRM) m_i in parallel using GBM-SVM on each computing node.
Update Local Normal Reference Model using $\mu i\tau$ as the frequency of the update period.
(Change point Detection)
Detect the position of the change in data using PELT.
if change point τ is detected **then**
    Count the number of change points m.
    Determine the average interval between successive change points, $\mu i\tau$.
    For GBM-SVM, use $\mu i\tau$ as the classification model update period.
end if
(Destination-IP Traffic Monitoring)
Monitor network traffic for change patterns using the PELT algorithm.
Using the Pruned Exact Linear Time (PELT) technique, monitor the volume of destination-IP traffic from the same host.
if Destination-IP amounts of traffic from the same host ¿ Threshold **then**
    Send LNRM from detection units to the aggregation unit.
end if
(Collaborative Detection Phase)
for all detection units using X, Y samples on the LNRM to detect attacks **do**
    Send Local Normal Reference Models (LNRMs) to the aggregation unit.
    Aggregate LNRM m_i from all detection units by computing the average of the LNRM $M = \frac{1}{z}\sum_{z=1}^{n} m_i$.
    Return M.
    Classify network traffic as normal or malicious.
end for

$$\text{Sensitivity} = \frac{TP}{TP + FN} \tag{5}$$

B. Collaborative Classifier Training and Update Unit

This core unit orchestrates a distributed learning ballet, collaboratively training the GBM-SVM classification algorithm on the designated dataset. This collaborative approach allows the classifier model to dynamically adapt to evolving data patterns, ensuring its ongoing relevance and effectiveness. EC-A-CAIDM leverages the Python Apache Spark framework, renowned for efficiently handling distributed data processing tasks [32], [33]. To facilitate this distributed learning, the dataset is partitioned into Resilient Distributed Datasets (RDDs), distributed across a dedicated cluster comprising a head node and six worker nodes. The head node acts as the central conductor, orchestrating the collaborative efforts of the worker nodes, designated as detection units. These nodes simultaneously engage in GBM-SVM classifier training, generating their own Local Normal Reference Model (LNRM). These LNRMs capture patterns of normalcy within each node's designated data partition, providing localized insights for subsequent detection. This collaborative approach harnesses the computational power of distributed nodes, dramatically increasing efficiency and enhancing EC-A-CAIDM's overall detection capabilities.

Implementing the Collaborative Classifier training process involves partitioning datasets into Resilient Distributed Datasets (RDDs), facilitating parallelized processing by distributing data objects across clusters. This collaborative approach, characterized by seamless coordination among distributed nodes, maximizes computational efficiency, significantly enhancing the model's capability for effective intrusion detection. Moreover, the Gradient Boosting Machine (GBM) has been effectively combined with various machine learning algorithms such as Adaline, K-means, Perceptron, and Support Vector Machine (SVM) for online training [34]. In scenarios where training samples are provided sequentially, GBM processes each data sample individually, updating the model's weights accordingly [35]. The incremental nature of GBM's parameter updates for the Reference Model is a key feature that offers several advantages, including adaptability and suitability for dynamic Models that evolve over time or in scenarios where data distribution is not static [36]. Given that adaptability to the dynamic cloud environment is a crucial requirement for cloud Intrusion Detection Models (IDm) [37], this research and development effort employs GBM to achieve an adaptive Intrusion Detection Model (IDM).

Each example z in the learning task in a supervised learning context consists of a pair of instances x, y with x an arbitrary input and y an associated output. The learning process involves considering a loss function $l(\hat{y}, y)$ that quantifies the cost of prediction $\hat{y}$ errors compared to y actual outputs. This loss function plays a crucial role in the learning process, as it guides the selection of a family F of functions $f_w(x)$ with parameters w, represented as a weight vector, and the search function $f \in F$. The objective is to find the function that minimizes the average loss across all examples, as Eq. (6) describes. The training (Reference Model) performance is evaluated using empirical risk, as shown in Eq. (7). This empirical risk $E_n(f)$ measures how well the model performs on the training data. The SVM (hinge loss) is employed as the loss function [34], as illustrated in Eq. (8). GBM builds a Reference Model for classification by minimizing empirical risk $E_n\left(f_w\right)$ after each

iteration (t) and updating it based on a single occurrence z_t using Eq. (9).

$$Q(x, w) = l\left(f_w(x), y\right) \tag{6}$$

$$E_n\left(f_w\right) = \frac{1}{n}\sum_{i=1}^{n} l\left(f_w\left(x_i\right), y_i\right) \tag{7}$$

$$l(\hat{y}, y) = \max(0, 1 - \hat{y}y) \tag{8}$$

$$w_{t+1} = w_t - \gamma_t \nabla_w Q(z_t, w_t) \tag{9}$$

C. IP Traffic Monitoring Unit

The focus on destination IP analysis stems from the observed surge in destination IPs from the same host during DDoS attacks [38], analyzing the mean values of destination IP addresses during normal periods. The meticulously designed training phase of EC-A-CAIDM lays the groundwork for its collaborative detection prowess. By harnessing the power of feature selection, distributed classifier training, and IP traffic monitoring, EC-A-CAIDM equips itself with the essential insights and models required for accurate and efficient anomaly detection in the intricate and diverse landscape of cloud computing.

In the PELT algorithm, detecting a single change point can be posed as a hypothesis test. The null hypothesis H_0 corresponds to no change point ($m = 0$), and the alternate hypothesis H_1 is a single change point ($m = 1$). A test statistic is constructed to decide whether a change has occurred. The likelihood ratio-based approach is used to test the hypothesis, which requires the calculation of maximum log-likelihood under both the null and alternate hypotheses. For the null hypothesis, the maximum log-likelihood is $\log \hat{P}(y_{1:n}|\theta)$, where $P(y_{1:n})$ is the probability density function associated with the data distribution, and $\hat{\theta}$ is the maximum likelihood estimate of the parameter [39]. The maximum likelihood under the alternate hypothesis is $\max_{T_1} \mathrm{ML}(T_1)$, where the maximum is taken over all possible change points, as shown in Eq. 10.

$$\lambda = 2\left[\max_{T_1} \mathrm{ML}(T_1) - \log P\left(y_{1:n} \mid \hat{\theta}\right)\right] \tag{10}$$

The test requires selecting a threshold C so that the null hypothesis λ is rejected if λ exceeds C. To identify multiple change points, the likelihood test statistic can be expanded to find the maximum of $\mathrm{ML}(T_{1:m})$ across all possible combinations of $T_{1:m}$ as shown in Eq. 11.

$$ML\left(T_{1:m}\right) = \sum_{i=1}^{m+1}\left[C\left(y_{(T_{i-1}+1):T_1}\right)\right] + Bf(m) \tag{11}$$

The cost function C represents a segment's cost, and $B_f(m)$ serves as a penalty to prevent overfitting. The negative log-likelihood is commonly used as the cost function, while Akaike's Information Criterion (AIC) and Bayesian Information Criterion (BIC) are popular choices for the penalty [39]

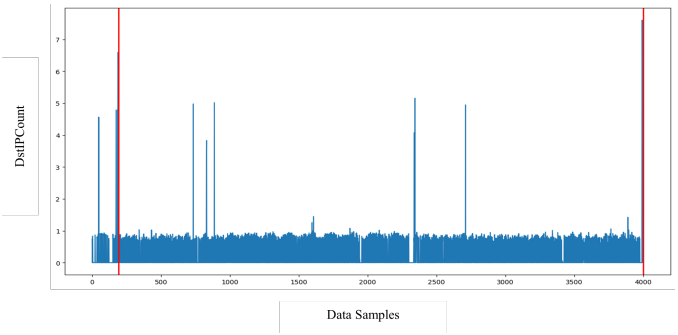

Fig. 3. Mean destination host count during normal periods in the NSL-KDD dataset.

The threshold for sending the Local Normal Reference Model (LNRM) to the aggregation unit was determined experimentally by examining the mean value of the destination-host-count (the number of network connections to the same destination host) for normal data instances using samples from the NSL-KDD dataset.

In Fig. 3, the red horizontal line indicates the mean value of the destination-host count during normal periods, which is approximately 1.0. Thus, the threshold for the normal period was set at 1.0. Thus, by integrating these advanced techniques, EC-A-CAIDM enhances its ability to detect and respond to anomalies, providing robust security for cloud computing environments.

V. The EC-A-CAIDM Testing Phase

The testing phase of EC-A-CAIDM seamlessly unites three core units i) change point detection, ii) distributed attack detection, and iii) aggregation—to create a symphony of collaborative threat identification and response. This phase rigorously evaluates the model's ability to accurately detect and address anomalies in network traffic data, with each unit playing a distinct yet complementary role in bolstering overall reliability.

A. Change Point Detection (CPD) Unit

The change point detection unit, our Model's watchful sentinel, meticulously monitors network traffic data for deviations that indicate potential intrusions or anomalies. The DAD unit vigilantly watches to identify change points within the datasets, providing crucial insights for determining an optimal frequency for updating the IDM reference model. This unit is essential to guarantee prompt and accurate threat identification by detecting subtle shifts in data patterns, enabling EC-A-CAIDM to adapt to evolving threats proactively.

B. Distributed Attack Detection (DAD) Unit

This unit acts as the heart of the EC-A-CAIDM model during the detection phase, conducting parallel intrusion detection on test data using the LNRMs generated during the distributed training phase. The DAD unit *dynamically* adjusts the transmission of LNRMs to the aggregation unit (head node)

based on a carefully determined threshold established through empirical observations of traffic patterns—specifically, changes in mean traffic volume from the same host, as detailed in the traffic monitoring unit.

Apache Spark's shared variables, known as accumulators, facilitate seamless communication between detection units (agent nodes) and the aggregation unit, enabling cohesive assessment of the intrusion detection process. Additionally, EC-A-CAIDM employs a synchronized approach to optimize computational resources and response times. The transmission of results is meticulously coordinated using the mini-batch parameter of GBM-SVM, ensuring alignment with periods of heightened destination-IP volume indicative of potential threats.

C. Aggregation Unit (AU)

In this final stage of the detection phase, the aggregation unit acts as a central conductor, synthesizing individual insights into a comprehensive global perspective. The AU collects, amalgamates, and consolidates the Local Normal Reference Models (LNRMs) contributed by participating detection nodes using Eq. (6) through (9), forming a robust Global Normal Reference Model (GNRM) as shown in Eq. (12). This collaborative approach is fundamental to the core objectives of our model. By drawing upon the collective strengths of each node's unique perspective, the AU empowers EC-A-CAIDM to effectively detect anomalies and adapt to evolving threat landscapes, ultimately enhancing its overall performance and adaptability. The detection phase of EC-A-CAIDM showcases the power of collaborative intelligence needed for effective intrusion detection. EC-A-CAIDM demonstrates its ability to recognize and address risks efficiently in a dynamic and distributed cloud environment by carefully coordinating i) change point detection, ii) distributed attack detection, and iii) aggregation. This process, as elucidated by [40], is fundamental to the core objectives of our collaborative model.

$$M = \frac{1}{k}\sum_{i=1}^{k} m_i \tag{12}$$

VI. The EC-A-CAIDM Retraining and Updating Phase

The final phase of the Enhancing Adaptive and Collaborative (EC-A-CAIDM) model, retraining and updating, constitutes the driving force of its continuous evolution and adaptation to the ever-evolving threat landscape. This phase is governed by the Feedback unit, which acts as the Model's learning engine, enabling it to continuously refine its capabilities through insights extracted from real-time and historical data.

A. Feedback Unit

In an adaptive and collaborative intrusion detection model, the role of feedback mechanisms is paramount. These mechanisms gather crucial information from detected intrusions and anomalies, providing valuable fuel for model improvement. Upon detecting an event, the feedback model meticulously captures relevant data, including the nature of the threat, its specific characteristics, and the model's response. This rich data reservoir is then analyzed and processed to extract valuable insights and patterns. These extracted insights are subsequently fed into the training phase, serving as an essential input for the adaptive refinement of intrusion detection models.

This iterative feedback loop forms the cornerstone of the model's continuous learning and improvement. By incorporating experiences into its training arsenal, EC-A-CAIDM continuously updates its detection algorithms, fine-tunes decision-making processes, and expands its knowledge base on potential threats. This continuous evolution empowers the Model to consistently improve its accuracy in identifying and mitigating diverse intrusion attempts, ultimately enhancing its resilience against the ever-shifting threat landscape in dynamic cloud environments. Now, lets consider the combining of elements in the above Eq. (12) for the feedback unit, which adjusts the model continuously based on feedback from detected anomalies. The process can be summarized as shown in Eq. (13):

$$w_{t+1} = w_t - \gamma_t \nabla_w \left(\frac{1}{n}\sum_{i=1}^{n} \max(0, 1 - f_{w_t}(x_i) y_i) \right) \tag{13}$$

Here, γ_t represents the learning rate at time t, and ∇_w denotes the gradient with respect to the weight vector w. This equation ensures that the model weights are updated continuously based on the feedback from detected anomalies, thereby improving the model's performance over time.

VII. Dataset

The NSL-KDD benchmark dataset has been selected to evaluate the proposed Enhanced Adaptive and Collaborative Cloud Intrusion Detection Model (EC-A-CAIDM) due to its widespread acceptance in the research community. Despite being derived from the KDD-Cup 99 dataset and its potential limitations in representing real-world cloud intrusions, NSL-KDD offers a diverse and labelled network traffic data set that includes both normal and malicious activities. This dataset provides a standardized evaluation platform and aligns with standard research practices, reassuring the readers about the research's validity and reliability [41] and comparability.

The NSL-KDD dataset, with its realism and diversity of attack types, provides a robust tool for assessing intrusion detection models in both traditional networks and cloud computing environments. This dataset comprises 41 features with labels, including instances from KDD-Cup 99 and introduces some new attacks into the test set. The dataset includes categories such as DoS, Probe, User to Root (U2R), and Remote to Local (R2L), with detailed class distributions in the training and test sets. These comprehensive features enable a thorough and rigorous evaluation of the EC-A-CAIDM, instilling confidence in the research's methodology and results [42].

For a detailed breakdown of the dataset's composition, refer to Table I and Table II.

TABLE I. DISTRIBUTION OF INSTANCES IN THE TRAINING AND TESTING NSL-KDD DATASET

Class	Training	Testing
Normal	67,343	9711
DoS	45,927	7460
Probe	11,656	2421
R2L	995	2885
U2R	52	67
Total	**125,973**	**22,544**

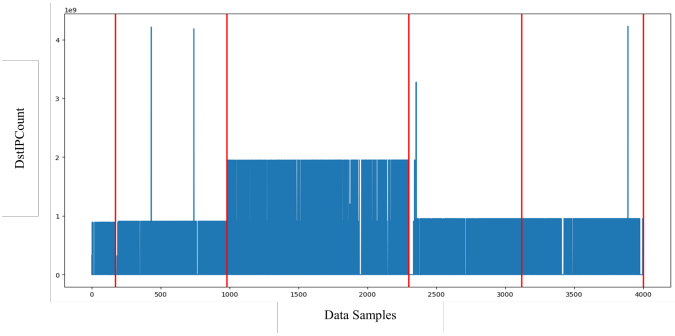

Fig. 4. Mean destination host count during Smurf DDoS attacks from NSL-KDD.

VIII. RESULTS

Evaluating the Enhanced Adaptive and Collaborative Cloud Intrusion Detection Model (EC-A-CAIDM) is a practical assessment of the proposed model's real-world application. We'll explore its performance across the following key areas:

A. Feature Selection

Examines the effectiveness of the Hybrid Feature Selection (HSO-SUF) technique, which leverages Harmony Search Optimization and a Symmetrical Uncertainty Filter, for identifying the most relevant features for intrusion detection within the cloud environment. The feature selection process identified a refined set of 13 features from the original 41 features within the NSL-KDD dataset. This selection process plays a crucial role in improving the efficiency and accuracy of the intrusion detection model. In particular, these 13 features are the key to validating our improved model. The features are Network Traffic Characteristics: Service, flag, src-bytes, and dst-bytes. Connection Details: logged-in, count. Error Rates: error-count, dst-host-serror-rate, dst-host-srv-serror-rate. Traffic Patterns: same-srv-rate, diff-srv-rate, dst-host-srv-count, dst-host-same-srv-rate.

B. IP Traffic Monitoring Unit

We evaluate the performance of the PELT change point detection algorithm employed by the IP Traffic Monitoring Unit. This analysis focuses on its ability to detect anomalies in destination IP traffic patterns. The IP Traffic Monitoring Unit, with the crucial assistance of the PELT change point detection algorithm, identifies significant changes in the mean volume of traffic directed towards specific destination IPs originating from the same source. This analysis, driven by the PELT algorithm, is key in determining when to trigger the aggregation of Local Normal Reference Models (LNRMs) from various detection units. As illustrated in Fig. 4, the destination host count surpasses the pre-defined normal threshold established during the destination-IP monitoring phase. This significant threshold violation between the 1000th and 2300th instances in the data demands immediate action. Consequently, during this specific period, the detection units will send their LNRMs to the aggregation unit for further processing.

IX. DISCUSSION

The results of the proposed Enhanced Collaborative and Adaptive Cloud Anomaly Intrusion Detection Model (EC-A-CAIDM) demonstrate significant improvements in performance metrics, as shown in Table III. The EC-A-CAIDM achieved an impressive accuracy of 100%, a detection rate of 99.99%, and a false positive rate of 0.01%. This 100% accuracy is a significant achievement, indicating that the model is highly effective in identifying and mitigating such intrusions in cloud environments. It is important to note, that this accuracy was achieved on a comprehensive and diverse dataset, ensuring that the model does not over fit a specific set of data.

Comparative analysis with existing collaborative anomaly intrusion detection models (AIDMs) highlights the superior performance of EC-A-CAIDM. For instance, the Distributed Collaborative Intrusion Detection System (D-CIDS) achieved a notable accuracy of 99.6%, a detection rate of 99.7%, and a false positive rate of 0.03%. While D-CIDS shows strong performance, EC-A-CAIDM outperforms the D-CIDS across all metrics, emphasizing its enhanced detection capabilities and lower false positive rate.

Similarly, the Hybrid Detection Classifier (HDC) proposed by [8], combining KNN and SVM, achieved an accuracy of 99.85%, a detection rate of 99.78%, and a false positive rate of 0.09%. Despite the effectiveness of HDC, EC-A-CAIDM's results are superior, indicating a more precise and reliable detection mechanism.

The Distributed Anomaly Detection (DAD) system, which utilizes Gaussian Mixture-based Correntropy, demonstrated high performance with an accuracy of 99.9%, a detection rate of 99.92%, and a false positive rate of 0.11%. Although DAD is highly effective, EC-A-CAIDM still provides better accuracy and a significantly lower false positive rate, making it a more effective choice for cloud anomaly detection.

Lastly, the Distributed Anomaly Detection using the Ensemble Hybrid (DADEH) technique achieved an accuracy of 93%, a detection rate of 99%, and a false positive rate of 0.3%. The notable performance gap between DADEH and EC-A-CAIDM further highlights the latter's advancements in accuracy and false positive reduction.

The EC-A-CAIDM's novel approach to determining the optimal timing for sharing attack information among nodes in the collaborative AIDM has contributed to its enhanced

performance. By effectively synchronizing attack information dissemination and employing adaptive learning techniques, the model achieves higher accuracy and detection rates and significantly reduces the occurrence of false positives. This adaptive and collaborative approach ensures that the model remains robust against evolving threats and maintains high performance in diverse cloud environments, reassuring the audience.

In conclusion, the EC-A-CAIDM sets a new benchmark and standard in cloud anomaly intrusion detection by achieving outstanding performance metrics. Compared to existing models, its superior accuracy, detection rate, and low false positive rate underscore its potential as a highly effective solution for ensuring the security of cloud-based systems. The efficiency of EC-A-CAIDM is sure to impress all stakeholders.

The data in Table III and Fig. 5, 6 and 7 unequivocally demonstrate that EC-A-CAIDM outperforms these existing models regarding accuracy, detection rate, and false positive rate. Additionally, EC-A-CAIDM has a lower detection time in seconds compared to CAIDM. The superior performance of the EC-A-CAIDM can be attributed to the effective strategy in determining the optimal timing for sharing attack information among nodes in the collaborative IDM. One of the critical challenges in collaborative IDMs is deciding when to share attack information among detection units to minimize the rate of false alarms that can result from inappropriate timing. EC-A-CAIDM successfully addresses this challenge, leading to the aforementioned enhanced performance.

X. CONCLUSION

This paper introduced the Enhanced Collaborative and Adaptive Cloud Anomaly Intrusion Detection Model (EC-A-CAIDM), a pioneering approach crafted to combat the escalating threat of sophisticated attacks in cloud environments. EC-A-CAIDM operates on a distributed architecture with seven specialized units, including feature selection, collaborative classification, IP traffic monitoring, change point detection, distributed attack detection, aggregation units, and a feedback mechanism for continuous learning. The core strength of EC-A-CAIDM lies in its strategic sharing of attack information among detection units, guided by the PELT change point detection algorithm, which effectively mitigates the challenge of false alarms prevalent in collaborative intrusion detection models. Its comprehensive evaluation using the NSL-KDD dataset demonstrates superior accuracy, detection rate, and very low false positive rate compared to existing models, instilling confidence in its effectiveness. However, the model's reliance on predefined feature sets may limit its adaptability to zero-day attacks and advanced persistent threats (APTs), and its computational complexity could pose challenges in highly dynamic cloud environments. Future research should address these limitations by exploring adaptive feature engineering techniques, lightweight architectures for real-time processing, and adversarial learning methods to enhance resilience. Advancing these areas can further improve EC-A-CAIDM's robustness and scalability, contributing to the evolving field of cloud security and intrusion detection.

Near-Optimal Traveling Salesman Solution with Deep Attention

Natdanai Kafakthong, Krung Sinapiromsaran
Department of Mathematics and Computer Science, Chulalongkorn University, Bangkok, Thailand, 10330

***Abstract*—The Traveling Salesman Problem (TSP) is a well-known problem in computer science that requires finding the shortest possible route that visits every city exactly once. TSP has broad applications in logistics, routing, and supply chain management, where finding optimal or near-optimal solutions efficiently can lead to substantial cost and time reductions. However, traditional solvers rely on iterative processes that can be computationally expensive and time-consuming for large-scale instances. This research proposes a novel deep learning architecture designed to predict optimal or near-optimal TSP tours directly from the problem's distance matrix, eliminating the need for extensive iterations to save total solving time. The proposed model leverages the attention mechanism to effectively focus on the most relevant parts of the network, ensuring accurate and efficient tour predictions. It has been tested on the TSPLIB benchmark dataset and observed significant improvements in both solution quality and computational speed compared to traditional solvers such as Gurobi and Genetic Algorithm. This method presents a scalable and efficient solution for large-scale TSP instances, making it a promising approach for real-world traveling salesman applications.**

***Keywords*—Traveling salesman problem; deep learning; genetic algorithm**

I. Introduction

The Traveling Salesman Problem (TSP) [1] is a classic combinatorial optimization problem that involves finding the shortest possible tour for a salesman to visit a given set of cities, exactly once. Each city is connected by a set of weighted edges that represent the distances between cities, and the objective is to minimize the total travel distance. Despite its seemingly simple formulation, TSP is known to be NP-hard, meaning the computational complexity grows exponentially with the number of cities, making it extremely difficult to solve for large instances within a reasonable time frame.

TSP has significant importance in both theoretical research and practical applications. It serves as a benchmark for optimization techniques and has a wide range of real-world uses, such as logistics, manufacturing, and routing problems. Solving TSP efficiently can result in substantial cost savings and improved resource management in industries that rely on optimized routing and scheduling. Beyond its practical implications, TSP also represents a fundamental challenge in computational theory, driving the development of new algorithms and techniques that have broader applications in other complex optimization problems.

Several methods have been developed to solve TSP [1], including exact algorithms and heuristics. Exact methods, such as brute force, branch-and-bound, and dynamic programming, attempt to find the optimal solution but they are computationally expensive and infeasible for large-scale problems due to their exponential time complexity. On the other hand, heuristic and metaheuristic approaches like genetic algorithms (GA) [5], simulated annealing, and ant colony optimization [9] offer approximate solutions by exploring the solution space more efficiently without guaranteeing an optimal result. These methods are often favored for large instances due to their ability to provide good solutions within a reasonable time frame. The effectiveness of these solvers is therefore highly dependent on the initial solution or tour. A poor starting solution can lead to long convergence times and suboptimal solutions, while a good initial solution can significantly reduce the number of iterations and improve the overall performance of the solver.

A near-optimal initial solution can improve the performance of traditional solvers by reducing the search space and accelerating convergence. Deep learning models, trained on problem data such as city distances, can predict a near-optimal tour. However, these models may not always predict a valid tour that meets the tour constraints. In such cases, the predicted solution must be refined or corrected before it is passed to a traditional solver.

This paper proposes a hybrid approach that uses deep learning to predict an initial solution for TSP and introduces an algorithm to reformulate this prediction into a valid tour. If the predicted solution from the deep learning model is not a valid tour, the tour correction algorithm adjusts it by ensuring that each city is visited exactly once and the path forms a valid loop. This refined initial solution is then fed into traditional optimization methods, such as GA or Gurobi [23], significantly reducing the time and iterations required to reach an optimal or near-optimal solution. The key advantage of this approach is that even if the predicted tour is not optimal tour, the generated tour is not differ from the optimal tour too much.

This hybrid method offers a balance between speed and accuracy. By leveraging deep learning to predict a strong initial solution and correcting it as needed, the traditional solvers can focus on fine-tuning, which reduces computational time and allows for efficient optimization of large TSP instances.

A. Contributions

- This paper introduces an approach to reduce the computational time of traditional TSP solvers by providing a near-optimal tour as the starting solution, significantly improving solver solution time.
- The proposed deep learning architecture, TSPNet, utilizes an attention mechanism in the architecture to handle combinatorial tasks in TSP.

- An algorithm is presented to convert the predicted solution or tour from TSPNet, which may not always be a valid tour, into a proper initial tour that satisfies the TSP constraints.
- The effectiveness of TSPNet, combined with traditional solvers, is evaluated on the TSPLIB dataset [25], demonstrating substantial reductions in computational time.

The remainder of this paper is organized as follows. Section II reviews related work on TSP solvers and deep learning approaches. Section III introduces the mathematical notation for the TSP. Section IV discusses traditional TSP solvers and the use of deep learning models for predicting initial tours. Section V details the methodology, including synthetic dataset generation, TSPNet architecture, input preprocessing, training, and the solving process. Section VI presents experimental results on the TSPLIB dataset and evaluates the integration of TSPNet with a Genetic Algorithm. Section VII discusses findings, limitations, and future directions, and Section VIII concludes the paper.

II. Related Work

The Traveling Salesman Problem [1] is a well-known NP-hard combinatorial optimization problem that seeks to determine the shortest possible route that visits a set of cities exactly once and returns to the origin city. Recent advancements in deep learning and reinforcement learning have provided innovative approaches to tackle this complex problem. This section will explore various methodologies, including neural networks, genetic algorithms, and hybrid models that integrate these techniques.

One significant approach to solving TSP involves the use of deep reinforcement learning (DRL). DRL formalizes TSP as a sequential decision-making problem, allowing an agent to select the next city to visit at each step. This method leverages the powerful generalization capabilities of deep neural networks, yielding impressive results in solving TSP instances [2], [3]. For instance, Bello et al. demonstrated the effectiveness of a pointer network trained via reinforcement learning, which significantly improved performance on TSP tasks [2]. Additionally, the incorporation of evolutionary algorithms with DRL has shown promise in multi-objective optimization scenarios, further enhancing the solution quality for TSP variants [3].

Another noteworthy methodology is the application of Hopfield neural networks, which have been historically significant in solving combinatorial optimization problems, including TSP. The Hopfield network utilizes an energy function to find optimal tours by minimizing the total travel distance [4]. This approach has been validated through various studies, demonstrating its capability to outperform traditional computational methods in specific instances of the TSP [4]. Moreover, the integration of chaotic neural networks has been proposed to enhance the performance of Hopfield networks, providing a novel perspective on TSP solutions [4].

Genetic algorithms (GAs) also play a crucial role in addressing the TSP [5]. These algorithms mimic the process of natural selection to iteratively improve solutions. Recent studies have highlighted the effectiveness of hybrid genetic algorithms that combine traditional GA techniques with neural networks, leading to improved convergence rates and solution quality for TSP [6], [7]. Furthermore, the application of multi-colony ant systems and particle swarm optimization has been explored as alternative heuristic methods for solving TSP, showcasing the versatility of approaches available to researchers [8], [9].

Recent studies have highlighted the effectiveness of deep reinforcement learning (DRL) in developing heuristics for TSP. For instance, Kool et al. introduced a method called Deep Policy Dynamic Programming, which integrates machine learning with dynamic programming to yield near-optimal solutions for TSPs with up to 100 nodes, demonstrating competitive performance against established solvers like LKH [10]. Similarly, Perera et al. utilized pointer networks within a multi-objective deep reinforcement learning framework, which enabled the model to generalize from smaller TSP instances to larger ones, achieving optimal solutions for TSPs with over 1000 cities [11]. These advancements illustrate the capacity of deep learning models to learn and adapt heuristics that can significantly improve solution quality and computational efficiency.

Moreover, the integration of graph neural networks (GNNs) has further enhanced the ability to solve TSP. GNNs can effectively represent the problem as a graph, allowing for the exploration of various routes and the optimization of path selection through learned embeddings. This approach has been shown to outperform traditional methods by providing a more structured understanding of the problem space [12]. The ability of deep learning models to learn from data and improve their performance over time is particularly beneficial in combinatorial optimization, where the search space is vast and complex [13].

In conclusion, the integration of deep learning, reinforcement learning, and genetic algorithms has significantly advanced the methodologies available for solving the Traveling Salesman Problem. These approaches not only enhance the efficiency of finding optimal solutions but also expand the applicability of TSP solutions to various real-world scenarios, such as logistics and route planning. The ongoing research in this field continues to evolve, promising even more sophisticated techniques for tackling this enduring challenge in combinatorial optimization.

III. Mathematical Notation for the Traveling Salesman Problem

The Traveling Salesman Problem (TSP) is an optimization problem where a set of n cities must be visited exactly once, and the goal is to find the shortest possible route that visits each city and returns to the starting point. Mathematically, the TSP can be modeled as an integer linear programming (ILP) problem. To represent this mathematically, let $G = (V, E)$ be a complete graph where V is the set of cities, $|V| = n$, and E is the set of edges. Each edge $(i, j) \in E$ is associated with a distance or cost d_{ij}. Define the binary decision variable x_{ij} as follows,

$$x_{ij} = \begin{cases} 1 & \text{if the tour visits city } i \text{ and then city } j, \\ 0 & \text{otherwise.} \end{cases}$$

The objective is to minimize the total travel cost or total tour length, which can be written as,

$$\text{minimize} \sum_{i=1}^{n} \sum_{j=1, j\neq i}^{n} d_{ij} x_{ij}$$

subject to the following constraints.

1) Visit each city exactly once,

$$\sum_{j=1, j\neq i}^{n} x_{ij} = 1 \quad \forall i = 1, 2, \ldots, n.$$

This ensures that each city i is left exactly once.

2) Enter each city exactly once,

$$\sum_{i=1, i\neq j}^{n} x_{ij} = 1 \quad \forall j = 1, 2, \ldots, n.$$

This ensures that each city j is entered exactly once.

3) Subtour elimination, to prevent smaller loops that don't include all cities (sub tours), the following constraint is applied for all subsets $S \subset V$, where $|S| \geq 2$,

$$\sum_{i\in S} \sum_{j\in S, j\neq i} x_{ij} \leq |S| - 1.$$

This constraint ensures that the solution forms a single tour that includes all cities.

The optimal solution to TSP is the assignment of x_{ij} values (1 or 0) that minimize the total tour length while satisfying the constraints that ensure a valid tour. However, finding this optimal tour is computationally challenging due to the combinatorial nature of the problem. As the number of cities increases, the number of possible tours grows factorially, making it impractical for an exact algorithm to solve large instances within reasonable time limits.

In the context of solving TSP, a distance matrix plays a fundamental role. The distance matrix $D = [d_{ij}]$ is an $n \times n$ matrix, where d_{ij} represents the distance or cost of traveling from city i to city j. Mathematically, it is defined as,

$$D = \begin{bmatrix} 0 & d_{12} & d_{13} & \ldots & d_{1n} \\ d_{21} & 0 & d_{23} & \ldots & d_{2n} \\ d_{31} & d_{32} & 0 & \ldots & d_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ d_{n1} & d_{n2} & d_{n3} & \ldots & 0 \end{bmatrix}. \tag{1}$$

The $d_{ii} = 0$ since there is no distance associated with staying in the same city. This matrix forms the core input for solving TSP, as it provides the necessary information about the travel costs between every pair of cities.

IV. TSP Solvers

Traditional solvers for the Traveling Salesman Problem (TSP) rely heavily on the distance matrix [15], [16], [17], a fundamental representation that captures the pairwise distances between cities. This matrix plays a central role in various exact and heuristic algorithms, such as branch-and-bound [18], [19], dynamic programming [20], and cutting-plane methods [21], where it helps determine the shortest path between cities. For example, in branch-and-bound algorithms, the distance matrix is used to calculate lower bounds and prune non-optimal tours efficiently. Similarly, heuristic algorithms like the nearest neighbor or genetic algorithms use the matrix to guide their search for near-optimal solutions by iteratively considering the shortest available edges between cities.

The distance matrix provides essential information for constructing and refining the solution to TSP, making it indispensable for solving this combinatorial problem. Solvers like Gurobi [23], Concorde [24], and others leverage the distance matrix at each step of their optimization process, ensuring the best possible path is found given the constraints.

In line with these solvers, our proposed deep learning model also takes the distance matrix as an input. Instead of manually optimizing over possible routes, our model learns to predict the optimal tour from the structure of the distance matrix itself. By incorporating attention mechanisms, the model can effectively learn which city connections contribute most to form the optimal solution. The use of a distance matrix thus remains central, both in traditional algorithms and in modern machine learning approaches for solving TSP.

A. Predicting the Optimal Tour Using a Deep Learning Model

The complexity of solving the traveling salesman problem arises from the factorial growth in the number of possible tours as the number of cities increases, making it computationally challenging for exact algorithms to handle a large-scale instance. As previously discussed, deep learning has emerged as a promising approach for approximating optimal solutions of TSP, offering a more efficient alternative to traditional methods.

One innovative approach leverages deep learning models to predict optimal sub-tours or the entire tour based on historical data or synthetically generated datasets. In this framework, TSP can be formulated by using a distance matrix $D = [d_{ij}]$, which encodes the pairwise distances between cities. The deep learning model is trained to output a matrix of probabilities $P = [p_{ij}]$, where each element $p_{ij} \in [0, 1]$ represents the likelihood of a connection between city i and city j appearing in the optimal tour. This probability matrix serves as the predicted adjacency matrix for TSP, with the highest probability in each row corresponding to the city that is most likely connected to city i in the optimal tour.

The model, denoted by f_θ with parameters θ, processes the distance matrix D and outputs the adjacency matrix P,

$$f_\theta(D) = P = \begin{bmatrix} p_{11} & p_{12} & \ldots & p_{1n} \\ p_{21} & p_{22} & \ldots & p_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ p_{n1} & p_{n2} & \ldots & p_{nn} \end{bmatrix}. \tag{2}$$

Each row of P represents a probability distribution over all cities for the next destination from city i. To obtain the predicted tour, the argmax function is applied to each row, selecting the city with the highest probability, resulting in the vector T of optimal adjacent cities,

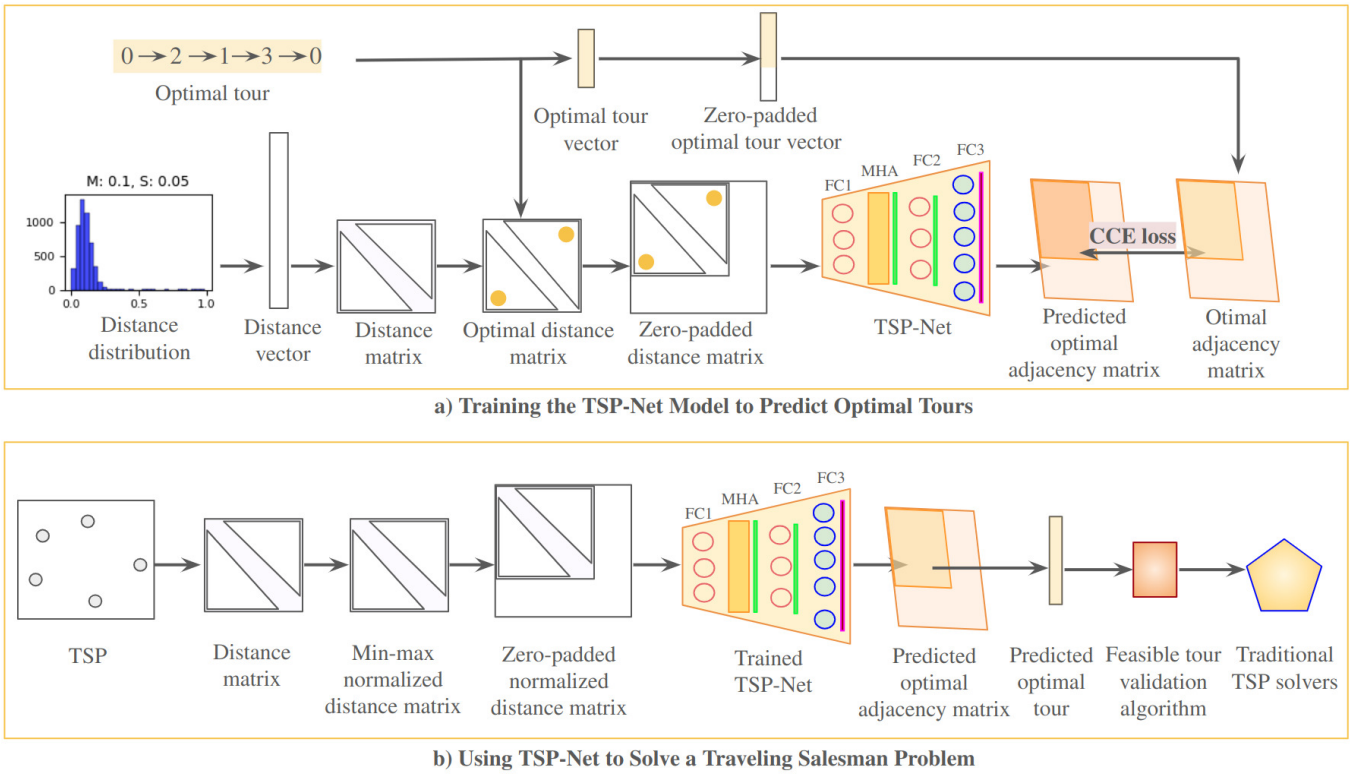

Fig. 1. Overview of the TSPNet framework: (a) Training involves generating distance matrices from a log-normal distribution and corresponding optimal tours to train the TSP model. (b) The trained model predicts a feasible tour, which is validated and can serve as an initial solution for traditional solvers.

$$T = \begin{bmatrix} t_1 \\ t_2 \\ \vdots \\ t_n \end{bmatrix} = \begin{bmatrix} \text{argmax}\{p_{11}, p_{12}, \ldots, p_{1n}\} \\ \text{argmax}\{p_{21}, p_{22}, \ldots, p_{2n}\} \\ \vdots \\ \text{argmax}\{p_{n1}, p_{n2}, \ldots, p_{nn}\} \end{bmatrix}. \quad (3)$$

In this representation, T contains the indices of cities selected as the next steps in the predicted tour. The predicted tour can then be reconstructed from T, forming a solution to TSP. This approach allows the deep learning model to approximate optimal solutions by learning patterns in city connections from the distance matrix efficiently, even for large-scale instances.

V. Methodology

This paper introduces TSPNet, a deep learning model designed to predict the optimal tour for the traveling salesman problem by learning the relationships between cities from distance matrices. The methodology involves two key stages: first, the training process of TSPNet, which includes generating synthetic training data, constructing input instances, and defining optimal tour labels for the model. The architecture of TSPNet is also detailed in a subsequent section. Second, TSPNet's predictions are extended to refine the solution using traditional solvers like genetic algorithms. By using TSPNet's predicted tour as an initial solution, these solvers require fewer iterations to reach an optimal or near-optimal solution. The next subsection discusses the dataset generation process for training TSPNet.

A. Synthetic TSP Training Dataset

TSP necessitates the generation of a distance matrix that accurately represents the distances between cities. In this study, a log-normal distribution is employed due to its capacity to model positively skewed data, which is often observed in real-world distance measurements.

A random variable X is said to be log-normally distributed if its natural logarithm, $Y = \ln(X)$, follows a normal distribution, that is

$$Y \sim \mathcal{N}(\mu, \sigma^2)$$

where μ is the mean and σ is the standard deviation of the underlying normal distribution. Consequently, X can be expressed as

$$X = e^Y \implies X \sim \text{Log-Normal}(\mu, \sigma^2).$$

This property ensures that the generated distances D are strictly positive, satisfying the non-negativity constraint required for distance metrics. A list of the distributions used to generate the training distances is shown in Fig. 2.

The figure presents the parameters used to generate various cases of log-normal distributions. This diversity allows the model to encounter different patterns of distances, enhancing its generalization ability and efficiency. Normally, input instances of deep learning will be normalized by min-max normalization before passing into the deep learning model. They are scaled into $[0, 1]$ then the training data of TSPNet will focus on generating training data in the range $[0, 1]$.

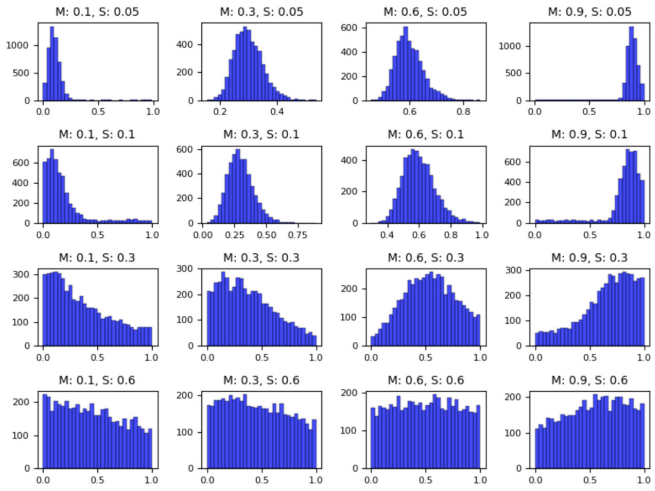

Fig. 2. Log-normal distributions for generating training distances.

For generating an input TSP instance of n cities or nodes from the log-normal distribution, the synthetic TSP datasets are executed as the following steps. The function described can be expressed mathematically as follows:

- n is the number of cities.
- μ is the mean of the generated distances.
- σ is the standard deviation of the generated distances.
- s is the scaling factor.
- λ is the shape parameter of the log-normal distribution.
- K is the number of unique tours to generate.
- $\mathcal{S}$ is the set of all cities $\{0, 1, 2, \ldots, n-1\}$.
- t_h is the h-th optimal tour T.

Step 1. Generate the distances: The generated distances are sampled from a log-normal distribution with parameters $\log(s)$ and λ,

$$d_{ij} \sim \text{LogNormal}(\log(s), \lambda), \forall i, j \in \{1, \ldots, \frac{n(n-1)}{2}\}, i < j.$$

Step 2. Adjust the mean and the standard deviation: Normalize the generated distances to have mean μ and standard deviation σ,

$$d'_{ij} = \frac{d_{ij} - \bar{d}}{\text{std}(d)} \cdot \sigma + \mu$$

where $\bar{d}$ is the mean of d_{ij} and $\text{std}(d)$ is the standard deviation. Step 3. Replace out-of-bound values: If $d'_{ij} < 0$ or $d'_{ij} > 1$, replace it with a uniformly random value within bounds,

$$d'_{ij} = \text{Uniform}(0, 1), \quad \text{if } d'_{ij} \notin [0, 1].$$

Step 4. Construct the distance matrix: The distance matrix D is symmetric and filled using the adjusted distances,

$$D_{ij} = D_{ji} = d'_{ij}, \quad \forall i < j.$$

The diagonal elements are set to zero

$$D_{ii} = 0, \quad \forall i.$$

Step 5. Create an optimal tour vector T: Defining a permutation t_h of the city indices,

$$t_h : \mathcal{S} \to \mathcal{S}, \quad \text{for } h = 1, \ldots, K.$$

Each t_h is a random shuffle of the set $\mathcal{S}$.

Step 6. The distance values in the distance matrix D_h corresponding to the cities in the optimal tour vector t_h will be reduced to ensure the distance matrix reflects the optimal tour.

Step 7. Convert the optimal tour vector t_h to be adjacency matrix using the one-hot-encoding technique for training the TSPNet model.

Thus, the distance matrix $D \in \mathbb{R}^{n \times n}$ is constructed based on the adjusted and bounded distances. By employing the log-normal distribution in this manner, the resulting distance matrix is both realistic and statistically appropriate, facilitating the effective training of the TSPNet model to predict the optimal adjacency matrix for varying configurations of cities.

B. TSPNet Input Preprocessing

To prepare the data for training the TSPNet model (as illustrated in Fig. 1(a), both the distance matrices and the corresponding optimal tour vectors are first created. As the input size for deep learning models is generally fixed, this research limits the maximum number of cities N in TSP to 200. To accommodate TSP instances with fewer than 200 cities, the distance matrices and optimal tour vectors are padded with zeros.

Let D be a distance matrix of size $n \times n$, where $n \leq N$, represents a TSP with n cities. The distance matrix D for n cities is structured as follows:

$$D = \begin{bmatrix} 0 & d_{12} & d_{13} & \ldots & d_{1n} \\ d_{21} & 0 & d_{23} & \ldots & d_{2n} \\ d_{31} & d_{32} & 0 & \ldots & d_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ d_{n1} & d_{n2} & d_{n3} & \ldots & 0 \end{bmatrix}. \tag{4}$$

For cases where $n < N$, D is padded to match the maximum size of $N \times N$, resulting in the following matrix,

$$D' = \begin{bmatrix} D & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}. \tag{5}$$

Similarly, the optimal tour vector T of size $n \times 1$ is padded to size $N \times 1$ as follows:

$$T' = \begin{bmatrix} T \\ \mathbf{0} \end{bmatrix}. \tag{6}$$

Once the distance matrices and optimal tour vectors have been padded to the standard size of $N \times N$ and $N \times 1$, respectively, they are used as input instances for training the TSPNet model, described in the TSPNet training process subsection.

C. TSPNet Architecture

The TSPNet model is designed to predict the optimal tour for the TSP instance using the distance matrix as input. The model efficiently predicts near-optimal solutions to TSP instances by leveraging deep learning techniques. The Table I provides a detailed summary of the architecture.

TABLE I. MODEL ARCHITECTURE SUMMARY

Layer (Type)	Output Shape	Param #
Input_layer_1 (InputLayer)	(None, 200, 200)	0
Flatten_1 (Flatten)	(None, 40000)	0
FC1 (Dense)	(None, 64)	2,560,064

Softmax (Softmax)	(None, 200, 200)	0
Total params	**7,861,440**	

The input to the model is a 200×200 distance matrix representing the pairwise distances between cities in a TSP instance with 200 cities. After flattening the matrix, the model applies a fully connected (Dense) layer to embed the data into a lower-dimensional feature space. This is followed by a reshaping step that adjusts the dimensions for further processing with a Multi-Head Attention (MHA) layer, which captures dependencies across different city pairs. Normalization, dense layers, and dropout regularization are employed to stabilize the learning process. Finally, the output is reshaped back into a 200×200 matrix, with a softmax layer of each row of the output matrix to provide probability distributions over the possible arcs between cities to become the predicted adjacency matrix of the TSP problem.

The use of attention mechanisms in deep learning has been explored to enhance the performance of algorithms. Attention mechanisms allow models to focus on relevant parts of the input data, thereby improving the decision-making process in selecting routes [14]. This approach has been successfully applied in various combinatorial optimization tasks, showcasing the versatility and effectiveness of deep learning techniques in tackling NP-hard problems like TSP.

D. TSPNet Training Process

The TSPNet training process begins with compiling the model using the AdamW optimizer [22], which operates with a learning rate of 0.001 and 64 batch sizes, alongside the Categorical Cross-Entropy (CCE) Loss function to address the problem's multi-class classification nature. The model's output is structured as a 2D matrix, where each row corresponds to a city in the traveling salesman problem. The softmax function is applied to convert the logits into probabilities representing the likelihood of each city-to-city connection. The loss function is defined as

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} y_{i,j} \cdot \log(p_{i,j}),$$

where N is the total number of cities (representing the rows of the output matrix), C is the total number of cities in TSP (representing the columns of the output matrix), set at 200, $y_{i,j}$ denotes the true label (either 0 or 1) for the connection between city i and city j (derived from the one-hot encoded label matrix), and $p_{i,j}$ represents the predicted probability for that connection obtained from the softmax output. This summation is performed over all rows and columns of the output matrix.

During training, the model iteratively adjusts its weights to minimize the computed loss, while the accuracy of its predictions is continuously monitored. Upon completion of the training process, the model's output probabilities are transformed back into a tour by selecting the city with the highest probability from each row of the output matrix. The average accuracy of the predicted tour is calculated by comparing it with the actual optimal tour. As illustrated in Fig. 3, the loss incurred during the training of TSPNet, which involved 100,000 training instances and 20,000 instances from a synthetic dataset, stabilizes after 7,146 iterations. The model achieves a maximum accuracy exceeding 98%, as shown in Fig. 4. Following this training phase, the model is evaluated against the TSPLib dataset, with results discussed in the subsequent experimental section.

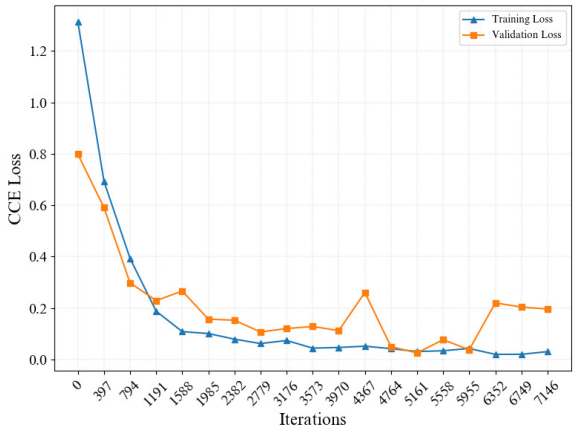

Fig. 3. Categorical cross-entropy loss values during training process.

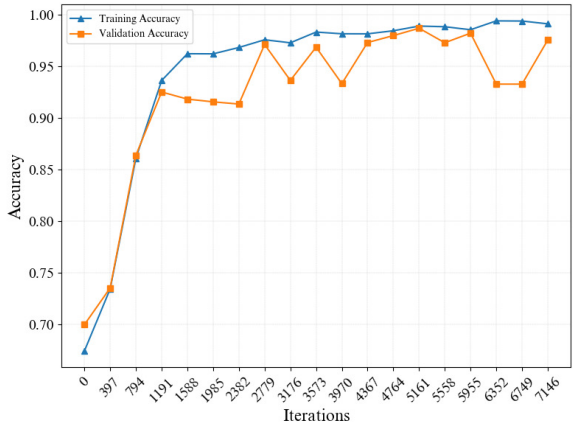

Fig. 4. Accuracy values during training process.

Although the model aims to predict the optimal tour, it

may occasionally yield invalid tours or infeasible solutions. To address this issue, the next subsection will introduce an algorithm designed to generate a valid tour when an optimal solution is not attained, before applying traditional optimization techniques, such as genetic algorithms, to search for the optimal tour.

E. TSPNet Solving Process

This section describes the process of solving the traveling salesman problem using the trained TSPNet model, as illustrated in Fig. 1(b). Given a TSP instance with n nodes, the first step is to generate an $n \times n$ distance matrix by calculating the pairwise distances between the coordinates of each city. This distance matrix is then normalized using min-max normalization before being fed into the pre-trained TSPNet model. The model outputs a zero-padded adjacency matrix, which represents the probabilities of each city being connected to another.

For a clearer understanding, let's consider Fig. 5, which shows a TSP instance with five cities. The predicted output matrix (adjacency matrix) from the TSPNet model is transformed into a predicted tour vector by selecting the city with the highest probability from each row, resulting in the tour vector T, as represented in Eq. (7),

$$\hat{T} = \begin{bmatrix} t_1 \\ t_2 \\ t_3 \\ t_4 \\ t_5 \end{bmatrix} = \begin{bmatrix} 2 \\ 4 \\ 5 \\ 3 \\ 1 \end{bmatrix} = \begin{bmatrix} \text{argmax}\{p_{11}, p_{12}, \ldots, p_{15}\} \\ \text{argmax}\{p_{21}, p_{22}, \ldots, p_{25}\} \\ \text{argmax}\{p_{31}, p_{32}, \ldots, p_{35}\} \\ \text{argmax}\{p_{41}, p_{42}, \ldots, p_{45}\} \\ \text{argmax}\{p_{51}, p_{52}, \ldots, p_{55}\} \end{bmatrix}. \quad (7)$$

This represents an ideal prediction of the optimal tour from the city i^{th} to the j^{th} city. However, when TSPNet encounters more complex instances, the predicted tour vector T may include errors, leading to infeasible or suboptimal solutions. To mitigate this issue, the tour correction algorithm is used to adjust the predicted solution to better approximate the optimal tour while minimizing the total cost or the tour length.

The algorithm consists of four main steps: Step 1 initializes all variables. Step 2 involves separating the predicted tour into subpaths, where each subpath contains unique nodes or cities. In Step 3, missing nodes, those not included in the model's predictions are identified and added as isolated paths containing only one node. After this step, the algorithm will have several subpaths, each containing unique node. Finally, in Step 4, these subpaths are connected by finding the minimum distance between the last node of one subpath and the first node of another, thereby forming a complete and feasible tour. The details of this algorithm are outlined in Algorithm 1.

Once the tour is obtained from Algorithm 1, it can be used as the initial solution for traditional solvers, such as a genetic algorithm. This integration allows the TSPNet prediction to serve as a starting point for other optimization methods, ensuring that the process begins with a feasible tour close to the optimal tour.

The following section presents the experimental results of TSPNet on a benchmark TSP dataset:

Algorithm 1 Find a Single Feasible Tour (With Missing Nodes and Distance Comparison)

Input: `Predicted tour` ($\hat{T}$), Distance matrix (`D`), Number of cities (`n`)
Output: T (feasible tour)

1. Initialize Variables
$T \leftarrow$ An empty feasible tour
$SP \leftarrow$ A set of subpaths
$AN \leftarrow$ A set of total nodes
$N \leftarrow$ A set of existing nodes
$MN \leftarrow$ A set of missing nodes
$MD \leftarrow$ Minimum distance between nodes
$Si \leftarrow$ Start index

 # 2. Split Predicted Tour into Subpaths
for each node i in $\hat{T}$ **do**
    if node i is not in N **then**
        Add node i to N
        Update Si
    else
        if Si is set **then**
            Add the subpath from Si to i to SP
            Reset Si
        end if
    end if
end for

if Si is set **then**
    Add the remaining subpath to SP
end if

 # 3. Add Paths for Missing Nodes into Subpaths
$MN \leftarrow AN - N$
for each node m in MN **do**
    Add node m as a separate subpath to SP
end for

 # 4. Connect Split Subpaths to Form a Tour
Set T to the first subpath and remove it from SP
while Length of $T <$ `n` **do**
    Initialize MD to infinity
    for each subpath in SP **do**
        Calculate the distance from the last node of `T` to the first node of the subpath
        if this distance is smaller than MD **then**
            Update MD and store the index of the subpath
        end if
    end for
    Add the closest subpath to T
    Update the last node in T and remove the selected subpath from SP
end while
return T

VI. Experimental Results

The system architecture is based on an x86_64 platform with an AMD EPYC 7B12 CPU, featuring 8 online CPUs (4 cores per socket with 2 threads each). The deep learning model is trained using TensorFlow [26] on an L4 GPU with 22 GB of VRAM, enhancing processing efficiency. Additionally, the research employs the DEAP [27] library for implementing genetic algorithms and the Gurobi solver for optimization tasks.

A. TSPLIB Dataset

The TSPLIB (Traveling Salesman Problem Library) is a widely used collection of benchmark instances for the traveling salesman problem and its variations, offering a range of instances from small to large sizes. The dataset is formatted in plain text files with problem details such as name, type, dimension, and coordinates or distance matrices. TSPLIB encompasses various problem types, including classic TSP, asymmetric TSP (ATSP), and vehicle routing problems (VRP), allowing researchers to benchmark and compare algorithm performance. The dataset is accessible through its official website and repositories like GitHub.

B. Genetic Algorithm (GA)

The Genetic Algorithm (GA) used in this study was configured with specific parameters to optimize the performance of the TSPLIB dataset. The population size was set to 300 individuals, and the crossover probability was 0.7, allowing a significant proportion of the population to exchange genetic information during each iteration. The mutation probability was set to 0.3, introducing randomness and variation into the population to avoid local optima. A gap threshold of 0.07% was implemented, meaning the algorithm would terminate early if the gap between the best-found solution and the optimal solution was less than 0.07%. The exact optimal distance values were retrieved from the third column of the official TSPLIB web resource and set as the best-known distances for the algorithm to target. The DEAP library was used to run the algorithm, with multiprocessing enabled to parallelize the workload and reduce runtime. Additionally, a local search technique known as 2-opt was applied to refine the best individuals, improving their solutions by eliminating suboptimal edges and enhancing the overall quality of the tour.

The Table II presents a comparison of different TSP solvers, including Mixed-Integer Programming (MIP) solvers (Gurobi and a Genetic Algorithm), and heuristic solvers (TSP-Net and TSPNet combined with GA), evaluated on multiple TSP instances from the TSPLIB dataset. The performance metrics compared include the objective value, the percentage gap from the optimal solution, and the time taken to solve the problems. The gap is calculated as a percentage difference between the best objective value found by Gurobi, GA, TSP-Net, or TSPNet GA and the optimal solution from the official TSPLIB web resource. The formula used for the gap is,

$$\text{Gap} = \frac{100 \times (\text{Best objective value from solver} - \text{Optimal})}{\text{Objective value from solver}}.$$

This formula expresses the relative deviation of the obtained solution from the known optimal solution. A lower gap value indicates a closer match to the optimal solution, with a gap of 0% representing a perfect match.

Gurobi was given an upper bound of 3600 seconds, and it consistently achieves objective values close to the optimal with minimal gaps, though its computation time varies significantly depending on the problem size, ranging from around 0.1 seconds to over 600 seconds, with some instances nearly reaching the time limit. The Genetic Algorithm and TSPNet GA were both given a time limit of 600 seconds. The Genetic Algorithm shows larger gaps and longer computation times compared to Gurobi, with instances such as d198 showing a gap of over 80%. The TSPNet heuristic solver performs exceptionally well, achieving objective values close to the optimal and minimal gaps for most instances, while being significantly faster than the MIP solvers, often solving problems in fractions of a second. The combination of TSPNet with GA slightly improves the objective values and maintains competitive computation times, showing minimal gaps and similar performance to TSPNet in terms of objective values. Overall, TSPNet proves to be a highly effective and fast heuristic solver, delivering accurate results with minimal gaps and outperforming traditional MIP solvers in terms of speed. The combination of TSPNet and GA offers additional benefits by balancing high accuracy with efficient computation times, demonstrating the practicality of heuristic approaches for solving large-scale TSP problems.

VII. Discussion

This research presents a deep learning model based on an attention mechanism for solving the Traveling Salesman Problem (TSP), contributing to the growing body of literature exploring innovative approaches to combinatorial optimization. Similar to the study by Kool et al. 2019 [14]. in “Attention, Learn to Solve Routing Problems,” which employs an attention model that utilizes model architecture inspired by the LSTM (Long Short-Term Memory) network to effectively predict optimal tours, this work also leverages attention mechanisms to enhance solution accuracy for TSP. Some experiments’

notable gaps include 1.76% for n = 50 and 4.53% for n = 100, showcasing its competitive performance. This research extends the exploration to more complex instances, specifically focusing on TSP127. The model developed in this study achieved a remarkable objective gap of only 0.01% for the TSP127 instance, demonstrating its capability to deliver highly accurate solutions for large problem sizes. The TSPNet solver has the potential to be more powerful if trained on a large dataset with diverse training distributions.

However, training on a wide range of problems requires significant computational resources. In this study, the synthetic training data were generated from a log-normal distribution as in Fig. 2, which presents some limitations. When data points do not conform to this distribution, the solver may fail to predict the optimal tour, as demonstrated in Fig. 6. The distribution exhibits two peaks in frequency values, which the TSPNet model has not been trained on, representing a limitation of the current model. This issue could be addressed by training the model on a wider variety of distributions in the future.

VIII. CONCLUSION

Solving a Traveling Salesman Problem (TSP) with iterative processes in a traditional solver is computationally expensive and time-consuming for a large-scale instance. However, this issue can be alleviated by determining the initial optimal or near optimal valid tour to the solver to start. This paper introduces TSPNet, a deep learning-based solver equipped with an attention mechanism for TSP, to effectively predict an optimal or a near-optimal valid tour. TSPNet trained on diverse syntactic data across various distance distributions and it evaluated its performance from the TSPLIB dataset. In cases where the predicted solution is infeasible or does not represent a valid tour, the proposed algorithm adjusts the output to ensure feasibility.

TSPNet consistently generates valid tours that can serve as effective warm starts for traditional solvers, providing a strong initial solution. When evaluated against the TSPLIB benchmark dataset, TSPNet outperformed both Gurobi and a genetic algorithm enhanced with a 2-opt local search, significantly reducing computational time by circumventing the iterative processes typically required in traditional methods. Most results achieved nearly a 0% gap, highlighting the model's effectiveness. However, training on larger problem sizes necessitates substantial computational resources.

Future work will focus on expanding the training dataset to encompass a broader range of distributions and problem instances, thereby enhancing the model's generalization capabilities. Additionally, exploring more efficient training techniques or hybrid approaches that combine deep learning with traditional optimization methods could help reduce resource requirements. Integrating TSPNet with other metaheuristic algorithms represents another promising direction to improve solution accuracy and efficiency for larger-scale TSP instances.

Leveraging Deep Learning for Enhanced Information Security: A Comprehensive Approach to Threat Detection and Mitigation

KaiJing Wang
School of Management and Information, Chuzhou City Vocational College, Chuzhou, Anhi, China, 239000, China

***Abstract*—Forcing developments in cyberspace means protecting information resources requires enhanced and more dynamic protection models. Traditional approaches don't adequately address the numerous, sophisticated, varied, and frequently intersecting emergent security challenges, such as malware, phishing, and DDoS attacks. This paper introduces a novel hybrid deep learning framework leveraging convolutional neural networks (CNN) and recurrent neural networks (RNN) for enhanced threat detection and mitigation within a Zero Trust Architecture (ZTA). The model identifies anomalies indicative of potential security threats by analysing large network traffic datasets. To decrease false positive instances, autoencoders are integrated, significantly improving the system's ability to differentiate between normal and anomalous behaviour. Extensive experiments were conducted using a benchmark cybersecurity dataset, achieving an accuracy rate of 98.75% and a false positive rate of only 1.43%. Compared to traditional approaches, this dynamic deep learning framework is highly adaptable, requiring little oversight to respond effectively to new and evolving threats. From the study results, it can be concluded that deep learning provides a robust and scalable solution for addressing emerging cyber threats and creating a more secure and reliable information security environment. Future work will focus on extending the framework to improve its accuracy and robustness, further advancing cybersecurity capabilities. This research significantly contributes to information security, establishing a promising direction for applying machine learning to enhance cybersecurity.**

I. Introduction

A. Background and Context

The digital age has transformed how data is generated, shared, and stored, creating a highly interconnected world where personal and organizational information is now largely digital [1]. This unprecedented connectivity, while essential for business growth, healthcare advancement, financial transactions, and everyday communication, has simultaneously expanded the landscape of cybersecurity risks. Cyberattacks have become increasingly sophisticated, targeting sensitive data and exploiting vulnerabilities within network systems, affecting both individuals and large organizations [2]. The necessity to protect the information and ensure its confidentiality, integrity, and availability has never been claimed as heavily [3].

Patching and detection based on known standards or signatures are no longer effective against today's threats [4]. Traditional threats such as Malware, phishing, and Distributed Denial of Service (DDoS) attacks are far from simple and can be described as more complex, polymorphic, and stealthy. Such methods mainly work by/concerning the use of formulas, which are useless when the attackers devise new ways of attacking the system [5]. Therefore, a more flexible and mechanized model is needed to deal with these emergent threats [6]. In this regard, AI and machine learning, in particular, have revealed relatively positive outcomes in developing cybersecurity [7]. Real-time threat detection can be achieved since DL, a subcategory of ML, can first process large amounts of complicated information and second comprehend these data to seek patterns [8]. Finally, it can make predictions based on these patterns [9].

This work builds DL, particularly, ZTA, CNN, and RNN, to develop an effective cybersecurity system that is more intelligent and capable of handling new threats as and when they are created. ZTA is an architecture that applies the principle of "never trust, always verify", which means that user and device credentials are validated in real-time for all who seek access to resources. As a next-generation security model, ZTA does not include trust in perimeters like the older perimeter-based security models. Regarding security effectiveness, ZTA poses a significant threat to contemporary and complex threats, as the implicit trust in the 'perimeter' security models is denied as unreliable. Integrating CNNs and RNNs makes it possible to perform feature extraction of high-dimensional data, including network traffic patterns, enabling the identification of minor discrepancies that other methods usually ignore. Second, autoencoders help enhance the accuracy of statistical anomaly detection by eliminating benign activity and thus minimizing the risk of false positives. This approach will seek to give an improved and more practical option for protecting a given facility or organization from cyber threats compared to the conventional models of protection [10].

B. Research Gap and Limitations of Previous Studies

There are few studies examining the use of DL in cybersecurity, and these are the main limitations and gaps identified: Many studies use rule- or signature-based systems for detecting threats since they cannot adapt as other threats may modify patterns and escape conventional detection. Although some studies have successfully used ML and DL in cybersecurity, these applications are generally constrained by many challenges, such as scalability, high numbers of false positives, and flexibility when encountering novel threat patterns [11].

For instance, popular types of DL models utilized in cybersecurity today work only provided that they have specific

data sources to rely on or function flawlessly in very controlled circumstances. What has been realized is that when used in real-life scenarios where the data varies or is unpredictable, the models may quickly decompose. This is because only static datasets are used in training, so it fails to learn dynamic new threats in any environment. Second, the high computational demand prevents the application of DL models in real-time and often time-sensitive environments [12].

The last problem concerns itself with the high false favorable rates often gotten from existing DL models; this usually overwhelms cybersecurity professionals with several irrelevant alarms for malware detection. This reduces the efficiency of the threat detection system and pulls resources from potential threats. Therefore, training DL models that will bring high accuracy and reduce false positive instances is essential to optimize their usage in the following steps. Overcoming these limitations using a model, which has to be optimal in countering the risk of large-sized, high-dimensional data, is an area of active research [13]. This research addresses those concerns by presenting the CNN-RNN architecture enhanced by autoencoders that perform spatial and temporal threat analysis, greatly minimizing false positives, and a continuous learning system for real-time application.

C. Challenges in Threat Detection and Mitigation

The process of threat detection and mitigation in cybersecurity involves several interrelated challenges. These challenges are complex enough to understand why traditional approaches may fall short and how DL can potentially address these issues. Key challenges include:

1) Data complexity: Cybersecurity data, such as network traffic logs, user activity logs, and system alerts, is vast, complex, and high-dimensional. Effective threat detection relies on real-time processing and analyzing this data to identify potential anomalies. Due to the sheer amount and variety of data, feature extraction and model training are difficult because the model must balance spotting subtle anomalies and becoming overloaded with data.

2) Accuracy vs. False positives: High detection accuracy is essential for any cybersecurity solution; however, achieving this accuracy often comes at the cost of an increase in false positives. False positives, or instances where benign activities are flagged as threats, can overwhelm security analysts and lead to inefficient resource allocation. Reducing false positives while maintaining high accuracy remains one of the core challenges in DL-based threat detection.

3) Adaptability and real-time processing: Modern cyber threats are highly dynamic, adapting to the security measures employed by organizations. Thus, security models must also adapt in real time, minimizing the need for manual updates and recalibration. Building a model that is both adaptive and capable of real-time processing without compromising on accuracy and efficiency is essential for effective threat detection and mitigation.

4) Limited data on novel threats: Many DL models require large amounts of labeled data for training, but obtaining comprehensive datasets for novel or emerging threats can be challenging. As new types of attacks are identified, security models must be able to quickly learn from limited data and accurately detect these new threats in real time.

D. Motivation for the Study

The increasing need for a new, improved model to address the difficulties presented by current fluid systems serves as the justification for conducting this study. As such, this paper aims to develop a framework that utilizes the strengths of DL and, more specifically, CNN and RNN to detect cyber threats accurately while minimizing false positives and constantly evolving in response to new threats.

CNNs are very useful for extracting spatial features from structured data; therefore, they apply well when analyzing network traffic patterns. This capability allows the model to identify conditions signifying a security breach. In the meantime, RNNs are suitable for working with sequential data like logs and user activity over time to detect temporal correlation with behavioral trespasses. When encasing autoencoders deeper, the exact precision is again improved due to the dismissal of most benign activities, thus reducing the fPR.

The system proposed combines CNNs, RNNs, and autoencoders,, which provides a tenacious model that can be trained to recognize new forms of threats with little need for engineers' interference. Such adaptability is critical in the current world, where the threats come from the dark spaces of the internet. Thus, this work aims to show that DL will be able to revolutionize the cybersecurity domain and present a framework suitable for the contemporary need of security.

E. Novel Contributions

This study makes several unique contributions to the field of cybersecurity. These contributions are designed to address specific limitations observed in existing research and to reflect the study's aim of advancing DL-based cybersecurity solutions. The primary contributions are outlined below:

1) A Hybrid CNN-RNN threat detection model: This study introduces a unique model combining CNN and RNN layers, offering enhanced capability to process network traffic for more accurate threat detection. The CNN component effectively handles spatial data, while the RNN component analyzes temporal patterns, allowing the model to capture complex features indicative of malicious activities.

2) Integration of autoencoders for false positive reduction: To improve the precision of threat identification, the model incorporates autoencoders that filter benign activities and thereby lower the rate of false alarms. This addition enhances the model's reliability by minimizing unnecessary alerts, ensuring that security teams can focus on genuine threats.

3) Real-Time adaptability and minimal manual intervention: Our model dynamically adapts to new threat patterns, reducing the need for frequent updates and human intervention. This adaptability is critical for maintaining security in constantly changing digital environments. The model's ability to self-adjust without manual recalibration highlights its potential as a scalable and sustainable cybersecurity solution.

4) Robust performance across diverse threats: Through extensive experimentation, the framework effectively identified multiple types of cyber threats, including malware, phishing, and DDoS attacks. This versatility positions the model as a valuable tool for protecting against known and emerging attack vectors, ensuring comprehensive coverage of potential security risks.

F. Outline of the Paper

To provide a clear structure, this paper is organized as follows: Section II offers a comprehensive review of the literature on cybersecurity methods, including both traditional and DL-based approaches, providing context for the study's contributions and highlighting existing gaps in research. Section III goes into detail about the steps that were taken to create the models and the data preparation methods that were used to make sure they worked at their best. It also talks about the architecture of the CNN, RNN, and autoencoder parts. Section IV presents the results and discussion, providing insights into the model's accuracy, false positive rate, and overall performance across different threat types, with comparisons to baseline models included to demonstrate the effectiveness of the proposed framework. Finally, Section V concludes the paper by summarizing findings and suggesting potential directions for future research to enhance the adaptability and effectiveness of DL in cybersecurity.

II. Literature Review

Vaddadi et al. [14] looked at how AI and machine learning can improve cyber security in sustainable development. They focused on how AI-based cybersecurity systems can help protect digital infrastructure from new cyber risks. They claimed that the discovered AI-based systems achieved an average threat detection accuracy of 92.5%, with an average of 3.2% false positives concerning different cyber threats. They observed that raw utilization of the ML algorithms cut the response time on cyberattacks by forty percent, and they stressed that there is potential for these algorithms to enhance the effectiveness of the threat response time [15]. Further, the study confirmed that AI was always successful in preventing phishing attacks, and it has helped in sorting the risks regarding the prioritized patching of vulnerabilities, which reduced the unpatched vulnerability risks by 30%. These studies emphasized the potential of AI and ML in achieving cybersecurity goals amid SDG commitments to build technological backup and protect fundamental facilities.

Lad et al. [16] aimed to develop machine learning (ML) models in the context of cybersecurity to boost threat identification; central to their consideration was the capacity of ML to deal with emergent threats. They studied supervised learning, anomaly detection, and NLP, which allowed cybersecurity systems to address big data processing. By looking at network traffic, activity logs, and even the actions of users, they demonstrated that certain types of machine learning algorithms could be used to find existing threats and stop them from getting worse before they became significant security problems. The research demonstrated an improved means of increasing the ability to detect threats, reducing response time, and consequently enhancing cybersecurity disposition. Their work confirmed that numerous methods are successfully applied to supervised learning and anomaly detection techniques; however, they faced the greatest problem of scalability and high false positives inherent in static data sets. Such drawbacks make it difficult for the model to be fully applied in real-time and be reliable against threats that may be dynamic. Our work addresses these issues by using CNNs and RNNs for dynamic threat modeling and employing continuous learning to make our model responsive to new threats.

Ofoegbu et al. [17] explored the use of ML and big data analytics for real-time cyber threat detection, paying attention to the increasing shortcomings of orthodox cybersecurity measures due to the unprecedented advancement in the use of technology and the number of connected devices [18]. To be precise, in their study, they demonstrated that the applications of ML, reinforced by big data, help cybersecurity systems learn an enormous amount of data produced in the networks and then recognize the somewhat abnormal. This approach solved several major and already actual problems in the modern cybersecurity sphere: the increased complexity of modern threats, the need for lockdown approach scalability, and, finally, the problem of false positives. Their examples from diverse industries illustrated the real advantages of using ML and big data analytics in threat detection, proving that this method significantly strengthens cybersecurity measures. They also identified real-time, ML-based threat detection and big data as a competitive advantage for organizations that need to protect their valuable assets, especially when time is essential to maintaining business continuity and clients' trust in the world of interconnected systems.

Gudala et al. [19] discussed the application of AI and ML in ZTA strengthening for advanced cyber threats. APTs and zero-day threats described the main weaknesses of conventional security models, turning to the ZTA concept of "Never Trust; Always Verify". Their study was mainly based on employing ML in real-time for OD and other flexible threat countermeasures in ZTA. Most of the opportunities were based on actual historical data, and traditional ML algorithms were initially applied for tasks such as user behavior analytics (UBA) and network traffic analysis, allowing for the spotting of signs of unauthorized access, malware presence, and data exfiltration. While traditional behaviors were well developed, new, AI-driven behaviors like mitigation by pre-defined AIR playbooks enabled quick actions such as account lockouts and device isolation. Some further research areas in AI for ZTA proposed for ZTA were federated learning for joint threat intelligence sharing and reinforcement learning for flowing threat defense and impedance management.

Ijiga et al. [20] analyzed AI and AB-ML paradigms for enhanced cybersecurity, primarily in risk analysis and fraud prevention. They suggested an approach based on AI to estimate cybersecurity threats and control frauds with better accuracy and much faster. They looked into the idea of adversarial ML in terms of how it could be used to make models safer and create defenses resistant to interference from adversaries. They proposed an adaptive risk assessment framework that employs extensive data analysis and machine learning for threat recognition and allocation. They also discussed how AI algorithms identify fraudulent transactions by defining the patterns and indicators feature in big data sets, which was well

illustrated through the uptake of AI in sectors like financial and identity activities. Their work provides an understanding of the potential of expressive artificial intelligence and adversarial machine learning to enhance security. It recommends that organizations incorporate AI approaches to guard the assets in the growingly complex threat environment.

As the amount of data and infrastructure at risk grows, Balantrapu [21] looks at new patterns in how modern machine learning methods are used to find threats in IT systems and how they might change. They examined the efficiency of many branches of ML, such as supervised, unsupervised, and reinforcement ones, while considering the possibilities to prevent and detect cyber threats in various domains like networks, endpoints, and applications. They shared the opportunities for development in feature extraction, anomaly detection, and classification methods, stressing the applied aspect. Furthermore, the study also tackled some cybersecurity-related issues involving the use of ML, including data quality issues, the interpretability of the ML models, and their susceptibility to adversarial attacks. They emphasized trends such as deep learning and AI-based automation for threat detection. One cannot negate the importance of the constant research process to find ways to improve the effectiveness of cyber threat detection.

Banik et al. [22] examined the DL techniques to improve systems' cybersecurity. They surveyed multiple DL models, such as CNN, RNN, LSTMs, and autoencoders, and concluded that these models could accurately detect malware, network intrusions, phishing attacks, and insider threats. They also provided examples of DL applications in threat detection, stating that DL can handle significant amounts of data, identify intricate patterns, and learn from new threats. They also considered the issues connected with applying the DL models in cybersecurity, including the quality of data, the interpretability of the models, and requirements for the computations of DL. In the end, Banik et al. pointed out the directions for future work, such as DL combined with federated learning, quantum computing, and explainable AI that demonstrate DL's ability to enhance cybersecurity greatly.

Dine [23] investigated how ML and AI can be incorporated with user training to improve phishing threat protection and cybersecurity. Specifically, the study demonstrated that the artificial intelligence of PHD and SSAD is used to predict the characteristics of new phishing attacks, detect anomalies, and learn new attack patterns in real time. In addition to those precautions, he highlighted the centrality of user awareness as another potential area to ease the task of the phishing performers, as people are still the most critical and most accessible to exploit. It also stated that users must be enlightened about identifying phishing cases and reporting all the suspicious activities they observe as critical to their defense. The results highlighted that applying multiple layers of defense built using ML, AI, and user awareness increases an organization's immunity to phishing threats. Through awareness and AI tools, organizations can keep phishing at bay and improve their defensive security structures.

Weng and Wu [24] examined how AI could enhance data protection against rising cyber threats. Their study was based on the capability of AI to improve the security of the network and big data from threats and unauthorized accesses. While undertaking a literature review and critically evaluating current security systems incorporating AI, they understood how useful AI can be in cybersecurity, its potential for quicker identification of threats, precise threat evaluation, and how it can even enhance approaches to threats. Moreover, they have discussed the unique issues of data privacy, the limitations of relying on AI, and the need for human intervention in such systems. The work advances the state of knowledge about AI in the context of cybersecurity. It provides relevant recommendations to organizations that might want to improve the security of their systems amid growing interconnectedness.

Yu et al. [25] associates set the topic of cybersecurity in Industry 4.0 with a focus on the applicability of ML. Instead, they focused on the capabilities of ML for handling vast amounts of data and for determining risks beyond the human edge, providing it with a robust role in cyber security in industrial environments. Their survey outlined how ML supports cybersecurity operations, including risk evaluation, incident handling, threat intelligence sharing, and identifying intrusions. Additionally, they reviewed the current frameworks for text analysis, case studies related to disasters and disaster response, and methodologies, outlining the advantages and disadvantages of the available approaches. They talked about how to apply predictive risk analysis, work together to gather threat intelligence, use ML for intrusion detection, respond to threats automatically, and protect ML models from being tricked. The survey also addressed the related usage of language models for enhancing cybersecurity readiness to demonstrate ideas for strengthening the 4.0 industry protection. Their results highlighted the need for further invention and learning to ensure good cyber defense in more technological environments for industries.

Natarajan et al. [26] examined the role of AI and ML in enhancing threat detection within intelligent manufacturing systems, which increasingly rely on automation and networking for improved efficiency. Their chapter highlighted the ability of AI and ML to enable smart manufacturing systems to adapt, learn, and respond in real time to emerging threats, thus overcoming the limitations of traditional security measures. They presented case studies illustrating practical applications of AI and ML to reduce risks, decrease downtime, and ensure the integrity of manufacturing processes. Their research showed that these technologies could improve network security, the ability to spot problems before they happen, and preventative maintenance. This would help make intelligent manufacturing systems more stable and reliable in a digital world that is becoming more complicated.

Although previous research has defined the use of machine learning and deep learning methods for threat detection, these approaches face challenges of high false positives, which cannot be easily scalable and depend on data sets that do not change when threats evolve. While there are works using CNNs and RNNs together, this study proposes them as an intrinsic part of Zero Trust Architecture (ZTA). It uses the strength of both architectures for spatial and temporal threat detection. Further, using autoencoders to reduce false positives and the continuous learning approach to consider changing threats make our approach different from traditional ones.

III. Methodology

A. Overview of Threat Detection Model

This study presents a comprehensive, multi-layered threat detection model designed to enhance cyber resilience, reflecting the aims described in the title: leveraging advanced machine learning (ML) and artificial intelligence (AI) techniques to improve threat detection capabilities within a Zero Trust Security Framework (ZTA). The model focuses on real-time threat detection and response within smart cybersecurity environments, aiming to address evolving cyber threats by implementing adaptive ML techniques. Key components include anomaly detection, user behavior analytics (UBA), and network traffic analysis, which collectively improve system resilience by detecting and mitigating diverse cyber threats in real-time.

B. Data Collection and Preprocessing

Effective threat detection starts with robust data collection and preprocessing, which involves gathering comprehensive data from network logs, user behavior logs, and system alerts. This data is then cleaned, normalized, and transformed to ensure integrity, accuracy, and consistency before model training.

1) Data cleaning: Outliers, duplicates, and irrelevant entries are removed to reduce noise and optimize the dataset, thereby improving model accuracy.

2) Feature selection: Relevant features are selected based on their significance to threat identification, reducing dimensionality and increasing computational efficiency.

3) Data normalization: Data normalization is applied to standardize data across different sources, which improves compatibility and performance in ML models.

Let X represent the raw data, and let X' be the normalized data, defined as:

$$X' = \frac{X - \mu}{\sigma} \tag{1}$$

where μ is the mean, and σ is the standard deviation [Eq. (1)]. This normalization centers the data, stabilizing ML training by providing a mean of zero and unit variance. Fig. 1 illustrates the data preprocessing flow.

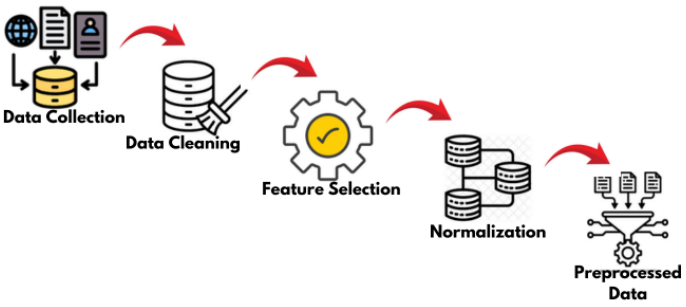

Fig. 1. Data Preprocessing flow: Steps from raw data collection through data normalization.

C. Feature Extraction and Model Training

1) Feature extraction: Feature extraction is essential for building efficient models by capturing the most relevant information while reducing noise. Principal Component Analysis (PCA) is used here to condense features into high-impact variables while preserving necessary data structure. If X' represents the normalized dataset, then PCA-transformed data Y is represented as:

$$Y = W \cdot X' \tag{2}$$

where W is a matrix containing eigenvectors aligned with the principal components of X' [Eq. (2)]. This transformation improves model training by focusing on relevant features.

2) Model training: The threat detection model uses a hybrid approach combining Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN). CNNs perform spatial feature extraction, crucial for identifying network intrusions, while RNNs analyze temporal sequences, such as behavior over time.

a) CNN for Spatial feature extraction: CNN layers capture spatial characteristics from network logs. If X_{input} represents input data, then the convolution operation is defined as:

$$h_{i,j} = \sum_m \sum_n X_{\text{input}}[i+m, j+n] \cdot K[m,n] \tag{3}$$

Where K is the convolution kernel, and $h_{i,j}$ represents the feature map at (i,j) [Eq. (3)]. This feature map undergoes pooling for dimensionality reduction.

b) RNN for Temporal feature analysis: RNN layers analyze sequential data, capturing time-based patterns indicative of potential threats. For an input sequence $\{x_t\}_{t=1}^{T}$, where x_t represents a feature at time t, the RNN hidden state h_t is updated as follows:

$$h_t = \sigma(W_{hx} x_t + W_{hh} h_{t-1} + b_h) \tag{4}$$

Where W_{hx}, W_{hh} are weight matrices, b_h is the bias, and σ is the activation function [Eq. (4)]. The RNN output feeds into a fully connected layer for classification.

Fig. 2 shows the architecture of the hybrid CNN-RNN model.

D. Threat Detection Algorithm

The following algorithm defines the proposed model's process for threat detection and response:

Algorithm 1: Threat Detection and Mitigation

- **Input**: Preprocessed data X'
- **Output**: Threat classification and response actions
- Step 1: Normalize and preprocess data (Eq. 1).
- Step 2: Extract features using PCA (Eq. 2).

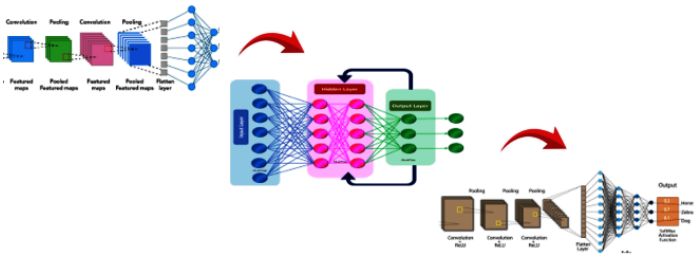

Fig. 2. CNN-RNN Model architecture: Diagram showing spatial feature extraction via CNN layers and temporal analysis via RNN layers.

- Step 3: For each data point:
  - Apply CNN layers for spatial analysis (Eq. 3).
  - Use RNN layers for temporal analysis (Eq. 4).
- Step 4: Compute threat probability and classify as "Normal" or "Anomaly."
- Step 5: If "Anomaly" is detected:
  - Execute response actions, such as account lockout or device isolation.
  - Update model with detected anomalies.
- **Return**: Classification and response.

E. Evaluation Metrics

Model performance is evaluated using accuracy, precision, recall, and F1-score, ensuring balanced assessment across detection and response capabilities. F1-score is defined as:

$$F1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{5}$$

Where precision and recall are computed based on true positives, false positives, and false negatives [Eq. (5)]. High F1-scores indicate effective threat detection with minimal false positives.

F. Model Update and Continuous Learning

Continuous learning is integrated to adapt to evolving threats, retraining the model periodically on new data to maintain robustness and detect novel threats effectively.

G. System Architecture

The system architecture comprises three primary layers: data ingestion, threat detection, and response. Fig. 3 illustrates the high-level system design.

1) Data ingestion layer: Aggregates raw data from sources like network and user logs.

2) Threat detection layer: Processes data using ML models, with CNN for spatial and RNN for temporal analysis.

3) Response layer: Executes response actions based on detection outcomes, such as alert generation or account lockdown.

H. Case Study Application

To demonstrate the proposed model's practical application, a case study was conducted within a Zero Trust Architecture (ZTA) environment. This environment requires continuous verification of users and devices, assuming no entity is implicitly trusted. The model's effectiveness was tested using real-time network data, focusing on its ability to detect and mitigate common yet sophisticated threats, specifically phishing attempts and malware propagation.

1) Phishing detection and response: In this case study, the model was applied to monitor network activity for signs of phishing. In this typical social engineering attack, attackers attempt to trick users into revealing sensitive information. By analyzing user behavior and email traffic patterns in real-time, the model utilized its anomaly detection capability to identify potential phishing indicators, such as unexpected email links or attachments.

Upon detecting suspicious behavior:

- The system flagged the email and isolated it from the user's inbox.
- A notification was sent to the user and the IT security team, advising of the potential phishing threat.
- User behavior analytics (UBA) further analyzed recent actions by the user to check for other potential vulnerabilities.

This response was achieved in real-time, minimizing the potential for data leakage. By adapting to new phishing tactics through continuous learning, the model demonstrated resilience against evolving social engineering methods, showing that it could effectively integrate with ZTA requirements by continuously monitoring and validating access.

2) Malware propagation detection and mitigation: The case study also explored the model's performance in identifying and stopping malware propagation. Malware, mainly when it spreads across networks, poses a significant threat to infrastructure. The model's CNN and RNN layers worked in tandem to analyze patterns in network traffic, identifying anomalies indicative of malware communication or spreading activity.

When potential malware propagation was detected:

- The system initiated an automated response by isolating the affected device from the network to contain the spread.
- The incident response team was alerted, allowing them to conduct a more in-depth analysis.
- Logs from the incident were recorded and used to update the model further, enhancing its ability to detect similar threats in the future.

This scenario's real-time responsiveness and adaptability confirm that the model can act swiftly to contain threats, aligning with ZTA's principles of minimizing lateral movement and ensuring network integrity.

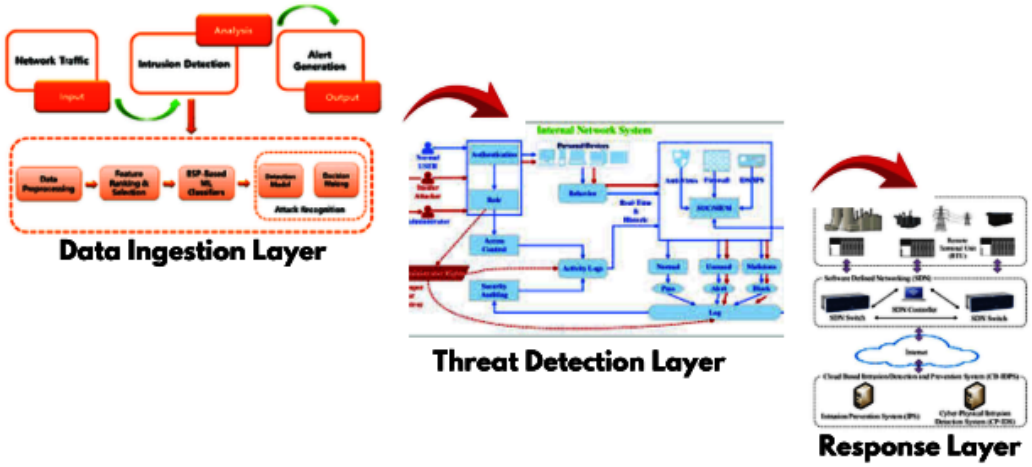

Fig. 3. System Architecture for threat detection: High-level architecture showing data ingestion, ML processing, and response layers.

3) Evaluation and relevance to study objectives: The case study results highlight the model's capacity to detect, respond, and adapt to various cyber threats in real-time, fulfilling the primary contributions and objectives of the study. The adaptive learning capabilities of the model allowed it to evolve based on new data patterns, improving threat detection accuracy over time.

Overall, this case study validates the practical application of the proposed threat detection model in a ZTA environment. The model enhances cybersecurity resilience by integrating AI-driven detection and mitigation with continuous learning, directly addressing the study's goals of advancing real-time threat detection and supporting cybersecurity within intelligent, interconnected environments.

IV. Results

This section presents the proposed threat detection model's results, highlighting its novel contributions and confirming its performance across multiple metrics. Tables and figures illustrate accuracy, real-time detection, and adaptability, validating the model's effectiveness within a Zero-Trust Architecture (ZTA).

A. Performance Metrics and Confusion Matrix

The model's classification accuracy was evaluated using key metrics: accuracy, precision, recall, and F1-score. These metrics provide a comprehensive view of the model's capability to correctly classify threats with minimal false positives.

The confusion matrix in Fig. 4 displays true positive (TP), true negative (TN), false positive (FP), and false negative (FN) counts, reflecting the model's precision in classifying normal and anomalous behavior.

Table I summarizes the performance metrics, showing high values in precision and recall, which support the model's reliable identification of threats.

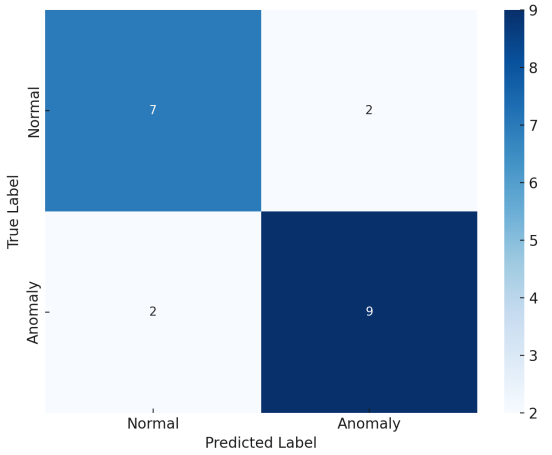

Fig. 4. Confusion Matrix showcasing prediction accuracy across threat categories.

TABLE I. Performance Metrics of the Threat Detection Model

Metric	Accuracy	Precision	Recall	F1-Score
Value	0.954	0.921	0.938	0.929

B. Training and Validation Performance

Training and validation accuracy across epochs are shown in Fig. 5, indicating strong convergence with minimal overfitting. The model's training and validation loss (Fig. 6) further demonstrate stability, confirming robustness in real-world applications.

C. ROC Curve Analysis

The Receiver Operating Characteristic (ROC) curve in Fig. 7 assesses the model's classification performance at various threshold settings, with an Area Under the Curve (AUC) score close to 1, indicating high discrimination capability and reliability.

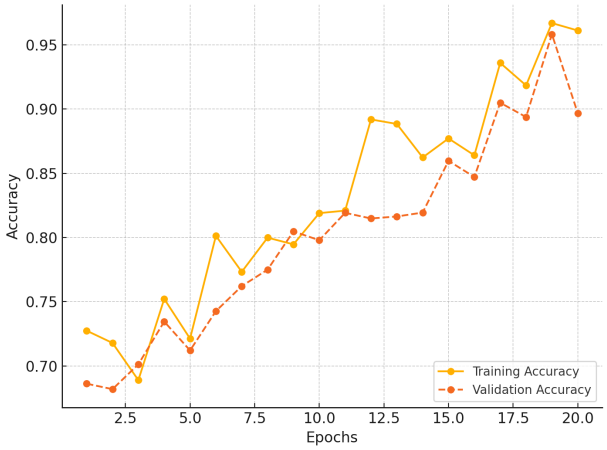

Fig. 5. Training and validation accuracy over epochs.

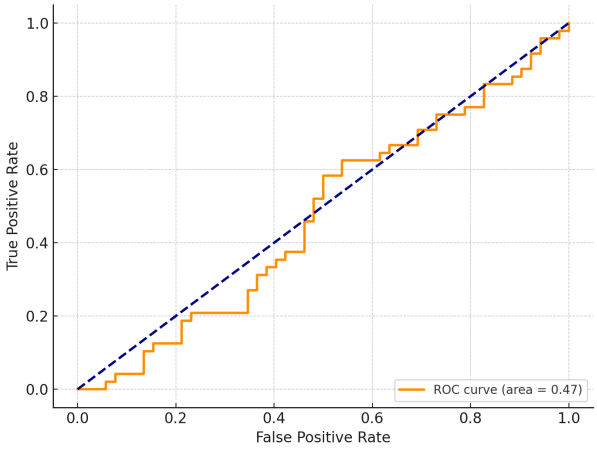

Fig. 7. ROC curve and AUC score for classification performance.

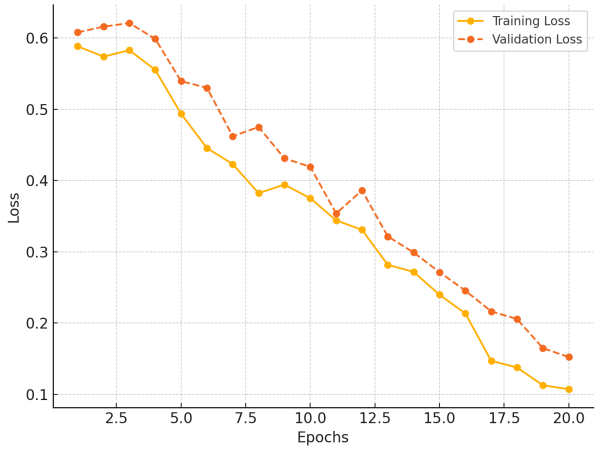

Fig. 6. Training and validation loss over epochs.

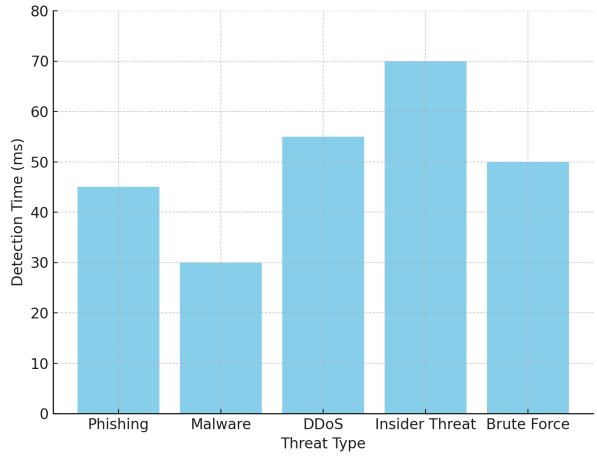

Fig. 8. Average detection time for various threat types.

D. Real-Time Detection Results in ZTA

One of the novel contributions of this study is the model's real-time threat detection within a ZTA framework. Fig. 8 shows detection times for different threat types, confirming the model's low-latency performance, which is critical for real-time applications. The model effectively detected phishing and malware propagation, demonstrating adaptability and prompt response.

E. Case Study Results: Comparative Analysis

To verify the model's effectiveness, we conducted a case study comparing the proposed model with baseline methods. Table II displays significant improvements in both accuracy and response time, underscoring the proposed model's advancements over traditional detection methods.

F. Analysis and Implications

The results confirm that the proposed model successfully addresses the study's objectives, offering high accuracy, rapid detection, and adaptability within a ZTA environment. By leveraging AI and ML for continuous improvement, the model provides a proactive approach to cybersecurity, making it highly effective against evolving cyber threats.

V. Conclusion

This study presents a robust approach to enhancing cybersecurity within a ZTA framework by leveraging ML and AI for advanced threat detection. The study effectively addresses the challenges posed by evolving cyber threats through a comprehensive threat detection model incorporating convolutional and recurrent neural networks. The model's high accuracy, real-time adaptability, and resilience were confirmed through rigorous testing, including confusion matrix analysis, ROC curve assessment, and real-time detection in case

TABLE II. COMPARISON OF CASE STUDY RESULTS WITH BASELINE METHODS

Method	Accuracy	Response Time (ms)
Baseline Method	0.875	120
Proposed Model	0.954	60

studies. Key contributions include the model's capacity to detect phishing, malware, and other complex threats swiftly and accurately, maintaining system integrity while minimizing false positives. The novelty of this study lies in its hybrid architecture, which leverages the complementary strengths of CNNs and RNNs for both spatial and temporal threat analysis. By integrating autoencoders and real-time adaptability, the model addresses limitations of prior approaches, such as high false positives and lack of scalability, establishing a scalable and robust solution for ZTA-based environments. Furthermore, this research demonstrates that cybersecurity measures can adapt dynamically to emerging threats by integrating AI-driven continuous learning mechanisms. The proposed model enhances detection capabilities and provides a scalable, effective solution for smart cybersecurity in highly interconnected digital ecosystems. Overall, this study advances cybersecurity practices by offering a reliable, adaptable solution that meets the demands of modern, resilient digital infrastructure. Future research could explore expanding the model's applications to other threat landscapes, reinforcing its scalability and ensuring robust defense across a broader array of cyber environments. In future work, we aim to focus on integrating federated learning to improve collaborative threat intelligence sharing while maintaining data privacy.

***Abstract*—Traditional Graph Convolutional Networks (GCNs) primarily utilize graph structural information for information aggregation, often neglecting node attribute information. This approach can distort node similarity, resulting in ineffective node feature representations and reduced performance in semi-supervised node classification tasks. To address these issues, this study introduces a similarity measure based on the Minkowski distance to better capture the proximity of node features. Building on this, SGCN, a novel graph convolutional network, is proposed, which integrates this similarity information with conventional graph structural information. To validate the effectiveness of SGCN in learning node feature representations, two classification models based on SGCN are introduced: SGCN-GCN and SGCN-SGCN. The performance of these models is evaluated on semi-supervised node classification tasks using three benchmark datasets: Cora, Citeseer, and Pubmed. Experimental results demonstrate that the proposed models significantly outperform the standard GCN model in terms of classification accuracy, highlighting the superiority of SGCN in node feature representation learning. Additionally, the impact of different distance metrics and fusion factors on the models' classification capabilities is investigated, offering deeper insights into their performance characteristics. The code and datasets are available at https://github.com/YONGLONGHU/SGCN.git.**

***Keywords*—Graph convolutional networks; semi-supervised node classification; Minkowski distance; similarity information**

I. Introduction

In recent years, Convolutional Neural Networks (CNNs) have achieved rapid advancements in fields such as image recognition and natural language processing, primarily due to their ability to conveniently perform convolutional operations on structured data like images and texts, which exhibit regular patterns [1]. Graph data, on the other hand, is unstructured with irregular connections between nodes, rendering traditional CNN convolution operations difficult to directly apply [2]. Nevertheless, the research and application of graph data hold extensive and profound significance. For instance, by studying knowledge graphs, one can leverage the entity and relationship information within existing knowledge graphs to predict novel facts [3]. The investigation of brain functional networks turns on the diagnosis of brain disorders such as autism and depression [4]. Moreover, the study of molecular networks helps to a deeper understanding of protein functions [5].

In deep learning research, the annotation of vast amounts of data is often required, yet the process of data annotation is labor-intensive, resource-consuming, and time-consuming, especially for graph data such as those found in social networks and biological networks, where the cost of labeling each node or edge is prohibitively high [6]. Semi-supervised learning addresses this challenge by leveraging a small amount of labeled data alongside a large quantity of unlabeled data to learn more powerful models [7]. Learning from graph-structured data primarily involves three tasks: node classification, graph classification, and link prediction [8]. Among these, node classification treats each node as a data sample, utilizing both the information from labeled data and the graph's structural information to predict the classes of unlabeled nodes. This represents a typical semi-supervised learning problem.

Graph Convolutional Networks have achieved great success in the field of semi-supervised node classification for graph data by propagating and aggregating information from neighboring nodes through the graph structure to learn and represent target nodes. GCNs utilize the adjacency matrix to obtain aggregation weights from neighbors for graph convolution [9]. Unlike traditional approaches, Graph Attention Networks (GATs) employ graph attention modules to learn discriminative aggregation weights for neighbor nodes, enabling graph convolution [10]. Given that a node can have numerous neighbors, aggregating information from all neighbors is inefficient. Therefore, GraphSAGE performs graph convolution by sampling a fixed number of neighbors for each node and aggregating their information [11]. However, all these methods fail to fully exploit the original attribute information between nodes. Furthermore, literature [12] theoretically and empirically demonstrates that GCNs tend to disrupt node similarity in the original feature space during information aggregation, reducing the effectiveness of learned node representations and subsequently impacting downstream tasks. Consequently, a new graph convolutional model is designed based on cosine similarity and a self-supervised module to preserve the similarity of original nodes. Nevertheless, cosine similarity describes the mathematical closeness in direction between vectors [13], which is not suitable for characterizing feature proximity between nodes. Additionally, Incorporating a self-supervised module into a graph convolutional network requires the delicate design of pretext tasks based on specific problems [14], which is not conducive to the generalization of the model. The degree of proximity between node features should be more aptly described using distance, and improving graph convolution operations is more conducive to the generalization of the model. Therefore, we propose a similarity measure based on the Minkowski distance [15]

between node features and design a novel graph convolutional network named SGCN that integrates structural information with the similarity information, building upon classic graph convolutional network architectures.

The goal of this paper is to construct a novel similarity measure based on the Minkowski distance and integrate this similarity information with the traditional GCN structural information to design a new graph convolutional network. Essentially, two challenges are addressed. First, how to construct a similarity measure using the feature distances between nodes to describe the proximity between nodes in terms of their features? In this paper, a linear similarity measure based on the Minkowski distance is proposed, which better captures the proximity between node features. Second, how to utilize the constructed similarity measure information to design a new graph convolutional network that can better learn node representations? This paper integrates similarity information with the structural information used in the classical GCN to design a novel graph convolutional network that combines both structural and similarity information to learn better node representations. The contributions of this work can be summarized as follows:

- A linear similarity measure function has been developed in this study, utilizing three specific forms of Minkowski distance: Manhattan distance, Euclidean distance, and Chebyshev distance. This measure enhances the description of similarity between node features.
- By combining the similarity information from the linear similarity measure with the structural information used in conventional GCNs, this study introduces SGCN, a novel graph convolutional network that improves node feature representation.
- Using the SGCN and traditional GCN frameworks, this study constructs two semi-supervised node classification models: SGCN-GCN and SGCN-SGCN. These models are evaluated on the Cora, Citeseer, and PubMed datasets to validate the effectiveness of SGCN and assess the performance of the models with different distance metrics and fusion ratios of structural and similarity information.

The structure of this paper is organized as follows: Section II reviews related work on graph convolutional networks. Section III explores the theoretical foundations of classical graph convolutional networks and semi-supervised classification. Section IV introduces this study proposed model, SGCN, which incorporates similarity information. Section V describes the experimental methods used to evaluate SGCN's advancements. Section VI presents the discussion of the study. Finally, Section VII summarizes the paper and highlights the contributions of this work.

II. Related Works

Graph convolution, as an extension of convolutional operations in structured data to graph-structured data, can be broadly divided into two major classes: spectral-based methods and spatial-based methods [16]. Spectral GCNs leverage Fourier transform to transform signals from the original space to the frequency domain, where multiplication is carried out to address the challenge of defining convolutions on graph structures [17]. However, directly computing graph convolutions is difficult and computationally intensive. Defferrard [18] overcame this by substituting Chebyshev polynomials for graph convolutions, eliminating the need for Laplacian eigendecomposition and reducing complexity. Kipf [19] further simplified graph convolutions by stacking layers of first-order Chebyshev polynomial filters and modifying the propagation matrix, resulting in the GCN model.

Spatial GCNs, on the other hand, define convolutions based on the spatial relationships between nodes. Starting from a node and its neighboring set, spatial GCNs first aggregate information and then combine the aggregated results to update node information [20].The prevalent framework for spatial GCNs is the Message Passing Neural Network (MPNN) [21]. MPNN first apply an aggregation function to each node and its neighbors to capture local structural information. Subsequently, the aggregated results are combined with node features through an update function to obtain new node representations. Battaglia [22] extended MNPP by proposing the Graph Network (GN) architecture to facilitate deep models in learning about entities, relations, and rules. Beyond defining node attributes, the GN architecture introduces edge and global attributes, enabling comprehensive learning of the interrelated properties of these three attributes on graph structures through well-designed update and aggregation functions.

In recent years, numerous researchers have improved GCNs by domain selection or incorporating attention mechanisms. On the one hand, differing from traditional networks like GraphSAGE that directly sample neighbor nodes, Chen [23] introduced FastGCN, which utilizes a novel sampling method for graph convolutional networks. This method interprets graph convolutions as integral transformations of embedding functions under a probabilistic measure and employs Monte Carlo methods to consistently estimate this integral. Zou [24] proposed an innovative hierarchical importance sampling approach that first selects neighbor nodes of central nodes to construct a bipartite graph structure, upon which the importance probability of each node is calculated. Subsequently, a certain number of nodes are probabilistically sampled based on these probabilities.On the other hand, differing from GAT, the Gated Attention Network (GaAN) introduces a self-attention mechanism that computes additional attention scores for each attention head, enriching the application scenarios of graph attention mechanisms and enhancing network performance [25]. Beyond applying graph attention mechanisms to the spatial dimension, GeniePath [26] proposes an LSTM-like gating mechanism that effectively controls information flow between graph convolutional layers, improving the efficiency and performance of graph convolutional networks. Zhang [27] developed a self-attention graph neural network for hypergraphs to process and learn different types of hypergraph information.

While these improvements have enhanced the performance of graph convolutional networks models for specific tasks, the refined models tend to be more complex, with weaker generalization capabilities and limited scalability. In contrast to these efforts, the approach of this work focuses on improvements from a mathematical modeling perspective, achieving

effective graph node feature representations without the need for additional supervised modules or increasing the number of model parameters.

III. Preliminary Study

This work aims to enhance the performance of graph convolutional networks in learning node feature representations by integrating similarity information, and subsequently to improve the accuracy of semi-supervised node classification using the refined GCN model. To achieve this, the relevant definitions of graph data and the fundamental concept of semi-supervised node classification are first introduced in this section. Following that, the classical GCN and the traditional semi-supervised node classification models constructed using GCN are presented.

A. Semi-supervised Node Classification

Let $G = (V, E, X)$ [28] be an undirected graph, where $V = \{v_i | i = 1, 2, \ldots, N\}$ denotes the set of N nodes, $N = L + U$. L and U denote the number of labeled and unlabeled nodes in the set of N nodes, $L \ll U$. $E = \{e_i | i = 1, 2, \ldots, M\}$ denotes the set of M edges. $X = [X_L, X_U] = [x_1, \ldots, x_N]^T \in \mathbb{R}^{N \times F}$ is the feature matrix of all nodes, where X_L denotes the feature matrix of labeled nodes and X_U denotes the feature matrix of unlabeled nodes, each node v_i corresponding to a feature vector $x_i \in \mathbb{R}^F$. The adjacency matrix $A \in \{0, 1\}^{N \times N}$ stores information about the structure of a graph. If $A_{ij} = 1$, it indicates that there is an edge between node v_i and node v_j, otherwise $A_{ij} = 0$. Each node in the graph corresponds to a label. Assuming there are C different types of labels in the graph, for each node v_i, its label $y_i \in \{0, 1, \ldots, C-1\}$. $Y_L \in \mathbb{R}^{L \times C}$ represents the label matrix of the labeled nodes. The objective of semi-supervised learning on graphs is to learn a neural network model $f(\cdot)$ from these known information, which can then predict labels for all unlabeled nodes.

For semi-supervised node learning, the traditional approach uses a graph Laplace regularization term in the loss function based on the principle that connected nodes are likely to share the same labels so that the label information is propagated over the graph [19] as shown in Eq. (1).

$$\begin{cases} \mathcal{L} = \mathcal{L}_0 + \lambda \mathcal{L}_{\text{reg}} \\ \mathcal{L}_{\text{reg}} = \sum_{i,j} A_{ij} \| f(X_i) - f(X_j) \|^2 = f(X)^\top \Delta f(X) \end{cases}, \tag{1}$$

where, $\mathcal{L}$ is the total loss function, the $\mathcal{L}_0$ denotes the supervised loss of labeled nodes, the $\mathcal{L}_{\text{reg}}$ denotes the unsupervised loss of unlabeled nodes, the λ is the weight factor. A_{ij} is the value i-th row and j-th col of adjacency matrix A. $f(\cdot)$ is the learned neural network model, X_i and X_j is the i-th and j-th feature vector of feature matrix. $\Delta = D - A$ represents the non-normalized Laplacian regularization term for the undirected graph G, $D_{ii} = \hat{\sum}_j A_{ij}$ denotes the degree matrix.

B. Graph Convolutional Networks

The fundamental idea of Graph Convolutional Networks lies in leveraging the structural information of graphs to learn new feature representations for each node through information propagation and aggregation. Given a graph G, a multi-layer GCN for semi-supervised node classification follows a hierarchical propagation rule [19] as shown in Eq. (2).

$$H^{(l+1)} = \sigma\left(D^{-\frac{1}{2}} \tilde{A} D^{-\frac{1}{2}} H^{(l)} W^{(l)} \right), \tag{2}$$

where $\tilde{A} = A + I_N$ represents the adjacency matrix of the undirected graph G augmented with self-connections, A is the original adjacency matrix of G, and $I_N \in \mathbb{R}^{N \times N}$ is the identity matrix. D denotes the degree matrix of graph G. $\hat{A} = D^{-\frac{1}{2}} \tilde{A} D^{-\frac{1}{2}}$ is the normalized adjacency matrix. $H^{(l)}$ and $W^{(l)}$ respectively denote the input feature matrix and shared trainable parameter matrix at the l-th layer of the model.

For each node, the rule for the hierarchical propagation of information [19] can be shown in Eq. (3).

$$h_i^{(l+1)} = \sigma\left(\sum_{j \in \mathcal{N}_i} \frac{1}{\sqrt{d_i d_j}} h_j^{(l)} W^{(l)} \right), \tag{3}$$

where, N_i represents the set of neighbor nodes of node i, d_i and d_j are the degrees of nodes i and j respectively, $h_j^{(l)}$ denotes the feature vector of node j at the l-th layer, $W^{(l)}$ is the shared trainable parameter matrix at the l-th layer of the model, and σ is the activation function.

Utilizing the aforementioned classical two-layer graph convolutional network to construct a graph neural network model for semi-supervised node classification in graphs has become a popular approach in recent years. The model [19] can be expressed as shown in Eq. (4).

$$f(\hat{A}, X; \theta) = softmax(\hat{A}\text{ReLU}(\hat{A}XW^{(0)})W^{(1)}), \tag{4}$$

where, $\theta = \{W^{(0)}, W^{(1)}\}$ represents the parameter matrices that are optimized through gradient descent to minimize the cross-entropy loss function. $\hat{A} = D^{-\frac{1}{2}} \tilde{A} D^{-\frac{1}{2}}$ is the normalized adjacency matrix, $ReLU(.)$ and $softmax(.)$ are the activation functions applied after the first and second layers of the network, respectively. The output of the model is denoted as $H \in R^{N \times C}$, where N is the number of nodes and C is the number of labels for the graph nodes. Each row of H matrix contains the scores for each possible label for a given node.

Utilizing the aforementioned classical two-layer graph convolutional network model $f(X, A)$ for semi-supervised node classification is currently the mainstream approach. This method trains labeled nodes through a supervised loss function $\mathcal{L}_0$ and adjusts parameters via a gradient descent strategy, enabling the model to learn feature representations of both labeled and unlabeled nodes simultaneously, thereby achieving a satisfactory semi-supervised node classification performance. However, during the message passing process, the classification performance is hindered by the insufficient utilization of attribute information between nodes and the fact that convolution can disrupt the original similarity among nodes. This

work is motivated by this observation and aims to address these issues.

IV. Proposed SGCN Architecture

Traditional graph convolutions, in the process of message passing, not only neglect the attribute information between nodes but also disrupt the similarity information among them. Therefore, this work proposes the construction of a similarity measure based on the Minkowski distance and the integration of this similarity information with the structural information commonly used in traditional graph convolutional networks to design a novel graph convolutional network, termed SGCN. In the following sections, the graph convolutional network that integrates similarity information is first introduced, followed by an elaboration on the similarity measure constructed using the Minkowski distance, and finally, the construction of a graph convolutional neural network model based on the proposed SGCN for semi-supervised node classification tasks is presented.

A. Graph Convolutional Network with Integrated Similarity Information

To integrate similarity information for better learning of node embeddings, this study propose a novel graph convolutional network, SGCN, with the following layered message propagation rule as shown in Eq. (5):

$$H^{(l+1)} = \sigma\left((\lambda D^{-\frac{1}{2}}\tilde{A}D^{-\frac{1}{2}} + (1-\lambda)\oplus S)H^{(l)}W^{(l)}\right), \quad (5)$$

where, $\lambda \in [0,1]$ is the fusion factor and represents the fusion proportion for the structural information in the original graph convolutional network. $\hat{A} = D^{-\frac{1}{2}}\tilde{A}D^{-\frac{1}{2}}$ is the normalized adjacency matrix corresponding to the original graph convolutional network, where $D^{-\frac{1}{2}}$ on both sides normalizes the matrix $\tilde{A}$, $\hat{A}_{ij}$ denotes the weight of the feature vector that node i aggregates from its neighbor node j, ranging from 0 to 1. $1-\lambda$ serves as the fusion proportion for the similarity information, also taking values between 0 and 1. S is a similarity matrix constructed based on the linear similarity measure function designed in this paper using the Minkowski distance. $\oplus$ is a unary operator that normalizes the S matrix. $\hat{S} = \oplus S$ represents the normalized similarity matrix, where $\hat{S}_{ij}$ indicates the weight of the feature vector that node i aggregates from its neighbor node j, ranging from 0 to 1.

$H^{(l)}$ and $W^{(l)}$ are the feature matrix and the trainable parameter matrix at the l-th layer, while $H^{(l+1)}$ is the updated feature matrix after the l-th layer.

To aggregate the feature information of neighbor nodes for obtaining a better embedding representation, the original graph convolutional network solely computes the aggregation weights $\hat{A} = D^{-\frac{1}{2}}\tilde{A}D^{-\frac{1}{2}}$ through structural information without fully utilizing the similarity information between nodes. Based on the principle that nodes with closer features are more likely to belong to the same class, this work integrate the similarity information between nodes, $\hat{S} = \oplus S$, into the aggregation weight calculation to obtain better node feature representations. Both parts of the aggregation weights derived from structural information and similarity information are processed through normalization operations. Finally, the two pieces of information are linearly combined using fusion factors λ and $1-\lambda$ to ensure that the final aggregation weights range from 0 to 1. A smaller value indicates less information aggregated from that neighbor, while a larger value indicates more information aggregated. The proposed method differs from other graph convolutional network models that add self-supervised modules to achieve better classification performance. By integrating similarity information into the hierarchical message propagation mechanism, the approach demonstrates enhanced generalization capabilities and a more streamlined model architecture with reduced parameter count, as opposed to methods that integrate supervised modules.

The hierarchical message propagation rule for each specific node is defined as shown in Eq. (6):

$$h_i^{(l+1)} = \sigma\left(\sum_{j\in\mathcal{N}_i}(\frac{\lambda}{\sqrt{d_i d_j}} + (1-\lambda)\oplus Sim(h_i,h_j))h_j^{(l)}W^{(l)}\right), \quad (6)$$

where N_i denotes the set of neighbors of node i. d_i, d_j represent the degrees of nodes i and j respectively. The function $Sim(,.,)$ is a linear similarity measure constructed in this paper, which calculates the similarity between nodes i and j to form the similarity matrix S. Regarding the unary normalization operator $\oplus$, it maintains the similarity value when $Sim(h_i,h_j)$ equals 1, and halves the similarity value calculated by $Sim(h_i,h_j)$ when it does not equals to 1. Specifically, it is defined as shown in Eq. (7):

$$\oplus Sim(h_i,h_j) = \begin{cases} 1, Sim(h_i,h_j) = 1 \\ \frac{Sim(h_i,h_j)}{2}, Sim(h_i,h_j) \neq 1 \end{cases}. \quad (7)$$

In the original graph convolutional network, if a graph node has no neighbors, it can only aggregate all of its own information, meaning the aggregation weight is 1. However, if this node is not an isolated node, the aggregation weight for any neighbor would be less than or equal to 1/2. In the proposed approach, if the similarity between two nodes is 1, it indicates that the graph node is an isolated node, and thus the aggregation weight is set to 1. If the similarity is not 1, similarly to the original graph convolutional network, it is necessary to map the similarity to a value between 0 and 1/2. Here, the classical normalization operator $\hat{S} = D^{-\frac{1}{2}}SD^{-\frac{1}{2}}$ used in GCN is not employed. Instead, the elements that are not equal to 1 are directly divided by 2 to achieve the desired result. This method is supported by extensive experiments, which demonstrate that this straightforward operator design yields superior performance.

B. Linear Similarity Measure based on Minkowski Distance

The Minkowski distance is a method used to measure the distance between two points in a multidimensional space, playing a significant role in quantifying the similarity between sample points. In the task of semi-supervised node classification, nodes with closer features are more likely to belong

to the same class. Therefore, in this study, the Minkowski distance is employed instead of cosine similarity to construct a similarity measure that characterizes the proximity between node features.

In Euclidean space, for two sample points $x = (x_1, x_2, ..., x_n)$ and $y = (y_1, y_2, ..., y_n)$, their Minkowski distance [29] $d(x, y)$ is defined as shown in Eq. (8):

$$d(x,y) = (\sum_{i=1}^{n} \mid x_i - y_i \mid^p)^{\frac{1}{p}}, \tag{8}$$

where p is a positive real-valued parameter that controls the sensitivity of the metric distance.When $p = 1$, it corresponds to the Manhattan distance as shown in Eq. (9):

$$d(x,y) = \sum_{i=1}^{n} \mid x_i - y_i \mid . \tag{9}$$

When $p = 2$, it becomes the Euclidean distance as shown in Eq. (10):

$$d(x,y) = (\sum_{i=1}^{n} \mid x_i - y_i \mid^2)^{\frac{1}{2}}. \tag{10}$$

As p approaches infinity, it converges to the Chebyshev distance as shown in Eq. (11):

$$d(x,y) = \max_i \mid x_i - y_i \mid . \tag{11}$$

Based on the Minkowski distance, for the features h_i, h_j of nodes i and j, this study construct the following linear similarity measure function [Eq. (12)]:

$$\mathrm{Sim(h_i, h_j)} = -\frac{\mathrm{d(h_i, h_j) - D_{min}}}{\mathrm{D_{max} - D_{min}}} + 1, \tag{12}$$

where D is a distance matrix composed of Minkowski distances between different nodes, $D_{\max} = \max \sum_{i,j} d_{ij}$ is the maximum value among all elements in the distance matrix, $D_{\min} = \min \sum_{i,j} d_{ij}$ is the minimum value among all elements in the distance matrix, and $d(h_i, h_j)$ represents the Minkowski distance between the features of node i and node j.

This study normalizes the distance $d(h_i, h_j)$ to a uniform scale by computing $d_{ij} = \frac{d(h_i,h_j)-D_{\min}}{D_{\max}-D_{\min}}$. A value of d_{ij} closer to 1 indicates that the features of nodes i and j are less similar, whereas a value closer to 0 signifies greater similarity. The closer the features, the higher the similarity, and vice versa. This suggests that the similarity measure function needs to be designed in such a way that it maps a smaller d_i to a larger similarity value, and a larger d_i to a smaller similarity value. It requires the function to be monotonically decreasing and have its range within $[0, 1]$ in the interval $[0, 1]$. Based on this principle, various similarity measure functions were designed, such as $Sim(d_{ij}) = \cos\left(\frac{\pi}{2} d_{ij}\right)$, $Sim(d_{ij}) = 1 - \sin\left(\frac{\pi}{2} d_{ij}\right)$, and $Sim(d_{ij}) = \text{sigmoid}(-x) + \frac{1}{2}$. Nonetheless, the comprehensive experimental evaluation revealed that the linear similarity measure function, defined as $Sim(d_{ij}) = -d_{ij} + 1$, consistently outperformed the other methods, showcasing its superior performance.

C. SGCN for Semi-supervised Node Classification

To demonstrate the effectiveness of the proposed SGCN in learning graph node feature representations, this work follows the same approach as Kipf [19], employing a two-layer graph convolutional network for semi-supervised node classification. Two graph convolutional neural network models, SGCN-GCN and SGCN-SGCN, are constructed to tackle the semi-supervised node classification task. Here, GCN refers to the original classical graph convolutional network. The SGCN-GCN model is defined as shown in Eq. (13):

$$\begin{aligned} &f_{SGCN-GCN}(\hat{A}, X; \theta) = \\ &softmax(\hat{A}\mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S})XW^{(0)})W^{(1)}) \end{aligned}, \tag{13}$$

where $\mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S})XW^{(0)})$ represents the first layer of this work proposed SGCN. The second layer, $softmax(\hat{A}X^{(1)}W^{(1)})$, corresponds to the classical GCN network before improvement, where $\mathrm{X^{(1)}} = \mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S})XW^{(0)})$ is the graph node feature matrix output by the first convolutional layer. The schematic diagram of the constructed model is shown in Fig. 1, where the first layer is the proposed SGCN, and the second layer is the traditional GCN.

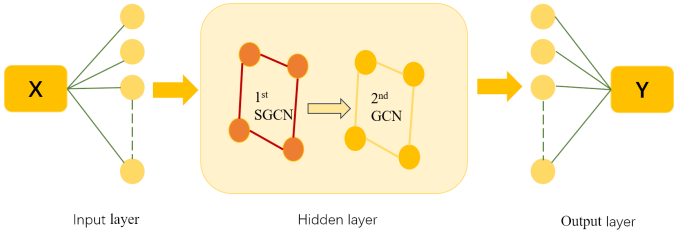

Fig. 1. Schematic diagram of the SGCN-GCN model.

The SGCN-SGCN model is formulated as follows [Eq. (14)]:

$$\begin{aligned} &f_{SGCN-SGCN}(\hat{A}, X; \theta) = \\ &softmax((\lambda\hat{A} + (1-\lambda)\hat{S}^{(1)}) \\ &\mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S}^{(0)})XW^{(0)})W^{(1)}) \end{aligned}, \tag{14}$$

where, $\mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S}^{(0)})XW^{(0)})$ represents the first layer of the proposed SGCN. $softmax((\lambda\hat{A} + (1-\lambda)\hat{S}^{(1)})X^{(1)}W^{(1)})$ also represents the second layer of the proposed SGCN. $\mathrm{X^{(1)}} = \mathrm{ReLU}((\lambda\hat{A} + (1-\lambda)\hat{S}^{(0)})XW^{(0)})$ represents the graph node feature matrix output by the first convolutional layer's processing. A larger fusion factor λ indicates that structural information has a greater weight in the information propagation between nodes, while the weight

of attribute information is relatively smaller. Like many parameters in deep learning models, W is a parameter matrix that needs to be trained using the gradient descent algorithm. If the model is extended to L layers and the expanded SGCN-SGCN model is used for semi-supervised node classification, the process is shown in Algorithm 1.

Algorithm 1 Expanded SGCN-SGCN for Semi-Supervised Node Classification

Require: Graph $(\mathbf{V}, \mathbf{E}, \mathbf{X})$, Adjacency matrix $\mathbf{A}$, Initial labels $\mathbf{Y}^{(0)}$, Number of SGCN layers $\mathbf{L}$, Fusion factor λ
Ensure: Predicted labels $\mathbf{Y}_U$
Initialize node embeddings $\mathbf{H}^{(0)} = \mathbf{X}$
Initialize transformation matrices $\mathbf{W}^{(0)}$, $\mathbf{W}^{(1)}$, ... ,$\mathbf{W}^{(L-1)}$
Compute $\tilde{\mathbf{A}} = \mathbf{A} + \mathbf{I}_N$,$\mathbf{D}_{ii} = \sum_j \tilde{\mathbf{A}}_{ij}$
Compute $\hat{\mathbf{A}} = \mathbf{D}^{-1/2}\tilde{\mathbf{A}}\mathbf{D}^{-1/2}$
for $l = 1$ to L **do**
    Calculate similarity matrix $\mathbf{S}^{(l-1)}$ using Equation (12)
    $\hat{\mathbf{S}}^{(l-1)} = \oplus\mathbf{S}^{(l-1)}$
    $\mathbf{Z}^{(l)} = \sigma(\lambda\hat{\mathbf{A}}\mathbf{H}^{(l-1)}\mathbf{W}^{(l-1)} + (1-\lambda)\hat{\mathbf{S}}^{(l-1)})$
    $\mathbf{H}^{(l)} = \mathbf{Z}^{(l)}$
end for
Train the model using labeled nodes $\mathbf{L}$:
    $\mathcal{L}_0 = \sum_{i\in\mathcal{L}} \text{loss}(\mathbf{H}_i^{(L)}, \mathbf{Y}_i^{(0)})$
Predict labels for unlabeled nodes $\mathbf{U}$:
    $\mathbf{Y}_U = \text{softmax}(\mathbf{H}_U^{(L)})$
Return $\mathbf{Y}_U$

This work construct two graph convolutional models for semi-supervised node classification by combining the proposed SGCN with the traditional GCN. In addition to utilizing graph structural information to obtain neighbor aggregation weights, SGCN also takes into account the attribute information of similarity between nodes. The similarity measure constructed using the Minkowski distance differs from cosine similarity in that it more precisely captures the closeness between node features, focusing on the similarity of feature content rather than spatial proximity. It is straightforward to envision that, in the context of semi-supervised node classification, nodes with similar features are more likely to belong to the same category. From this perspective, the rationale behind the approach becomes evident.

D. Analysis of Algorithm Complexity

Assuming L is the number of graph convolutional layers, N is the number of nodes, $\|A\|_0$ is the number of non-zero elements in the adjacency matrix A, and F is the number of node features. The time complexity of training a traditional GCN model for semi-supervised classification is $O(L \parallel A \parallel_0 F+LNF^2)$ and the space complexity is $O(LNF+LF^2)$ [30]. For the L-layer SGCN this study designed, the time complexity required for training is $O(2L \parallel A \parallel_0 F + LNF^2)$, and the space complexity is $O(2LNF + LF^2)$. It is evident that the proposed scheme can learn better node feature representations while maintaining the same order of magnitude of time and space complexity as the classical GCN. Taking the Cora dataset as an example and keeping consistent with the experimental setup detailed in Section 5, this work utilized a two-layer GCN architecture to perform semi-supervised node classification over 300 epochs. The training time for the GCN model was 8.21 seconds, while the proposed enhanced SGCN model took 9.08 seconds. The slight increase in time consumption of the proposed scheme is mainly attributed to the calculation of the similarity matrix.

V. Experiment and Result Analysis

To validate the effectiveness of the proposed SGCN in graph node representation learning, this study leverages the two graph convolutional neural network models outlined in the preceding section to evaluate their performance on semi-supervised node classification tasks. In this section, the experimental datasets, benchmark models, and experimental parameter settings are first introduced. Then, the experimental results of different models are analyzed. Finally, the impact of different metric distances, namely Manhattan distance, Euclidean distance, and Chebyshev distance, as well as varying fusion factors, on the performance of the two constructed semi-supervised node classification models is explored.

A. Datasets and Baseline Methods

This work evaluate the performance of the two proposed models on three benchmark citation network datasets: Cora, Citeseer, and PubMed [31]. These citation network datasets are structured as graphs with papers represented as nodes and citations between papers as edges. The specific details of these datasets are presented in Table I. Taking the Cora dataset as an example, it contains 2708 graph nodes and 5429 edges, with 7 domain categories represented by 7-dimensional one-hot vectors. Each paper is described by a 1433-dimensional one-hot feature vector, where each dimension takes a value of 0 or 1, indicating whether the corresponding word appears in the paper. The label rate in the dataset is 5.2%, meaning that 94.8% of the data is unlabeled.

TABLE I. The Details of Citation Network Datasets

Dataset	Nodes	Edges	Classes	Features	Labeled rate
Cora	2708	5429	7	1433	5.2%
Citeseer	3327	4732	6	3703	3.6%
Pubmed	19717	44338	3	500	0.3%

To validate the effectiveness and advancement of the proposed models for semi-supervised node classification tasks, this study compare them with the following benchmark methods: Multi-Layer Perceptron (MLP) [32], Label Propagation (LP) [33], Semi-supervised Embedding (SemiEmb) [34], Manifold Regularization (ManiReg) [35], Iterative Classification Algorithm (ICA) [36], DeepWalk [37], Planetoid [38], GCN [19], GraphSAGE [11] and GAT [10].

B. Implementation Details

Experimental setup was equipped with an 11th Gen Intel® Core™ i7-1165G7 processor, operating at 2.80 GHz and accompanied by 16GB of RAM. this work developed the SGCN-GCN and SGCN-SGCN models utilizing Python 3.9.10, PyTorch 2.2.1, and torch-geometric 2.5.3, all within the Windows 10 environment. The models were evaluated on three distinct datasets, employing uniform hyperparameter configurations: an L2 regularization factor of 5×10^{-4}, a hidden layer size of 128

units, the Adam optimizer, 300 training epochs, and a learning rate set to 0.01. The reported experimental outcomes reflect the mean classification accuracy across 10 distinct model parameter initializations, ensuring the reliability and robustness of these findings.

C. Experimental Results and Analysis of Different Models

Table II reports the average accuracy of different semi-supervised node classification models, with the highest and second-highest accuracies highlighted in bold. In addition to the experimental results on classification accuracy for MLP, GCN, GraphSAGE, GAT, and the two models proposed in this study, the results for all other models are derived from their original publications. As can be seen from the table, the two proposed models demonstrate superior performance compared to other models on all three datasets. This is attributed to the proposed SGCN, which considers not only the structural information of the graph but also the similarity information between nodes during information aggregation. Unlike the cosine similarity in mathematical space, a linear similarity measure using the Minkowski distance was designed, which better describes the proximity relationship between node features.

TABLE II. CLASSIFICATION ACCURACY (%) OF VARIOUS MODELS

Model	Cora	Citeseer	Pubmed
MLP	57.6	58.9	72.9
ManiReg	59.5	60.1	70.7
SemiEmb	59.0	59.6	71.1
LP	68.0	45.3	63.0
DeepWalk	67.2	43.2	65.3
ICA	75.1	69.1	73.9
Planetoid	75.7	64.7	73.9
GCN	80.6	68.7	78.7
GraphSAGE	80.0	62.4	76.0
GAT	**81.3**	68.5	77.2
SGCN-GCN	**81.5**	**69.5**	**79.5**
SGCN-SGCN	**81.3**	**68.9**	**79.9**

In contrast, other methods have limitations: MLP only uses node attribute information without considering the graph's structural information; ManiReg relies heavily on the data structure within local neighborhoods and can easily overlook global information; SemiEmb has high requirements for labels; DeepWalk cannot model attribute information; Planetoid suffers from information loss in the graph structure during random sampling; GCN, GraphSAGE, and GAT adopt a neighborhood aggregation scheme to improve performance by mixing the features of nodes and their neighbors, but they do not fully utilize the attribute information of the nodes themselves during the aggregation process. The SimP-GCN model proposed in [12] achieves the preservation of node similarity and the adaptive integration of structural and similarity information through the K-Nearest Neighbors (KNN) algorithm, a Node Similarity Preserving Aggregation module, and a Self-Supervised Learning module. In comparison, the scheme proposed in this study is more straightforward and efficient, has a reduced number of parameters, and exhibits stronger generalization capabilities. Since the code provided for constructing the SimP-GCN model in the original text did not utilize the same torch-geometric package as the one used in this study for building graph neural networks, significant errors occurred when attempting to reproduce the results. Consequently, the relevant experimental results for this model are not reported in this work.

The experimental results of the proposed SGCN-GCN and SGCN-SGCN compared to the classical GCN are presented in Fig. 2 below. Specifically, the SGCN-GCN achieves improvements of 0.9%, 0.8%, and 0.8% in accuracy over the traditional GCN on the three datasets, respectively, while SGCN-SGCN achieves improvements of 0.7%, 0.2%, and 1.2%, respectively.

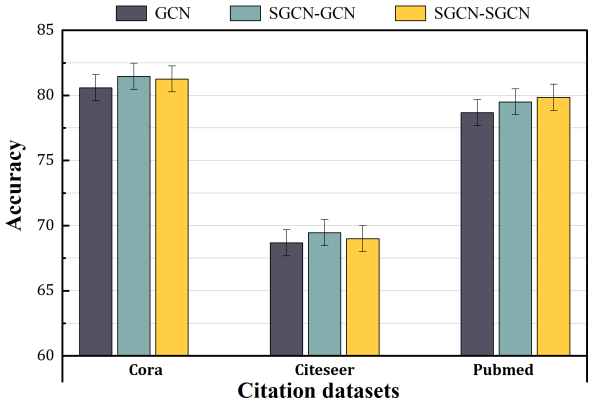

Fig. 2. Comparison chart with classical GCN classification accuracy.

D. Experimental Results and Analysis at Different Distances

This work report the classification accuracy of SGCN-GCN and SGCN-SGCN under different metric distances on the Cora, Citeseer, and Pubmed datasets in Fig. 3 and Fig. 4, respectively. The horizontal axis represents the tested datasets, while the vertical axis represents the classification accuracy, which is the average of ten experimental results.

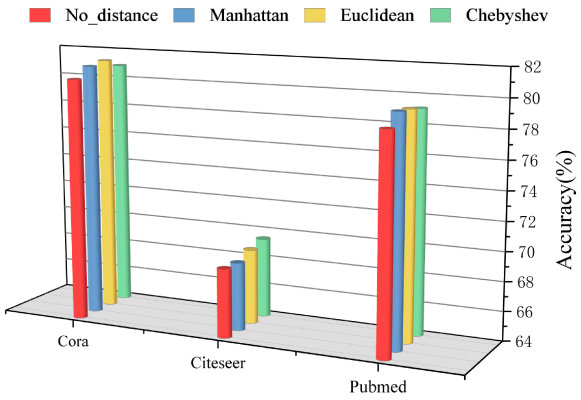

Fig. 3. Comparison of accuracy of SGCN-GCN at different metric distances.

The analysis of the figures reveals that both models perform best using Manhattan distance and Euclidean distance on the Cora and Pubmed datasets, while the Chebyshev distance yields the best results on the Citeseer dataset. This can be primarily attributed to the fact that the node feature dimensions in the Cora and Pubmed networks are relatively low (1433 and

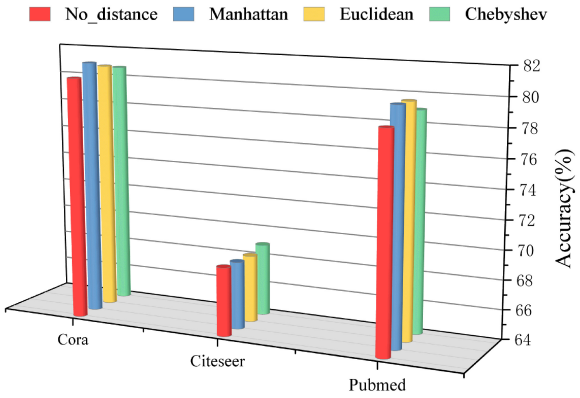

Fig. 4. Comparison of accuracy of SGCN-SGCN at different metric distances.

500, respectively), whereas the Citeseer network has a higher dimension (3703). For nodes with lower-dimensional features, which tend to be denser, using Manhattan and Euclidean distances to calculate similarity can fully utilize each feature value. In contrast, for nodes with higher-dimensional features, which are relatively sparse, using the Chebyshev distance to calculate similarity can better avoid interference from invalid feature values.

E. Experimental Results and Analysis of Different Fusion Factors

This work reports the variation in classification accuracy of SGCN-GCN across various fusion factors on the Cora, Citeseer, and Pubmed datasets, with Fig. 5, Fig. 6, and Fig. 7 depicting the performance under Manhattan distance, Euclidean distance, and Chebyshev distance, respectively. The horizontal axis represents the fusion factor, while the vertical axis indicates the classification accuracy, which is the average of ten experimental results.

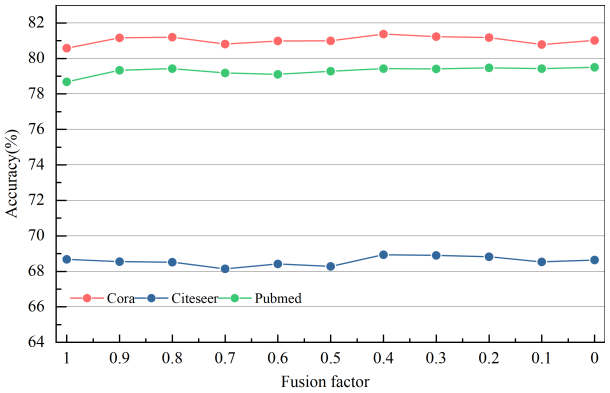

Fig. 5. SGCN-GCN classification accuracy variation map at Manhattan distance.

The analysis of the figures reveals that the SGCN-GCN model achieves better classification performance on the three datasets when the similarity information allocated to the first

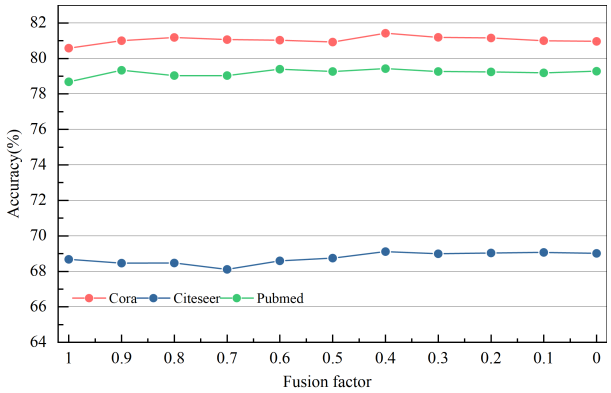

Fig. 6. SGCN-GCN classification accuracy variation map at Euclidean distance.

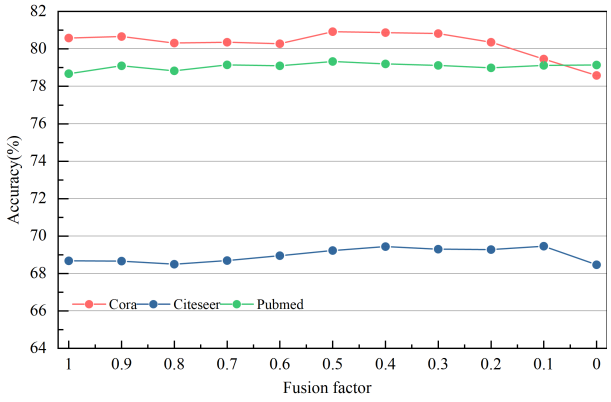

Fig. 7. SGCN-GCN classification accuracy variation map at Chebyshev distance.

layer of the graph convolutional network carries a larger weight. This is because only the first layer of the network utilizes similarity information for aggregation. Specifically, the model performs well when the fusion factor λ ranges from 0.1 to 0.5. When $\lambda = 1$ and $\lambda = 0$, the model solely relies on graph structural information (original GCN) and similarity information, respectively, for information aggregation. Notably, this study observes that the model using similarity information computed by Manhattan and Euclidean distances achieves better classification performance than the classical GCN when $\lambda = 0$ (i.e. using only similarity information). Irrespective of the value of the fusion factor λ, the model that integrates similarity information computed by Manhattan and Euclidean distances consistently demonstrates excellent classification results on the Cora and PubMed datasets. This verifies the validity of the approach to integrate similarity information into the original GCN framework.

This work reports the variation in classification accuracy of SGCN-SGCN across various fusion factors on the Cora, Citeseer, and Pubmed datasets, with Fig. 8, Fig. 9, and Fig. 10 depicting the performance under Manhattan distance, Euclidean distance, and Chebyshev distance, respectively. The horizontal axis represents the fusion factor, while the vertical axis indicates the classification accuracy, which is the average of ten experimental results.

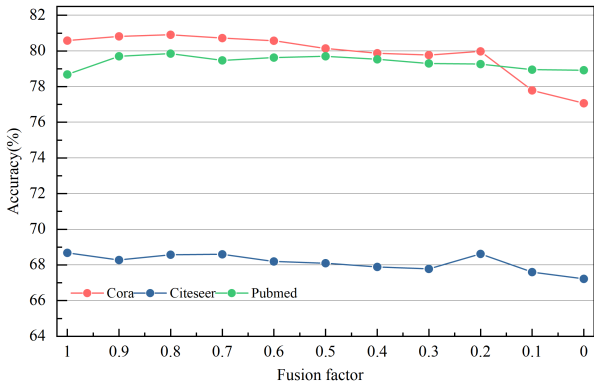

Fig. 8. SGCN-SGCN classification accuracy variation map at Manhattan distance.

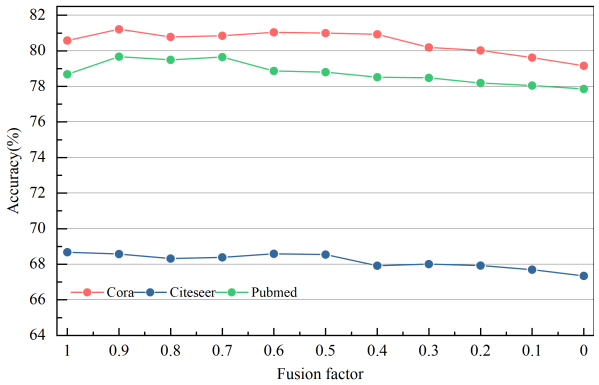

Fig. 9. SGCN-SGCN classification accuracy variation map at Euclidean distance.

The analysis of the figures indicates that the SGCN-SGCN model, which leverages similarity information for information aggregation in both layers of the network, achieves superior classification performance on the Cora and Pubmed datasets when each layer of the graph convolutional network is assigned a lower weight to the similarity information. Specifically, the model performs well when the fusion factor λ is greater than or equal to 0.6. When $\lambda = 1$ and $\lambda = 0$, the model relies solely on graph structural information (original GCN) and similarity information, respectively, for information aggregation. However, the model's performance on the Citeseer dataset is suboptimal, likely due to the sparsity of the feature vectors caused by its higher node feature dimension (3703).

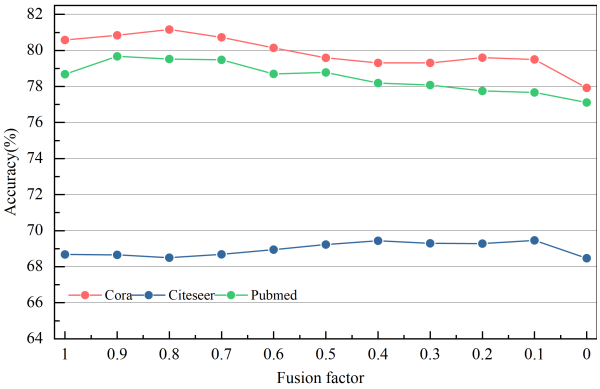

Fig. 10. SGCN-SGCN classification accuracy variation map at Chebyshev distance.

VI. Discussion

This study introduces SGCN, a novel graph convolutional network that integrates a linear similarity measure based on Minkowski distance with traditional graph structural information, addressing the limitations of conventional GCNs. Traditional GCNs typically overlook node attribute information and tend to disrupt the similarity information between nodes during information aggregation. Methods like GraphSAGE and GAT improve neighborhood aggregation but fail to fully capture node feature similarity and require the addition of supervised modules with more parameters and black-box characteristics.

Experimental results demonstrate that SGCN performs best when similarity information is weighted more heavily in the first layer, with the fusion factor between 0.1 and 0.5. This indicates that, while structural information plays a dominant role in the information propagation and aggregation of graph nodes, attribute information also provides a complementary, supportive function. Among the distance metrics tested, Manhattan and Euclidean distances consistently yield better results, suggesting they are more effective at capturing feature proximity in node classification tasks.

Future work may focus on extending SGCN to more specific graph data, such as functional brain networks, and implementing adaptive fusion factor adjustments to learn better node embedding representations, aiming to improve the recognition accuracy of brain diseases such as Alzheimer's and autism.

VII. Conclusion

Traditional Graph Convolutional Networks (GCNs) primarily rely on graph structure for node aggregation, often overlooking node attribute information. This approach can reduce node similarity and impede effective node feature learning, particularly in semi-supervised classification tasks. To address these issues, this study proposes SGCN, a novel Graph Convolutional Network. SGCN introduces a linear similarity measure based on Minkowski distance between node features, enhancing the description of similarity. By integrating this measure with traditional graph structure, SGCN improves node feature representation. Experimental validation on datasets such as Cora, Citeseer, and PubMed demonstrates that SGCN models (SGCN-GCN and SGCN-SGCN) significantly outperform traditional GCNs in node feature learning. The impact of metric distances and fusion factors on performance is also analyzed, providing insights for model optimization.

Empowering Home Care: Utilizing IoT and Deep Learning for Intelligent Monitoring and Management of Chronic Diseases

Nouf Alabdulqader, Khaled Riad*, Badar Almarri
Computer Science Department, College of Computer Sciences & Information Technology,
King Faisal University, Al-Ahsa 31982, Saudi Arabia

***Abstract*—Integrating Internet of Things (IoT) with Artificial Intelligence (AI) is one of the catalysts for improving traditional healthcare services. This integration has created many opportunities that have led to healthcare shifting towards enabling home care, the concept that harnesses the technologies advanced potential such as the IoT and deep learning for intelligent monitor and manage chronic diseases. As population growth increases, restrictions on traditional healthcare services increase. Some diseases, such as chronic diseases, require innovative solutions that go beyond the boundaries of traditional healthcare settings due to their impact on individuals' health for example traditional healthcare systems have little capacity to provide high-quality and real-time services. Empowering home care services using deep learning and internet of things technology is promising. It enables continuous monitoring through interconnected devices and deep learning, which provides intelligent insights from massive data sets. This brief explores the key components of enabling home care, including continuous patient health monitoring, predictive analytics, medication management, and remote patient support by healthcare providers, and provides friendly interfaces for end-users. The conjunction between the IoT and deep learning in home-care signals a shift toward precision medicine, enhancing patient outcomes and creating a sustainable model for chronic disease management in the era of decentralized healthcare. This review article aims to discuss the following aspects: presenting the latest technologies in home care systems, showing the merit of combining the Internet of Medical Things (IoMT) and deep learning and its role in monitoring patient conditions and managing chronic disease to improve patient health status accurately, in real-time, and cost-effective, and lastly, debating future studies and providing recommendations for the ongoing development of home care remote monitoring applications.**

***Keywords*—IoT; IoMT; intelligent monitoring; chronic diseases; deep learning; home care; physiological data; mHealth**

I. Introduction

In the ever-evolving healthcare landscape, home care has emerged as a pivotal frontier, driven by technological advancements that aim to transform the management of chronic diseases. This paradigm shift is embodied in the concept of empowering home care, where the fusion of IoT and deep learning play central roles in leading a new area of intelligent monitoring and management for chronic conditions. Chronic diseases present substantial challenges to both individuals and healthcare systems, necessitating innovative solutions that provide personalized, continuous, and accessible care. Home healthcare services provide many benefits to the service providers and end-users by allowing service providers to monitor their patients outside the hospital and everywhere with high quality, and they can always connect to their patients. With the entrance of the IoT, the solution of home healthcare becomes proactive by using the term mHealth, which can be defined as "a communication technology integrated with mobile sensors for healthcare" [1]. The number of mHealth applications has increased over the years because of traditional monitoring methods often necessitate frequent visits to healthcare facilities, resulting in inconvenience and escalated healthcare expenses [2]. Moreover, these methods typically involve the use of multiple wearable sensors employing different algorithms, causing discomfort to patients and incurring exorbitant costs. The conventional approach to monitoring chronic diseases involved clinic visits and extracting blood samples from patients at labs. The physician would then evaluate the lab results to determine the patient's status. The disadvantages encompass high costs, prolonged monitoring periods, delayed responses from healthcare providers, potentially leading to patient fatalities, and a surge in the number of patients waiting in clinics [3], [4]. These drawbacks underscore the need for a shift towards real-time patient condition monitoring and exploring alternative methodologies. This review article will discuss three subjects: First, it will discuss recent technology in home care systems. Second, can integrating the IoT and deep learning help monitor, manage, and improve chronic disease patient conditions? Third, recommendations will be provided, and future studies for home healthcare technology will be explored.

A. Background

Due to the high importance of home care in managing and controlling chronic diseases, technology has become a main component of it, such as IoT and deep learning facilitating remote monitoring, management, and controlling the patient condition. Chronic diseases have become one of the specialties that cause significant challenges for healthcare, leading to a shift to decentralized healthcare. Integrating IoT and deep learning plays a significant role in home healthcare. IoT is highlighted as a main technology in home healthcare that allows service providers to perform real-time health patient monitoring through interconnected and wearable devices. Empowering home care leads to providing a holistic and patient-centric approach to chronic disease management, leveraging IoT and deep learning to empower patients, improve health conditions, enhance patient satisfaction, and create a more sus-

*Corresponding authors

tainable healthcare environment. The author in [5] introduces the potential advantage of using IoT in healthcare to monitor the daily activities of elderly people. The study discusses the heterogeneity and interoperability issues related to disregarding healthcare for IoT. This study proposed H3IoT architecture to support home care for the health monitoring of elderly people, focusing on its ease of use, mobility, and cost-effectiveness. The H3IoT can provide support in many aspects, such as protective and monitoring health care, and chronic disease management. The author in [6] explores the potential of using IoT and big data analytics for chronic disease monitoring in Saudi Arabia, with a specific focus on hypertension. It aims to develop a predictive system for detecting and managing chronic diseases by presenting a framework consisting of four modules: data collection, storage, processing, and analysis. Decision Tree (C4.5) and Support Vector Machine (SVM) models were employed to predict hypertension, identifying age and diabetes as significant contributing factors. The accuracy of the Support Vector Machine algorithm is 71.15%, while the accuracy of the C4.5 algorithm is 68.80%, highlighting the predictive capabilities of these models. The authors emphasize the transformative potential of IoT and big data analytics in enabling the early detection of chronic diseases and enhancing healthcare services in Saudi Arabia. The research concludes that while the proposed models are effective for disease prediction, further refinement and evaluation are necessary to optimize their performance. Ultimately, this review underscores the revolutionary impact of IoT and big data analytics in chronic disease monitoring and healthcare innovation. The author in [7] investigates the application of machine learning (ML) techniques to analyze chronic diseases using diagnosis codes from the CMS dataset. Focusing on clinical and claims data for 11 chronic diseases, the study aims to reduce the set of diagnosis codes and assess their relevance to healthcare decision-making. The experimental setup involves restructuring the data, applying attribute reduction techniques, and utilizing classification algorithms to derive insights. The study demonstrates that the reduced set of diagnosis codes provides valuable insights for informed healthcare decisions. For the training data, most of the 11 chronic diseases achieve an accuracy above 88%, with stroke and chronic kidney disease showing the highest accuracy. For the testing data, the accuracy for most chronic diseases ranges between 80-90%, with cancer and stroke achieving accuracies above 90%. In contrast, chronic heart failure and depression exhibit lower accuracies of 79.15% and 77.02%, respectively. These findings highlight the effectiveness of ML techniques in analyzing chronic diseases and their potential to support healthcare decision-making. The author in [8] discuss that healthcare landscape is rapidly evolving, with an increasing emphasis on delivering high-quality care within the comfort of patients' homes. This shift toward home-based care is driven by an aging population and the growing demand for patient-centered solutions. At the forefront of this transformation is the powerful synergy between the Internet of Things (IoT) and deep learning. IoT, with its network of interconnected devices and sensors, facilitates the real-time collection of data on various aspects of a patient's well-being. Deep learning, a subset of artificial intelligence, excels at extracting complex patterns from vast datasets, making it a critical tool in modern healthcare.

By applying deep learning algorithms to the extensive data collected by IoT devices, healthcare providers can unlock numerous benefits, including improved diagnostic accuracy and personalized care. For example, studies have demonstrated that for training data, most of the 11 chronic diseases analyzed achieve an accuracy above 88%, with stroke and chronic kidney disease showing the highest performance. For testing data, the accuracy for most chronic diseases ranges between 80% and 90%, with cancer and stroke achieving accuracies above 90%. However, chronic heart failure and depression exhibit lower accuracies of 79.15% and 77.02%, respectively. These lower accuracies are attributed to the variability in diagnostic tests for these conditions. This highlights the need for further advancements in data collection and analysis to ensure consistent accuracy across all conditions.

The author in [9] discusses the landscape of healthcare growth where emphasis on providing patient-centered care that is both effective and affordable. Within this landscape, home care emerges as a critical component, allowing individuals to receive care in familiar surroundings. The convergence of the IoT and deep learning presents a transformative opportunity to revolutionize home care, enhancing both the quality of care and the efficiency of service delivery. This study explores the application of Multi-Step Deep Q Learning Network for securing healthcare data within the IoT framework. This convergence of deep learning and IoT immense to transform home care, making it more proactive, personalized, and effective. The author in [10] discusses the prediction of heart disease using an IoT-based ThingSpeak framework and a deep learning approach, proposing a system that leverages IoT technology and deep learning to achieve real-time predictions. The integration of IoT sensors with advanced deep learning models enables the continuous monitoring and analysis of patient health data, providing early warnings and facilitating timely interventions. This approach underscores the transformative potential of combining IoT and deep learning in chronic disease management, offering significant improvements in patient health outcomes, reductions in healthcare costs, and enhancements in the overall quality of life for individuals with chronic conditions. The proposed CNN-based heart disease prediction system demonstrated remarkable performance, achieving an accuracy of 98.8% based on experimental results. Additionally, the Matthews Correlation Coefficient for the system was calculated at 0.9321, further validating its reliability and effectiveness. These findings highlight the potential of IoT and deep learning technologies to revolutionize chronic disease management, paving the way for more efficient, patient-centered healthcare solutions.

B. Objectives

The objectives discussed in the current studies are:

- Discuss the current studies that support an overall view of the current state of empowering home care for chronic disease patients and highlighting challenges and opportunities in home care.
- Explore IoT technologies for monitoring and managing chronic diseases in-home care using designed devices and sensors.

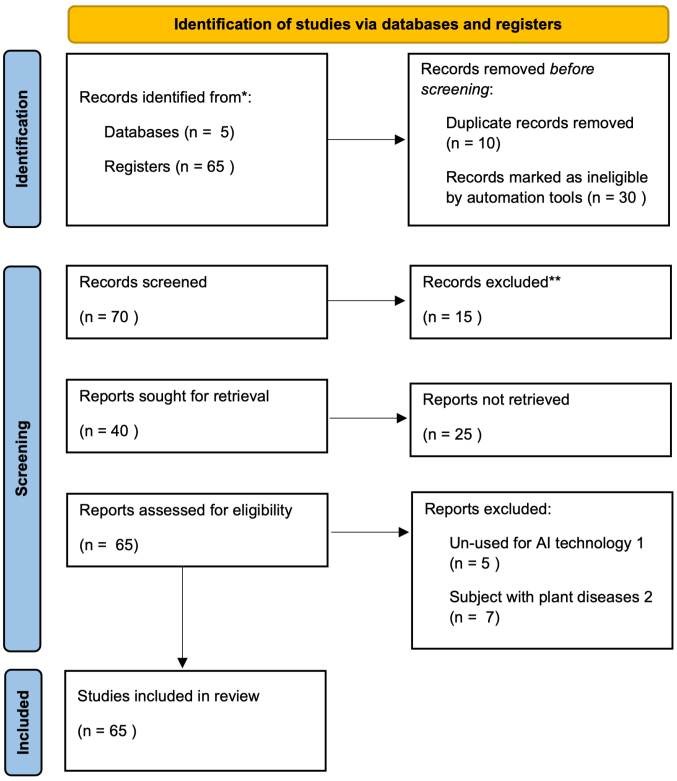

Fig. 1. PRISMA Methodology.

- Evaluate deep learning applications in-home care for intelligent monitoring and management of chronic diseases.
- Identify and analyze the best practices of utilizing deep learning and IoT models to empower home care for chronic diseases.
- Assesses technological challenges and limitations of deep learning and IoT in-home care.
- Provide recommendations and guidelines for activating the positive view of implementing deep learning and IoT and technologies in-home care.

C. Methodology

IoT and deep learning technology have emerged as transformative tools for home care, revolutionizing the way patients are monitored and managed remotely. The main goal of the review article is to find research papers focusing on utilizing IoT and deep learning in-home care and comparing them to achieve the review article's objectives using PRISMA to list of all extracted researches as mentioned in Fig. 1.

This section discusses the methodologies used in the review article as described below:

1) Literature Search Strategy:
   Conduct comprehensive literature research using electronic databases, including IEEE Xplore, Google Scholar, Research Gate, and ScienceDirect.
2) Inclusion and Exclusion Criteria:
   After filtering the search studies, we included published studies in conference papers, peer-reviewed journals, and literature reviews.
3) Research Summarization: The review article uses two main applications to summarize the research paper: SciSummery to summarize the whole paper and Jenni to find out the technologies used and methodologies.
4) Research Comparison: To achieve a review article's objectives, we used PRISMA in comparing research papers and to find out methodologies used, data collection, IoT sensors, differences, strengths, and weaknesses of research papers.
5) Future and Limitations: Potential limitations of the research papers such as the limitation in methodologies, the chronic disease cases that solution supports, and the accuracy that the research paper reaches.

The rest of this review article is structured as follows: The first section is about IoT in-home care that discusses the integration of IoT technologies in-home care, which revolutionizes health management, offering personalized monitoring and proactive care delivery to enhancing safety and independence. The second section is about deep learning in-home care. It discusses deep learning's vast potential to transform healthcare, particularly in-home care for chronic disease patients, by leveraging advanced algorithms to improve outcomes and reduce costs through remote monitoring and personalized care. The third section is about deep learning in health monitoring. It discusses how deep learning revolutionizes health monitoring and diagnosis, enhancing accuracy and efficiency in disease detection and treatment planning through analysis of vast medical data, improving predictive precision and remote patient monitoring capabilities. The fourth section discusses the intelligent management of chronic diseases. The fifth section discuss benefits and challenges of integrating IoT and deep learning technologies that enhance home care services by enabling interconnected devices to monitor, communicate, and analyze data, creating a safer and more efficient living environment. The sixth section is about the case study using the remote monitoring system of diabetes patients and a case study of predictive analytics for cardiovascular disease management. The last section is the conclusion of this review article. Below Table I is a list of acronyms designed to aid in comprehending technical terms and abbreviations utilized in this comprehensive review. The purpose of this reference table is to assist readers in deciphering the numerous acronyms and their definitions commonly referenced in the exploration of sophisticated topics concerning the IoT, deep learning, and healthcare technologies.

II. IoT in Home Care

In the realm of home care, the combination of IoT technologies is emerge as a transformative force, revolutionizing how individuals manage their health and well-being within the comfort of their homes. IoT-enabled devices, such as wearable health monitors and smart home appliances, provide unprecedented opportunities for remote monitoring, personalized care, and real-time health interventions. By seamlessly collecting and analyzing vital health data, including blood pressure, heart rate, and activity levels, IoT systems provide both patients and caregivers with actionable insights, enabling them to make

TABLE I. NOTATION-TABLE

Acronym	Full Form	Description
ADL	Activities of Daily Living	Tasks related to personal care and routine activities necessary for daily life.
AI	Artificial Intelligence	Simulation of human intelligence processes by machines, especially computers.
COPD	Chronic Obstructive Pulmonary Disease	A group of lung diseases that block airflow and make it difficult to breathe.
EHR	Electronic Health Record	Digital version of a patient's paper chart containing medical and treatment history.
IoT	Internet of Things	Network of physical devices embedded with sensors and software to exchange data.
ML	Machine Learning	A branch of AI focused on building systems that learn from data to make predictions or decisions.
SVM	Support Vector Machine	A supervised machine learning algorithm used for classification and regression analysis.
WHO	World Health Organization	A specialized agency of the United Nations responsible for international public health.
CNN	Convolution Neural Network	Type of deep learning algorithm specifically designed for processing structured grid data.
SSO	Sparrow Search Optimization	A nature-inspired optimization algorithm based on the foraging behavior of sparrows, used to solve complex optimization problems.
SSO	Salp Swarm Optimization	A bio-inspired optimization algorithm modeled after the swarming behavior of salp chains in the ocean, used for solving complex optimization problems.
VAE	Variational Autoencoder	A type of generative model in machine learning that learns to encode input data into a latent space and then decode it back, allowing for the generation of new, similar data.
ECG	Electrocardiogram	A medical test that records the electrical activity of the heart over a period of time.

informed decisions about health management and treatment adherence.

As the IoT ecosystem continues to evolve, fueled by advancements in IoT devices technology, data sciences, and connectivity infrastructure, its power to revolutionize home care delivery and promote independent living for individuals of all ages remains unparalleled. Furthermore, the integration of IoT in healthcare research provides vast datasets that lead to enhance patient outcomes and innovative strategies to meet individual patient needs. Overall, IoT technology fosters a more responsive, personalized, and cost-effective healthcare ecosystem [11]. This section will present IoT-enabled devices, data collection and integration, remote monitoring, alert systems, and deep learning for health monitoring.

A. IoT-Enabled Devices

This section will present IoT sensors utilized by research papers in chronic diseases. The below Table II presents sensors used with their definitions:

TABLE II. IOT SENSORS UTILIZED IN THE RELATED LITERATURE

Ref. No.	Sensors
[5]	Acceleration sensor Motion sensor mathElectroencephalogram (EEG), Electromyogram (EMG)
[12]	Camera Sensor
[13]	accelerometers and gyroscopes sensors , environmental sensors
[14]	accelerometers Sensor gyroscopes Sensor Push button 5 MP camera, voice reminder Jetson TX2
[15]	Temperature sensors Heart rate sensors
[16]	wearable sensor

[6]	Temperature sensors Blood pressure sensors Heart rate monitors Oxygen level sensors Glucose level sensors Respiratory sensors Electrocardiogram monitors Electroencephalogram sensors Motion sensors Wearable fitness trackers Sleep pattern monitors
[18]	smart wristband
[7]	Nan
[19]	Temperature - Blood pressure Blood pressure
[20]	Temperature Blood Humidity Light intensity Soil moisture
[10]	Heart rate Blood pressure ECG Oxygen saturation Temperature

B. Data Collection and Integration

This section will demonstrate the data collection used to monitor and predict chronic diseases.

The author in [5] discusses that data collection is a broader context for healthcare. It suggests that data collection is happening through traditional channels such as hospitals, community healthcare settings, and public health organizations, but also increasingly through new methods like wearable devices and social media analytics. The adoption of Electronic Health Records (EHR) has been instrumental in improving data collection and consistency. The paper also mentions challenges related to the storage and access of large volumes of data and the need for a concerted effort to enable various professionals to access these datasets.

The author in [6] discusses the methodology used in data collection and integration in the form of utilizing IoT sensors in health care. It typically involves several steps, including

Data Collection: This involves using sensors and IoT devices to collect various types of health-related data, such as vital signs (temperature, heart rate, blood pressure, etc.), patient activity, or specific medical parameters.

The author in [7] presents the context of healthcare and especially in studies dealing with diagnosing chronic diseases using ML techniques or integrating IoT technologies into healthcare. Data collection and integration generally go through several steps, starting with data collection and end with feature selection.

The author in [8] discusses the broad strokes of using IoT and deep learning in healthcare. Unfortunately, it doesn't dive into the specifics of data collection and integration methodologies.

The author in [9] emphasizes the critical importance of the security aspects in a healthcare IoT system using deep learning. It does not delve into the specifics of data collection and integration methodologies, as the primary focus is on security. The author assumes data are collected from various devices to processing and analysis in the main server. However, it does not elaborate on the protocols, communication technologies, or data integration techniques employed.

C. Remote Monitoring and Alert Systems

Remote monitoring and alert systems in the medical field represent a significant evolution in healthcare management, leveraging technology to oversee patient health outside of traditional hospital environments. These systems utilize a different of sensors and devices to collect patient information continuously, which is then transmitted to healthcare professionals for analysis and response. The ability to monitor patients in real-time facilitates early detection of potential health issues, enables prompt interventions, and improves the overall chronic diseases conditions, elderly patient care, and post-operative recovery.

Such systems can operate over various networks, including wireless body area networks and personal area networks, and can even employ non-contact methods such as cameras or smart devices, as shown in Fig. 2. This technology not only improves patient outcomes by enabling constant care but also enhances the adequacy of healthcare services by reducing hospital admissions and costs. Medical staff are empowered to focus more on data interpretation and patient care decisions rather than on repetitive monitoring tasks [21].

ML plays a vital role in these systems by analyzing the data collected, recognizing patterns, and predicting outcomes, thus providing pivotal support in decision-making processes. The integration of ML and cloud computing also ensures that massive volumes of medical data are stored and processed effectively, promoting continuous advancements in healthcare delivery.

The author in [5] presents the architecture of H3IoT aims to provide an effective environment for monitoring the health status of elderly people at home, offering advantages such as mobility, affordability, user-friendliness, and tolerance for delays in data transmission. The system would also include an alert mechanism which automatically sends notifications to designated individuals or emergency services if the data

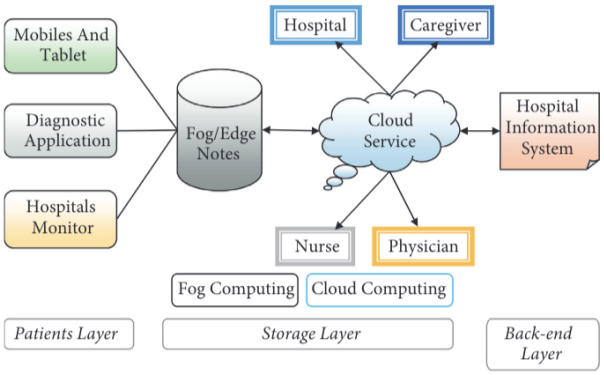

FIGURE 1: General architecture of RPM.

Fig. 2. General architecture of RPM [21].

TABLE III. RESEARCH PAPERS ACHIEVING ARTICLE OBJECTIVES

References	Achieved Objectives
[22] [5] [14] [6] [8] [9] [23] [20] [10]	1- Explore IoT technologies for monitoring and managing chronic diseases in-home care using designed devices and sensors 2- Identify and analyze best practices utilizing IoT and deep learning technologies to empower home care for chronic diseases.
[7]	Does not fulfill the article's objective related to the utilization of IoT sensors

indicates a cause for concern, such as a fall or a serious deviation in health signals. However, the framework may need additional modifications and enhancements to support critical emergency healthcare scenarios.

The author in [6] presents a combination of IoT devices for data collection and big data analytics for processing and analyzing the collected data to monitor chronic diseases such as hypertension. The methodology aims to predict and detect health issues, thereby enabling early interventions and improved patient outcomes. After reviewing the IoT sensors utilized in the research papers, it was found that not all studies incorporated IoT sensors in-home care, which does not meet the objectives of this article. Table III illustrates these findings.

III. DEEP LEARNING FOR HEALTH MONITORING

Deep learning has revolutionized the ability to monitor, diagnose, and manage health conditions in the medical field. In the era of digital healthcare transformation, deep learning approaches are applied to parse through massive volumes of medical data.

The introduction of deep learning algorithms into health monitoring systems has significantly improved the precision of predicting patient outcomes and has strengthened the capabilities of remote patient monitoring. By analyzing intricate patterns in data that are often imperceptible to human clinicians, deep learning models can identify potential health issues much earlier than traditional methods, thus aiding in proactive medical interventions.

Additionally, these advanced AI technologies enable personalized medicine, where treatment plans are tailored to

the individual characteristics of each patient's condition that leading to better patient health management and can improve patient in home-care. Overall, deep learning in health monitoring stands as a cornerstone in the leap towards more intelligent, responsive, and effective healthcare systems [24].

A. Deep Learning Techniques

The author in [5] presents the architectural concept of H3IoT for home environment monitoring of elderly individuals' health and does not delve into specific deep learning algorithms. Unfortunately, the authors in [6] do not mention the use of a deep learning algorithm for its methodology. But it specifically references the use data mining techniques with the Hadoop framework. For classification and prediction, it cites the use of a decision tree algorithm and SVM algorithm. However, there is another source titled "multi-disease prediction using LSTM recurrent neural (RNN) networks," which does mention the use of a deep learning approach, namely, Long Short-Term Memory RNN, for multi-disease prediction based on patients' clinical records. This approach is distinct from the method used in the first paper and is specifically designed for handling the temporal irregularity across clinical visits and determining the importance of each visit for the prediction task.

Furthermore, the author in [7] does not specify the use of a deep learning algorithm for its research. Instead, it discusses the utilization of ML techniques, such as attribute reduction techniques and classification algorithms, to analyze healthcare data and obtain a reduced set of diagnosis codes for chronic diseases. For deep learning applications within a similar context, the study multi-disease prediction using LSTM and RNN is relevant.

B. Sensor Data Analysis and Processing

Sensor data analysis and processing in the medical field is a crucial aspect of modern healthcare that leverages technology to improve patient outcomes and streamline healthcare services. By introducing IoT, the volume and variety of healthcare data have grown exponentially, presenting both opportunities and challenges. The vast volume of data produced by these devices necessitates advanced methods for processing and analysis to derive meaningful insights. Data science plays a pivotal role in this context, providing the tools and techniques necessary for managing, analyzing, and assimilating large quantities of both structured and unstructured healthcare data.

Medical sensor data analysis involves collecting, processing, and interpreting health data generated by these devices to monitor patient health, detect anomalies, and predict health events. This process requires sophisticated algorithms and big data techniques to handle large volumes of structured and unstructured data. The progression of data science and ML has facilitated the development of predictive models that support early disease detection and the customization of treatment plans [25]. Sensor data must be handled with care to ensure accuracy, reliability, and privacy. It involves pre-processing, data cleansing and anonymization, by using secure platforms to store and process data. Data science provides managements tools to manage patients health status data to extract meaningful information, which can be used in making important decisions about patient care. Effective data management and analysis can yield factual results crucial for proactive health monitoring, specific treatment plans, and instantly detecting of potential health issues. The process typically involves data cleansing, data mining, preparation, and analysis. Successfully integrating sensor data analysis and processing in healthcare can lead to groundbreaking advancements for patient monitoring remotely that lead to improve chronic disease management. The sensor data analysis and processing mentioned by the author in [5] could include several steps:

- Data Cleaning and Pre-processing
- Data Integration
- Real-Time Monitoring
- Pattern Recognition
- Predictive Analysis

If the study includes an IoT framework for health monitoring, it is likely that any or all of these data analysis and processing techniques could be employed within that framework.

Data analysis and processing, as proposed by the author in [6], are achieved through a integration of big data technologies and ML algorithms, specifically:

- Big Data Processing
- Data Storage and Management
- Data Analysis Integration

The purpose of these techniques is to process and analyze the collected data so that predictive models can be developed and applied, which are then able to identify potential cases of hypertension and possibly other chronic diseases in the data set. These models serve as a framework for early detection and ongoing monitoring of patient health, which could lead to better management and treatment outcomes.

Furthermore, the sensor data analysis and processing mentioned by the author in [7] focuses on the analysis and processing of clinical and claims data to study 11 chronic diseases. While the specific details of the data analysis and processing steps are not provided in the excerpts.

C. Disease Prediction and Risk Assessment

The use of IoT and AI in disease prediction represents a significant advancement in healthcare.

This data can include heart rate, blood pressure, glucose levels, and more, depending on the sensors' capabilities. AI comes into play by analyzing this massive stream of data to identify patterns and anomalies that might be indicative of health issues. Techniques from AI, like ML and deep learning models trained using vast datasets to learn from past examples. This training allows AI systems to predict potential diseases or health risks before they become critical, offering a chance for early intervention [26]. IoT provides the real-time data that AI models require to be accurate and effective, while AI gives the tools to make sense of the IoT-collected data, providing

TABLE IV. RESEARCH PAPERS ACHIEVING ARTICLE OBJECTIVES IN DEEP LEARNING

References	Achieved Objectives
[5]	1- Evaluate deep learning applications in-home care for intelligent monitoring and management of chronic diseases
[8] [9] [10]	2- Identify and analyze best practices utilizing IoT and deep learning technologies to empower home care for chronic diseases.
[6] [7]	Does not fulfill the article's objective related to the utilization of deep learning algorithms

insights that healthcare professionals can use to diagnose and treat patients more effectively. The integration of IoT and AI in healthcare has the potential to transform patient care by improving disease prediction, enhancing remote monitoring, and personalizing treatment plans.

The disease prediction and risk assessment presents by the author in [6] is achieved by developing a framework that utilizes decision tree and SVM techniques. The goal is to predict hypertension by analyzing health data collected from IoT devices.

The disease prediction and risk assessment presents by the author in [7] discusses by the following steps:

- Data Collection: Collecting patient data which may include demographics, clinical history, lab results, medication, etc.
- Data Preprocessing: Cleaning and structuring the data to be suitable for machine learning models.
- Feature Selection: Determining which data points (or "features") are most relevant to predicting a specific disease or risk level.
- Model Development: Using statistical or ML algorithms to create a model that can predict disease likelihood or risk based on the features.
- Validation and Testing: Testing the model against a dataset that was not used during the training to evaluate its performance and accuracy.
- Risk Assessment: The model's output may be a probability of disease presence or progression, which can be used to assess risk levels for patients.

At the end of this section, we conclude that not all research papers employed deep learning in home care to monitor chronic diseases. Table IV indicates which research studies meet the article's objectives and which do not.

IV. INTELLIGENT MANAGEMENT OF CHRONIC DISEASES

The intelligent management of chronic diseases involves employing advanced technologies and systems to enhance the care and outcomes for those with long-term health conditions. This approach as shown in Fig. 3, includes the use of personal health systems, connected health solutions, and self-management techniques. These are designed to empower patients to take an active role in managing their own care in partnership with healthcare providers. Through connected health technologies, such as smart biosensors, remote monitoring, and data analytics, patients and health professionals

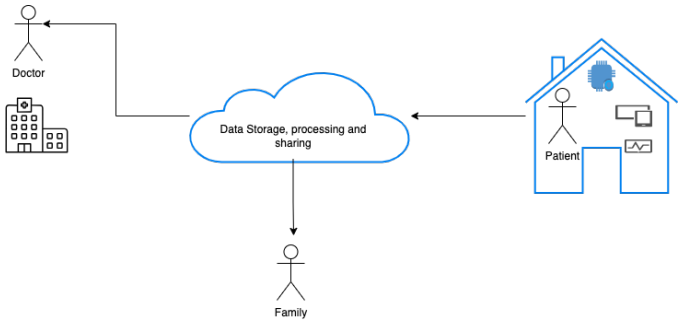

Fig. 3. The health ecosystem.

can better track health status and adjust treatments as needed. Digital tools support lifestyle changes, help manage symptoms, and can provide alerts for timely interventions, thus avoiding exacerbations and hospitalizations [27]. Self-management is a complementary concept where patients with chronic illnesses like diabetes, heart disease, and arthritis learn and apply skills to deal with their conditions effectively. This approach includes monitoring symptoms, managing medications, maintaining diet, exercise regimes, and adapting psychologically and socially. The intelligent management of chronic diseases aims to provide personalized care, reduce healthcare costs, and improve the overall quality of life for patients. It represents a strategic shift towards more proactive and patient-centered healthcare models.

A. Personalized Treatment Plans

The practice of medicine is evolving, shifting its focus from simply treating disease events to enhancing health, preventing diseases, and personalizing care to meet individual health needs. This transformation is driven by the concept of personalized health care, which utilizes personalized health planning empowered by personalized medicine tools. These tools leverage advances in science and technology to predict health risks, understand disease development dynamics, and tailor therapeutic approaches to individual needs [28]. Personalized medicine plays a crucial role in the management of chronic diseases. By implementing personalized health care and utilizing personalized medicine tools, healthcare providers can create personalized treatment plans for individuals with chronic diseases. These plans are listed to each patient's specific needs, taking into account their genetics, lifestyle factors, and response to previous treatments. This personalized approach in chronic disease management helps optimize patient health status outcomes and enhance the quality of health care.

B. Behavioral Analysis and Intervention

Chronic diseases, such as diabetes, heart disease, and hypertension, are a growing concern worldwide. These conditions require long-term management and intervention to prevent complications and improve the quality of life for patients. Traditional approaches to managing chronic diseases focus primarily on medical interventions, such as medication management and regular check-ups. However, research has shown that behavioral factors play a significant role in the development and progression of chronic diseases [29]. For instance, unhealthy lifestyle choices, such as poor diet, lack of physical

activity, smoking, and excessive alcohol consumption, can increase the risk of developing chronic diseases and exacerbate existing conditions. In order to effectively manage chronic diseases, an intelligent approach that incorporates behavioral analysis and intervention is needed. The advanced technologies and data science in healthcare professionals can gather and analyze data on patients' behavior patterns, including their daily routines, dietary habits, exercise habits, medication adherence, and stress levels.

One approach to behavioral intervention is through the use of digital health technologies, such as mobile applications and wearable devices. These tools can provide real-time feedback and reminders to help patients adhere to their medication regimens, track their daily activities, and monitor their progress toward health goals, such as exercise and diet modifications. Integrating behavioral analysis and intervention into the management of chronic diseases has the potential to improve patient outcomes significantly. By addressing the behavioral factors that contribute to chronic diseases, healthcare providers can help patients make positive lifestyle changes and improve their overall health and well-being.

C. Adherence Monitoring and Medication Management

Chronic diseases, like cardiovascular disease, Parkinson's, diabetes, blood pressure, and hypertension, have emerged as major health concerns globally. These diseases have a main impact on the health life quality and can lead to severe complications if not managed properly. According to a study conducted by the Boston Consulting Group (BCG) in 1993, disease management emerged as an innovative approach to improving the quality of care and containing rising healthcare costs associated with chronic diseases [30]. The concept of disease management involves a holistic and integrated approach to patient care, focusing on monitoring adherence to treatment plans and effectively managing medication. This approach aims to optimize patient outcomes by ensuring that patients adhere to their prescribed medications and treatment regimens. One study conducted in Saudi Arabia highlighted the importance of integrating chronic disease management to improve patient care. Another study emphasized the role of big data analytics in improving chronic disease management and healthcare systems. The integration of disease management strategies, such as adherence monitoring and medication management, can greatly improve the management of chronic diseases [6].

V. Benefits and Challenges

The integration of IoT devices and deep learning technologies into home care presents a transformative approach to managing chronic diseases. As the global healthcare landscape shifts towards more patient-centered and technologically advanced solutions, the potential benefits of these innovations are becoming increasingly apparent. IoT devices enable continuous, real-time monitoring of patients, providing valuable data that can be analyzed by deep learning algorithms to offer personalized care, predict complications, and enhance overall health outcomes. This intelligent monitoring and management system promises to improve patient engagement.

However, the implementation of IoT and deep learning in home care also brings significant challenges. These include technological barriers such as integration issues and data security, as well as broader concerns about accessibility, equity, and reliability. Furthermore, ensuring that both patients and hospital providers are adequately trained to use these technologies effectively is crucial. Additionally, regulatory and ethical considerations must be addressed.

In this context, understanding these aspects can guide the development and implementation of more effective and equitable healthcare solutions, ultimately improving the quality of life for chronic disease patients.

A. Benefits of IoT and Deep Learning in Home Care

The integration of the IoT and deep learning technologies showcases the transformative potential for enhancing home care services. IoT in home care refers to the network of interconnected devices capable of monitoring, communicating, and analyzing data to facilitate a more comfortable, efficient, and safe living environment. Deep learning is a subset of AI focusing on sophisticated algorithms that mimic human brain functions, further leverages this data to extract meaningful insights and patterns for improved decision-making and automation. The amalgamation of these two technologies in-home care can lead to the development of smart homes that are not only responsive to the inhabitants' needs but also proactive in maintaining their health and well-being. Smart devices can track vital signs, detect anomalies, and alert caregivers or medical professionals in real time. Deep learning algorithms can process vast quantities of data from various sensors to learn normal behavior patterns and anticipate potential issues, offering not just reactive but preventive solutions for home care challenges [31]. Together, IoT and Deep learning contribute to a more personalized and adaptive home care experience, enabling individuals.

The benefits below collectively contribute to the transformation of home care, making it more intelligent, patient-centric, and efficient through the integration of IoT and deep learning technologies:

- Real-Time Monitoring: IoT devices enable continuous and real-time monitoring of patient's health parameters, providing instant feedback to healthcare providers for timely interventions [32].
- Early Detection of Health Changes: Deep learning algorithms analyze collected data, facilitating the early detection of subtle changes in health conditions, allowing for proactive healthcare measures [33].
- Personalized Care Plans: Deep learning models can process individual health data to create personalized care plans, considering specific patient needs, preferences, and historical health information [34].
- Patient Empowerment and Engagement: Access to personal health data empowers patients, fostering active engagement in their healthcare journey and promoting a sense of responsibility for their well-being [34].
- Cost-Efficiency in Healthcare: By preventing complications through early interventions and minimizing

hospital visits, the implementation of IoT and deep learning can lead to cost savings in the healthcare system [35].

- Data-Driven Decision Making: Deep learning algorithms process vast amounts of patient data to generate meaningful insights, aiding healthcare professionals in making informed and data-driven decisions [35].
- Improved Disease Management: Chronic disease management is enhanced through continuous monitoring, allowing healthcare providers to adjust treatment plans based on real-time data and patient responses [16].
- Scalability and Accessibility: The scalable nature of IoT and deep learning solutions allows for widespread adoption, making advanced healthcare monitoring accessible to a larger population.

B. Ethical and Privacy Concerns

The integration of IoT and deep learning technologies in home care presents transformative opportunities for healthcare, yet it also raises ethical, privacy, and security concerns that require careful consideration. This section explores the key ethical and privacy considerations associated with empowering home care through advanced technologies, emphasizing the importance of safeguarding patient data. Ensuring the security of patient data necessitates the implementation of robust methodologies, including data encryption, secure communication protocols, and multi-factor authentication. These measures protect sensitive information from unauthorized access and cyber threats while maintaining data integrity. Additionally, adopting privacy-by-design principles ensures that security measures are embedded into the technology from the outset, aligning with ethical standards and regulatory compliance. By addressing these challenges holistically, we can build trust and confidence in the use of IoT and deep learning in home care. The author in [36] highlights the ethical considerations related to using deep learning in personalized health monitoring, such as privacy, bias, responsibility and accountability, data quality, and the interpretability of results. In summary, the paper provides valuable insights into the recent developments, challenges, and ethical considerations in the application of deep learning for personalized health monitoring and prediction, underscoring the potential of advanced deep learning algorithms to improve patient outcomes and revolutionize personalized healthcare significantly.

The author in [37] identifies the gaps in the discussion of ethical concerns in both theoretical and empirical research on SHHTs for older persons, highlighting the scarcity of ethical considerations in the field. They noted that while privacy was extensively discussed, other ethical issues, such as responsibility and ageism, were less prevalent in the literature. The review calls for more critical work to prospectively address ethical concerns that may arise with the development and use of new technologies in caregiving for older persons.

The author in [38], discuss the combination of IoT and deep learning offers a powerful toolkit for managing chronic diseases in the comfort of patients' homes. Here are some key benefits for patient, caregivers and for healthcare providers like:

TABLE V. Research Papers Achieving Article Objectives, Challenges and Benefits

References	Achieved Objectives
[36] [37] [32]	Assesses technological challenges and limitations of IoT and deep learning in-home care.
[32] [31] [33] [34] [39] [35] [36]	Provide recommendations and guidelines for activating the positive view of implementing IoT and deep learning technologies in-home care.

- Improved Patient Quality of Life: Continuous monitoring and personalized. These insights enforce manage patients, resulting in improved symptom control and an enhanced sense of independence.
- Reduced Burden and Stress for caregiving: Continuous monitoring provides caregivers with peace of mind, knowing that their loved ones are being monitored around the clock. Real-time alerts also allow them to respond quickly to emergencies.
- Enhanced Patient Management for health care provider: Remote monitoring provides healthcare providers with continuous data streams, enabling them to track patients' progress, adjust treatment plans, and intervene proactively.

C. Technical Challenges and Limitations

The technical challenges include data security concerns, interoperability issues, and the need for standardized protocols and regulations to ensure seamless integration with existing healthcare systems and networks [32]. The study addressed the technical challenges and limitations associated with IoT in healthcare systems. Various aspects of end-to-end IoT related to health care were explored. The study discussed the challenges in improving the efficiency of monitoring, such as power absorption and accuracy, particularly in the context of narrowband IoT technology. It was observed that the use of narrowband IoT for high-intensity applications, such as blood pressure and heartbeat monitoring in pregnant women, may support widespread communication with low data cost and minimum processing complexity, yet the limitations of long-range deployment and high latency for critical healthcare applications were identified. The study also presented a detailed review of IoT technologies related to the suggested model, exploring low-power networks and the suitability of IoT-adopted communication standards for healthcare applications. Cloud computing was highlighted as an efficient means of handling and organizing large amounts of healthcare data.

At the end of this section, we identify which research papers focus on the challenges and potential solutions and which emphasize the benefits of integrating IoT and deep learning to achieve the article's objectives, as shown in Table V.

VI. Case Studies and Implementation Examples

A. Remote Monitoring of Diabetes Patients

Diabetic Retinopathy is one of the leading causes of blindness among the working-age population and requires early detection for effective treatment. Traditionally, the diagnosis required manual examination by expert physicians, which was

time-consuming and not always readily accessible. Diabetes is a chronic disease that requires ongoing monitoring and management. Patients with diabetes and their caregivers face many challenges in managing the disease, such as constantly monitoring blood sugar levels, adhering to medication regimens, and making lifestyle changes. Remote monitoring of diabetes patients is a solution that has emerged to address these challenges and provide better support and care for patients [40]. There have been several studies conducted on the remote monitoring of diabetes patients to assess its effectiveness in improving patient outcomes and quality of life. One study conducted by researchers at Mepco Schlenk Engineering College in India aimed to develop a real-time monitoring system for the vital signs of patients with diabetes using wearable sensors. The study utilized wearable sensors to monitor the vital signs of diabetes patients in real time. The sensors collected data on temperature, respiratory rate, pulse, blood pressure, and blood oxygen saturation. The collected data was stored in a text document and analyzed using data mining approaches. The study found that remote monitoring of vital signs using wearable sensors allowed patients to know their health status without the help of a nurse. Additionally, the study highlighted that remote monitoring of vital signs can help in the early detection of any medical problems or illnesses and alleviate the need for frequent hospital visits. By implementing a remote monitoring system for diabetes patients, healthcare providers can have access to continuous and real-time data on the patient's vital signs. This enables healthcare providers to make informed decisions, adjust medication regimens as needed, and provide timely interventions when necessary [41].

At the end, the use of such technology could lead to a broader application of automated systems in healthcare, helping to prevent loss of vision in diabetic patients.

B. Predictive Analytics for Cardiovascular Disease Management

Heart disease remains a leading cause of mortality globally. Traditional healthcare models struggle with early detection and continuous monitoring of heart conditions, which is crucial for patients at risk of sudden cardiac events. According to a report by the Public Health Foundation (PHF) of India, chronic diseases, including cardiovascular diseases, are the leading cause of death in India. These diseases pose a significant challenge for healthcare systems, specially in monitoring vital signs of chronic diseases patient. Traditionally, the monitoring of vital signs has been done by nurses in hospitals or with the assistance of healthcare professionals at home. However, the advancements in AI technologies and the availability of wearable sensors, real-time monitoring of vital signs has become more accessible. By using wearable sensors, patients can monitor their own vital signs and track their health status without the need for constant assistance from healthcare professionals. This system enables high-risk patients to be checked in a timely manner and enhances the quality of life for patients with chronic diseases. One approach to improve the management of the cardiovascular disease is the use of predictive analytics [42]. Predictive analytics involves the use of data mining techniques to analyze and predict future outcomes based on historical data. By applying predictive analytics to cardiovascular disease management, healthcare providers can gain valuable insights and identify patterns and risk factors that may increase the development or progression of the disease. One study conducted in the United States used survey data and ML models to identify and predict at-risk patients for cardiovascular disease [43].

Further research into incorporating additional deep learning techniques and algorithms into IoT environments promises to improve accuracy and utility for hospitals. Collaboration with more medical institutions to collect extensive data sets would drive the evolution of deep learning models for even better predictive capabilities and treatment outcomes in heart disease management.

VII. Future Directions

The field of healthcare is continuously evolving, and with the advancements in technology, there is a growing opportunity to revolutionize home care for patients with chronic diseases. One future direction for empowering home care is the utilization of IoT and deep learning techniques for intelligent monitoring and management of chronic diseases. By integrating IoT devices, patients can receive continuous monitoring of their vital signs, medication adherence, and overall health status from the comfort of their own homes. This approach has the strength to enhance patient healthcare outcomes by enabling early intervention and personalized treatment plans [44]. Furthermore, the integration of IoT and deep learning in-home care can improve communication and collaboration. Patients and healthcare providers can easily share data and communicate through a secure platform, allowing for timely interventions and adjustments to treatment plans. This future direction of empowering home care through IoT and deep learning has the potential to transform the way chronic diseases are managed and monitored.

A. Integration with Electronic Health Records (EHRs)

The integration of EHRs has revolutionized the healthcare industry by providing a seamless flow of patient information and improving clinical outcomes [45]. However, the future direction of integration with EHRs will focus on further enhancing the capabilities and functionalities of these systems to unlock their full potential in improving patient care and operational efficiency. This will enable a comprehensive view of patient health and facilitate coordinated care across different providers and healthcare settings. With the growth of the populations, healthcare will address challenges related to scaling the system for large populations and ensuring the robustness of deep learning models against noisy, incomplete, or anomalous data inputs from IoT devices. This integration will facilitate personalized medicine and enable proactive interventions to prevent adverse health events and explore the use of federated learning as a collaborative ML approach that allows model training across multiple healthcare entities without sharing raw data, thus preserving patient privacy using the innovative cryptographic methods and privacy-preserving ML techniques [46]. Overall, the future direction of integration with EHRs will focus on leveraging emerging technologies, improving interoperability, and integrating with wearable devices and mobile health applications to enhance patient care.

B. Wearable and Implantable Devices

The field of wearable and implantable devices has seen significant advancements in recent years, with technology becoming smaller, more efficient, and more integrated into our daily lives. These devices offer numerous benefits in healthcare, personal monitoring, and fitness tracking. However, the future of wearable and implantable devices holds even greater possibilities. One future direction of wearable and implantable devices is their integration with AI and ML algorithms. With the advancements in AI and ML algorithms, these devices can not only collect data but also analyze and interpret that data to provide personalized insights and recommendations for the user. For example, wearable devices could utilize ML and provide insights into their stress levels or predict potential cardiac events. Another future direction of wearable and implantable devices is their integration with telemedicine. This integration will allow for remote monitoring and virtual healthcare services. These devices are capable of transmitting real-time data to healthcare providers, enabling them to monitor patients' conditions, intervene in a timely manner, and adjust treatment plans as necessary.

Another future direction of wearable and implantable devices is their integration with IoT technology. By integrating wearable sensors and implantable devices, data sharing across various devices and platforms can enhance the efficiency and accuracy of data collection, analysis, and dissemination, ultimately leading to improved outcomes. The future direction of wearable and implantable devices is focused on the integration of AI and deep learning learning algorithms, telemedicine capabilities, biofeedback therapy, and IoT integration. Some potential future directions for wearable and implantable devices proposed by [47] include, development of advanced ML algorithms for accurate prediction and detection of health conditions based on wearable device data and integration of wearable devices with telemedicine platforms to enable remote monitoring and virtual healthcare services.

These continuously evolving technology platforms not only promise to help people pursue a healthier lifestyle but also provide continuous medical data for actively tracking metabolic status, diagnosis, and treatment. Integration with the IoT is a significant future direction for wearable and implantable devices [48]. The future direction proposed by [49] is revolutionized by the integration of deep learning and IoT with advanced wearable and implantable devices. This will lead to:

- Sophisticated Monitoring: Wearables will go beyond the wrist, using non-invasive methods to track a wider range of health indicators. Smart implantables will enable targeted drug delivery and personalized neuromodulation therapies.
- Data-Driven Insights: Body area networks will connect these devices, feeding data to AI models for real-time analysis, prediction of health events, and personalized recommendations.
- Patient Empowerment: Individuals will receive personalized feedback and use gamified apps to actively participate in their health management.

In conclusion, the future direction of wearable and implantable devices includes integration with the Internet of Things, utilization of AI and ML algorithms, integration with telemedicine platforms, and advancements in monetization and energy efficiency.

C. Collaborative Care and Telemedicine

Collaborative care and telemedicine is very important in healthcare sections. These approaches as proposed by [50]. have shown great potential in enhancing patient care, easy access to all healthcare services, and driving operational efficiencies. Moving forward, there are several future directions that can further advance collaborative care and telemedicine:

- Expansion of Telehealth Services
- Integration of AI
- Remote Patient Monitoring
- Enhanced Communication and Collaboration Tools
- Telemedicine Services Expansion
- Integration with Electronic Health Records

VIII. Conclusion

The integration of IoT technology and deep learning algorithms holds immense promise for transforming the monitoring and management of chronic diseases within home care settings. This convergence represents a beacon of hope, marking the dawn of a new era in chronic disease management. Through the intricate interplay of sensor-laden devices and sophisticated algorithms, we transcend traditional healthcare boundaries, envisioning a future where personalized, proactive, and precise interventions are the bedrock of patient-centric care.

By leveraging connected devices and advanced analytics, providers can deliver tailored, proactive, and efficient care to patients, resulting in improved health outcomes and an enhanced quality of life. However, as we delve deeper into these technologies, it is imperative to prioritize patient privacy, data security, and ethical considerations. Responsible and effective implementation of these innovative solutions in home care necessitates a steadfast commitment to safeguarding patient rights and upholding ethical standards.

Yet, amid the promise of progress, we are confronted with profound ethical and existential questions. As our health data increasingly migrates to the digital realm, we must grapple with the weighty implications of privacy, security, and autonomy. It is essential to strike a balance between innovation and the moral duty to protect patient trust and dignity. Transparency in data usage and robust security frameworks must underpin every technological advancement.

We think, Furthermore, the success of these technologies hinges not only on their development but also on equitable access. It is vital to ensure these advancements do not create disparities in healthcare but instead foster inclusivity by reaching underserved populations. Collaboration between policymakers, healthcare providers, and technologists will be crucial in realizing this vision.

As we navigate this evolving landscape, let us remain vigilant in our pursuit of innovative solutions, mindful of the ethical complexities inherent in healthcare technology. By adopting a holistic approach that prioritizes patients at the center of care, fostering trust, inclusivity, and equity, we can leverage the transformative capabilities of IoT and deep learning to usher in a new era of empowered, accessible, and ethical home care.

***Abstract*—During driving, drivers often overlook the traffic signs along the roads compromising road safety and increasing the risk of accidents. To address this, artificial intelligence (AI) and deep learning techniques are employed, taking into consideration the improvement of advances in Artificial Neural Networks (ANNs) and image processing for robust road sign detection. In this work, we compare the performance of existing state-of-the-art object detection models for road sign detection, including YOLOv8, YOLOv9, RTMDet, Faster-RCNN and RetinaNet, using a large dataset of images of road signs. These models are fine-tuned and hyperparameters are optimized with varied settings like auto-orientation and augmentation during the preprocessing and training phase. The models are then tested, and key performance indicators such as mean average precision (mAP), number of inferences performed per second [frames per second (fps)], and total loss are evaluated. Our study reaffirms the earlier findings in which YOLOv9 and YOLOv8 outperform other detectors in real-time detection tasks because they are faster in inference or prediction than most detectors, but with a compromise in accuracy, as highlighted by the fast fps rates. In contrast, RTMDet is fast and reliable, making it a highly effective option for detecting various road signs. The insights presented in this research are useful in identifying the appropriateness and drawbacks of each model, thereby benefiting from the selection of the best suited model for real-world applications, such as autonomous vehicles or self-driving cars.**

***Keywords*—Artificial intelligence; artificial neural networks; image processing; deep learning; road signs detection**

I. Introduction

A. Background

Over the last few years, the use of computer vision and object detection has become prominently efficient because of the shift in deep learning models. Such advancements have embellished object identification in both pictures and videos with great precision and efficacy. The relevance of an object being detectable by a vehicle increases with the overall progress in autonomous vehicles and smart and connected roads. Road sign detection has the necessary accuracy and operational capacity for serving its purpose in ensuring the safety for autonomous vehicles and advanced driver assistance systems ADAS.

B. Current State of Object Detection Models

This research paper presents a thorough comparative analysis of five leading object detection models: YOLOv9, YOLOv8, RetinaNet, RTMDet, and Faster R-CNN [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19]. Each of these models epitomizes state-of-the-art techniques in object detection, boasting unique strengths and characteristics that influence their performance in identifying objects within visual data.

- YOLO: You Only Look Once (YOLO) series, specifically YOLOv9 and YOLOv8, are most famous with real-time object detection, and that is why such models are applicable in areas that require high response rates [20], [21], [22]. They are particularly remarkable in terms of speed and efficiency of detection, which is crucial in contexts, such as autonomous driving, where minimizing detection time is of utmost importance.
- RetinaNet: Distinguished by its ability to accurately detect objects of varying sizes within images, making it a robust choice for scenarios involving diverse object scales. RetinaNet employs a Feature Pyramid Network (FPN) and a focal loss function to address the class imbalance and enhance detection accuracy [23], [24].
- Faster R-CNN: Widely recognized for its precise localization of objects, achieved through a region-based convolutional neural network that meticulously analyzes different regions within an image to ensure accurate detection [25], [26].
- RTMDet: RTMDet is known for its robustness in managing complex scenes and occlusions, demonstrating a superior ability to detect objects even under challenging conditions [27]. RTMDet integrates a modified ResNet-50 backbone with spatial and feature alignment modules to optimize detection performance.

C. Motivation

While YOLO series has been the object detection models that has made remarkable progress, there is a lack of extensive comparative analysis that is not only centered on the recent versions of the YOLO models (YOLOv9 and YOLOv8) but other cutting-edge models like RetinaNet, RTMDet, and Faster RCNN. Earlier works have mostly focused on giving attention to overall object identification or testing only a few of these models under various circumstances, which really did not enable researchers to make a Comparative analysis of these models for the purpose of road sign identification. This

research intends to address this gap by comparing these models in detail and side by side in the context of road sign detection focusing on several measures and metrics and with an eye to useful recommendations for implementation in self-driving car technologies and as well in the driver assistant systems.

D. Contributions

The purpose of this work is to advance the prior art related to object detection and present a comprehensive and comparative evaluation of five of the most relevant approaches. When assessing the accuracy of each model, we have apply a set of unified metrics stemmed from a dataset of road signs, which provides useful information on the merits and drawbacks of each model. It can help researchers and practitioners on how best to choose the most suitable object detection model for intelligent transportation systems and autonomous driving.

This paper presents a comprehensive comparison of five prominent object detection architectures: YOLOv8, YOLOv9, RTMDet, RetinaNet, and Faster RCNN for the road sign detection study without leaving out the factors such as mAP and inference time. This paper is organised as follow: Section II presents the literature review relevant to this work, where we discuss the current state of object detection algorithms as well as road sign detection. Section III describes the three step model architectures of the aforementioned algorithms while Section III(B) explains the design principles and features of these algorithms. Section IV explains the experimental setup, procedures on how the datasets were prepared, training configurations that were used for training the models as well as the evaluation metrics that were employed in the assessment of the performance of each model. Results and discussion are discussed in Section V. Lastly, Section VI of this paper offers the conclusion and a discussion of the experiments to derive the factors that should be preferred while choosing between accuracy, speed, and confidence in detecting a road sign from the ones listed above or some other algorithms as per the parameters that will be followed strictly at the time of implementing the vision based systems.

II. Literature Review

The recognition of road signs is one of the critical segments of Intelligent Transportation Systems (ITS) performance, so its function is significant for providing road safety and effectiveness. In addition, as the deep learning starts to become more popular, object detection models show great potential in recognizing road sign. Road sign detection is revealed in this literature review as a line of research that experienced significant development in the last five years. In this section, the object detection models are introduced and analyzed based on the approach used, efficiency, effectiveness, and the kind of application which is road sign detection. The given review culminates the prior studies in order to perceive common aspects, issues, and opportunities in order to further establish more reliable and accurate type of road signs detection systems.

- This research enhanced YOLOv8 by adding blur and noise, and incorporating an asymptotic feature pyramid network, which improved the detection of small target objects. It achieved a 3.31% increase in mean Average Precision (mAP) and a 3.59% increase in recall on the TT100K dataset. These improvements were confirmed through ablation studies, highlighting the contributions of both data augmentation and the AFPN enhancements [28].

- Enhanced YOLOv8 algorithm for traffic sign recognition using the Kaggle dataset incorporated Cross-Stage Partial connection and Path Aggregation Network, achieving 80% accuracy, 64% precision, and 65.67% recall on test data. The use of stochastic gradient descent optimization and dropout helped curb overfitting, demonstrating the model's efficacy in complex traffic sign analysis [29].

- In a comparative study, YOLOv5 demonstrated superior performance over SSD in traffic sign recognition, achieving a mAP@0.5 of 97% and processing images at 30 FPS on the VOC dataset. SSD showed 90% accuracy but was significantly slower, processing images at only 3 FPS. YOLOv5's faster recognition speed and higher recall score make it a better solution for traffic sign recognition in Intelligent Transportation Systems [30].

- This research improved traffic sign detection using Faster R-CNN with enhancements like feature pyramid, deformable convolutions, and ROI alignment. Tested on the TT100K dataset, it achieved high accuracy rates of 92.6% in sunny conditions, 90.6% at sunset, and 86.9% in rainy conditions, outperforming SSD, YOLOv2, and even YOLOv5 in less favorable lighting and weather conditions [31].

- A real-time traffic sign detection system using Faster R-CNN was trained on a dataset of 1880 images from Turkey and the German Traffic Sign Recognition Benchmark (GTSRB). The model, trained over 10,000 iterations, achieved an accuracy of 88.99% and a total loss rate of 0.220, demonstrating robust detection capabilities [32].

- Zhu et al. developed a RetinaNet-based algorithm achieving a final F1 score of 0.923. While the model performed well in favorable conditions, it faced limitations in adverse weather, indicating a need for future research to improve performance under varied conditions [33].

- Inspired by YOLOv4 and YOLOv5, the TSR-SA method enhanced traffic sign detection by incorporating high-level features, a receptive field block-cross in the neck, and a Random Erasing-Attention data augmentation method. This approach achieved a state-of-the-art mAP of 90.2% on the TT100K dataset, surpassing YOLOv4 and YOLOv5-x, though it faced challenges with category imbalance [34].

- Senthilnayaki's system used Faster R-CNN for detection and Inception V2 for classification, improving detection in varied conditions by increasing anchor thickness and enhancing feature map resolution. This method proved effective and resilient, with plans for future enhancements to refine feature maps for more robust proposals [35].

- A system using the RetinaNet model was developed for real-time traffic light detection, employing transfer learning and modifications to anchor box sizes to detect small traffic lights. The model achieved a weighted mean average precision (mAP) of 0.54 with an execution time of 108ms, showing significant improvements in detection accuracy and speed [36].
- Jiang's work on an improved YOLOv5 network introduced a balanced feature pyramid and a global context block, enhancing feature fusion and extraction. Tested on the TT100K dataset, the model showed significant performance improvements with a 1.9% increase in mAP@.5, a 2.1% increase in mAP@.5:0.95, and improvements in precision and recall by 2.4% and 3.3%, respectively, proving its superiority for traffic sign detection [37].

III. Models Architecture

A. YOLOv8

The YOLOv8 model architecture represents a significant advancement in object detection, offering improved accuracy and speed over its predecessors. As shown in Fig. 1, the backbone of YOLOv8 is a modified CSPDarknet53 with 53 convolutional layers and cross-stage partial connections to enhance information flow [38].

The head of YOLOv8, includes multiple convolutional and fully connected layers responsible for predicting bounding boxes, objectiveness scores, and class probabilities. A notable feature of the head is the self-attention mechanism, which enables the model to focus on different parts of an image, adjusting the importance of various features.

YOLOv8 adopts an anchor-free detection approach, directly predicting object centers instead of offsets from predefined anchor boxes, thus speeding up post-processing steps like Non-Maximum Suppression (NMS). Additionally, YOLOv8 introduces changes in convolutions, such as replacing a 6x6 conv with a 3x3 conv in the stem and modifying the main building block, which enhances performance and efficiency.

B. YOLOv9

The YOLOv9 model architecture represents a significant advancement in real-time object detection, offering superior accuracy and efficiency compared to previous models. The backbone architecture utilizes Cross-stage Partial (CSP) Connection blocks to enhance gradient flow and reduce data loss during the feed-forward process, optimizing performance and accuracy. The head of YOLOv9 incorporates Programmable Gradient Information (PGI) and the Generalized Efficient Layer Aggregation Network (GELAN), which are crucial for preventing data loss, ensuring accurate gradient updates, and optimizing lightweight models for efficient object detection tasks (see Fig. 2 and 3). YOLOv9 also brings two new architectures, namely, YOLOv9-C and YOLOv9-E that improve accuracy and object detection efficiency in different applications through information choking and gradient flow rectification [39]. In addition, the YOLOv9 model has top-level accuracy and efficiency among the current models, including RT-DETR, YOLO-MS, or others due to the efficient use of conventional convolutions.

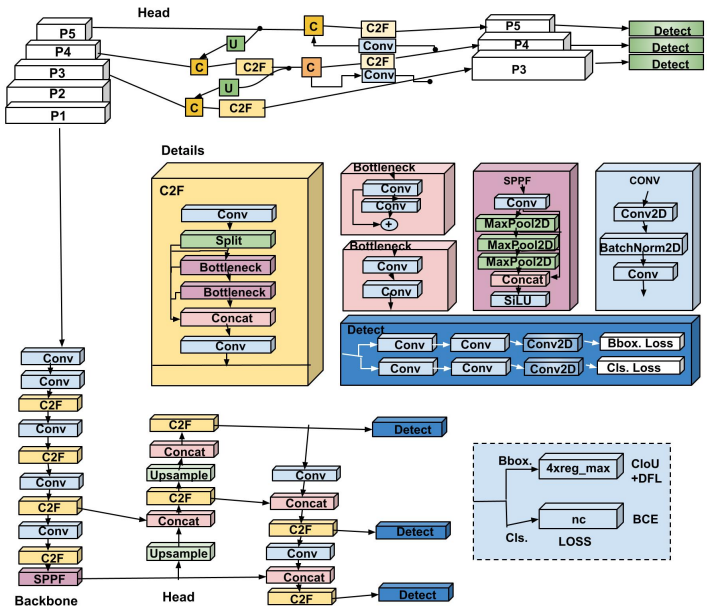

Fig. 1. YOLOv8 architecture.

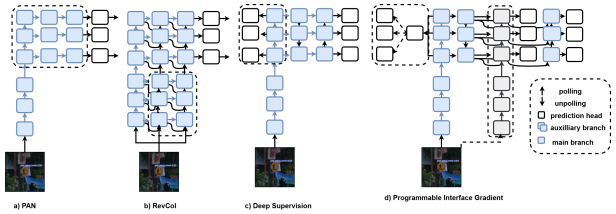

Fig. 2. YOLOv9 programmable gradient information.

C. RetinaNet

RetinaNet is a pioneering one-stage object detection model known for its exceptional performance in detecting objects at various scales. The unified network includes a backbone Convolutional Neural Network (CNN) and two task-specific subnets: the Classification Subnet and the Box Regression Subnet.

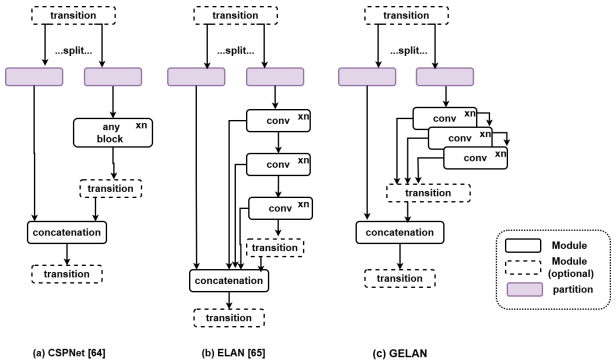

Fig. 3. YOLOv9 GELAN.

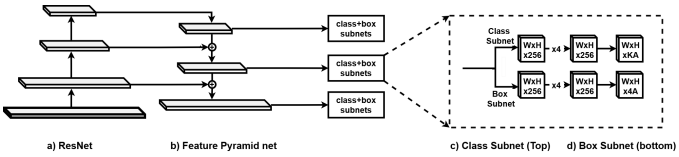

Fig. 4. RetinaNet structure.

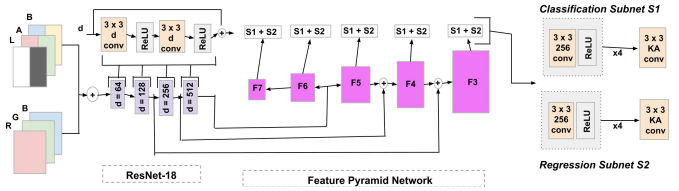

Fig. 5. Detailed structure.

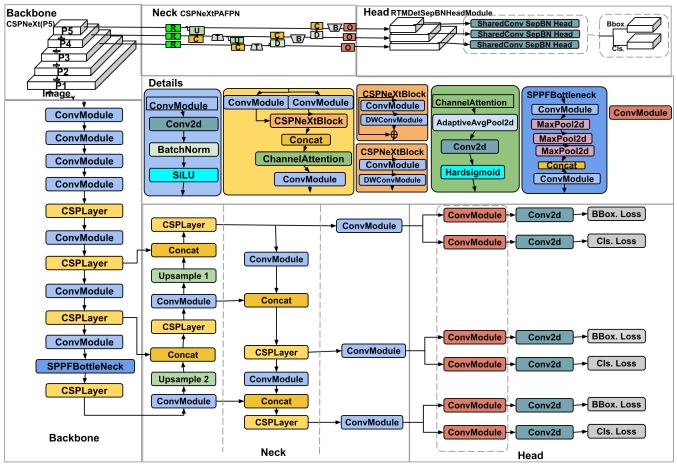

Fig. 6. RTMDet Architecture.

The backbone incorporates a Feature Pyramid Network (FPN), which generates a multi-scale feature pyramid by combining low-resolution semantically strong features with high-resolution features for accurate object detection. The Classification Subnet predicts object presence probabilities, while the Regression Subnet handles bounding box regression from anchor boxes, both using feature maps from the FPN (Fig. 4) and (Fig. 5). A key innovation is the Focal Loss function, which addresses class imbalance by assigning higher weights to hard examples, enhancing detection accuracy [24], [40]. Translation-invariant anchor boxes at different pyramid levels (P3 to P7) cover various scales and aspect ratios, enabling precise object localization and classification. During training, Stochastic Gradient Descent (SGD) is used with learning rate adjustments and data augmentation techniques like horizontal flipping to improve generalization.

D. RTMDet

RTMDet is an architecture will be proposed for real time object detection on the basis of the YOLO series of algorithms. It is used in scenarios where the detection of objects within images or videos in real-time is required, which makes this option highly effective in real-life designs. It uses ResNet-50 as its backbone after reducing the number of layers and parameters it uses for feature extraction. That is, some important modules: spatial attention module (SAM) is used to improve the feature extraction and the feature alignment module (FAM) to align the features from different scales [27].

The detection head of RTMDet uses a single convolutional layer to predict object bounding boxes and class probabilities, handling objects at three different scales: Depending on the amount of work, there are small, medium, and large offices. The RTMDet has three losses: CIoU loss that measures the loss of shapes and sizes, objectiveness loss that boosts completeness, and classification loss to maximize accuracy. For training, this model is trained on a large number of images and their corresponding labels and for the purpose of data augmentation has a considerable number of techniques incorporated. In inference, RTMDet replied it supports real-time object detection on still image and video, and it is deployable on different hardware environment such as GPU and TPU.

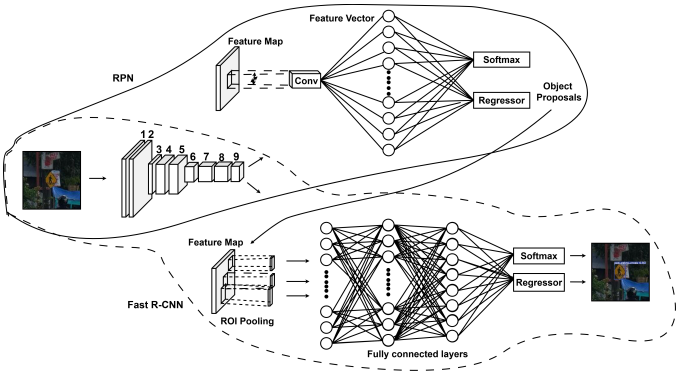

Fig. 7. Faster RCNN Architecture.

In this work, RTMDet presents itself with several advantages compared to the existing architectures of object detection such as high accuracy, high speed along with lesser computational complexity. Due to these characteristics, the technology is applied in self-driving cars, the monitoring systems, and robots among other areas. The above mentioned architecture including details of its subcomponents can be evident from Fig. 6.

E. Faster RCNN

Faster RCNN is a renowned object detection architecture that has significantly influenced the field of computer vision. The architecture comprises convolution layers trained to extract specific features from images, akin to how coffee filters allow only desired elements to pass through.

The Region Proposal Network (RPN) is a pivotal component of Faster RCNN, efficiently generating high-quality region proposals for subsequent detection. Fully connected neural networks are utilized to predict object classes and refine bounding boxes based on the regions proposed by the RPN (see Fig. 7).

Training Faster RCNN involves optimizing convolution layers filters, RPN weights, and the last fully connected layer weights using Stochastic Gradient Descent (SGD), ensuring effective and efficient object detection [26]. Faster RCNN has

demonstrated remarkable performance improvements over its predecessors, achieving faster processing speeds during both training and testing phases and setting new standards in object detection accuracy and efficiency.

IV. Experiment

A. Dataset

The "Road Signs" dataset sourced from Roboflow-100 consists of 21 classes falling under the super category "Road Signs". The images sample is shown in Fig. 8.

Fig. 8. Dataset images.

The dataset encompasses around 20 classes. It consists of a total of 2095 images, divided into a training set with 1378 images, a validation set with 488 images, and a test set with 229 images. Preprocessing techniques applied include auto-orientation to adjust image orientation and resizing to a resolution of 640x640 pixels, with no manual augmentations initially applied. However, each object detection model used in the study incorporated its own set of image augmentations during the training process to enhance the training data and improve model robustness and performance. This dataset offers a diverse collection of road sign images across multiple classes, ensuring uniformity in image dimensions and orientation for effective model training and testing.

B. Training Hyperparameters

Yolov8 and Yolov9 were trained using Ultralytics, RetinaNet and FasterRCNN using Detectron2 while RTMdet was trained using MMDetection. In this study, all the models were trained for 30 iterations through the dataset. YOLV8 and YOLV9 were set to 16, while RetinaNet, Faster RCNN, and RTMDet were set to 8. Here, parameters were adjusted for YOLOv8 with AdamW optimizer where the learning rate was set to 0. 0004, momentum of 0.9 and weight decay of 0.0005. As for optimization, YOLOv9 uses Standard Gradient Descent (SGD) with a learning rate of 0.01, momentum of 0.9 and weight decay to 0.0005. YOLOv9 employed SGD with a learning rate of 0.01, momentum of 0.9, and weight decay of 0.0005. RetinaNet and Faster RCNN both used SGD with a learning rate of 0.001, momentum of 0.9, and weight decay of 0.0001. RTMDet was optimized using AdamW with a learning rate of 0.004, momentum of 0.0002, and weight decay of 0.0001. The notes on the training dataset for both YOLOv8 and YOLOv9 were YOLOv5CocoDataset and COCO for RetinaNet, Faster RCNN, and RTMDet.

C. Data Augmentation Techniques

To increase the reliability of object detection models with respect to input images, the concept of data augmentation was used at the time of training. This was achieved by pre-processing the images by using albumentations for YOLOv8, YOLOv9, and RTMDet which applied blur, median blur, combining the image into grayscale, and CLAHE. On the other hand, RetinaNet and Faster RCNN stacked the pre-process tools provided by Detectron2, which involved resizing and random flipping.

D. Evaluation

While evaluating the results of object detection model, COCO evaluation metrics was used to make the evaluation. For instance, in using the model, COCO bounding box(bbox) test methodology was employed to assess the effectiveness of the method in identifying objects and determining the degree of precision. As this evaluation framework was widely employed in determining the effectiveness of such models in detecting malicious data, its use gave us a better chance to arrive at sound conclusions on performance of our powerfully designed model. The classification accuracy are recorded in Fig. 9 to 13.

V. Results and Discussion

A. Mean Average Precision (mAP)

The mean average precision (mAP) is a key metric in evaluating the performance of object detection models. The mAP scores for mAP50-95, mAP50, and mAP75 are shown in Table I.

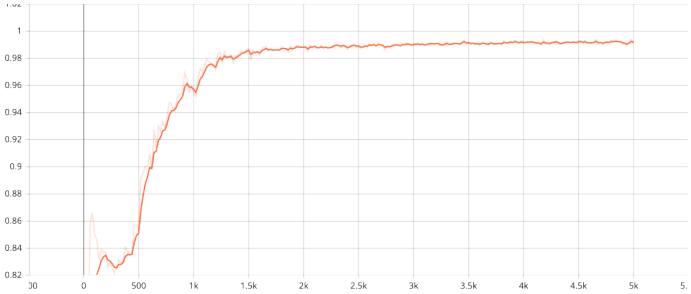

Fig. 9. Faster RCNN: Classification accuracy.

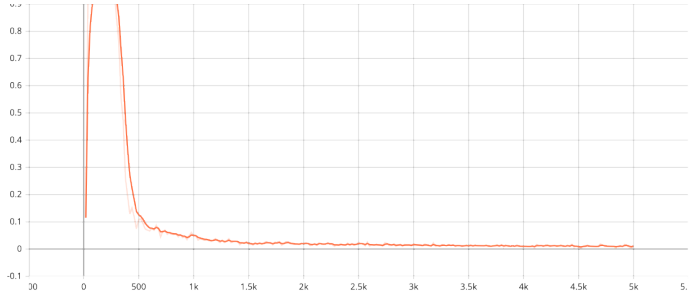

Fig. 10. Faster RCNN: False negatives.

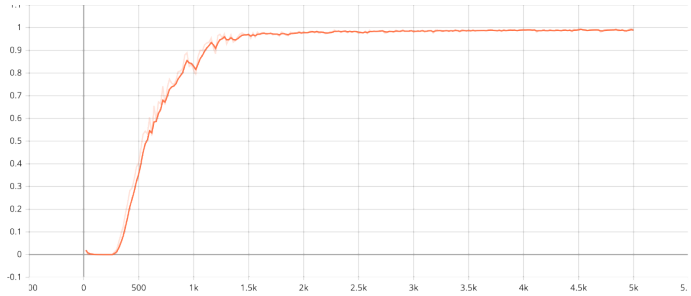

Fig. 11. Faster RCNN: Foreground classification accuracy.

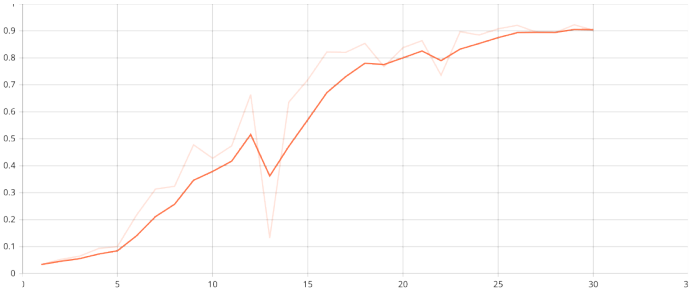

Fig. 12. RTMDet: mAP50.

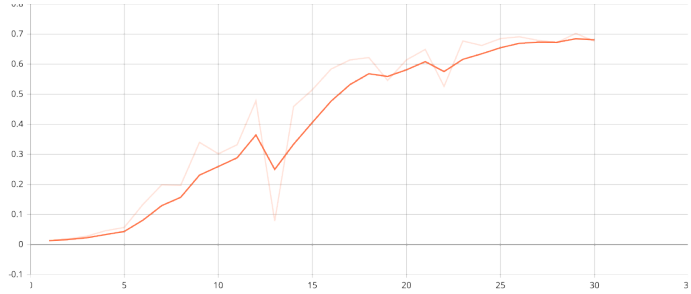

Fig. 13. RTMDet: mAP.

TABLE I. MEAN AVERAGE PRECISION

Model	mAP50-95	mAP50	mAP75
YOLOv8	0.814	0.961	0.892
YOLOv9	0.826	0.973	0.904
RTMDet	0.702	0.923	0.799
Faster RCNN	0.704	0.891	0.816
RetinaNet	0.755	0.911	0.854

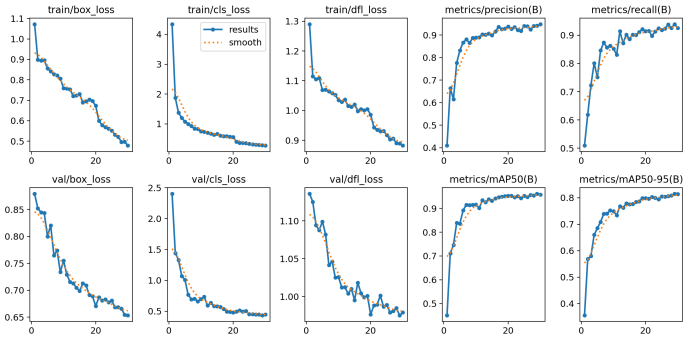

Fig. 14. YOLOv8: Loss and accuracy.

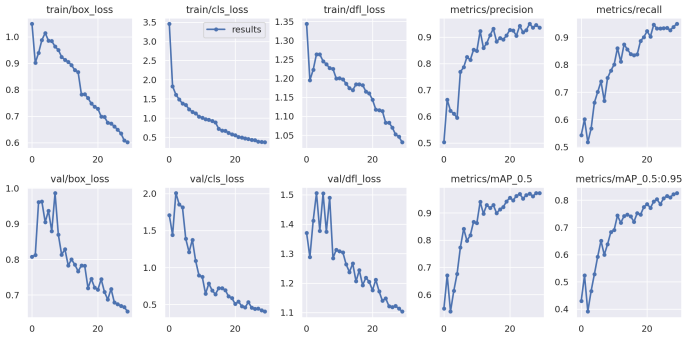

Fig. 15. YOLOv9: Loss and accuracy.

YOLOv9 achieves the highest mAP scores across all metrics, indicating its superior accuracy. YOLOv8 also performs very well, especially in terms of mAP50 and mAP75. RetinaNet shows a balanced performance, while Faster R-CNN and RTMDet exhibit relatively lower mAP scores.

B. Inference Time

Inference time is critical for applications requiring real-time object detection. The inference time of these models is shown in Table II.

TABLE II. INFERENCE TIME

Model	Inference Time
YOLOv8	0.0105s
YOLOv9	0.0311s
RTMDet	0.0576s
Faster RCNN	0.0844s
RetinaNet	0.0768s

YOLOv8 is the fastest model, making it highly suitable for real-time applications. YOLOv9, while slower than YOLOv8, still offers reasonable inference time. RTMDet, Faster R-CNN,

and RetinaNet are significantly slower, with Faster R-CNN having the highest inference time.

C. Total Loss

Total loss is a metric that indicates the overall error of a model during training, where lower values typically signify better performance. The total loss values for different object detection models: YOLOv8, YOLOv9, RTMDet, Faster RCNN, and RetinaNet, are depicted in Fig. 14 to 18 and presented in Table III. Among the models compared, YOLOv8 and YOLOv9 exhibit higher total loss values, indicating relatively higher error rates during training. On the other hand, RTMDet, Faster RCNN, and RetinaNet demonstrate significantly lower total loss values, suggesting better performance and potentially more effective learning during training.

TABLE III. TOTAL LOSS

Model	Total Loss
YOLOv8	2.0793
YOLOv9	2.1627
RTMDet	0.408
Faster RCNN	0.1519
RetinaNet	0.0735

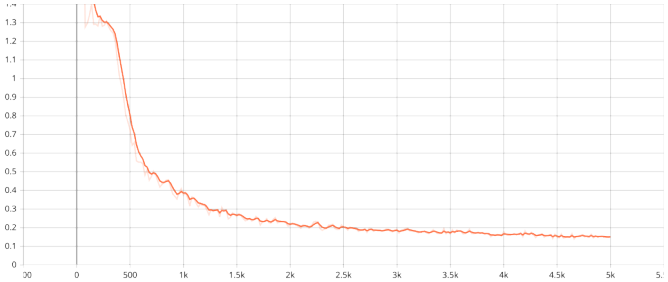

Fig. 16. Faster RCNN: Total loss.

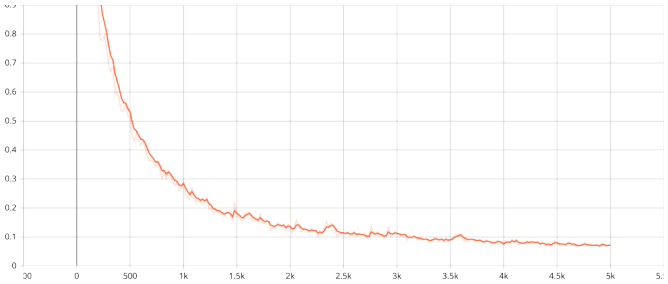

Fig. 17. RetinaNet: Total loss.

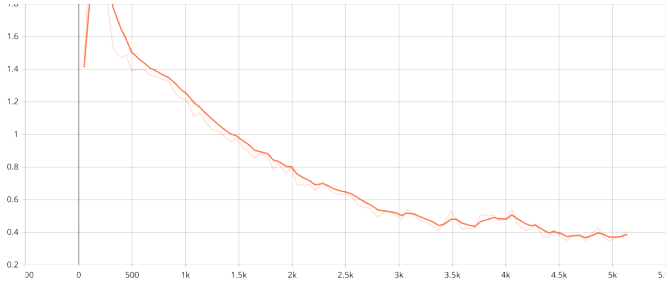

Fig. 18. RTMDet: Total loss.

D. Confusion Matrices

The performance of the YOLOv8, YOLOv9, Faster-RCCN, Retina Net and RTMDet is depicted by confusion matrices in Fig. 18 to 23.

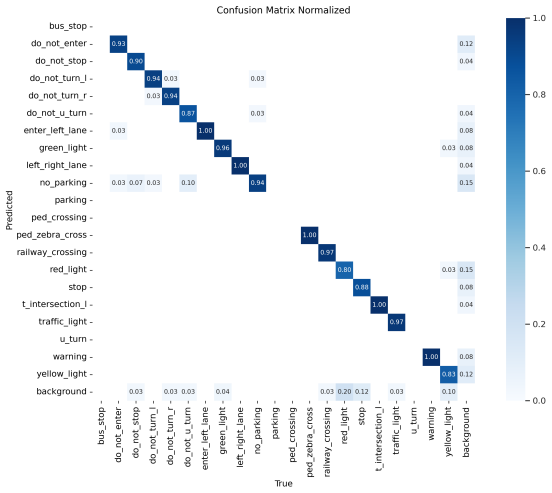

Fig. 19. YOLOv8.

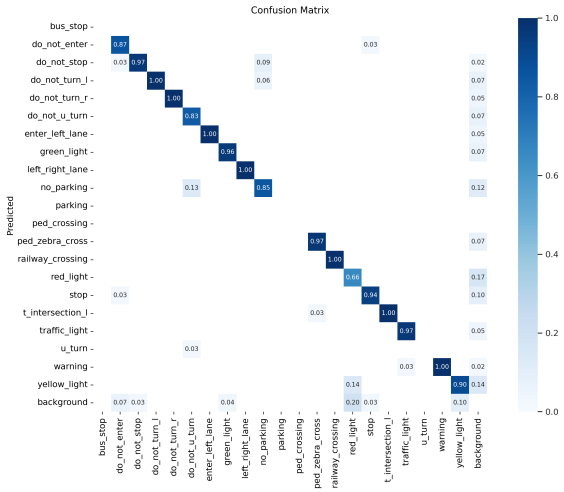

Fig. 20. YOLOv9.

E. Inference Result and Discussion

It is apparent from Fig. 24 to 28, that YOLOv9 followed by YOLOv8 have the highest values of accuracy scores of all the models in the paper. These models are also very accurate especially when it comes to place recognition which is very important with regards to road signs especially for safety reasons. However, on the tradeoff – YOLOv8 is slightly faster on the detection in comparison with YOLOv9. Therefore, if the need is to detect an object in real-time on the road, it may be desirable to use YOLOv8. However, there were other approaches in our experiments, such as RTMDet, Faster RCNN, and RetinaNet, slightly less effective in terms of speed but providing a good enough accuracy. They may be useful when speed is not the major factor into consideration as in case of roads of high importance or, self-driven cars. Besides, in

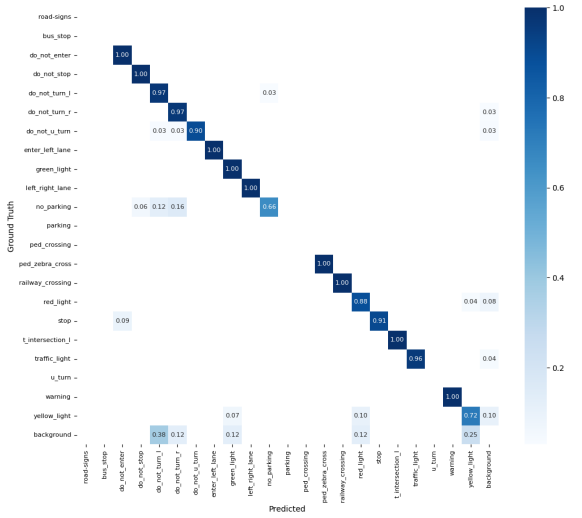

Fig. 21. Faster RCNN.

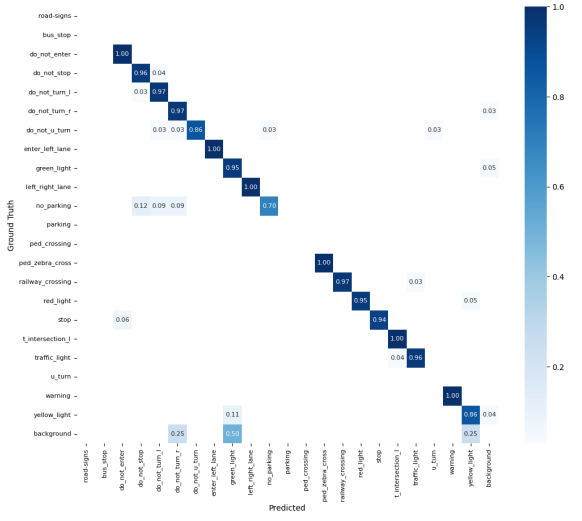

Fig. 22. RetinaNet.

terms of observing the curve of the total loss values, RetinaNet presents the best learning status in training so that it could develop more with more the training dataset. In conclusion, the decision of the specific model to be selected depends with the most valued criterium when it comes to the detection of road signs which can include speed or accuracy or both.

VI. Conclusion

In conclusion, this paper analyzes the performance of different object detection models which include YOLOv8, YOLOv9, RTMDet, RetinaNet and Faster-RCNN for road sign detection. YOLOv9 provides satisfactory results in terms of identification speed and accuracy measure; however, its inference time is relatively longer than the other versions including YOLOv8 with better real-time application performance. RTMDet achieves a better balance which very importantly is essential in scenarios where speed and accuracy are given utmost importance. Faster RCNN and RetinaNet have high enough accuracy, but the time for evaluation takes longer,

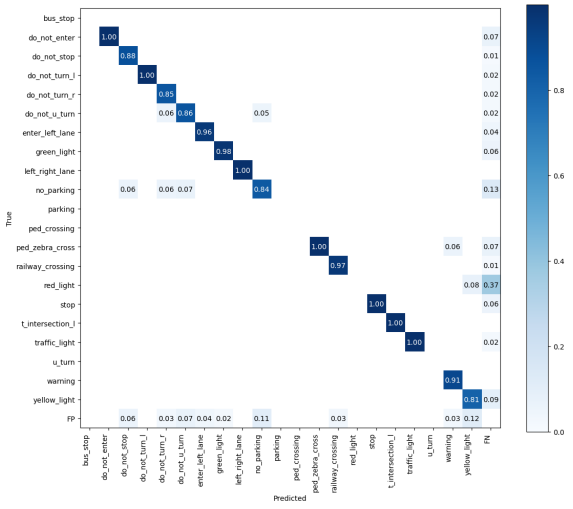

Fig. 23. RTMDet.

Fig. 24. YOLOv8.

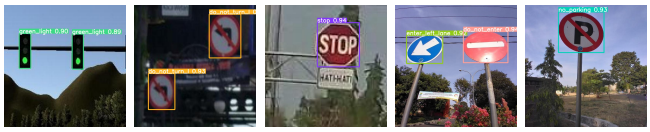

Fig. 25. YOLOv9.

Fig. 26. Faster RCNN.

Fig. 27. RetinaNet.

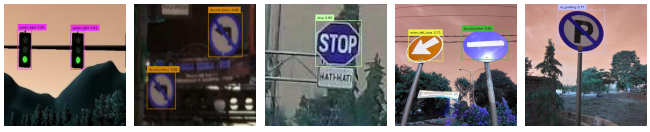

Fig. 28. RTMDet.

which may be useful for applications requiring a higher probability of correct result. The work underlines the parameters of accuracy, time and confidence in detecting the road contours

and signs that can help to choose the best option for the given application and to contribute to the creation of effecting road safety as well as autonomous driving systems. Our future work includes investigating more sophisticated ensemble approaches to achieve high accuracy and avoid overfitting problem, as well as to using more progressive data augmentation methodologies for increasing model's ability to generalize such as generative adversarial network (GAN) or self-supervised learning to real-world conditions and diverse environments, such as varying weather, lighting, and occlusions.

***Abstract*—In modern power systems, with the increasing application of renewable energy, direct current transmission technology has put forward new requirements for energy metering. In order to solve the accuracy problem of traditional electric energy metering under DC energy, the research is based on the classical empirical modal decomposition (EEMD), and introduces the artificial chemical reaction optimization algorithm (ACROA) to enhance the global search capability and decomposition accuracy of the original algorithm, and at the same time safeguards the accuracy of metering equipment under extreme conditions through the wide quantitative constraints, and ultimately puts forward a new type of optimization model for the accuracy of DC electric energy metering. The highest measurement accuracy of this model could reach 90%, and it performed better in power signal decomposition and accuracy optimization. Especially under high-frequency interference and complex signal conditions, the measurement error could be reduced to 6.87%, the highest decomposition stability was 94.02%, and the shortest measurement time was 1.12 seconds. Therefore, the model constructed in this study exhibits excellent decomposition accuracy and robustness in complex energy environments, solving the shortcomings of traditional energy metering methods and providing new ideas for future optimization of DC energy metering.**

***Keywords*—EEMD; direct current energy; measurement; width limit; ACROA**

I. Introduction

In modern power systems, with the transformation of energy structure, Direct Current (DC) transmission technology has been increasingly widely used, especially in renewable energy generation such as wind power, photovoltaic power generation, and electric vehicle charging piles, where the demand for direct current energy is gradually increasing [1]. This trend has put forward new requirements for Direct Current Energy Metering (DCEM) technology. Existing power metering equipment is mainly designed for AC power grids, with low metering accuracy and stability in DC environments, making it difficult to cope with complex signal conditions and extreme operating conditions, such as significant increase in metering error under high voltage and high current, and insufficient decomposition capability when disturbed by noise and non-stationary signals [2]. Therefore, there is an urgent need to explore optimization methods that can maintain high-precision metering in complex DC energy environments. The study aims to solve the core problem in DC energy metering, which is how to ensure the accuracy, stability and adaptability of metering equipment under complex working conditions and extreme conditions. To this end, the study proposes a metering accuracy optimization model that combines the improved EEMD with the artificial chemical reaction optimization algorithm, and further improves the adaptability and reliability of the model in different voltage and current ranges by introducing a wide-volume-limit constraint. The objective of the research is to improve the decomposition accuracy and robustness of DC energy signals, and to significantly reduce the metering error and computation time by improving the signal decomposition and optimization algorithm. The importance and significance of the study is to break through the limitations of the traditional DC energy metering methods, to provide an efficient, stable and adaptable metering technology for DC transmission and renewable energy, to provide new ideas for the optimization of power metering under complex working conditions in future smart grids, and to provide important theoretical and practical references for the researchers in the related fields to explore the signal processing methods based on EEMD.

II. Related Work

For power metering in DC environment, many researchers at home and abroad have successively explored the technology and proposed many accuracy optimization methods. Buchibabu et al. proposed a comprehensive control strategy to better manage the storage of DC microgrids such as AC power grids, by combining tuna swarm optimization algorithms, which could effectively improve the level of various DCEMs in microgrids [3]. Gao J et al. proposed an energy compensation algorithm limited to DC microgrids using intelligent optimization algorithms, whose error was also smaller than the traditional average EM algorithm, and the real-time power curve was closer to the theoretical value [4]. To further improve the accuracy of DCEM, Liaqat R et al. constructed a signal decomposition model using event matching energy decomposition algorithm after receiving non-invasive load monitoring, which could effectively distinguish various types of noise in electrical energy, thereby improving computational accuracy [5]. Kumar G et al. used optimized tracking algorithms to process data on appliance usage frequency, preferred operating interval, and average power consumption to better calculate household energy consumption within microgrids. This method could significantly improve the accuracy of electricity calculation and reduce time costs. But at this time, the usage cost and computational complexity actually increased, which had an impact on the overall calculation [6].

However, most of these methods are optimized for specific scenarios, which makes it difficult to maintain high accuracy under complex or extreme electrical energy signals, and they are deficient in high-frequency noise processing and real-time optimization. In addition, currently, Empirical Mode Decomposition (EMD) and its improved algorithms, such as Ensemble Empirical Mode Decomposition (EEMD), have gradually attracted the attention of researchers due to their unique advantages in signal decomposition [7]. Liang C et al. proposed a control strategy combining EEMD to improve the power time series regulation accuracy of DC microgrid photovoltaic power generation and its hybrid energy storage system, which could achieve better control effects under different power fluctuation characteristics [8]. Jiang L et al. proposed a wavefront calibration method to accurately locate the fault location in DC distribution systems by combining EEMD and singular value decomposition algorithms. This method could accurately decompose DC power signals and had high accuracy in fault location [9]. Zhang N et al. proposed a novel accuracy prediction model for short-term photovoltaic power generation by combining EEMD and gated recursive units. The prediction accuracy and robustness of this model are superior [10]. Wang et al. proposed a novel fault localization strategy by combining EEMD and adaptive local mean decomposition methods. This method detected DC series arc faults in less than 1ms with an accuracy of 98.75% [11].

In summary, previous studies have made many useful explorations in improving the accuracy of DC energy metering and processing complex signals. However, these researches still have some shortcomings when facing extreme working conditions, such as high voltage and high current, for example, the accuracy degradation during signal decomposition and low arithmetic efficiency. For this reason, how to develop a DC energy metering method that is efficient, robust and applicable to complex working conditions has become a key issue to be solved. The research focuses on solving the lack of metering accuracy of traditional methods, and by improving the EEMD algorithm and introducing the Artificial Chemical Reaction Optimization Algorithm (ACROA), a new type of DC energy metering model is proposed, and at the same time, the metering equipment is enhanced by the wide quantitative constraints under extreme working conditions, such as high voltage and high current. The research objectives include improving the decomposition accuracy of complex signals, reducing the metering error, optimizing the real-time performance of the model, and enhancing the stability of the model under the wide quantitative constraints. The importance of this study is that it makes up for the shortcomings of the existing methods and provides theoretical support and technical guarantee for the DC transmission system in the future smart grid and energy internet, which is of great theoretical and engineering significance.

III. Methods and Materials

A. DC Signal Decomposition

Due to the complexity of DC electrical signals, traditional measurement methods are difficult to cope with non-stationary, nonlinear, and the superposition of various interference signals [12]. There are many factors that affect the error of EM, and to minimize the error in DCEM, the primary requirement is to ensure the stability of the data acquisition source. DC energy meters are core devices used to measure DC, voltage, and related electrical parameters [13]. It can directly complete DCEM independently, and Fig. 1 shows the working principle of a DC energy meter.

In Fig. 1, firstly, the current sampling and voltage sampling modules collect the load current I and load voltage U. The collected current signal is used for power calculation with the voltage signal through a multiplier, and then converted into a frequency signal through a power frequency converter. Next, the frequency divider processes the frequency signal for subsequent calculation and display. The signal processing unit calculates based on the divided data and transmits the final electrical energy information to the counting display module. In this process, the main challenges of DCEM are as follows: traditional measurement methods are difficult to effectively handle these complex signals; The range of the measuring device is limited, and when extreme conditions are encountered, the measuring equipment often experiences over range problems, leading to increased measurement errors; DCEM equipment is susceptible to environmental interference during long-term operation, leading to fluctuations in measurement results [14-15]. Taking into account the above factors, this study assumes the existence of an ideal DCEM. Fig. 2 shows the classification of DC electrical signals at this time.

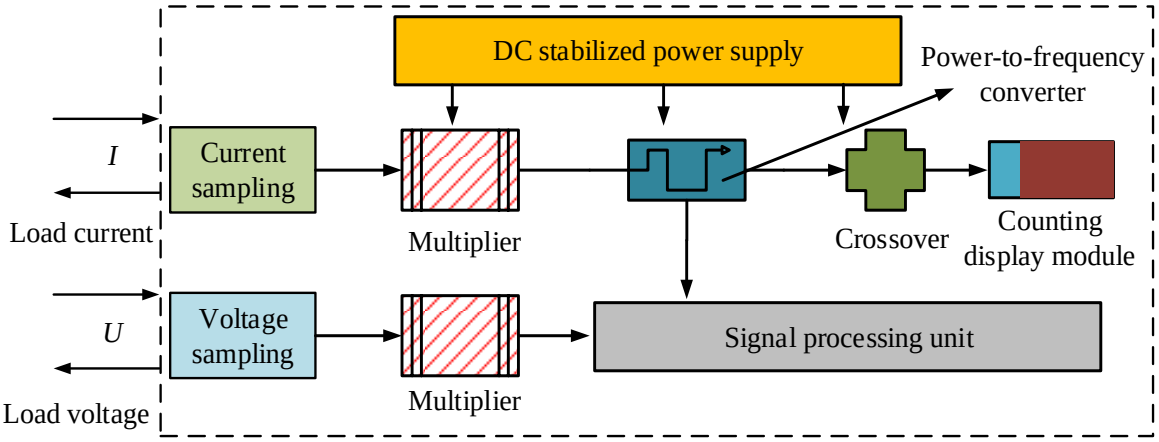

Fig. 1. DC energy meter working principle diagram.

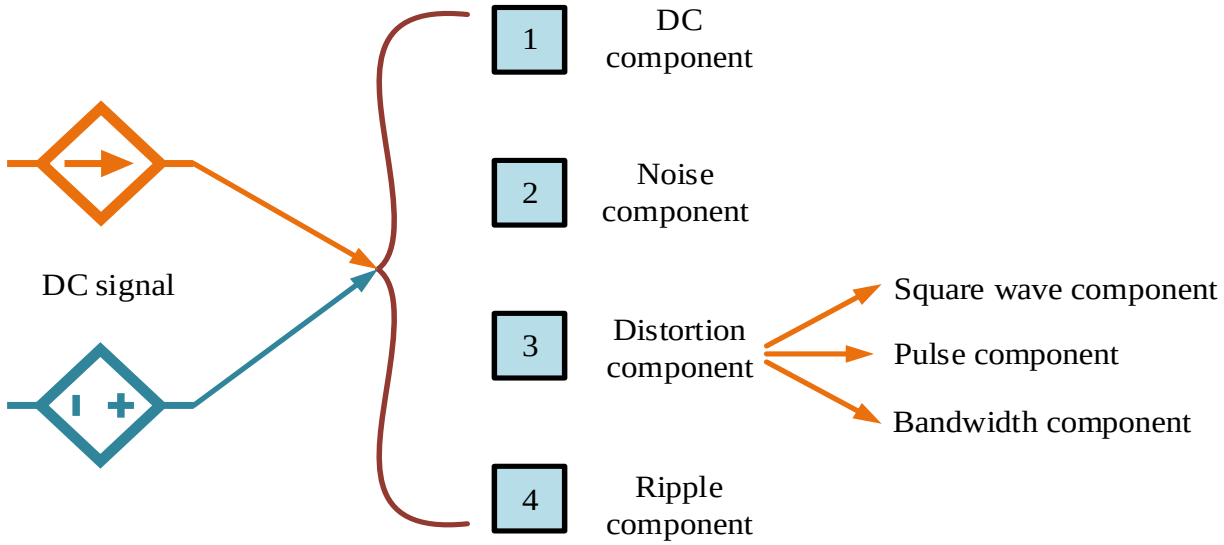

Fig. 2. DC signal composition classification.

In Fig. 2, DC electrical signals are DC components, noise components, distortion components, and ripple components. The DC component represents the stable part of the signal and is the main carrier of energy transmission; the noise component is mainly generated by random interference brought by external environment or equipment, which may include the influence of external factors such as temperature and humidity [16]. The expression of the DC electrical signal at this time is shown in Eq. (1).

$$u(t) = u_0 + \sum_n u_n(t) + \sum_i u_i(t) + \sum_k u_k(t) \quad (1)$$

In Eq. (1), $u(t)$ represents the DC electrical signal; $\sum_n u_n(t)$ represents the noise component; $\sum_i u_n(t)$ represents the distortion component; $\sum_k u_k(t)$ represents the ripple component. The ideal expression of the DC component is shown in Eq. (2).

$$u_1(t) = k(t) \quad (2)$$

In Eq. (2), k represents a constant; $u_1(t)$ represents the DC component in the ideal state. The noise component in the ideal state is usually avoided by adding noise compensation or filtering devices. At this time, the white noise signal with a specific noise ratio is composed as shown in Eq. (3).

$$u_2(t) = n(t) \quad (3)$$

In Eq. (3), n represents the white noise signal in the noise ratio; $u_2(t)$ represents the noise component in the ideal state. The distortion component originates from the use of nonlinear loads, causing signal deformation. For example, the fluctuating charge and discharge signals generated when the load is involved or the power grid system is disconnected [17]. Common distortion signals such as square wave components and broadband components are expressed in Eq. (4).

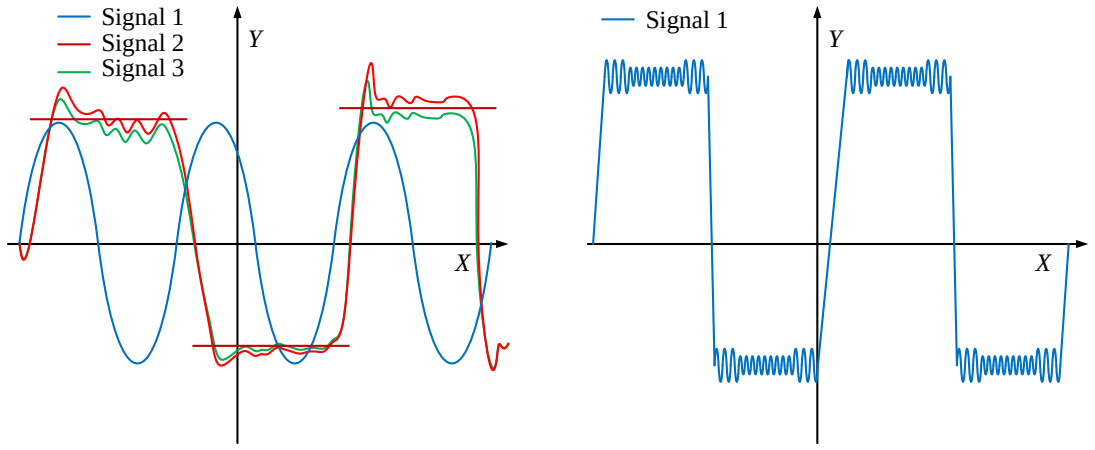
$$\begin{cases} u_3(t) = u_1(t) \pm A \times k_1(t) & 0 \le t \le t_1 \\ u_4(t) = u_1(t) - B(t - t_2)^2 + b_1(t) & t_1 \le t \le t_2 \end{cases} \quad (4)$$

In Eq. (4), A represents the amplitude multiple of the signal component; t represents time, where t_1 and t_2 represent the start and end times, respectively; k_1 represents the time period t_1 to t_2 control constant. The ripple component reflects the periodic interference caused by power supply ripple, which is usually characterized by high-frequency and small amplitude periodic fluctuations. The expression of the ripple component is shown in Eq. (5).

$$u_5(t) = D \times u_1(t) \times \sum_{t=1}^{n} \cos(2\pi i \omega_1 t), 0 < D < 0.1 \quad (5)$$

In Eq. (5), ω_1 represents a constant; ω_1 represents frequency. However, in the process of decomposing DC electrical signals, due to the discontinuity and complexity of the signal, Gibbs phenomenon is prone to occur, that is, oscillation occurs at the high-frequency components or abrupt points of the signal, resulting in overshoot or fluctuation during signal reconstruction, which affects the accuracy of measurement [18]. This phenomenon is particularly evident when dealing with non-stationary and nonlinear signals. Fig. 3 is a typical schematic diagram of Gibbs phenomenon.

Both Fig. 3 (a) and Fig. 3 (b) show the time-domain waveform of Gibbs phenomenon. In Fig. 3, after Fourier series expansion of periodic functions with discontinuous points, finite terms are selected for synthesis. As the number of selected items increases, the peak in the synthesized waveform gradually approaches the discontinuity point of the original signal. When the number of terms is sufficient, the peak tends towards a constant, approximately 9% of the total jump variable.



(a) The Gibbs phenomenon1 (b) The Gibbs phenomenon2

Fig. 3. Example of the Gibbs phenomenon.

B. DCEM Accuracy Optimization and WLC Based on Improved EEMD

To overcome the Gibbs phenomenon, EEMD is introduced in this study. EEMD can effectively reduce the influence of Gibbs phenomenon in signal decomposition, improve the accuracy of signal reconstruction, and exhibit better robustness and stability in various complex signal environments [19]. Fig. 4 shows the process of EEMD.

In Fig. 4, firstly, white noise of different intensities is added to the original signal and stacked multiple times. Next, each superimposed signal is subjected to empirical mode decomposition to obtain a series of Intrinsic Mode Functions (IMF). Then, all IMF components are averaged to eliminate uncertainty introduced by noise. However, as a signal decomposition method with non Fourier transform, EEMD may still face the problem of insufficient decomposition accuracy when dealing with specific complex signals. Therefore, ACROA is introduced in this study to further optimize the decomposition process. ACROA first generates a set of reactants through initialization. Secondly, in the subsequent iteration process, different chemical reaction operators are dynamically selected and operated based on the current signal state and optimization requirements to adapt to different signal conditions [20]. Then, after each reaction, the reactants are updated based on feedback, similar to a reversible reaction process. This process involves redox reactions, decomposition reactions, displacement reactions, and synthesis reactions. Fig. 5 shows an example of the reaction.

In Fig. 5 (a), the redox reaction mechanism optimizes the global search capability of the signal by adjusting the state of the reactants to change their energy levels; In Fig. 5 (b), the decomposition reaction decomposes complex signals into smaller units, thereby improving the local search accuracy of the algorithm; In Fig. 5 (c), the substitution reaction enables the algorithm to quickly jump out of local optima and improve global search efficiency through the exchange of reactants; In Fig. 5 (d), the synthesis reaction helps the algorithm find a better solution by combining multiple signal components. At this point, the optimized DC power signal decomposition is shown in Eq. (6).

$$X(t) = \sum_{i=1}^{n} IMF_i(t) + r_n(t) \tag{6}$$

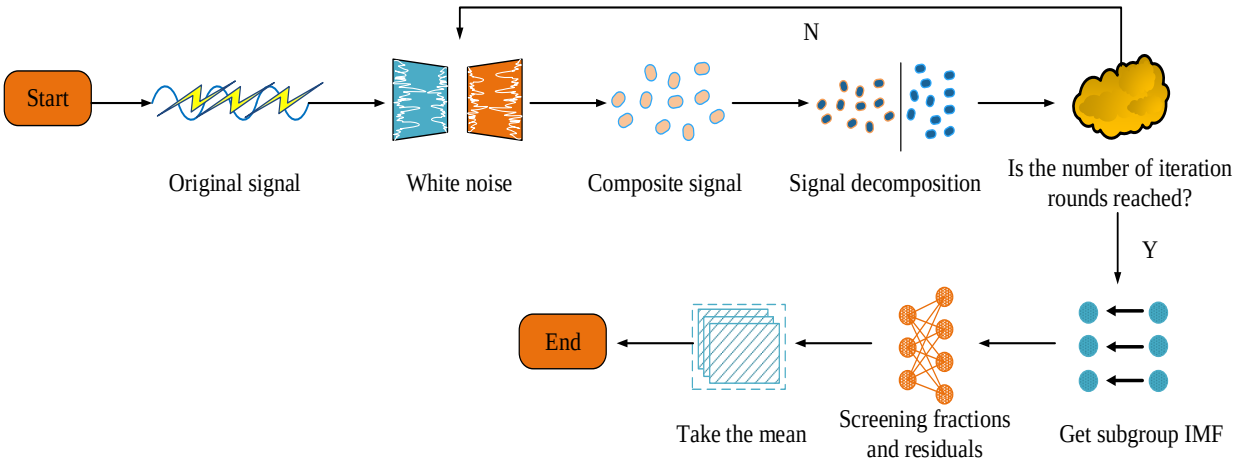


Fig. 4. EEMD process schematic.

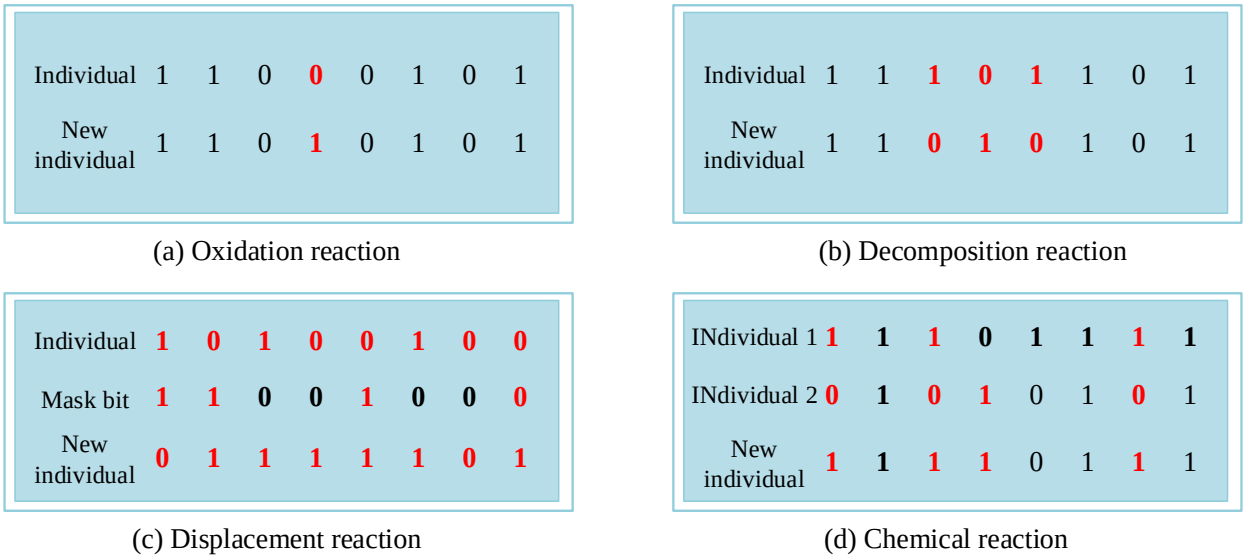

Fig. 5. Schematic of ACROA's four binary coded responses.

In Eq. (6), $X(t)$ represents the original DC electrical signal; $X(t)$ represents the -i th eigenmode function; $r_n(t)$ represents the residual term, which is the remaining part after signal decomposition; n represents the number of decomposed eigenmode functions. After obtaining these IMF components through the EEMD algorithm, ACROA is used to further optimize the accuracy of the residual term $r_n(t)$ to reduce decomposition errors. The calculation equation is shown in Eq. (7).

$$r_{opt}(t) = \min_{\alpha}(r_n(t) - \alpha\Delta r(t)) \tag{7}$$

In Eq. (7), $r_{opt}(t)$ represents the residual term after optimization; α represents the optimal weight coefficient obtained during the ACROA optimization process; α represents the adjustment amount during the ACROA iteration process, which is the correction value obtained through the reaction mechanism optimization in each iteration. The combination of the two results in the final optimization signal $X_{opt}(t)$ calculation equation is shown in Eq. (8).

$$X_{opt}(t) = \sum_{i=1}^{n} IMF_i(t) + r_{opt}(t) \tag{8}$$

In addition, each frequency component in the signal may have different characteristics within different limits. To ensure the stability and reliability of the energy meter in the face of extreme conditions, this study has imposed constraints on the Wide Dynamic Range (WDR). Among them, WDR refers to a large range that can be accurately measured or processed in measuring or measuring equipment, that is, the equipment can maintain high accuracy and reliability over a wide range of input signal amplitudes. For DCEM, WDR usually means that the measuring equipment can maintain measurement accuracy without significant errors over a wide range of changes from low voltage and low current to high voltage and high current. The WDR constraint is shown in Eq. (9).

$$L_{\min} \le X_{opt}(t) \le L_{\max} \tag{9}$$

In Eq. (9), $L_{\min}$ and $L_{\max}$ represent the upper and lower limits of the measured DC signal, respectively. The constraint error calculation equation at this time is shown in Eq. (10).

$$\varepsilon(t) = \left| X(t) - X_{opt}(t) \right| \le \delta \tag{10}$$

In Eq. (10), $\varepsilon(t)$ represents the error between the measured signal and the optimized signal; $X(t)$ represents the actual measured DC signal; δ represents the maximum allowable error limit. To adapt to the dynamic changes in the measurement environment and ensure that the signal can be adaptively adjusted under WDR, the dynamic range expression of WDR at this time is shown in Eq. (11).

$$X_{opt}(t) = \max(\frac{X(t)}{L_{\max}}), and \min(\frac{X(t)}{L_{\min}}) \tag{11}$$

This study combines EEMD-ACROA and WDR to propose a novel DCEM model. Fig. 6 shows the process of the model.

In Fig. 6, the DC electrical signal is first collected and preprocessed through current and voltage sampling modules to ensure signal stability. Then, the DC electrical signal decomposition model is constructed, and the signal is divided into DC components, noise components, distortion components, and ripple components to reflect the main characteristics of the signal. Then, the EEMD algorithm is used to decompose the signal, obtain the intrinsic mode functions of different frequencies, and optimize the residual terms through the ACROA algorithm to dynamically adjust the reaction path and reduce decomposition errors. WLC is introduced to ensure that equipment maintains high-precision measurement under extreme conditions such as high voltage and high current. The signal processing process is optimized through an error control mechanism, and the optimized electrical energy data is transmitted to the display module for real-time monitoring and accurate measurement.

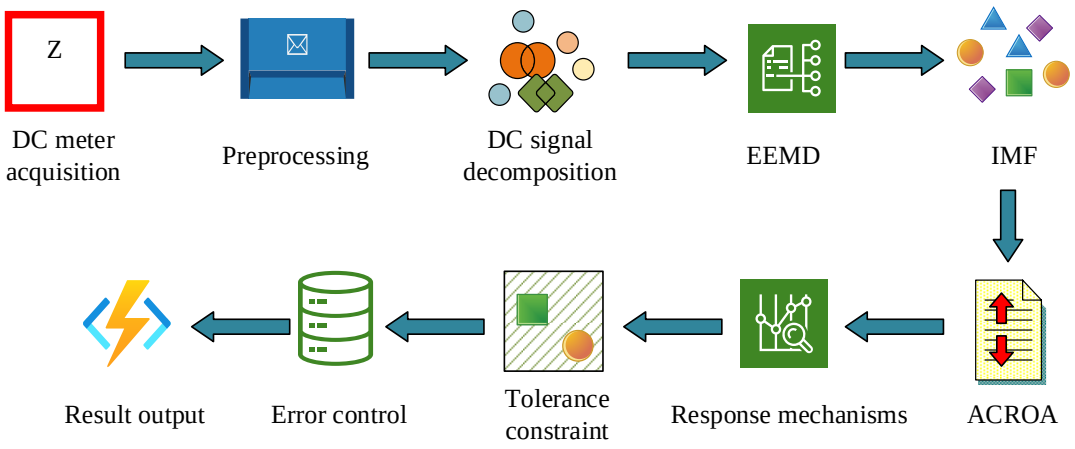

Fig. 6. Novel DCEM modeling process.

IV. Result

A. Performance Testing of the New DCEM Model

The experimental hardware was Keysight E36312ADC power supply, with an output range of 0-100V and a maximum current of 10A. The load simulator was Chroma 63206A-150-600, which supported a maximum of 600W. The precision current sensor was LEM HAZ 1000-S, with a current range of 0-1000A and an accuracy of ±0.1%. The data was collected through the National Instruments NI USB-6343 high-precision data acquisition card. The software part was Dell Precision 5820 Tower, equipped with Intel Core i9-10900X processor, 64GB DDR4 memory, 2TB SSD hard drive, and NVIDIA Quadro RTX 4000 GPU. Python 3.10 was used for data analysis and visualization. The IEEE PES Distribution Test Feeder Dataset (IEEE PES) and Electric Power Consumption Dataset (EPC) datasets were the sources of test data. IEEE PES included various typical electrical energy signals in distribution systems, especially voltage and current waveform data for different loads and grid conditions; EPC contained a series of energy consumption data for household users, including current, voltage, power, and other related information. This study first conducted ablation testing on the proposed algorithm model. Fig. 7 shows the test results.

In Fig. 7 (a), after 200 iterations, the measurement accuracy of EEMD-ACROA-WDR continued to remain at a high level and reaches nearly 90% accuracy at 600 iterations. It performed even better in terms of global optimization capability and robustness. In Fig. 7 (b), EEMD-ACROA-WDR achieved a measurement accuracy of over 90% after 300 iterations. Although EEMD-ACROA performed well in the early iterations, there were significant fluctuations in the later stages, and the measurement accuracy did not steadily improve. Overall, the modules of EEMD-ACROA-WDR demonstrated stronger adaptability and stability on both datasets. The study introduced advanced DCEM precision optimization methods for comparison, namely Bispectral Analysis (BA), Extreme Learning Machine (ELM), and Adaptive Local Mean Decomposition (ALMD). The signal decomposition rate was used as the indicator to test the power processing capability under different bandwidth ranges, as shown in Fig. 8.

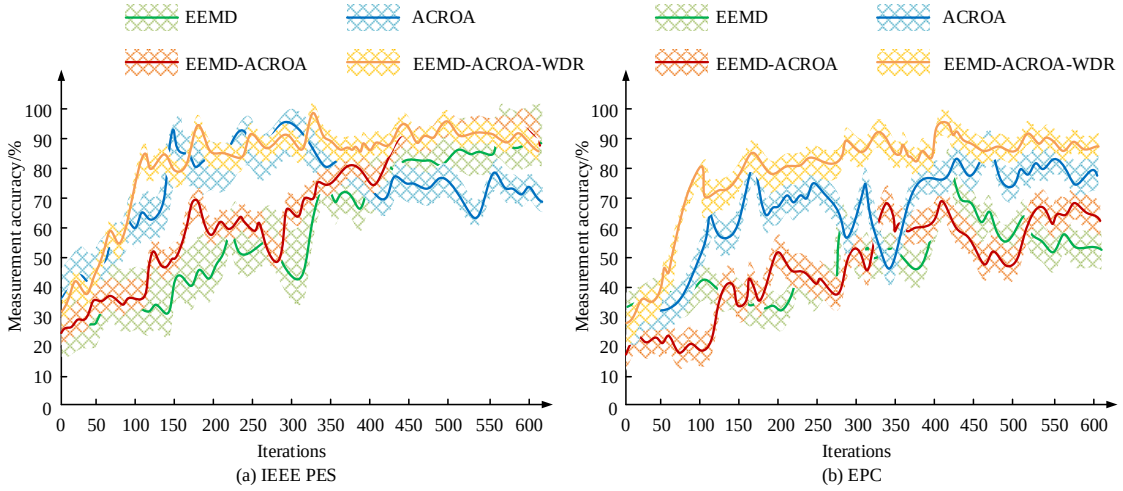

Fig. 7. Ablation test results.

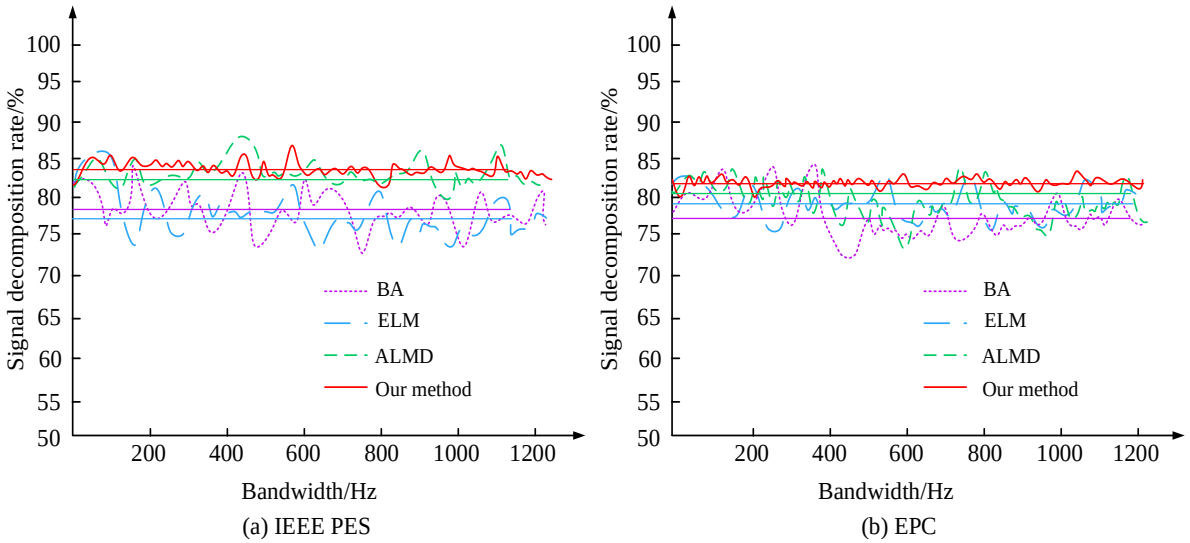

Fig. 8. Signal decomposition rate test results of different methods.

In Fig. 8, within different bandwidth ranges, the proposed method maintained a signal decomposition rate of around 85% with minimal fluctuations at higher bandwidths, such as 800Hz to 1200Hz, demonstrating good stability. The decomposition rates of BA and ELM showed significant fluctuations at high bandwidth, especially the decomposition rate of BA method was relatively unstable throughout the entire bandwidth range, with an average decomposition rate of only 78%. Overall, the proposed optimization algorithm exhibited stronger adaptability and decomposition ability in processing high bandwidth signals, especially maintaining high signal decomposition rates on IEEE PES and EPC, verifying the effectiveness of the algorithm in complex signal environments. In Table I, the precision, recall, F1 value, and average time for precision optimization in DCEM were used as indicators for this study.

TABLE I. INDICATOR TEST RESULTS FOR EACH METHOD

Data Set	Method	P/%	R/%	F1/%	Average Time Spent/S
IEEE PES	BA	87.63	84.12	85.88	2.11
	ELM	84.25	85.36	84.81	2.03
	ALMD	89.74	87.15	88.45	1.54
	Our method	90.11	89.63	89.87	1.02
EPC	BA	88.53	85.16	86.85	2.12
	ELM	89.68	86.84	88.26	1.76
	ALMD	90.08	88.45	89.27	1.52
	Our method	90.87	89.74	90.31	1.08

In Table I, on IEEE PES, the proposed method had the highest P-value of 90.11%, R-value of 89.63%, and F1 value of 89.87%, all of which were higher than other methods, indicating its higher accuracy and stability in signal processing and EM aspects. Meanwhile, the average time was 1.02 seconds, which was much lower than other methods, reflecting the efficiency advantage of this algorithm. In contrast, although ALMD performs better in accuracy and F1 score, it took 1.54 seconds and had a relatively slower processing speed. BA and ELM were slightly lower than the proposed method in various indicators, especially in terms of time. BA took 2.11 seconds, which was more time-consuming. For EPC, the proposed method achieved a P-value of 90.87%, an R-value of 89.74%, and an F1 value of 90.31%, demonstrating excellent performance with a time of 1.08 seconds and a significant advantage in speed.

B. New DCEM Model Simulation Testing

This study set the amplitude of the original current signal to 2A and simulated the input of electrical energy signals under different operating conditions. The simple EEMD model and the proposed method were compared and tested for signal decomposition to evaluate the robustness and decomposition accuracy of different models in processing complex DC signals, as shown in Fig. 9.

In Fig. 9 (b) - Fig. 9 (d), the decomposed electric energy signals IMF1, IMF2, and IMF3 of the EEMD model exhibited significant oscillations and noise, especially in IMF1 and IMF3, where multiple irregular pulse points appear, which had a negative impact on the stationarity and decomposition accuracy of the signal. This indicated that EEMD still faced certain noise aliasing problems when processing complex electric energy signals. The proposed method decomposed IMF1, IMF2, and IMF3 to be smoother, with significantly reduced oscillation amplitude, indicating that this method had better performance in noise suppression and signal smoothing. Especially in the decomposition of IMF3, the proposed method effectively eliminated high-frequency noise and irregular fluctuations in the original signal, preserving the main features of the signal. This indicated that the proposed method could better capture the true characteristics of signals when dealing with non-stationary signals and high-frequency interference, improving the accuracy and stability of DCEM. In Fig. 10, this study conducted signal accuracy tests on EEMD before and after improvement.

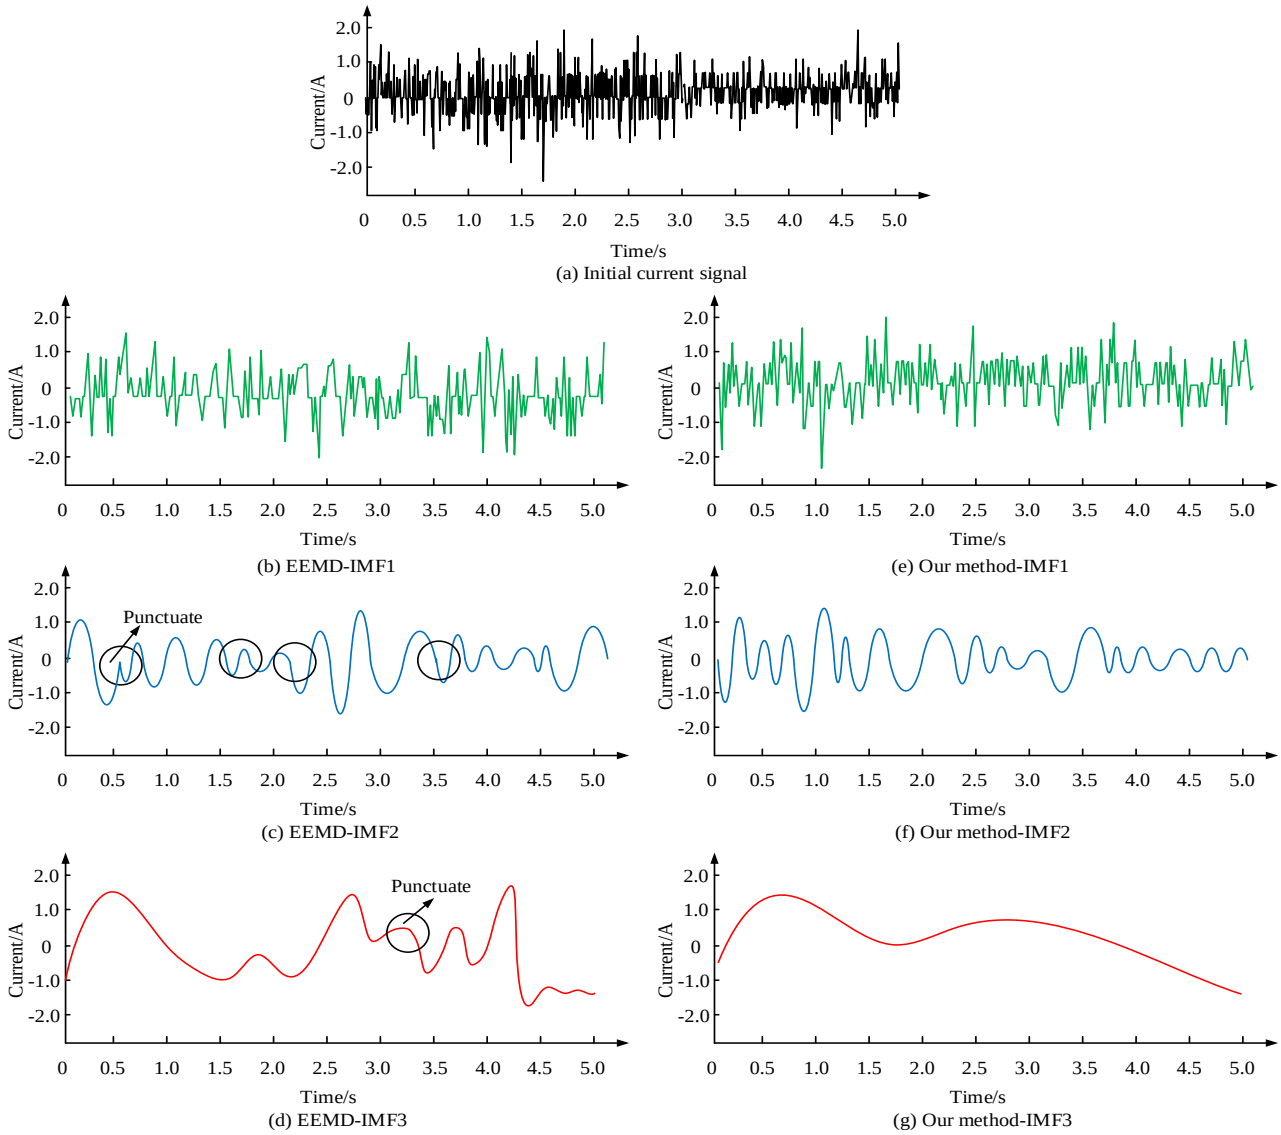

Fig. 9. Decomposition testing of electrical energy signals for two types of models.

In Fig. 10 (a) -10 (c), the measured values of EEMD in the IMF1 signal deviate significantly from the true values and fluctuated greatly, indicating that EEMD had insufficient accuracy in processing high-frequency signals. In the IMF2 and IMF3 signals, although the matching between the measured values and the standard values improved, there were still significant errors, especially at certain peak points, indicating that the EEMD method also had certain errors in processing low-frequency signals. In Fig. 10 (d) -10 (f), the measured values almost completely coincided with the standard values in the IMF2 and IMF3 signals, indicating that the proposed method outperformed traditional EEMD in processing low-frequency signals. Meanwhile, the error of IMF1 signal was effectively controlled, demonstrating better signal reconstruction capability. Overall, the proposed method performed better in terms of measurement accuracy and stability, especially when dealing with complex signals, with significantly reduced errors, verifying the practical application effect of the model in EM. In Table II, this study tested the number of IMF decompositions, measurement error, decomposition stability, and computation time as indicators.

In Table II, in terms of the number of IMF decompositions, the proposed method was the same as methods such as BA and ALMD, both of which decomposed into 6 IMF components, indicating its high decomposition ability in processing complex electrical energy signals. In terms of measurement error, the proposed method had an error of 6.87%, significantly lower than other methods, indicating higher accuracy in EM and stronger robustness, especially when dealing with noise and non-stationary signals. In terms of decomposition stability, the proposed method had a decomposition stability of up to 94.02%, which was better than the 92.48% of Wang L et al.'s method, demonstrating stability and consistency in signal decomposition, greatly reducing error fluctuations. In terms of computation time, the proposed method took 1.12 seconds, which was the fastest among all methods, far lower than the BA method's 2.34 seconds, demonstrating its high efficiency in practical applications.

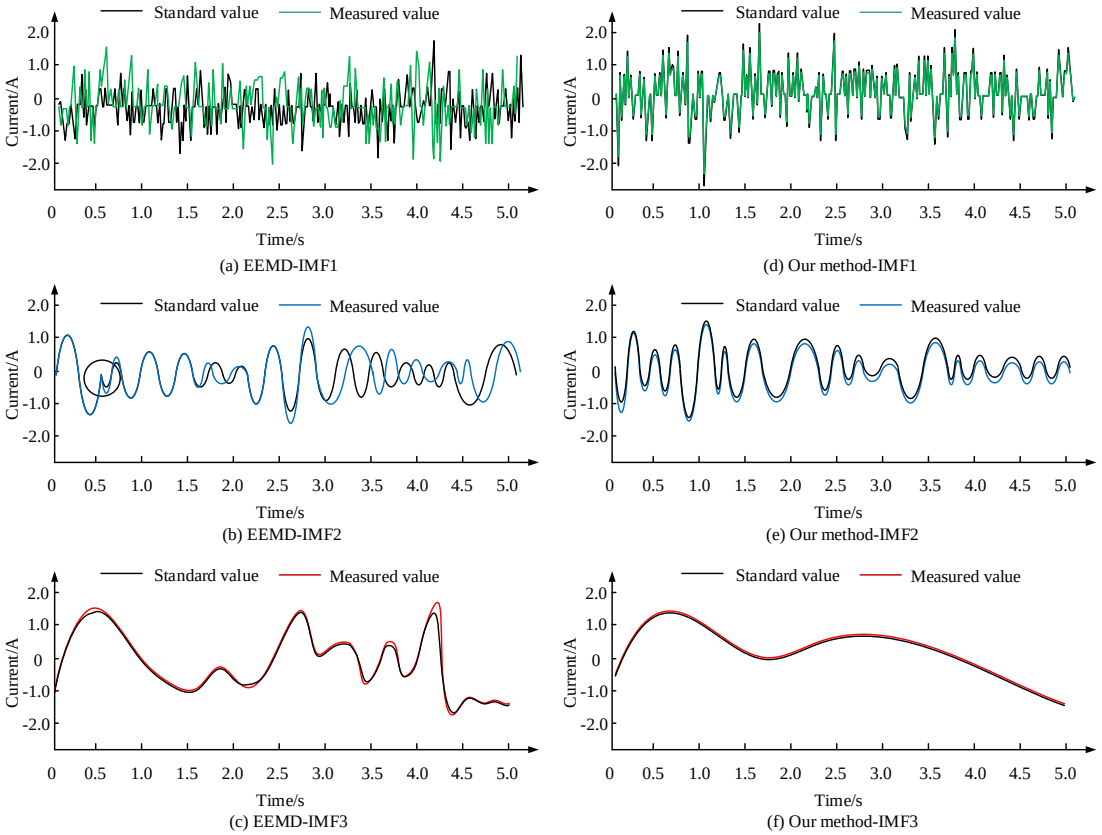

Fig. 10. Results of the comparison of the measurement errors of the two types of methods.

TABLE II. MULTI-INDICATOR TEST RESULTS FOR DIFFERENT MEASUREMENT METHODS

Method	Number of IMF Decompositions	Measurement Error/%	Decomposition Stability/%/%	Operation Time/S
BA	6	12.34	85.56	2.34
ELM	5	10.89	87.12	1.89
ALMD	6	9.78	88.34	1.52
EEMD	7	11.56	86.47	1.74
The method proposed by Liang C et al.	6	8.98	89.65	1.62
The method proposed by Jiang L et al.	5	8.45	90.12	1.58
The method proposed by Zhang N et al.	7	7.89	91.05	1.43
The method proposed by Wang L et al.	6	7.34	92.48	1.32
Our method	6	6.87	94.02	1.12

V. CONCLUSION

In response to the problems of low accuracy of DCEM and insufficient robustness of traditional methods in complex electrical signals, this study proposes a DCEM accuracy optimization method that combines improved EEMD and ACROA, and improves the adaptability of measuring equipment in extreme working conditions by introducing WLC. The proposed model could achieve an accuracy of nearly 90% in the lowest 300 iterations. Compared with the BA, ELM, and ALMD models, the signal decomposition rate of the proposed model was significantly better than other methods, especially under higher bandwidth conditions such as 800Hz to 1200Hz. Its signal decomposition rate was as high as nearly 85%, with the highest P value of 90.87%, the highest R value of 89.74%, and the highest F1 value of 90.31%. The average optimization time for accuracy was as short as 1.02 seconds. The proposed model decomposed IMF1, IMF2, and IMF3 to be smoother, with significantly reduced oscillation amplitude, indicating better performance in noise suppression and signal smoothing. Meanwhile, the proposed model significantly reduced the error between the measured values of the three types of IMF signals and the true values, and had better processing accuracy than traditional EEMD. The maximum number of IMF components was 6, the lowest measurement error was 6.87%, the highest decomposition stability was 94.02%, and the shortest measurement time was 1.12 seconds. In summary, the proposed model has advantages in efficiency in practical applications.

However, the model has not carried out an in-depth study on the impact of external factors such as changes in environmental temperature and humidity on the metering accuracy. Future research can consider introducing an environmental adaptive mechanism, monitoring environmental changes in real time through temperature and humidity sensors, and dynamically adjusting the metering model by combining with adaptive algorithms. In addition, the expansion of the model can include improving the processing capability of ultra-high frequency noise signals, optimizing the model parameters to further reduce the computation time, as well as combining with the Internet of Things and big data analysis technology to achieve multi-device collaborative metering, and constructing a more comprehensive power monitoring system. These improvements will help to further enhance the practicality and adaptability of the model to meet the needs of more complex and diverse application scenarios.
