Table I shows the results of the comparison of the classification performance of the CNN model with Ghost Feature for 10 classes of Palembang Songket motifs. Compared to CNN with Conv2D, CNN with Ghost feature (ratio 2) is able to provide better classification performance. This is proven by the increase in accuracy, precision, recall, and f1-score for all classes of Palembang Songket motifs. For the Songket Bintang Berantai motif, there was an increase in accuracy from 0.94 to 0.98, precision from 0.63 to 0.83, recall remained at 1.00, and f1-score from 0.77 to 0.91. Furthermore, the Bunga Jatuh motif increased with accuracy from 0.99 to 1.00, precision remained at 1.00, recall from 0.90 to 1.00, and f1-score from 0.95 to 1.00. Then, the Kenanga Makan Ulat motif increased with accuracy from 0.98 to 1.00; precision remained at 1.00, recall from 0.80

to 1.00, and f1-score from 0.89 to 1.00. After that, for the Naga Besaung motif, accuracy increased from 0.95 to 0.98, precision from 0.86 to 1.00, recall from 0.60 to 0.80, and f1-score from 0.71 to 0.89. Then, for the Nampan Perak motif, there was an increase in accuracy from 0.98 to 1.00, precision from 0.90 to 1.00, recall from 0.90 to 1.00, and f1-score from 0.90 to 1.00. The rest, the Bunga Cina, Cantik Manis, Jando Beraes, Pacar Cina, and Pulir motifs, did not increase because they were already very well recognized.

Table II shows the results of the overall comparison of the performance of the CNN model with Ghost Feature. The

comparison consists of total parameters, overall accuracy, and model size. The total parameters referred to are the overall parameters used from the input layer to the output layer, namely ghost feature maps, flatten, up to the fully connected layer. Based on the results in Table II, it was found that the CNN model with Ghost Feature provided an overall accuracy of 0.98 with fewer total parameters compared to the CNN model with Conv2D which had an overall accuracy of 0.92. In addition, the CNN model with Ghost Feature ratios of 4 and 5 was able to provide the same overall accuracy of 0.93 with much more reduced parameters with a smaller model size.

TABLE I. COMPARISON OF MODEL PERFORMANCE BASED ON PALEMBANG SONGKET MOTIF CLASS

Songket Motif	Accuracy		Precision		Recall		F1 – Score	
	Conv2D	Ghost Feature	Conv2D	Ghost Feature	Conv2D	Ghost Feature	Conv2D	Ghost Feature
Bintang Berantai	0.94	0.98	0.63	0.83	1.00	1.00	0.77	0.91
Bunga Cina	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
Bunga Jatuh	0.99	1.00	1.00	1.00	0.90	1.00	0.95	1.00
Cantik Manis	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
Jando Beraes	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
Kenanga Makan Ulat	0.98	1.00	1.00	1.00	0.80	1.00	0.89	1.00
Naga Besaung	0.95	0.98	0.86	1.00	0.60	0.80	0.71	0.89
Nampan Perak	0.98	1.00	0.90	1.00	0.90	1.00	0.90	1.00
Pacar Cina	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
Pulir	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00

TABLE II. COMPARATIVE RESULTS OF THE PROPOSED METHOD

Model	Total Parameters	Overall Accuracy	Model Size (MB)
CNN with Conv2D	68,060,746	0.92	259.63
CNN with Ghost Feature ($r = 2$)	67,721,898	0.98	258.34
CNN with Ghost Feature ($r = 3$)	44,983,411	0.95	171.60
CNN with Ghost Feature ($r = 4$)	33,909,850	0.93	129.36
CNN with Ghost Feature ($r = 5$)	27,061,049	0.93	103.23

B. Discussion

A comparison was also conducted with two previous studies on Songket motif classification using CNN-based methods, as summarized in Table III. Ariessaputra et al. [7] utilized a CNN architecture comprising Conv2D, Max Pooling, and Fully Connected layers, while Hambali et al. [8] implemented a CNN model with additional Dropout layers to enhance generalization. Both approaches leveraged CNN's feature extraction and classification capability for traditional fabric patterns. These studies highlight the relevance of CNN architectures for motif recognition, providing a contextual foundation for evaluating the proposed method's design and performance.

TABLE III. METHOD COMPARISON

Authors	Methods	Dataset	Overall Accuracy
Ariessaputra et al. [7]	CNN (Conv2D, MaxPooling, Fully Connected)	Lombok Songket Motifs	0.84
Hambali et al. [8]	CNN (Conv2D, MaxPooling, Dropout, Fully Connected)	Lombok Songket Motifs	0.86
Ours	CNN with Ghost Feature ($r = 2$)	Songket Palembang Motifs	0.98

Each method has its strengths and limitations. However, the proposed approach, which retains the basic CNN architecture with Dropout but replaces Conv2D and Max Pooling with Ghost Feature maps involving the Ghost Module and Max Pooling, shows improved performance over the previous studies. The hierarchical combination of Ghost Module and Max Pooling in the proposed method leads to better classification results compared to the state-of-the-art methods from Ariessaputra et al. [7] and Hambali et al. [8]. This improvement highlights the effectiveness of the proposed method in enhancing motif recognition accuracy.

In addition to key parameters such as the learning rate and batch size, the experiment also involved setting a Dropout rate

of 0.5 in the dense layer. This configuration aimed to improve the model's generalization in recognizing complex and diverse Songket motifs. During training, Dropout randomly deactivates units, helping the model learn feature representations that are more adaptive to the distinctive patterns of Songket motifs, such as geometric curves and overlapping color variations.

The proposed model addresses the limitations of previous approaches by integrating the Ghost Module and a hierarchical combination of Max Pooling, which significantly enhances the efficiency of dominant feature extraction without losing the primary characteristics of motif patterns. Unlike conventional convolutional layers that rely on a large number of parameters, this model leverages the Ghost Module for a more lightweight feature generation mechanism, while the hierarchical integration of Max Pooling reduces redundancy and ensures a more focused feature extraction process. This approach not only improves efficiency in filtering less relevant features but also strengthens the model's ability to capture intricate patterns, especially in motifs with significant visual similarities and minor variations. With this structure, the model demonstrates enhanced efficiency and effectiveness in recognizing Songket motifs.

V. CONCLUSION

The use of Ghost feature maps, which involve the Ghost module, in the CNN model leads to a significant reduction in the number of parameters and the model size compared to traditional CNNs utilizing Conv2D. This efficiency is highlighted by the model achieving an impressive accuracy of 0.98 at a ratio of 2, with only a minor parameter reduction of about 0.5% and a slightly smaller model size. However, as the ratio of Ghost feature maps increases, a further decrease in parameters and model size occurs, accompanied by a decline in accuracy. Specifically, a ratio of 3 results in a 34% reduction in parameters but lowers accuracy to 0.95. Ratios 4 and 5 stabilize accuracy at 0.93 while achieving over 60% reductions in model size and parameters compared to the Conv2D model. Thus, a trade-off between accuracy and model size becomes evident, particularly at a ratio of 3, where significant size reductions are achieved with only a slight impact on accuracy.

The proposed Ghost Feature maps in this model are constructed hierarchically through a combination of Ghost Modules and Max Pooling, applied four times. Each pair forms a pyramid-like feature representation, allowing the model to learn increasingly complex feature hierarchies as the depth of the layers increases. However, the optimal number of feature repetition levels required for achieving the best performance remains to be explored. Future research should investigate whether adding deeper hierarchical layers could reduce performance or significantly improve recognition accuracy. Therefore, further development of deeper architectures and evaluation at various layer depths is necessary to determine whether this approach can significantly improve Songket motif recognition.

ACKNOWLEDGMENT

A Novel Hybrid Algorithm Based on Butterfly and Flower Pollination Algorithms for Scheduling Independent Tasks on Cloud Computing

Huiying SHAO

Hebei Vocational University of Technology and Engineering, Xingtai 054000, China

Abstract—Cloud computing is an Internet-based computing paradigm where virtual servers or workstations are offered as platforms, software, infrastructure, and resources. Task scheduling is considered one of the major NP-hard problems in cloud environments, posing several challenges to efficient resource allocation. Many metaheuristic algorithms have been extensively employed to address these task-scheduling problems as discrete optimization problems and have given rise to some proposals. However, these algorithms have inherent limitations due to local optima and convergence to poor results. This paper suggests a hybrid strategy for organizing independent tasks in heterogeneous cloud resources by incorporating the Butterfly Optimization Algorithm (BOA) and Flower Pollination Algorithm (FPA). Although BOA suffers from local optima and loss of diversity, which may cause an early convergence of the swarm, our hybrid approach outperforms such weaknesses by exploiting a mutualism-based mechanism. Indeed, the proposed hybrid algorithm outperforms existing methods while considering different task quantities with better scalability. Experiments are conducted within the CloudSim simulation framework with many task instances. Statistical analysis is performed to test the significance of the obtained results, which confirms that the suggested algorithm is effective at solving cloud-based task scheduling issues. The study findings indicate that the hybrid metaheuristic algorithm could be a promising approach to improving resource utilization and optimizing cloud task scheduling.

Keywords—Task scheduling; cloud computing; butterfly optimization algorithm; flower pollination algorithm; mutualism

I. INTRODUCTION

Cloud computing is an Internet-based approach that enables elastic, easy-to-scale access to a broad set of resources, including storage, computing, and networking applications delivered via the Internet [1]. In contrast to traditional systems, dependent on locally stored resources, cloud computing allows flexible and scalable access to resources from any location. There are three main service configurations: Platform as a Service (PaaS), Infrastructure as a Service (IaaS), and Software as a Service (SaaS) [2]. IaaS involves virtualized assets accessible through the internet, offering elementary amenities like servers, storage facilities, and networking, empowering companies to expand slanted utopias without trusting physical devices [3].

While IaaS provides virtualized computing resources, PaaS is an extension that offers developers a platform complete with

tools and frameworks [4]. This allows the developer to create, evaluate, and launch applications without explicitly managing the underlying infrastructure. SaaS directly delivers ready-to-consumer applications to end-users, including email, CRM, and collaborative software, accessed via web browsers [5]. Together, these models catalyze innovation and cost-efficiency in sectors by allowing companies to lessen their IT overhead, hasten product deployment, and respond dynamically to market demands.

Scheduling tasks in cloud computing belongs to fundamental NP-hard problems that need to be solved to ensure better efficiency in resource allocation within virtual environments [6]. This problem falls under the combinatorial optimization class wherein multiple heterogeneous tasks must be assigned to available resources for maximum efficiency [7]. As finding an optimal resource allocation problem in scheduling tasks with different requirements is often combinatorial, more advanced strategies provide an alternative to conventional approaches. Common objectives in task scheduling include reducing execution time (or makespan) to ensure tasks are completed as quickly as possible, which enhances user satisfaction and system performance [8].

The other objective is to perform load balancing, in which tasks should be allocated to resources to avoid bottleneck situations and overutilization of particular servers, providing better system resiliency [9]. Last but not least, efficient usage of resources will prevent the idleness of resources and minimize operational costs by utilizing the maximum availability of infrastructure [10]. Therefore, efficient scheduling strategies are crucial for cloud environments, where dynamic scaling of resources relies on accurate and adaptive scheduling to accommodate the diversified requirements of end-users and applications.

Simultaneously, advancements in mobile robotics, particularly in navigation and mapping, provide valuable insights into addressing dynamic resource allocation challenges in cloud environments. Techniques such as reinforcement learning have demonstrated the potential to enhance decision-making and adaptability in complex scenarios [11]. These insights could inspire novel approaches to optimizing task scheduling in cloud computing, where dynamic and unpredictable demands necessitate intelligent and resilient solutions.

Metaheuristic algorithms, including the Flower Pollination Algorithm (FPA) and Butterfly Optimization Algorithm (BOA), are employed in cloud task scheduling because of their flexibility in handling complicated optimization challenges [12]. BOA is inspired by butterflies' sensory communication through fragrance. The fragrance guides each solution or member chemically to an optimal solution, mirroring the prey's natural process. This mechanism will help explore potential solutions within the search space and zoom into promising, high-quality areas [13]. On the other hand, FPA draws inspiration from flowers' pollination behavior, combining local and global pollination processes to examine the solution domain effectively. The global pollination phase facilitates the exploration of diverse solutions, while local pollination fine-tunes promising areas [14].

While BOA and FPA have emerged as promising optimization techniques, they face significant limitations when applied to task scheduling. BOA often experiences early convergence and can become trapped in local optima due to its limited ability to fully utilize the optimal solution. Additionally, BOA's phase-switching mechanism may become disoriented, deviating from the best global solutions. Similarly, FPA, despite its strength in balancing exploration and exploitation, can suffer from reduced diversity over time, limiting its capacity to explore novel solutions. To overcome these challenges, this study introduces a novel hybrid algorithm that integrates BOA and FPA through a mutualism mechanism inspired by ecological interactions.

In this context, the strengths of one algorithm offset the weaknesses of the other, creating a synergistic optimization

process. Furthermore, we propose an adaptive switching probability mechanism, a key innovation of this study, which dynamically adjusts the balance between the exploitation and exploration phases. This unique combination enhances the search process, improves convergence, and significantly optimizes cloud-based task scheduling, marking a substantial contribution to cloud computing optimization.

The remainder of the paper is organized as follows: The state-of-the-art review is outlined in Section II, about different existing cloud task-scheduling approaches as well as different meta-heuristic algorithms. This is followed by describing, in Section III, the problem statement, which includes the challenges and objectives that characterize cloud task scheduling. Section IV outlines our hybrid novel algorithm, illustrating its various components, including the mechanism behind the mutualism and switching probability adaptation process. Section V describes the experimental setup and discusses the results of the simulation. The implications of the findings are discussed in detail in Section VI. Finally, the paper concludes by summarizing the contributions in Section VII and presenting possible further research.

II. RELATED WORK

This section summarizes recent advancements in cloud task scheduling algorithms, as summarized in Table I. Various hybrid and metaheuristic approaches are highlighted, focusing on optimizing makespan, resource utilization, and load balancing to handle scheduling challenges in cloud computing environments.

TABLE I. SUMMARY OF RELATED WORKS ON CLOUD TASK SCHEDULING ALGORITHMS

Research	Description	Performance metrics	Key Findings
[15]	Genetic algorithm and multi-verse optimization are integrated to optimize task scheduling, focusing on bandwidth, virtualization, task counts, and sizes in cloud environments.	Time minimization and task transfer efficiency	Shows promising results in minimizing time for massive tasks by optimizing resource allocation.
[16]	Combination of genetic algorithm and thermodynamic simulated annealing, with crossover operator and thermodynamic mechanisms for balanced exploration and exploitation.	Effectiveness, speedup, schedule duration, and makespan	Effective in balancing exploration and exploitation and reducing makespan compared to other approaches.
[17]	Multiple objective task scheduling using grey wolf optimization, prioritizing tasks based on resource status and demand using HPC2N and NASA workload archives.	Makespan and resource allocation efficiency	Achieves significant improvements in scheduling parameters and adapts well to workload variability.
[18]	A novel method merging particle swarm optimization and genetic algorithms using phagocytosis-inspired merging for population diversity with a feedback mechanism.	Task completion time and convergence accuracy	Enhances task completion time and accuracy by guiding population movement toward optimal solutions.
[19]	Hybrid grey wolf optimization and genetic algorithm	Makespan, cost, and energy consumption	Outperforms GWO, GA, and PSO in minimizing makespan, energy use, and cost for large scheduling tasks.
[20]	The chameleon and remora search optimization algorithm integrates CSA and RSOA with a greedy approach focusing on MIPS and network bandwidth.	Makespan, load balancing, and cost	Effectively minimizes completion time and balances VM load, outperforming baseline approaches.
[21]	Uses dense spatial clustering to schedule tasks, aiming to optimize execution time and enhance the quality of service for user tasks.	Execution time, average start time, and completion time	Achieved a 13% reduction in execution time and a 49% improvement in start and completion times over ACO and PSO algorithms.

Abualigah and Alkhrabsheh [15] presented MVO-GA, a hybrid multi-verse optimizer and genetic algorithm to optimize task scheduling. In such a way, this approach enhances task transfer efficiency in a cloud system by investigating various aspects of cloud assets, including bandwidth, virtualization, task counts, and task sizes. The technique has shown promising results in minimizing the time used for massive cloud tasks.

Tanha, et al. [16] developed a combined meta-heuristic algorithm using the thermodynamic simulated annealing and genetic algorithms to resolve the cloud task scheduling issue. The performance of the algorithm is improved by a crossover operator and thermodynamic simulated annealing. In this approach, there is a reasonable equilibrium between exploration and exploitation.

Mangalampalli, et al. [17] suggested the multi-objective task scheduling grey wolf optimization algorithm, MOTSGWO, in which tasks are prioritized based on cloud resource status and workload demand. This approach is implemented in the Cloudsim toolkit with workloads generated from the HPC2N and NASA parallel workload archives. The experiments show the outstanding performance of MOTSGWO.

Fu, et al. [18] created a novel methodology using phagocytosis combined with particle swarm optimization and genetic algorithms. The method divides particles, adjusts their positions, and merges subpopulations for diversity. It uses a feedback mechanism to ensure the population moves towards the optimal solution. Simulations show it enhances cloud task completion time and convergence accuracy.

Behera and Sobhanayak [19] developed an algorithm that combines the Grey Wolf Optimization Algorithm (GWO) and Genetic Algorithm (GA) to improve cloud computing task scheduling. It aims to minimize cost, makespan, and energy usage while leveraging the GA-driven GWO algorithm's accelerated convergence in significant scheduling challenges.

Pabitha, et al. [20] developed a Chameleon and Remora Search Optimization Algorithm (CRSOA) to optimize cloud task scheduling by considering MIPS and network bandwidth. The CRSOA model, a multi-objective model, integrates the strengths of the Chameleon Search Algorithm (CSA) and Remora Search Optimization Algorithm (RSOA) through a greedy strategy. Simulation results showed that the CRSOA approach minimizes completion time and effectively handles load balancing between available VMs. The experimental investigation confirmed its effectiveness in reducing makespan, cost, and imbalance levels over baseline approaches.

Mustapha and Gupta [21] designed an approach based on DBSCAN (Density-Based Spatial Clustering) for task scheduling to ensure optimal effectiveness. DBSCAN-based task scheduling methodology enhances user satisfaction and optimises execution times, average start times, and end times. The experimental results reveal that the suggested model surpasses the current PSO and ACO, demonstrating 15% better execution times and 48% better start and completion times.

III. PROBLEM STATEMENT

The cloud task scheduling problem revolves around efficiently assigning multiple tasks to Virtual Machines (VMs) within a Cloud System (CS) to achieve the shortest possible execution time [22]. An overview of the proposed task scheduling system for a CS is shown in Fig. 1. The task manager component in this system collects tasks from different users. Upon receiving user tasks, the task manager arranges and forwards them to the scheduler component. The task manager also knows the basis for VMs' information. As a result, it supplies the task scheduler component with information about the status of VMs and task requests. In this context, the CS is represented by multiple Physical Machines (PMs), each housing several VMs [23], expressed as follows:

Fig. 1. System model for cloud task scheduling.

$$CS = \{PM_1, PM_2, \dots, PM_i, \dots, PM_m\} \quad (1)$$

Where m reflects the number of PMs in the system, and each PM i comprises a set of VMs as follows:

$$PM = \{VM_1, VM_2, \dots, VM_k, \dots, VM_n\} \quad (2)$$

Where n denotes the number of VMs within a particular PM. Each VM_k is defined by its processing speed $MIPS_k$ (measured in millions of instructions per second) and unique

identifier SID_{VMk} [24]. The tasks to be scheduled in the cloud are detailed as follows:

$$T = \{T_1, T_2, \dots, T_l, \dots, T_z\} \quad (3)$$

Where z stands for the total number of tasks, and each task T_l is described by an identifier SID_{Tl} , its length in terms of instructions (task_length), the expected completion time ECT_l , and priority PI . The expected completion time for a task T_l on VM_k is calculated using Eq. (4) [25].

$$ECT_{lk} = \frac{T \cdot length_l}{MIPS_k} \quad (4)$$

This scheduling problem is, therefore, formulated as an optimization problem. The objective is to distribute tasks across VMs to minimize total execution time, thereby maximizing resource utilization. The objective function to shorten the overall makespan can be expressed as:

$$fit = \min \left(\max_{k=1,2,\dots,n} \sum_{l=1}^z ECT_{lk} \right) \quad (5)$$

This approach aims to balance the load across virtual machines and optimize resource usage within the cloud infrastructure.

IV. METHODOLOGY

A. Butterfly Optimization Algorithm

BOA is a metaheuristic algorithm inspired by butterflies' cooperative foraging behavior. In the BOA, butterflies can find optimal solutions based on a fragrance function, influenced by parameters such as power exponent (a) and sensory modality (c) [26]. This fragrance, which represents the butterfly's fitness, is defined by Eq. (6).

$$f(t) = c \cdot I(t)^a \quad (6)$$

Where $I(t)$ denotes the stimulus intensity at a given step t , controlled by the sensory modality and power exponent. The fragrance emitted by each butterfly attracts others and guides their movement through the solution space.

BOA operates in three primary phases: initialization, iteration, and finalization [27]. During the initialization process, the objective function and the solution area are defined, generating a population of butterflies. Each butterfly's position is set, and fitness and fragrance scores are computed. In the iteration stage, BOA alternates between global and local key search strategies. Based on Eq. (7), each butterfly is guided toward the fittest solution $*$ in the global search.

$$x_i^{t+1} = x_i^t + (r^2 \cdot (g^* - x_i^t)) \cdot f_i \quad (7)$$

Where x_i^t represents the position of the i^{th} butterfly at iteration t , g^* denotes the best current solution, f_i is the fragrance of the i^{th} butterfly, and r is a random number between 0 and 1. In the local search mode, butterflies move based on the influence of nearby individuals. The position update is given by:

$$x_i^{t+1} = x_i^t + (r^2 \cdot (x_j^t - x_k^t)) \cdot f_i \quad (8)$$

Where x_j^t and x_k^t are positions of two randomly selected butterflies in the population. This local interaction allows BOA to explore diverse regions within the solution space.

A switch probability (p) controls the balance between global and local searches, enabling the algorithm to dynamically shift from broad exploration to intense local refinement. This adaptive strategy helps BOA avoid premature convergence and enhances its ability to find optimal solutions effectively, making it suitable for complex optimization tasks such as cloud scheduling.

Generally, BOA involves five steps. The first step is initializing all BOA and problem parameters. BOA has five parameters: population size (N), number of iterations (Itr), c , a , and p . In the second step, the BOA generates all solutions randomly. The solutions take the form of length vectors with the same dimension as the problem dimension d . A matrix containing all the solutions creates the population as follows.

The BOA typically consists of five sequential steps. The initial step involves setting up all BOA-related parameters and problem-specific variables. BOA utilizes five key parameters: population size (N), number of iterations (Itr), and the constants c , a , and p . During the second step, BOA generates all solutions randomly. These solutions are represented as vectors of equal length, corresponding to the dimensionality of the problem (d). The collection of these solution vectors forms a population matrix, structured as follows.

$$Population = \begin{bmatrix} x_1^1 & x_2^1 & \dots & x_d^1 \\ x_1^2 & x_2^2 & \dots & x_d^2 \\ \vdots & \vdots & \dots & \vdots \\ x_1^N & x_2^N & \dots & x_d^N \end{bmatrix} \quad (9)$$

The optimization problem's objective function serves to assess all potential solutions during the third step. Subsequently, the best-performing solution is designated as g^* . In the fourth step, all solutions are revised according to the fitness values determined in the previous phase. To guide the search process locally or globally, a random number r is generated and compared to the threshold p . If r is smaller than p , the butterfly executes a global movement following Equation 7; otherwise, it performs a local movement based on Equation 8. If the newly generated solution outperforms the previous one, it replaces the earlier solution. The value of g^* is then updated accordingly. Finally, the termination condition is evaluated. The pseudo-code outlining the general steps of the BOA is presented in Fig. 2.

Step 1:

Set up the problem-specific parameters.
Initialize BOA parameters, including the maximum iterations Itr , population size N , sensory modality c , power exponent a , and switch probability p .

Step 2:

Create an initial population matrix for butterfly positions.

Step 3:

Begin the main loop: repeat until the maximum number of iterations is reached.

For each solution in the population:

- Calculate its fitness value.
- Identify the current best solution g^* .

Step 4:

For each butterfly in the population:

- Generate a random number r within the range $[0, 1]$.
- If $r < p$:
 - Update the butterfly's position using Eq. 7.
- Otherwise:
 - Update the butterfly's position using Eq. 8.
- If the updated solution improves, update the population with this new solution.
- Adjust the sensory modality c if necessary.

Step 5:

Check if the iteration count has reached the maximum limit:

If not, increment the iteration counter by one and continue the loop.

End the loop when Itr is reached.

Return the best solution g^* found by the algorithm.

Fig. 2. Pseudo-code of BOA.

B. Flower Pollination Algorithm

FPA is a metaheuristic technique designed to solve complex optimization problems mimicking natural pollination. FPA follows the principles of two types of pollination found in nature: local and global pollination. Global pollination promotes exploration, allowing the algorithm to escape local optima, while local pollination emphasizes exploitation, speeding up convergence. The algorithm performs exploration or exploitation for each iteration based on a switching probability p , ensuring optimal solutions are found efficiently.

The algorithm searches for the global most attractive flower for each candidate solution in FPA, representing a flower in a d -dimensional space. This search is carried out to minimize the fitness function and locate the flower with the lowest fitness score, corresponding to the optimal solution. Four main steps are involved in the FPA's operation: initialization, fitness evaluation, pollination process, and selection. At first, the population of flowers F is defined using Eq. (10). Then, each solution X_{ij} within the defined search bounds is initialized using Eq. (11).

$$F = \begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{pmatrix} = \begin{pmatrix} x_{1,1} & \dots & x_{1,d} \\ \vdots & \ddots & \vdots \\ x_{n,1} & \dots & x_{n,d} \end{pmatrix} \quad (10)$$

$$X_{ij} = x_{min} + (x_{max} - x_{min}) \cdot \mu \quad (11)$$

Where μ varies between 0 and 1. Eq. (12) refers to the objective function to evaluate fitness.

$$f(x), \quad X = (x_1, x_2, \dots, x_d) \quad (12)$$

The fitness of each flower is determined, and the current optimal solution g^* is identified, which has the lowest fitness value among all flowers. A random number $rand$ is determined by a uniform distribution between (0,1) for each flower. If $rand > p$, global pollination is accomplished as follows:

$$X_i^{t+1} = X_i^t + L \cdot (X_i^t - g^*) \quad (13)$$

Where L follows a Lévy flight distribution to simulate long-distance pollination, represented as follows:

$$L(\lambda) \sim \frac{\lambda \Gamma(\lambda) \sin(\pi\lambda/2)}{\pi} \cdot \frac{1}{s^{1+\lambda}} \quad (14)$$

With $\lambda=1.5$ and $s>0$ as the step size. If $rand \leq p$, local pollination occurs, and the flower's position is updated based on the positions of two randomly selected solutions as follows:

$$X_i^{t+1} = X_i^t + \epsilon \cdot (X_j^t - X_k^t) \quad (15)$$

Where ϵ comes from the [0,1] range, and X_j and X_k correspond to randomly chosen flowers. Each flower is rounded up to the closest valid position. The new positions are evaluated for fitness and each flower is updated if fitness has improved. The best solution g^* is also updated if a better solution is found.

C. Mutualism-based Hybrid Approach

MHA aims to enhance BOA's exploration and exploitation abilities by combining this algorithm with the FPA. Previous studies, such as BOA/DE and BOA/ABC, have shown that hybridizing BOA with other algorithms can balance exploration

(exploring the solution space broadly) and exploitation (improving solutions locally). However, these approaches still need more diversity, as they can become overly focused on high-performing solutions early on, leading to premature convergence.

The effectiveness of metaheuristic algorithms is determined by their capacity to maintain harmony throughout exploration and exploitation. Exploration refers to the search for solutions across the entire space while exploitation fine-tunes solutions around promising areas. Our approach introduces mutualism, a cooperative interaction between BOA and FPA to address this balance. This interaction allows the two algorithms to complement each other, with BOA providing global search capability and FPA enhancing local search.

MHA divides the population into two subgroups: butterflies and flowers. Each subgroup evolves independently, benefiting from BOA and FPA search properties. Dynamic switching probability is applied to determine when individuals should alternate between global and local searches, adapting based on the current optimization stage.

Mutualism in this context refers to the mutual benefit observed between butterflies and flowers in ecosystems. For instance, butterflies aid in pollination, while flowers provide nectar, benefiting both species. The hybrid algorithm simulates this mutualism using the Symbiotic Organisms Search (SOS) algorithm, which models ecosystem cooperation through mutualism, communalism, and parasitism. The mutualism stage, in particular, facilitates collaboration between two solutions by averaging their traits as follows:

$$Mutual_{agent} = \frac{x_i^t + x_j^t}{2} \quad (16)$$

The positions of the two interacting solutions X_i and X_j are then updated as follows:

$$X_i^{t+1} = X_i^t + rand[0,1] \times (g^* - Mutual_{agent} \times BF1) \quad (17)$$

$$X_j^{t+1} = X_j^t + rand[0,1] \times (g^* - Mutual_{agent} \times BF2) \quad (18)$$

Where g^* represents the most optimal solution in the population, $BF1$ and $BF2$ refer to attraction variables, and $rand[0,1]$ gives a random value to introduce variability. In addition, a dynamic switching probability p regulates the equilibrium between exploration and exploitation, calculated by Eq. (19).

$$p = 0.8 - 0.1 \times \frac{(Max_{iter} - iter)}{Max_{iter}} \quad (19)$$

Where Max_{iter} indicates the total number of iterations and $iter$ denotes the ongoing iteration. This probability decreases over time, favoring exploration early in the search and shifting towards exploitation as the algorithm progresses.

As shown in Fig. 3, through mutualism and adaptive switching, this hybrid strategy effectively incorporates the best features of both BOA and FPA, enhancing the diversity and convergence rate of the solution population. This hybrid method improves task scheduling performance by ensuring a comprehensive search in the solution space and optimizing the allocation of resources in cloud computing.

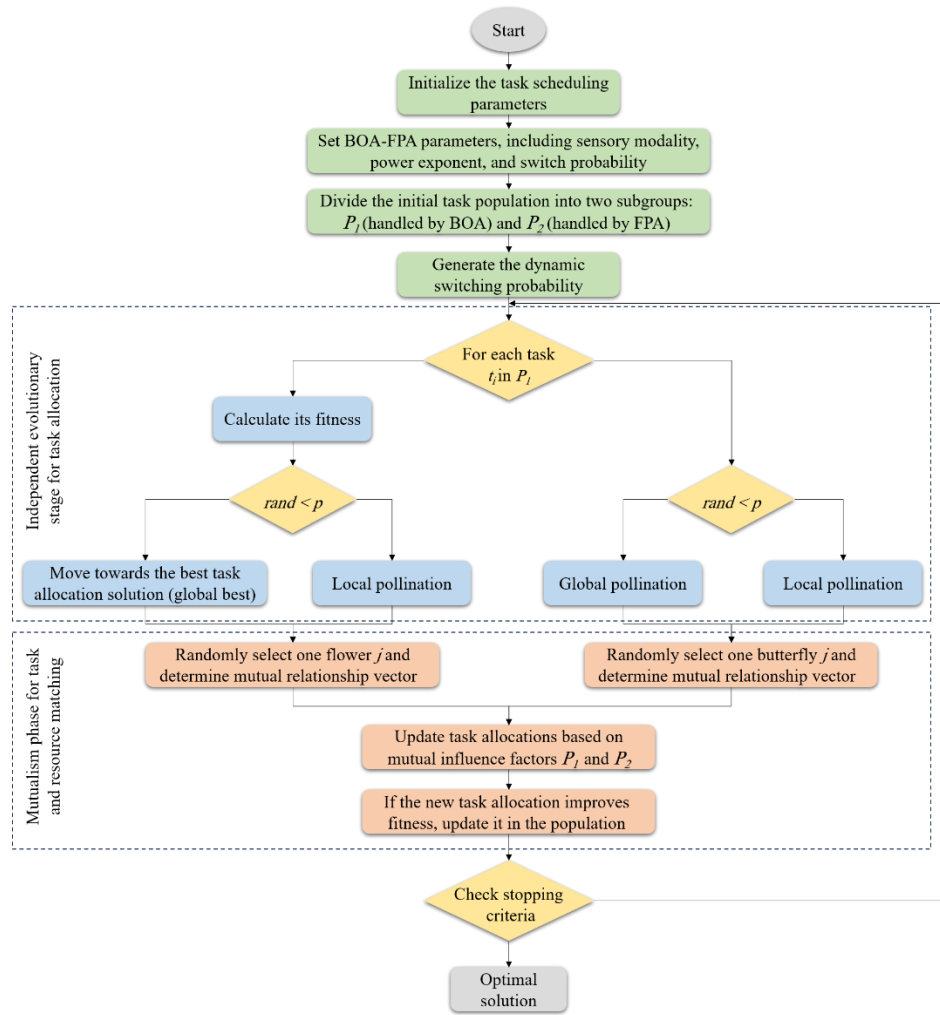

Fig. 3. Flowchart for proposed hybrid algorithm.

V. PERFORMANCE EVALUATION

To assess the performance of the algorithm, MHA, for cloud environments, simulations were performed on a synthetic dataset using MATLAB2018b on a PC powered by an Intel Core i5 3.5GHz CPU and 8GB RAM, running Windows 10. The experimental configuration, including the range of parameter values, is detailed in Table II. MHA was benchmarked against other algorithms, such as the Whale Optimization Algorithm (WOA), BOA, and FBA, using several key metrics: Makespan, Resource Utilization (RU), and imbalance degree.

TABLE II. EXPERIMENTAL CONFIGURATION AND PARAMETER RANGES

Parameter	Value range
Bandwidth	500 Mbps
VM Memory (RAM)	1 GB
VM CPU Speed (MIPS)	3,000 to 5,000
No. of VMs	20
Task Size (Million instructions)	1,000 to 20,000
No. of tasks	100 to 1,000

Makespan, the interval between task starts and endpoints, measures scheduling efficiency. Fig. 4 compares average makespan values across different algorithms. For 100 tasks, MHA achieved an average makespan of approximately 15.2, outperforming comparative algorithms. MHA maintained lower makespan values as task sizes increased to 500 and 1000, with 71.4 and 140.2, respectively. Regarding large-scale cloud scheduling, MHA is significantly better at handling larger task sets. Imbalance degree measures the stability and balance of workload distribution across VMs. A lower value indicates better balance, reducing overload risk. This metric is calculated as follows:

$$ID = \frac{ET_{max} - ET_{min}}{ET_{avg}} \quad (20)$$

Where ET_{min} and ET_{max} are the minimum and maximum execution times across VMs, and ET_{avg} is the average execution time. Fig. 5 shows ID comparisons for different algorithms. For 100 tasks, MHA achieved an imbalance degree of 0.71, lower than other algorithms. This trend of lower imbalance degree persisted as the number of tasks increased, demonstrating MHA's ability to maintain balanced workloads

across VMs. RU measures the extent of VM utilization during task scheduling and is given by:

$$RU = \frac{\sum_{j=1}^n ET_j}{\text{makespan} \times m} \quad (21)$$

Where ET_j refers to the execution time of each VM and m represents the number of VMs. Fig. 6 illustrates that MHA achieved the highest RU values, indicating better resource usage.

Fig. 4. Makespan results.

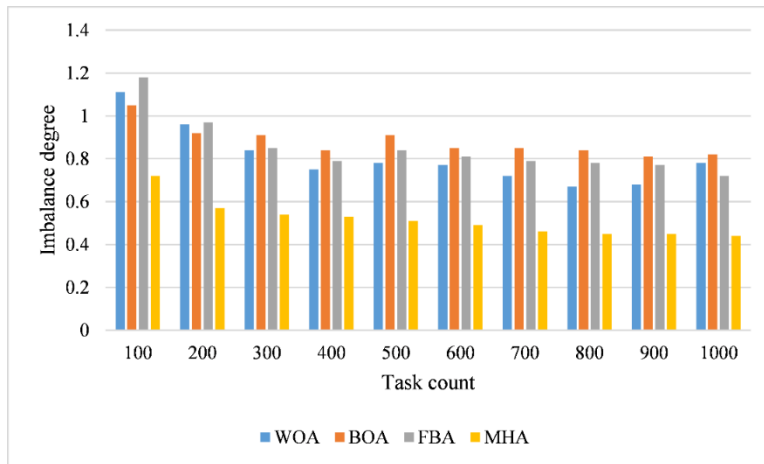

Fig. 5. Imbalance degree results.

Fig. 6. Resource utilization results.

VI. DISCUSSION

The proposed hybrid algorithm significantly enhanced the challenge of cloud-based task scheduling. This section presents the implications of the results, the strengths of the proposed approach, and future avenues.

The hybridization of BOA and FPA through a mutualism-inspired mechanism addresses the individual limitations of each algorithm. BOA's tendency to converge prematurely is mitigated by FPA's enhanced diversity in exploration, while FPA's limited exploitation capabilities are bolstered by BOA's local search strengths. The introduction of an adaptive switching probability further enhances the balance between exploration and exploitation, allowing the algorithm to dynamically adjust its search strategy based on the progress of the optimization process. This innovative mechanism ensures robust performance, reducing the likelihood of stagnation in local optima and improving convergence speed.

Experimental results showed that the proposed hybrid algorithm achieved much better performance when compared to the benchmark methods on important metrics in this area, namely, makespan, resource utilization, and load balancing. Significance statistical tests are carried out that further establish the proposed algorithm's efficiency in handling diversified and dynamic challenges of task scheduling problems in cloud environments. The algorithm was found to work well with increased loads and much better performance according to scalability tests, hence its applicability to real-world applications.

The ability of the hybrid algorithm to optimize task scheduling has great implications for cloud computing environments. It can reduce operational costs, improve user satisfaction, and enhance system performance by efficiently allocating resources. Besides, it is a promising solution due to its adaptability and scalability in heterogeneous and dynamic cloud infrastructures.

Although the proposed algorithm outperforms the other methods by a great margin, some limitations must be conceded. Its performance is related to some parameters that might be fine-tuned in some situations. Therefore, Future work could address the proposition of automatic parameter-tuning mechanisms to make them more usable. Future work might also explore the effectiveness of the proposed hybrid approach for other optimization problems, such as load balancing in a distributed system or energy-aware scheduling.

VII. CONCLUSION

The paper proposed a new hybrid task scheduling algorithm called MHA, which combines BOA and FPA within a mutualism-based mechanism. MHA can effectively meet the most important challenges during Cloud platforms for effective task scheduling, such as minimizing makespan, maintaining workload balance across virtual machines, maximizing resource utilization, and improving overall scheduling performance. It achieves an excellent balance between exploration and exploitation through effective exploitation of BOA and FPA, with a guaranteed optimal distribution while the scheduling tasks continue to increase in scale and complexity. As reported from simulations, results show the outperformance

of the MHA compared to traditional algorithms, proven by comparisons, which always have the best makespan with reduced imbalance degree and resource utilization. More specifically, the rate of performance improvement proves that MHA has considerably improved scheduling efficiency.

The adaptive dynamic switching probability in MHA enables the algorithm to scale up efficiently for large task sizes, presenting a robust approach for real-world cloud computing environments where dynamic and efficient task allocation is paramount. These results reflect that MHA can solve the current cloud scheduling requirements and provide a base for further enhancements in resource allocation strategies. Future research will be done on further hybridization with other metaheuristic algorithms, deep learning usage in the process for predictive scheduling, or even extending MHA to multi-objective optimization frameworks. These will eventually enhance scalability, adaptability, and efficiency in task scheduling in complex cloud computing scenarios.

Task Scheduling in Fog Computing-Powered Internet of Things Networks: A Review on Recent Techniques, Classification, and Upcoming Trends

Dongge TIAN

Department of Information Engineering, Hebei Chemical & Pharmaceutical College, Shijiazhuang 050000, China

Abstract—The Internet of Things (IoT) phenomenon influences daily activities by transforming physical equipment into smart objects. The IoT has achieved a wealth of technological innovations that were previously unimaginable. IoT application areas cover various sectors, including medical care, home automation, smart grids, and industrial operations. The massive growth of IoT applications causes network congestion because of the large volume of IoT tasks pushed to the cloud. Fog computing mitigates these transfers by placing resources near the edge. However, new challenges arise, such as limited computing power, high complexity, and the distributed characteristics of fog devices, negatively affecting the Quality of Service (QoS). Much research has been conducted to address these challenges in designing QoS-aware task scheduling optimization techniques. This paper comprehensively reviews task scheduling techniques in fog computing-powered IoT networks. We classify these techniques into heuristic-based, metaheuristic-based, and machine learning-based algorithms, evaluating their objectives, advantages, weaknesses, and performance metrics. Additionally, we highlight research gaps and propose actionable recommendations to address emerging challenges. Our findings offer a structured framework for researchers and practitioners to develop efficient, QoS-aware task scheduling solutions in fog computing environments.

Keywords—Internet of Things; task scheduling; fog computing; quality of service; network congestion; optimization

I. INTRODUCTION

The Internet of Things (IoT) phenomenon has changed the real world into a smart environment by turning everyday objects into smart objects/agents. This is accomplished by integrating sensors or microchips into these devices, along with internet connectivity [1]. These smart objects can independently interact and collect data, performing assigned duties [2]. The IoT is perceived as the upcoming model for ubiquitous computing and communication in the current technological environment. This ever-evolving environment is a network of billions of diverse, smart, connected devices that can revolutionize applications [3]. The applications of IoT range from individual home automation (smart homes) to overall city management (smart cities) [4]. It encompasses a variety of applications, including tracking high-precision agriculture and large-scale agricultural operations [5], monitoring individual building energy usage [6], and analyzing intelligent power grids [7].

The IoT also affects healthcare, providing personalized services for patients and the general public [8]. In addition, it

also drives automation in industries and provides business information [9]. Moreover, IoT applications exist in weather forecasting and monitoring tools locally and remotely [10]. Cloud, fog, and edge technologies enable deploying distributed data processing solutions essential for the IoT paradigm [11].

Fog computing is a variation of cloud computing that distributes data across several geographical regions [12]. It positions the processing and communication resources closer to the network boundary, where several fog hubs are located. Proximity to end-users and IoT devices enhances performance and responsiveness [13]. Many applications are limited by cloud-centric architectures, particularly those demanding real-time performance within smart cities and buildings [14]. In such conditions, most data require processing, analysis, and storage on remote cloud servers. This dependency on remote resources may have detrimental effects on response time, privacy, elasticity, and system integrity [15].

The emergence of delay-sensitive and location-aware applications similarly reveals the weaknesses of cloud-based approaches, which often fail to meet their demands for high efficiency and low latency [16]. The presence of fog layers near IoT objects within a smart city environment decreases latency. This feature enables fog computing to meet demanding latency criteria effectively. Fog computing functions as a supplementary layer to the cloud, allowing advanced applications and services to be created and implemented [17].

Integrating IoT, fog, and cloud computing paradigms requires efficient task scheduling techniques. While these intricate and vast ecosystems emerge, it becomes essential to improve the entire tone of the environment, reduce delays, and efficiently utilize resources. Task scheduling solutions are required to control and allocate computational processes in clouds and other processing nodes, such as edges and IoT gadgets. As the demand for such environments increases, developing innovative and highly effective task scheduling initiatives to improve the performance and efficiency of IoT, fog, and cloud-based systems becomes crucial. To tackle this challenge, the current research adopts a multifaceted approach. The main contributions of this paper are as follows:

- We offer a detailed classification of task scheduling algorithms based on their impact on Quality of Service (QoS) for both users and fog service providers, providing a clear framework for understanding various approaches.

- Our study includes an extensive review of existing research, evaluating objectives, advantages, weaknesses, performance metrics, computing environments, and future work, thus providing a holistic view of the field.
- We identify current research gaps in the area of QoS-aware task scheduling in fog computing, offering a clear direction for future studies to address these gaps and advance the field.
- We provide explicit and actionable recommendations for future research based on identified trends and gaps, guiding scholars and practitioners in their efforts to develop more effective and efficient task scheduling algorithms.

Various performance metrics evaluate task-scheduling techniques, resulting in optimal resource utilization and efficient system performance. The most important factors are makespan, representing the total time taken to execute tasks; energy consumption, evaluating the power efficiency of the system; throughput, measuring how many tasks can be efficiently processed within a certain amount of time; reliability, guaranteeing no failure during the execution of a task; and latency, reflecting the reflection of delay time during the processing of tasks. These metrics are important in developing the effectiveness of task-scheduling approaches for IoT networks powered by fog computing and serve as a basis for our evaluation and classification in the study.

This investigation will reveal emerging research issues and future research prospects. To ensure this methodology remains coherent and specific, the following questions serve as a guideline for this research.

- What are the key performance metrics used to assess different task scheduling techniques?
- What are the recent trends and potential prospects in research on task scheduling for fog computing?
- What approaches and parameters can be used to tune fog computing task scheduling algorithms to achieve optimal resource utilization, throughput, and reliability without compromising energy consumption, makespan, and delay?

The remaining sections are organized in the following manner. Section II presents the basic insights on the effect of the IoT and a brief introduction to fog computing. Section III presents the classification of task scheduling techniques, including heuristic-based, metaheuristic-based, and machine learning-based algorithms. Section IV summarizes results from previous studies and their implications. Section V discusses potential future research for bridging identified gaps. Finally, Section VI concludes with actionable recommendations to further advance task scheduling for fog computing.

II. BACKGROUND

A. IoT and its Impact

Numerous components, such as sensors, actuators, smartphones, and intelligent vehicles, are equipped with unique

identities in IoT environments [18]. IoT optimizes daily activities by utilizing data to facilitate remote access control and configuration via cloud-based platforms. However, the increasing number of IoT devices poses a challenge: effective load balancing across these devices is essential to ensure optimal network performance [19]. This task is complicated primarily due to changing traffic patterns and the lack of a centralized network structure. Therefore, non-optimal load balancing is a major concern, which has motivated researchers to develop IoT load balancing and routing solutions.

The rapid proliferation of gadgets in modern networks and infrastructures has created a highly complex digital world. These systems create content having various packet sizes, inter-packet arrival intervals, and transmission lengths [20]. Therefore, managing and controlling traffic have emerged as significant concerns in many areas, such as healthcare, data centers, big data, smart cities, and other fields. Different communication protocols have been adopted to accommodate these diverse networks. Nevertheless, the lack of defined data formats and protocols poses a major obstacle to traffic control in traditional IoT architectures. The absence of consistency in communication protocols used by different IoT devices impedes the comprehensive analysis of data gathered from several sources [21].

The main responsibilities involve coordinating data transfer, ensuring it is timely, and optimizing network utilization while reducing bottlenecks, delays, and inefficiencies. Traffic management extends beyond particular settings and includes intelligent healthcare systems, urban environments, big data applications, and numerous other areas. Urban settings and smart healthcare utilize networked sensors and gadgets to acquire and collect relevant information. Therefore, it is necessary to deploy smart traffic control strategies to satisfy QoS criteria for these diverse technologies. To effectively control traffic flows in healthcare and automated transportation systems while also considering environmental sustainability, it is necessary to build complex algorithms and real-time data analytics to handle mobile IoT devices.

The IoT grows through the interconnectedness of numerous devices and sensors, resulting in ever-increasing data communication. The large amount of data might cause network congestion, especially in wireless networks with a natural tendency to encounter transmission obstacles [22]. Congestion in an IoT environment arises when the quantities of transmitted data are larger than the capacities of available transmission resources. This phenomenon has significant implications for load balancing routing protocols. There are two main forms of congestion: link-level and node-level.

At the link level, congestion can be defined as the arrival rate of the packets is more than the rate at which the packets are served, resulting in buffer overflow. This scenario is similar to one in which the amount of water pouring in exceeds the drainage system capacity [23]. On the other hand, node-level congestion happens when many active sensor nodes transmit packets simultaneously on the same channel, causing interference and preventing successful transmission [24].

The limited energy resources of devices present a substantial obstacle to implementing IoT networks. Energy-

conscious routing protocols must confront complex issues associated with energy usage during sensing, data transmission, and receiving [25]. Data aggregation techniques can help reduce transmissions, but establishing the best level of aggregation is a complex operation that requires efficient solutions to maximize network device lifespan [26]. The natural diversity of IoT devices causes energy usage problems. These gadgets demonstrate notable disparities in computing power, energy profiles, and connectivity capabilities. Integrating these varied attributes into routing decisions is a considerable obstacle.

B. Introduction to Fog Computing

IoT deployment benefits from cloud computing in terms of computation, storage resources, and QoS constraints. It involves moving data to other servers at data centers, which is processed and returned to the end user [27]. Cloud computing also provides centralized virtual servers for data processing, storage, and analysis. These services are available on demand and are categorized as Software as a Service (SaaS), Platform as a Service (PaaS), and Infrastructure as a Service (IaaS).

Nevertheless, IoT and the cloud components exchange more tasks and data, affecting the overall response time and resulting in network latency. The substantial physical separation between cloud-based IoT devices causes security problems. These delays can have severe consequences, especially in extremely sensitive tasks, such as real-time health monitoring, posing a danger to patients. Therefore, architectural plans are shifting from centralized data centers to distributed computing devices at the edge of the network. The decentralized nature of this mechanism also aims to eliminate the mentioned delays and security concerns.

Researchers have recently focused on investigating fog computing, a novel paradigm bridging the gap between IoT platforms and cloud computing. Fog computing leverages a decentralized architecture to reduce task transmission delays while upholding QoS requirements. Thus, this approach has developed into a sensible strategy for time-constrained operations within the IoT context. Unlike cloud computing, which relies on centralized servers to perform computations and relay outcomes to IoT devices, fog computing distributes these processes to fog nodes close to IoT devices to reduce latencies and enable increased response times in IoT applications.

The proximity of fog nodes to IoT devices provides further advantages, such as reduced total delay and increased protection of transmitted information. However, the resource limitations of fog devices necessitate offloading computationally intensive workloads to the cloud. Fig. 1 illustrates the overall structure, depicting the placement of IoT and edge devices with varying computational capabilities, cloud computing, and fog layers.

The goal of fog computing is to bring storage, transmission, and computing services closer to the network's edge. The proximity of the data center facilitates efficient data processing, low delays, and minimal bandwidth consumption. Fog devices, conversely, are characterized by lower processing, storage, and bandwidth capabilities due to their compact size. It is, therefore, important that all these constraints are considered when

scheduling tasks to have an effective scheduling strategy. This problem is defined as non-deterministic polynomial-time hard (NP-hard) due to the optimization of the problem with many parameters, including energy consumption, task deadlines, cost, makespan, and response time. This designation indicates that finding the optimal solution becomes computationally intractable as the problem grows.

Certain constraints are crucial for both end-users and system designers. For instance, task deadlines represent a critical QoS parameter for end-users, while energy usage of fog nodes is a QoS requirement of concern for the fog service provider. Consequently, assigning IoT tasks to fog nodes and the cloud necessitates careful consideration of these diverse constraints.

III. CLASSIFICATION OF TASK SCHEDULING TECHNIQUES

This research adopts a systematic review approach to analyzing and classifying various task scheduling techniques in IoT networks powered by fog computing. Related literature concerning task scheduling and QoS improvements was searched from reputable databases such as IEEE Xplore, Springer, and Elsevier. Techniques identified were further classified into heuristic-based, metaheuristic-based, and machine learning-based approaches and assessed based on the key performance metrics of latency, energy consumption, throughput, and reliability. Critical reviews have been done regarding the objectives, advantages, and limitations of each technique. Research gaps were identified, with recommendations for improvement also given for actionable purposes.

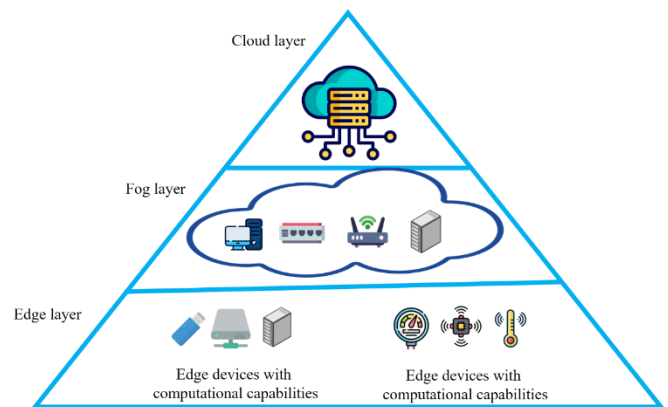

Fig. 1. IoT, edge, fog computing, and cloud computing architecture.

A. Heuristic-based Algorithms

As summarized in Table I, heuristic-based algorithms offer approximate solutions for computationally complex task scheduling problems within fog computing environments. These algorithms are specifically designed to efficiently manage the dynamic and heterogeneous characteristics inherent to fog environments.

Krivic, et al. [28] established the classification of IoT services, a crucial factor that directly influences scheduling algorithms. In addition, they introduced an innovative scheduling method that considers service context, user context, and processing devices. This approach allows for the efficient calculation of the most efficient schedule for executing service

components in a distributed fog-to-cloud context. The effectiveness of the suggested algorithm was confirmed by simulations, in which its distinguishing innovation and dynamic scheduling were particularly highlighted.

Aburukba, et al. [29] formulated scheduling IoT service queries as an optimization problem to shorten the total service request latency. They employed integer programming to model the problem; however, due to its NP-hard nature, this approach becomes impractical for large-scale scenarios. To solve this problem, they combined an individualized version of the Genetic Algorithm (GA) as an efficient heuristic for scheduling IoT tasks, considering holistic latency optimization. They evaluated the performance of the designed GA using an evolutionary simulation model, which reflects the inherent dynamism of real IoT environments.

Ibrahim, et al. [30] introduce a load-balanced and delay-aware scheduling model for fog computing environments, particularly for critical IoT applications. The developed mechanism prioritizes minimizing task execution delays and maximizing task acceptance rates. Furthermore, the mechanism is designed to output an optimal outcome by ensuring uniform and minimal load imbalances to fog resources to improve resource utilization and lower the average response time.

Wireless Sensor Networks (WSNs) generate many tasks with varying priorities and durations in healthcare monitoring,

transmitting them concurrently to fog computing platforms. This necessitates the implementation of an effective task scheduling algorithm capable of accurately prioritizing tasks according to their priority, regardless of their duration. Aladwani [31] introduced the Tasks Classification and Virtual Machines Categorization (TCVC) approach to improve the performance of static task scheduling algorithms. It classifies tasks by importance to patient health. The new method divides incoming IoT tasks into three levels of importance: high, average, and low.

Effective resource management is paramount for achieving optimal system performance, particularly concerning latency, within fog-cloud computing environments. Resource planning in such environments presents a computationally complex problem, classified as NP-hard. Khezri, et al. [32] investigated the optimization challenges associated with scheduling data-intensive jobs within fog-cloud based IoT systems, specifically focusing on maximizing job longevity. The proposed method starts by formulating the problem into an Integer Linear Programming (ILP) optimization scheme. Subsequently, a heuristic algorithm, Data-Locality Aware Job Scheduling in Fog-Cloud (DLJSF), is designed. Performance evaluations demonstrated that the proposed DLJSF algorithm achieves results closely approximating those obtained through the ILP model, with an average deviation of only 13.

TABLE I. SUMMARY OF HEURISTIC-BASED ALGORITHMS

Reference	Approach	Advantage	Disadvantage
[28]	Dynamic scheduling algorithm considering processing devices, user context, and service context	Significant increase in performance efficiency; adaptability to time-varying network conditions and QoS parameter changes	Complexity in implementation due to the need for constant monitoring and adjustments to QoS parameters
[29]	Individualized genetic algorithm for minimizing overall service request latency	Reduced overall latency	The genetic algorithm might be computationally expensive for large-scale scenarios
[30]	Load balancing mechanism prioritizing task execution delays and task acceptance rate	Improved resource utilization and lower average response time	Potential overhead in managing load balancing and ensuring task acceptance rates
[31]	Tasks classification and virtual machines categorization using the MAX-MIN scheduling algorithm	Improved performance in algorithm complexity, resource availability, execution time, waiting time, and finish time	The static nature of the approach might not handle highly dynamic environments effectively
[32]	Data-locality aware task scheduling in fog-cloud derived from an ILP optimization model	Results closely approximate the ILP model with a 13% average deviation; outperforms local processing by 99.16%	The ILP-based model might be complex, computationally intensive, and requires effective data locality awareness.
[33]	Priority-Aware Semi-Greedy (PSG) and PSG with Multistart (PSG-M) procedures	High performance on makespan, deadline violation time, energy consumption, and deadline compliance	Balancing multiple objectives (energy usage and QoS) can be challenging and may require fine-tuning for different scenarios
[34]	Heuristic for dynamic resource scheduling and allocation of real-time IoT workflows	Superior performance compared to static provisioning; real-time data awareness	Complexity in implementing dynamic resource provisioning and maintaining real-time data awareness.

Azizi, et al. [33] explored the issue of task scheduling in fog computing to find a compromise between reducing energy consumption in fog points and maintaining the QoS standards for IoT operations. They mathematically model the problem of optimizing these conflicting criteria as a multi-objective optimization problem. They also focused on minimizing deadline violation time in their approach, which they handled by proposing two new semi-greedy based algorithms: Priority-Aware Semi-Greedy (PSG) algorithm and a PSG with Multistart (PSG-M) procedure.

Stavrinides and Karatza [34] proposed a dynamic resource provisioning mechanism for cloud resources within a three-layer IoT-fog-cloud framework. This approach prioritizes real-time data awareness and dynamic scaling to optimize resource allocation. Additionally, they introduced a heuristic for scheduling instant IoT tasks. The efficacy of the suggested scheme was measured through experiments that compared its performance against a static provisioning strategy. These simulations employed various workload patterns to assess the impact on the framework's performance under different provisioning scenarios.

B. Metaheuristic-based Algorithms

Building upon heuristic approaches, metaheuristic-based algorithms leverage advanced strategies to efficiently explore and exploit the search space. These algorithms strive to identify near-optimal solutions while exhibiting improved convergence rates, as shown in Table II.

Abdel-Basset, et al. [35] introduced an energy-conscious task scheduling method for fog environments based on the Harris Hawks Optimization (HHO) algorithm integrated with Local Search, called HHOLS. HHOLS optimizes the QoS in IoT applications by focusing on energy efficiency. Their work commences with a detailed description of the highly virtualized layered fog computing model, emphasizing its heterogeneous architectural characteristics. To address the non-linear character of the task scheduling problem, they incorporated a scaling and normalization stage to adapt the standard Harris Hawks optimization algorithm.

Service execution plays a vital role in IoT networks, which is also an important problem in scheduling services in fog

computing. Consequently, fog infrastructure provides the execution environment for devices with limited computational capability. A fog environment comprises many fog nodes that can be some-edge servers, cloudlets, small-size ISPs, and caching nodes offering user-requested services. Najafizadeh, et al. [36] offered a privacy-preserving task scheduling architecture for IoT systems based on service execution to overcome these problems. In this design, a multi-objective algorithm is proposed to lower both service cost and execution time simultaneously.

Abd Elaziz, et al. [37] suggested AEOSSA, an alternative task scheduling approach for managing IoT tasks within a cloud-fog computing context. This approach builds upon a modified Artificial Ecosystem-Based Optimization (AEO) algorithm. The modified algorithm incorporates operators derived from the Salp Swarm Algorithm (SSA) to augment the exploitation capabilities of AEO in the search for optimum results for the task scheduling problem. An evaluation of AEOSSA is performed on some synthetic and real datasets that include a variety of computation sizes.

TABLE II. SUMMARY OF METAHEURISTIC-BASED ALGORITHMS

Reference	Approach	Advantage	Disadvantage
[35]	Harris hawks optimization with local search	Optimizes QoS in IoT applications focusing on energy efficiency	Complexity due to normalization, scaling, and local search phases
[36]	Multi-objective algorithm for privacy-preserving task scheduling	Minimizes service execution time and cost; maintains the privacy of IoT devices; performs well across different service composition complexities	Higher computational overhead due to multi-objective optimization
[37]	Modified artificial ecosystem-based optimization with salp swarm algorithm	Superior performance in makespan and throughput; effective for synthetic and real datasets	Potentially higher resource consumption due to extensive exploitation capabilities
[38]	Energy-aware model with arithmetic optimization algorithm and marine predators algorithm	Significant reductions in energy consumption and makespan	Increased complexity and potential for higher computational cost
[39]	Multi-cloud to multi-fog architecture with dynamic threshold strategy	Decreases service latency and increases fog node efficiency; achieves energy balance	Complexity in implementation and real-time dynamic scheduling
[40]	CHMPAD algorithm combining marine predators algorithm and disruption operator	Prevents local optimization; improves exploitation properties; significant reductions in makespan and throughput	Increased complexity and resource demands
[41]	Two-tiered approach with PSO and particle swarm genetic joint optimization artificial bee colony	Optimal load balancing and task scheduling; lower delay and energy consumption	Higher computational complexity due to multi-tiered strategy
[42]	Multi-tiered scheduling framework with Naïve Bayes classifier	Effective task classification and placement; enhances QoS parameters	Requires precise training data for classifier accuracy
[43]	Directed non-dominated sorting genetic algorithm	Minimizes energy consumption and response times; balances exploration and exploitation	Potential for higher computational overhead
[44]	Hunger games search with marine predators algorithm	Reduces energy consumption and makespan; effective for various workload traces	Complexity in algorithm integration and evaluation
[45]	Multi-objective gravitational search algorithm with star-quake operator	Reduces makespan, energy consumption, and cost; prevents local optima	Increased computational complexity and resource demands
[46]	Various algorithms, including machine learning and nature-inspired metaheuristics	Optimizes resource allocation, minimizes energy consumption and latency, and meets deadlines; consistent performance improvements	Varied complexity depending on the specific algorithm used

Abd Elaziz, et al. [38] overcame the task scheduling issue in fog computing by proposing an energy-aware model using a variant of the Arithmetic Optimization Algorithm (AOA) known as AOAM. Optimizing the makespan metric, they ensured that user QoS was the top priority. The authors integrated search operators inspired by the Marine Predators Algorithm (MPA) to overcome the limitations of the traditional

AOA. This modification encourages a wider range of solutions and avoids becoming stuck in suboptimal solutions. The efficacy of the proposed AOAM was validated through simulations that employed various parameters.

Luo, et al. [39] have suggested a unique multi-cloud to multi-fog model that involves two service models with

containerization technology, aiming to optimize fog resource usage and control service latency. On the other hand, the task scheduling algorithm provided in their proposal is particularly suitable for achieving an energy balance. Additionally, the algorithm takes the terminal device transmission energy requirements into account. It applies a flexible threshold algorithm to achieve real-time request scheduling while ensuring an energy balance state of the terminal device, thereby effectively avoiding transmission delays.

Attiya, et al. [40] presented a novel fog computing application-aware task scheduling algorithm called CHMPAD. It overcomes existing issues with the Chimp Optimization Algorithm by combining two key components of different algorithms: the Marine Predators Algorithm and a disruption operator. CHMPAD aims to prevent local optimization and improve the exploitation properties of the base ChOA algorithm. The applicability and effectiveness of CHMPAD are evaluated through extensive experiments performed on synthetic and real-world workloads.

Liu, et al. [41] developed a novel resource scheduling strategy for fog computing environments. This two-tiered approach optimizes load balancing and task scheduling to decrease energy consumption and execution time. The first tier leverages the Particle Swarm Optimization (PSO) algorithm for balancing loads within a fog cluster. This optimization seeks to identify the ideal distribution of tasks across fog nodes, minimizing computation time and energy usage. Building upon this foundation, the authors propose a novel Particle Swarm Genetic Joint Optimization Artificial Bee Colony (PGABC) algorithm. PGABC tackles the challenge of task scheduling across multiple fog clusters, utilizing the time and energy consumption data obtained from the initial load balancing phase.

Kaur, et al. [42] proposed a multi-tiered scheduling framework for managing IoT application tasks. This framework prioritizes QoS parameters to achieve optimal task placement. The framework operates on two levels: fog environment and fog node selection. The specific fog environment in which the task will be executed is set at the first level. Several factors, such as availability, physical distance, latency, and throughput, are used to choose an environment. After choosing the fog environment, a particular fog node is selected for analysis. They implemented a Naïve Bayes classifier to classify the task category (Compute-intensive, Memory-intensive, or GPU-intensive) based on the probability triad (C, M, G).

Mousavi, et al. [43] formulated a constrained bi-objective optimization problem for task scheduling in fog computing environments. This formulation aims to achieve two critical goals simultaneously: minimizing server energy consumption and reducing overall response times. To address this challenge, the authors proposed a novel Directed Non-dominated Sorting Genetic Algorithm (D-NSGA-II). This algorithm builds upon the foundation of NSGA-II, a well-established multi-objective optimization technique. The key innovation lies in the introduction of a new recombination operator. This operator empowers D-NSGA-II to regulate the selection pressure exerted on candidate solutions, thereby striking a balance

between the algorithm's exploration and exploitation capabilities.

Attiya, et al. [44] proposed a novel task scheduling algorithm, HGSMMPA, specifically designed for cloud-fog computing environments within the IoT domain. Their approach leverages the Hunger Games Search (HGS) algorithm as a foundation. The authors incorporated elements from the MPA to enhance the exploitation capabilities inherent in HGS. The efficacy of HGSMMPA was validated through experimental evaluations that employed various workload traces, both synthetic and real-world. The results convincingly demonstrate the superiority of HGSMMPA compared to existing scheduling algorithms.

Ahmadabadi, et al. [45] introduced a novel multi-objective task scheduling approach for fog-cloud computing systems. Their approach addresses three critical objectives simultaneously: minimizing monetary cost, energy consumption, and makespan. To achieve these goals, the authors proposed a new multi-objective function that incorporates all three objectives. Furthermore, they introduced a novel operator called star-quake, specifically designed for the Multi-Objective Gravitational Search Algorithm (MOGSA). This operator balances the algorithm's capabilities, such as selection pressure, exploration, and exploitation.

Alsamarai, et al. [46] have significantly improved task scheduling in fog-cloud computing environments for IoT applications. Their proposed algorithms address various challenges, including optimizing resource allocation (e.g., CHMPAD, DLJSF), minimizing energy consumption and latency (e.g., PGABC, Quality-aware Energy Efficient Scheduling), and meeting task deadlines (e.g., Bandwidth-Deadline Algorithm). They leverage a variety of techniques, including machine learning (PSO, ANN), heuristic approaches (genetic algorithms), and nature-inspired metaheuristics (Gravitational Search Algorithm, Ant Colony Optimization) to achieve these improvements.

C. Machine Learning-based Algorithms

Machine learning-based algorithms exploit historical data and learning models to predict near-optimal scheduling decisions [47]. Techniques such as reinforcement learning and neural networks have demonstrated significant potential in adapting to the dynamic characteristics of fog computing environments [48], as shown in Table III.

Bhatia, et al. [49] proposed a novel quantized approach for scheduling heterogeneous tasks within fog computing applications. The approach is built on a node-specific metric, the Node Computing Index (NCI), used to measure individual fog nodes' computational capability. They also proposed a QCI-Neural Network Model that forecasts the best available fog node for real-time execution of heterogeneous tasks. To validate the proposed approach, the authors conducted simulations in different scenarios.

Ali, et al. [50] tackled enhancing the overall efficiency of executing tasks for IoT applications. Their methodology revolves around selecting real-time jobs well-suited for execution at the fog layer. A fuzzy logic-based task scheduling algorithm is modeled for a fog-cloud computing environment.

This algorithm offers a smart scheme of allocating submitted tasks to the processing units within the fog layer. Heterogeneous resources can be found in fog.

Lim [51] addressed the low latency task execution in small-scale fog computing deployments. Their approach is based on a novel task scheduling strategy using partitioned Artificial Neural Networks (ANNs). Such partition allows parallel learning and hyperparameter optimization across different edge servers. This parallelism significantly reduces scheduling times and contributes to achieving desired service level objectives.

Aburukba, et al. [52] proposed a task scheduling solution for a three-tier fog computing architecture. This approach prioritizes maximizing the number of requests that meet their deadline requirements. To achieve this goal, the authors introduce an optimization model formulated using Mixed Integer Programming (MIP). This model aims to minimize the number of missed deadlines. The efficacy of the model was validated using an exact solution technique. However, the authors acknowledge that the task scheduling problem is NP-hard, rendering exact solutions impractical for typical fog computing environments due to problem size.

TABLE III. SUMMARY OF MACHINE LEARNING-BASED ALGORITHMS

Reference	Approach	Advantage	Disadvantage
[49]	Node computing index and QCI-neural network model	Significantly improved performance in execution delay, sensitivity, and precision; suitable for heterogeneous tasks	High computational complexity may require substantial training data.
[50]	Fuzzy logic-based task scheduling algorithm	Outperformed existing algorithms in task success ratio, makespan, average turnaround time, and delay rate; efficient for heterogeneous resources	Potential complexity in defining fuzzy rules may not scale well with large task sets.
[51]	Partitioned artificial neural network	Reduced scheduling times, maintained low energy consumption, achieved desired service level objectives	Limited scalability to larger fog computing environments, potential overhead in partitioning.
[52]	Mixed Integer Programming and genetic algorithm	Significant reduction in missed deadlines, effective for NP-hard scheduling problems; superior performance compared to round-robin and priority scheduling	The exact solution technique is impractical for large problem sizes, and the heuristic approach may not always find the global optimum.
[53]	Statistical techniques (moving averages, Heikin-Ashi patterns)	Enhanced precision in scheduling times, optimized task allocation across edge and fog nodes	The applicability of financial patterns to computing tasks may not be universally effective, and there is potential for increased computational overhead.
[54]	K-Means clustering and fuzzy logic	Accurate identification of groups, adapts to changing task distributions, improved execution time, response time, and network usage	Complexity in implementation and potential high computational overhead in large-scale dynamic environments
[55]	Distributed deep reinforcement learning with asynchronous proximal policy optimization	Fast convergence rate, high flexibility, upgradeability, and better time complexity in execution	Greedy nature of existing techniques and complexity in managing distributed experience trajectories
[56]	A2C-DRL based real-time task scheduling for edge-cloud environments	Simultaneous learning at multiple servers, flexibility with assignable hyperparameters, and superior load balancing	Complexity in defining reward functions and update policies
[57]	DRL-based algorithm for scheduling IoT applications	Adaptive response time, load balancing, significant cost reduction in execution and load balancing	Initial training phase might be resource-intensive, complexity in implementation on different platforms

The rapid rise in bandwidth requirements and computational load of the IoT has created opportunities for fog computing. However, maintaining the QoS of the data transfer process at an efficient cost in fog-based IoT networks remains a significant challenge. Potu, et al. [53] propose a novel scheduling algorithm that optimizes task allocation across edge and fog nodes. The proposed model integrates various statistical techniques, including moving averages and Heikin-Ashi patterns frequently employed in financial markets to visualize trends.

The basic scheduling strategies designed for special global cloud model do not really cope with static nature, heterogeneity, and resource constraints of the fog nodes. Sheikh, et al. [54] have addressed these limitations through the development of a new machine learning based approach that is aimed at dynamically allocating tasks in respect of the evolving status in the fog environment. Their approach builds on basics of K-Means clustering algorithm substantiated by fuzzy logic,

which can be considered an example of an unsupervised learning. Overall, this approach economically categorizes fog nodes based on resource and workload distribution. The proposed method builds on the strong points of the K-Means clustering that provides accurate identification of groups and fuzzy logic that allows one to adapt to changes concerning the distribution of tasks among the fog nodes.

Deep Reinforcement Learning (DRL) has recently gained traction in addressing complex service offloading problems. However, existing techniques are greedy in nature and are primarily designed for centralized problem formulation which results in slow convergence towards the global solution. In addition, data dependencies that are preconceived and QoS requirements inherent within the service components do not facilitate offloading. To overcome such limitations, Goudarzi, et al. [55] developed a distributed DRL strategy formulated through an actor-critic architecture named Asynchronous Proximal Policy Optimization (APPO). Thereby, it contributes

to creating a multitude of possible distributed experience trajectories to take place. Moreover, the authors use off-policy correction methods we have reviewed include PPO clipping and V-trape so as to enhance the rate of convergence to the optimal service offloading solutions.

Resource management in mobile edge and cloud systems often presents complex online decision-making challenges. Effective solutions necessitate real-time understanding of both workload and environment to facilitate the efficient utilization of distributed resources. However, geographically dispersed resources, limited capacity, unpredictable task characteristics, and network hierarchy inherent to edge environments significantly hinder efficient job scheduling. The above dynamic scenarios make heuristic-based methods inadequate since they are not easy to generalize or modify as would be required at times. One such unutilized yet potentially very beneficial technique is the DRL that names Advantage Actor-Critic (A2C). A2C learns quickly in environments with little data while DRL gains its knowledge from situations within the environment and applies them to make a decision. To address these challenges, Lu, et al. [56] propose an A2C-DRL based real-time task scheduling technique specifically designed for stochastic edge-cloud environments.

Wang, et al. [57] introduced a Deep Reinforcement Learning (DRL)-based algorithm for scheduling IoT applications, termed DRLIS. This approach is targeted to provide adaptive and efficient response time for wide range of IoT applications as well as the load balancing among the edge/fog servers. The authors incorporated DRLIS as an operational scheduler in the FogBus2, which is a function-as-a-service platform in the development of moving from edge to fog to cloud serverless computing model. The results of varied experiences indicate that the DRLIS bears a higher impact on the improvement of the execution cost of IoT applications.

IV. RESULTS AND DISCUSSION

A review and analysis of different task-scheduling techniques reveal tremendous variability in their performance based on the underlying methodologies and QoS metrics they try to optimize. Due to their simplicity, heuristic-based algorithms utilize low computational overhead; thus, they can be applied to only small-scale and resource-limited environments. Most of these techniques fail to optimize multiple QoS parameters like latency, energy consumption, and throughput simultaneously; hence, their usage is quite impractical in dynamic and large-scale fog computing scenarios. Contrarily, metaheuristic-based algorithms demonstrate much stronger adaptability in finding near-optimal solutions for complex scheduling problems. Despite the better performance, these algorithms usually introduce higher computation overhead, which may not be affordable for real-time applications.

While advanced algorithms based on machine learning leverage predictive and adaptive capabilities to optimize task scheduling dynamically, techniques such as reinforcement learning and deep neural networks have been promising in achieving significant reductions in latency and energy consumption while maintaining high throughput. For example, reinforcement learning-based models can predict the pattern of

task arrivals and resource availability to enable proactive scheduling. However, most machine learning techniques are implemented in a fog computing environment with extensive training in complex data computation resources and feature engineering, challenging widespread adaptation. Besides, machine learning interpretability may be one of the barriers if transparency in decision-making is essential.

Comparative analyses reveal that no method covers the fog computing-powered IoT network to date for all the challenges combined. Instead, heuristic and metaheuristic algorithms are more appropriate for scenarios with specific resource constraints, while machine learning-based approaches best apply to dynamic and complex environments. The hybridization of such techniques, though in very few instances, points out a bright future direction that can leverage the simplicity and efficiency of the heuristic approach together with adaptability and optimization capabilities from the metaheuristic and machine-learning-based techniques. Furthermore, much emphasis on standard frameworks is required to evaluate the benchmark techniques with regard to task scheduling properly; this ensures coherence in the performances reported through different scenarios. These insights emphasize the vital need for further research that should result in novel hybrid techniques applicable to the new demands put forward by IoT systems driven by fog computing.

Through extensive analysis of various methods for task scheduling in fog-cloud computing environments for IoT applications, several research gaps and limitations in prior studies have been identified. These limitations can include high run times, failure to meet the study's objectives, or negative impacts on other performance metrics. Common shortcomings include missing details on simulation parameters, comparisons with outdated algorithms, using small datasets for evaluation, omitting definitions of evaluation parameters and equations, neglecting relevant evaluation factors, and lacking results to support performance claims.

A critical limitation identified is using outdated benchmark algorithms for comparison in some studies. This makes it difficult to assess the efficiency of the proposed methods definitively. Additionally, several studies employed small datasets (fewer than 100 tasks) or omitted data set size information entirely. This raises concerns about the proposed algorithms' ability to handle real-world workloads with high throughput.

Our analysis also revealed a focus on specific objectives and performance metrics. Energy consumption emerged as the primary objective in many studies, followed by minimizing makespan, delay, and cost. Conversely, response time, resource utilization, deadline violation, security, and reliability received less attention. This focus is reflected in the most studied metrics: makespan, energy consumption, and cost. Most of the investigated algorithms were multi-objective, focusing on optimizing combinations like makespan and cost, makespan and energy, or delay and energy simultaneously.

V. FUTURE DIRECTIONS

As fog computing continues to evolve, several emerging trends and research directions are shaping the landscape of task

scheduling algorithms. These advancements aim to enhance the efficiency, scalability, and adaptability of fog computing systems to meet the growing demands of IoT applications. The future of task scheduling in fog computing is poised to leverage more sophisticated machine learning and Artificial Intelligence (AI) techniques. Reinforcement learning, deep learning, and federated learning are expected to play a significant role in developing more adaptive and intelligent scheduling algorithms. These approaches can enable real-time learning and decision-making, improving the allocation of resources and the overall performance of fog environments.

The collaboration between edge and cloud resources is anticipated to become more seamless, providing a hybrid model that optimally distributes tasks based on their computational and latency requirements. Future research will focus on developing algorithms that dynamically balance the load between edge and cloud, considering network conditions, energy consumption, and application-specific constraints. Energy efficiency will remain a critical concern in fog computing, particularly with the increasing number of connected devices and data-intensive applications. The research will continue to explore energy-aware scheduling algorithms that minimize power consumption without compromising performance. Sustainable computing practices, such as using renewable energy sources and energy-harvesting techniques, will also gain more attention.

With the proliferation of IoT devices and the sensitivity of the data they generate, ensuring security and privacy in task scheduling is paramount. Future research will delve into developing secure scheduling algorithms that incorporate encryption, anonymization, and other privacy-preserving techniques. These solutions must safeguard data integrity and confidentiality while maintaining efficient resource utilization. Integrating real-time analytics and predictive modeling into task scheduling algorithms will enhance responsiveness and accuracy. Using historical data and real-time monitoring, these algorithms can predict workload patterns, detect anomalies, and proactively adjust resource allocation, improving system reliability and performance.

Future scheduling algorithms will increasingly adopt multi-objective optimization techniques to balance various conflicting performance metrics, such as latency, throughput, energy consumption, and cost. Research will focus on developing algorithms that can effectively navigate the trade-offs between these objectives, providing optimal solutions that meet diverse application requirements. As quantum computing technologies mature, their integration into fog computing task scheduling could revolutionize the field. Quantum algorithms have the potential to solve complex optimization problems more efficiently than classical algorithms, offering unprecedented improvements in scheduling performance and resource utilization.

Developing standardized frameworks and protocols for task scheduling in fog computing ensures interoperability between different devices and platforms. Future research will explore ways to create universally accepted standards that facilitate seamless integration and collaboration across heterogeneous fog and edge environments. User-centric and context-aware

scheduling algorithms that consider the specific needs and preferences of end-users will become more prevalent. These algorithms will consider contextual information, such as user location, device capabilities, and application-specific requirements, to deliver personalized and efficient task scheduling solutions.

Federated learning, a decentralized machine learning approach where model training occurs locally on edge devices, will gain prominence in fog computing environments. The research will explore federated learning techniques for collaborative model training across distributed edge nodes, enabling privacy-preserving and resource-efficient machine learning. These approaches will empower edge devices to perform predictive analytics and decision-making tasks autonomously without relying heavily on centralized cloud servers. The integration of blockchain technology into task scheduling algorithms will enhance security, transparency, and trust in fog computing environments. Future research will investigate blockchain-based scheduling mechanisms that ensure verifiable task execution, prevent tampering or manipulation of scheduling decisions, and enable secure peer-to-peer transactions between edge devices. These blockchain-enabled solutions will facilitate decentralized task allocation and resource sharing while preserving data integrity and privacy.

VI. CONCLUSION

IoT technology applies to promote immense interconnectedness to data-driven functions like smart homes, cities, industrial automation, and health services. At the time of growth, this explosive creation of data created newer challenges for traditional models in cloud computing: latencies at high traffic volume and constricts scalability. Emerging as complementary mechanisms to remedy several limitations brought upon by traditional clouds in view of the huge impact created by IoT sensors continuously generating huge loads of information that requires computation, sometimes really urgent, Fog Computing extends the computational processes further toward network boundaries.

The present research gave an extensive review of different techniques for task scheduling in fog computing environments and broadly classified these techniques into three main categories, namely heuristic-based approaches, metaheuristic-based methods, and machine learning-based approaches. This research further analyzed the effects of different techniques on key QoS metrics related to latency, energy consumption, makespan, and reliability and, therefore, provided pragmatic insights into strengths, weaknesses, and applicability. The results revealed that these techniques can adapt dynamically to changing network conditions and workload demands, optimizing resource utilization and service quality in fog-enabled IoT systems.

Apart from indicating gaps, the study also identified several innovative solutions with regard to needs in proposals on hybrid techniques, along with standardized frameworks concerning the evaluation perspective. These lessons then provided concrete guidelines for both the researcher and the practitioner in creating algorithms on next-generation task scheduling at fog computing-powered IoT with efficiency and scalability, thus

guaranteeing enhanced QoS toward paving the right path for R-IoT.

Department of Management Science, Post Graduate, Universitas Pasundan, Bandung, Indonesia³

Abstract—The system dynamics methodology examines the intricate behaviors of complex systems through time, incorporating inventories, transfers, feedback cycles, lookup functions, and temporal delays. In fisheries systems, the interaction between resources and management entities is intricate, with the dynamics of fisheries significantly influencing the formulation of effective policies. Fisheries hold a vital position in Indonesia's economy, contributing to food security, nutrition, and the welfare of fishermen. Under Law Number 7 of 2016, the fisheries sector covers all activities, from resource management to the marketing of marine products. With its rich fishery resources, Indramayu Regency is a major contributor to West Java's fish production. TPI Karangsong, the hub of fishing activities in Indramayu, is a key player in the frozen fish supply chain, relying heavily on cold storage facilities to ensure product quality. Consequently, the system dynamics approach proves valuable in understanding the frozen fish supply chain by modeling the interactions between different variables and evaluating the impact of policies to improve fish quality. The system dynamics model in this study consists of six sub-models: fish at TPI, cold storage, refrigerated cabinets, total revenue, cash, and cold trucks. The simulation results provide policy recommendations to improve the quality of frozen fish at TPI Karangsong, namely the baseline scenario, cold truck scenario, cold truck scenario, truck and cold storage integration scenario, cold storage and fish catch drop integration scenario.

Keywords—Supply chain; system dynamics; frozen fish; six sub-models; simulation; policy scenario

I. INTRODUCTION

As a maritime nation where 70% of its territory is comprised of seas, Indonesia has substantial potential in the tourism and marine sectors, particularly in fisheries. The fisheries sector serves as a crucial contributor to the national economy by generating employment and supporting food security. By Law Number 7 of 2016 [1], the fisheries sector spans activities from pre-production to marketing, integrated within the fisheries business system. The rich diversity of fish resources is a core strength of Indonesian fisheries, with fishing operations governed by Law Number 45 of 2009 [2]. Additionally, the management of marine resources, both renewable and non-renewable, is regulated under Law Number 32 of 2014 [3]. The Marine Affairs and Fisheries Minister Regulation [4] outlines processing and product safety standards to maintain the competitiveness of Indonesian fishery products in global markets. Innovations in fish processing, whether through traditional or modern methods, are essential for adding value to fishery products and enhancing their global market position

[5][6]. In Indramayu Regency, a major fisheries hub in West Java, over 35,000 fishermen produced 551,632.81 tons of fish in 2023, contributing 34.63% to West Java's total fishery production (BPS, 2022).

A company's competitive advantage can be improved through production efficiency, effective distribution, and the timely delivery of products to consumers [7][8]. Supply chain management (SCM) involves key factors such as technology utilization, customer satisfaction, supply chain unification, and inventory management are essential components, while competitive advantage is influenced by factors such as pricing, product quality, market readiness, and sales growth. A company's performance is evaluated through both financial and operational metrics [8]. While a stronger innovation strategy typically enhances operational performance, competitive advantage alone does not fully mediate the link between innovation strategy and overall company performance [9].

SCM is integral to the sustainability of food supply chains, particularly in minimizing food loss and addressing the challenges posed by climate change. The cold chain is essential for preserving the quality of perishable products, such as fish, during their transportation and storage [8]. Despite the significant obstacles faced by cold chain infrastructure in Indonesia, its successful implementation is essential for enhancing the fisheries sector's competitiveness in the global marketplace [10]. Moreover, the establishment of an efficient logistics system is imperative to bolster food security [11].

The complex structure of frozen fish distribution networks requires more than simplistic methods or single-cause solutions. Thus, there is a need for a framework that facilitates an understanding of the multifaceted issues within a systemic context [12] [13]. System dynamics is instrumental in illustrating the interconnections among suppliers, producers, and distribution networks. [14]. This approach underscores the importance of temporal factors in comprehending the overall behavior of a system, demonstrating how such a system can respond to external disturbances or align with the model's objectives (Coyle, 1997 in Wati et al., 2021). Furthermore, system dynamics highlights the influence of policies on system behavior (Richardson & Pugh III, 1997 in Wati et al., 2021) and facilitates the analysis of complex dynamics through the feedback mechanisms among system components [15]. The Causal Loop Diagram (CLD) is extensively used to design complex supply chains, including perishable products like frozen fish [16] [17] while [18] designed a sustainable supply

chain model for the fisheries sector using a system dynamics approach.

TPI Karangsong is a leading fish distribution center in West Java, where the fisheries sector plays a vital role in promoting local economic development. Therefore, adequate cooling facilities are crucial to maintaining the quality of the distributed fish. This study aims to develop a system dynamics model that maps the frozen fish supply chain, expecting the simulation results to propose various policy scenarios that can potentially improve the quality of frozen fish products.

II. RELATED WORKS

A. Supply Chain Management (SCM)

There is integrates various entities collaborating to source raw materials transform into finished goods, deliver them to stores and then consumers [19][20]. Heizer et al. [21] Explain how a distribution network involves suppliers, manufacturers, distributors, and retailers, while Chopra and Meindl [22] emphasize the role of all stakeholders in meeting consumer demands. According to Apriani et al. [23], the interrelationship between goods, finances, and information is crucial. To optimize operations and enhance customer satisfaction, the supply chain mechanism must be effectively implemented through strong relationships with suppliers, efficient production processes, and excellent service [24] [25]. SCM is an integrated approach that efficiently Oversees the movement of products, finances, and insights from upstream to downstream to improve product quality, profitability, and organizational performance [26] [27] [28] [29]. Additionally, SCM enhances competitive advantage by driving efficiency in both production and distribution. [7] [8] [30].

B. System Dynamics (SD)

SD is initially presented by Forrester in the 1950s [31], who constructed a model to demonstrate the way policies influence the soundness of manufacturing systems [32], as well an advanced framework applied to model sophisticated feedback structures [33], making it highly valuable for analyzing interdisciplinary concerns [34]. Besides that, it can also identified using nonlinear relationships and feedback loops between system components, making it suitable for modeling complex socio-economic phenomena [35]. It enables the analysis of interactions among various processes at different levels, providing a holistic understanding of system behavior [15][36]. As part of systems theory, SD helps model nonlinearity through structural modeling incorporating feedback loops and time delays [37]. Key principles in the use of system dynamics include (1) building model structures that define system behavior, (2) integrating soft variables, and (3) interpreting mental models that provide substantial influence [38]. SD offers various benefits, such as visualizing causal links between variables, recognizing the effects of delays, and examining system responses to various scenarios (Zapata et al., 2019). In ecotourism management, Sjaifuddin's [39] model integrates biophysical, social, and economic variables simulated under multiple scenarios, while Utami et al. [40] highlight key response variables such as ecotourism revenue and mangrove rehabilitation. In production planning and control, Karaz et al. [41] emphasize the significance of dynamic interactions in

evaluating the impact of dynamic management (MD) on construction projects. Similarly, Ismail et al. [42] focus on determining optimal Catch capacity to support the sustainability of Malaysian fisheries.

III. METHODOLOGY

The system dynamics model of the frozen fish supply chain in Karangsong is classified as a qualitative-quantitative research study and model-based simulation. This approach combines qualitative and quantitative analyses to understand complex systems and predict dynamic behaviors and feedback structures within the system. The study integrates qualitative and quantitative methods to capture system complexity and simulate time-series data [43] [44].

1) Qualitative research is employed to identify key variables, causal relationships, and behavioral dynamics that influence the frozen fish supply chain. Data are collected through interviews, observations, and discussions with stakeholders, such as fishermen, traders, and cooling facility managers.

2) A quantitative approach is applied during the modeling and simulation phase, using numerical data to construct an analytical model. This method consists of seven stages: problem identification, conceptualization, model formulation, behavior analysis, review, policy examination, and model application [17] [46].

3) The model-based simulation utilizes concepts such as stocks, flows, and feedback loops to describe the movement of materials, information, and policy influences within the system. The results of these simulations are used to evaluate policy scenarios that could enhance fish quality, stabilize supply, and increase income.

Integrating both qualitative and quantitative approaches enables this study to offer more comprehensive insights. By combining the narrative understanding from qualitative analysis with the predictive capabilities of quantitative simulation, the study provides more effective solutions for managing the sustainable frozen fish supply chain at TPI Karangsong. Using Vensim PLE 10.1.3 software, researchers can map variable relationships, analyze system structures, and simulate the dynamic behavior of the supply chain [29] [47].

The stages of building a system dynamics model in frozen fish supply chain system research are (Fig. 1):

1) *Needs analysis*: The initial step aims to identify the problems and needs of the system to be modeled.

2) *Causal loop diagram*: Used to map the cause-and-effect relationships between variables in the system, illustrating feedback loops that influence system dynamics.

3) *Stock and flow diagram*: A more detailed representation of the system, with stocks representing accumulation and flows regulating stock changes. This diagram models the quantitative dynamics of the system.

4) *Simulation models*: The development of system dynamics-based simulation models that enable the analysis of system changes over time.

Fig. 1. Research steps.

5) *Validation*: Assessing the model's suitability against historical data or real-world conditions. The Pairwise Pearson Correlation method is used in system dynamics modeling or statistical models to evaluate the relationship between simulation results and actual data. Fish purchase data and fund allocation for fish purchases at one of the *Bakul* from 2021 to 2023 are used to calculate the validation. The formula is:

$$r = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^n (X_i - \bar{X})^2 \sum_{i=1}^n (Y_i - \bar{Y})^2}}$$

This method ensures that the simulation results can represent dynamics that correspond to the actual conditions of the modeled system.

1) *Sensitivity analysis*: After model validation, sensitivity analysis evaluates the impact of parameter changes on the model's results.

2) *Policy scenario*: The final stage involves using the model to test various policy scenarios to determine the best decision for improving system performance.

IV. RESULT AND DISCUSSION

This section is the completion stage in building a system dynamics model on the frozen fish supply chain and provides a selection of several policy scenarios obtained from the simulation results.

A. Results

The system dynamics model is a system modeling tool developed by Jay W. Forrester, which emphasizes feedback (closed loops) to understand the behavior as a whole. This model assumes that the system is always changing, with various

activities influencing each other. Interrelated sub-models are used to achieve certain goals. The main variables in this model include Level (accumulated flow over time), Rate (flow rate), and Auxiliary (helping variables).

1) *Needs analysis*: This stage involves analyzing the needs of stakeholders in PPI Karangsong, such as:

a) *Fishing port*: The main location of fishing industry activities, equipped with safety and other supporting facilities.

b) *Juragan*: The main supplier of frozen fish and ship provider.

c) *TPI Karangsong*: fish auction place.

d) *Fishermen*: The main actors in fishing in the waters.

e) *Bakul*: Fish suppliers to ports, retailers, or consumers.

f) *Consumers*: Actors who utilize the catch.

g) *Government*: Through the Fisheries and Marine Service, regulates and manages fishing activities.

2) *System identification*: System identification is an approach used to comprehensively describe and analyze a system, often employing cause-and-effect diagrams or causal loop diagrams (CLD) to clarify the responses interactions across the variables within the system [48]. This methodology enables the identification of patterns or cycles in the system, facilitating more effective analysis and strategy design.

CLD are constructed based on research data, interviews, and literature reviews to accurately depict causal relationships [49]. In this study, the model is employed to understand of frozen fish supply chain dynamics, beginning with the auction at TPI Karangsong, continuing with storage in cold storage facilities, and culminating in distribution using refrigerated vehicles. This approach allows for analyzing the impact of decisions and related variables, ultimately aiming to improve supply chain efficiency.

The frozen fish supply chain system dynamics model simulation is conducted using Vensim PLE 10.1.13 software, and the CLD for frozen fish distribution is illustrated in Fig. 2.

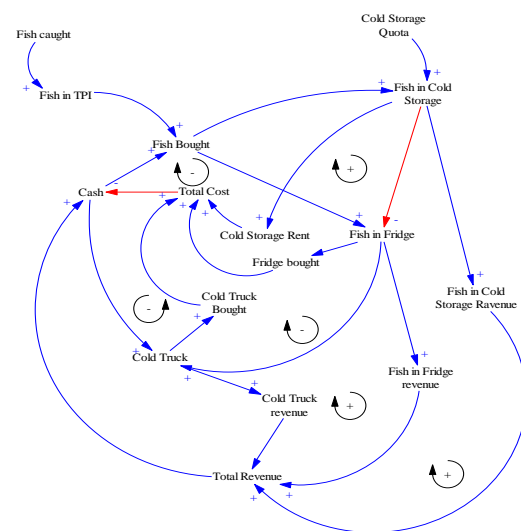

Fig. 2. Causal loop diagram.

Freezing and storage facilities for frozen fish products are crucial components in supporting the cold chain or supply chain system. These facilities help maintain the quality of fish products, enhance their added value, and ensure smooth distribution, price stability, and the availability of fishery products. As a result, the supply chain system can operate more efficiently and effectively.

3) *Boundary model:* The selection of model boundaries is a critical step in modeling, as it defines the scope of analysis relevant to the problem under investigation. These boundaries must encompass all cause-and-effect interactions within the frozen fish supply chain system to ensure a comprehensive representation. Effective decision-making in this supply chain depends on the model's accuracy and completeness, which directly influence the validity of the proposed decisions. The primary objective is to maintain product quality and safety throughout distribution, preventing any degradation that could negatively impact the selling price.

However, this model lacks a detailed analysis of the payback period, and risk analysis is not sufficiently addressed, limiting its ability to fully evaluate the financial feasibility and potential uncertainties associated with policy implementations.

4) *System dynamics simulation flowchart structure:* The simulation of system dynamics modeling results is used to observe behavior patterns and trends within the system, as well as the factors influencing it. However, Causal Loop Diagrams (CLD) have limitations in capturing the structure of stocks and flows in the system. To address this, a Stock & Flow Diagram (SFD) is employed, offering more detail and enabling more accurate simulations of system behavior. SFD incorporates the element of time, allowing for a more detailed analysis of interactions between variables. The frozen fish supply chain system is structured into six sub-models. These six sub-models enhance the system's overall analysis and simulation accuracy, as follows:

a) *Frozen Fish Sub Model at TPI:* Fig. 3 is a frozen fish sub-model at TPI Karangsong.

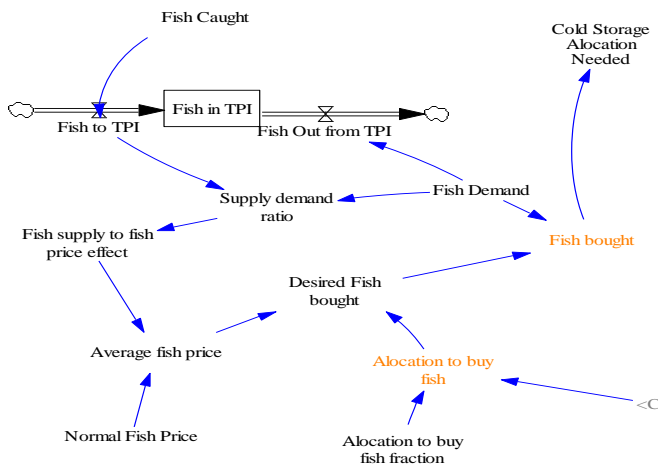

Fig. 3. Frozen fish sub model at TPI.

In this sub-model, frozen fish collected at the TPI represents a stock variable. Various types of frozen fish are auctioned at the TPI, and purchased by the *Bakul*, which reduces the stock of fish at the TPI. The supply-demand ratio is defined as the demand for fish relative to the availability of fish at the TPI. The average fish price is affected by the impact of fish supply on prices relative to the normal price level. The amount of fish purchased by the *Bakul* is determined by the allocation of funds available in the *Bakul's* cash reserves for buying frozen fish. The quantity of fish purchased then dictates the allocation of cold storage required.

b) *Cold storage sub model:* In this sub-model, the fish stored in cold storage is a stock variable. Fig. 4 is a sub-model of Cold storage at TPI Karangsong.

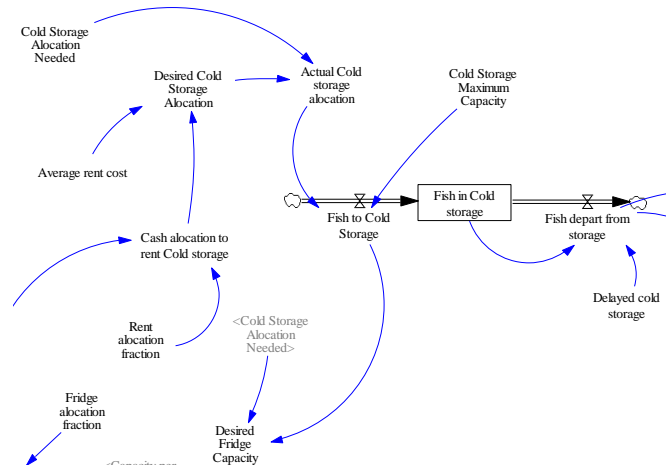

Fig. 4. Cold storage sub-model.

The purchased fish will initially be stored in cold storage. The allocation of fish that can be stored is determined by the cold storage's maximum capacity. The amount of fish stored will affect the cold storage rental cost, which will contribute to the total cost. If the cold storage reaches full capacity, the *Bakul* will store the excess frozen fish in a refrigerator, from which it will later be distributed.

c) *Fish fridge sub model:* In this sub-module, the stock variables are the number of refrigerators (Fish fridge) and fish stored in the Fish fridge. The simulation results of the Fish fridge sub-model are as shown in Fig. 5.

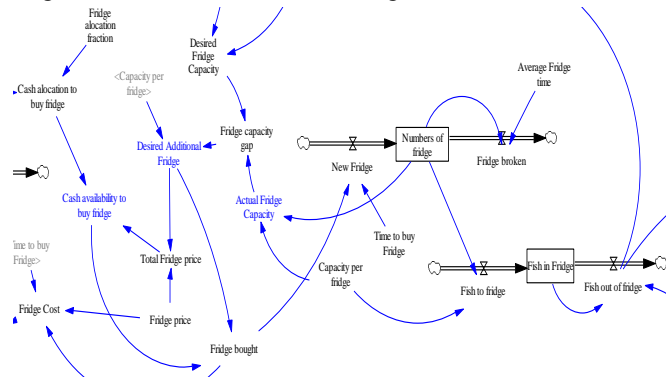

Fig. 5. Fish fridge sub model.

Fish that cannot be stored in cold storage must be placed in a refrigerator, although the quality will not be as well preserved as in cold storage. However, the *Bakul* must allocate funds to purchase the necessary refrigerators. The number of refrigerators required is determined by the amount of fish that exceeds the capacity of the cold storage. The need for additional refrigerators arises when a discrepancy exists between the desired and actual storage capacity to store the surplus fish.

d) *Total revenue sub-model*: Total income in this sub-model is calculated from how many frozen fish are in cold storage multiplied by the fish that come out of cold storage, plus income from fish in the fish fridge and those sent using cold trucks. The simulation results for total revenue are presented in Fig. 6.

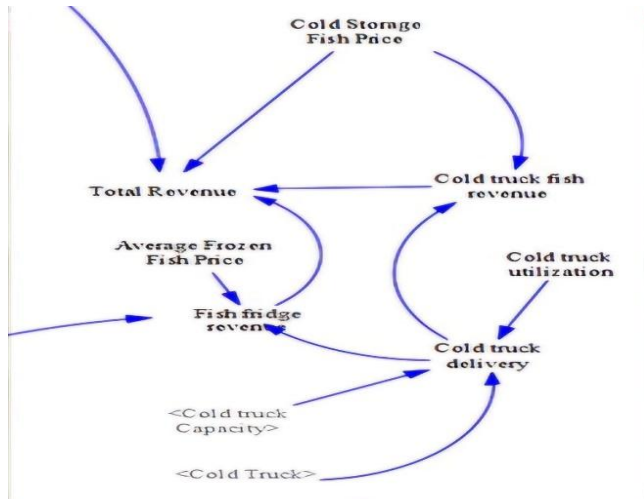

Fig. 6. Total revenue sub-model.

In this sub-model, it is assumed that all frozen fish purchased will be sold out. The assumption is that the price of frozen fish stored in cold storage is higher than that of fish stored in the Fish fridge. Then, frozen fish sent using a cold truck will maintain its quality to the maximum so that the selling price is the same as fish stored in the Fish fridge.

e) *Sub model cash*: Cash is a variable that increases due to income and decreases due to expenses. The total costs calculated in this model include cold storage rental costs, Fish fridge purchases and cold truck purchases (Fig. 7), so cash is income minus expenses.

f) *Sub Model Cold truck*: Cold trucks become stock variables in the sub-model (Fig. 8).

The cold truck is a model used for scenario simulations. In the baseline scenario, it is assumed that the *Bakul* does not own a cold truck, while in the subsequent scenario, the *Bakul* purchases a cold truck based on the amount of fish in the refrigerator and the availability of cash. The purchase of a cold truck depends on the cash allocation available to the *Bakul*. The procurement of the cold truck is determined by its capacity and the amount of fish in the refrigerator that needs to be transported. The price of the cold truck corresponds to the average market price, which varies depending on its specifications and capacity. The cold truck's role is to maintain the safety and quality of frozen fish during distribution, preventing quality degradation

that typically occurs when using non-refrigerated trucks. This ensures that the fish delivered to consumers remains in optimal condition, enhancing consumer satisfaction and loyalty. The overall model is represented by a stock and flow diagram (Fig. 9).

5) *Validation*: Is conducted to verify that a model comprehensively achieves its objectives and accurately represents real system conditions. This process involves evaluating and testing the accuracy of the quantitative framework by comparing the outcomes of the dynamic system simulation against historical data. In this study, model validation was performed using a sample of *Bakul* who passed the normality test from the total population of *Bakul* at TPI Karangsong, Indramayu Regency. The assumption is that the *Bakul* consistently purchase frozen fish. Using data from 2021 to 2023, The following is data on demand for frozen fish in one of the *Bakul*. And normality data is (Fig. 10).

Based on historical data, the forecast results using linear trends for the number of fish purchased and fund allocation are as shown in Fig. 11. Table I shows demand of frozen fish in *Bakul*.

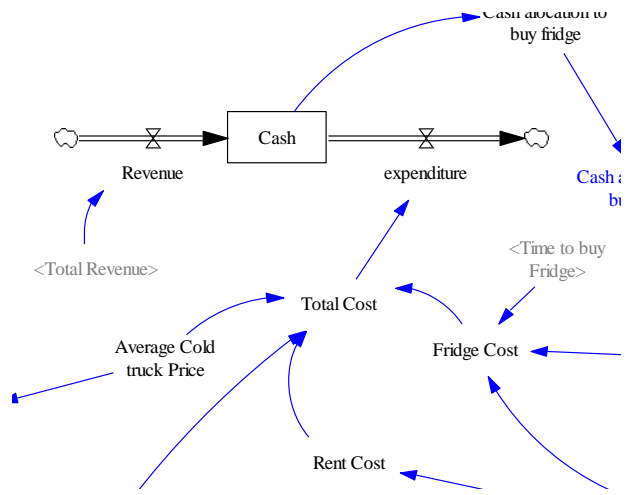

Fig. 7. Cash sub model.

Fig. 10. Normal P Plot test.

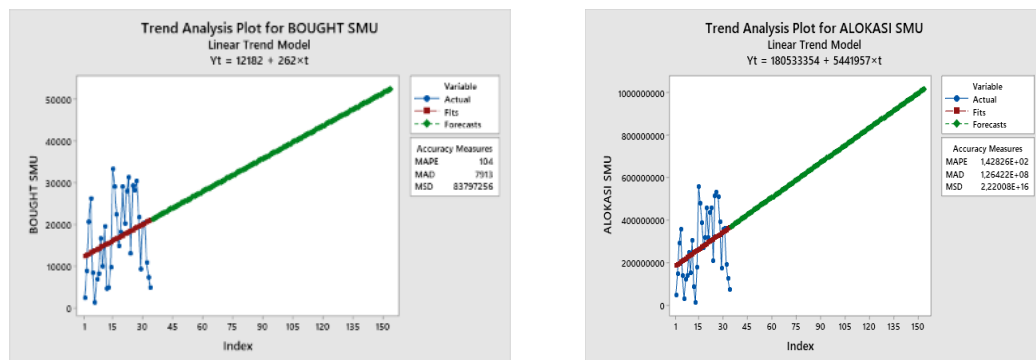

Fig. 11. Forecast results of the number of fish purchased and allocation of funds in one of the *Baku*.

TABLE II. FORECAST ERROR

Method	Value
Bought Fish	
MAPE	104
MAD	7913
MSD	83797256
Allocation to buy Fish	
MAPE	1,42826E+02
MAD	1,26422E+08
MSD	2,22008E+16

From the forecast (Table II) results, Bakul experienced an increase in both the amount and allocation of funds. The results of data processing using MINITAB 19.1.1.0: The following are forecasting errors, namely:

Using the pairwise Pearson correlation method with a 95% confidence and a 5% significance level, the P-value for bought fish was 0.122, and for allocation to buy was 0.051, indicating that the data is valid for predicting future values at *Bakul*.

6) *Sensitivity of system dynamics model*: Sensitivity tests are conducted to measure how sensitive the model is to changes in input parameters or model structure so that it can understand its impact on model output. The results of this sensitivity test are behavioral changes, which are used to analyze the effects of interventions on the model. Sensitivity tests in this study include:

a) *Functional intervention*: Functional intervention entails modifying a specific parameter within the model. This study applies it to the parameter that represents the fish quantity at the TPI. The quantity of fish caught influences the amount of frozen fish purchased by the *Bakul* at the TPI. An increase or decrease in the number of fish will affect the cash allocation available to the *Bakul*.

b) *Structural intervention*: Structural intervention refers to changes made to the model by modifying the relationships that form its structure, aiming to assess their effects on the model's variables. In this study, structural intervention is implemented in the cold truck and cold storage sub-models. The purpose of acquiring a cold truck is to preserve the quality of frozen fish during transportation. In contrast, the increase in cold storage capacity is designed to ensure sufficient storage space.

The (3) three sub-models, namely the fish sub-model at TPI (functional intervention the cold truck sub-model, and the cold storage sub-model (structural intervention) have output sensitivity.

Sensitivity tests help identify various modeling scenarios by adjusting the model's parameters or structure. Thus, sensitivity tests allow researchers to explore various conditions and see how changes in a model's parameters or structure can influence its output.

7) *Analysis of simulation results and policy scenarios*: System dynamics models are essential tools for supporting

practical decision-making, enabling policymakers to model different policy scenarios and assess the impact of each decision. This helps them select the most effective and efficient strategies for addressing complex and dynamic problems. The average price of frozen fish is often influenced by the availability of fish catches from the TPI. As fishing increases, the fish supply becomes more abundant. The harvested fish are then properly stored in cold storage to maintain the quality of frozen fish. Adequate cold storage allows frozen fish sales to occur throughout the year, stabilizing supply and creating more consistent demand and prices. The use of cold storage to preserve frozen fish quality is affected by several factors, including rental costs and storage capacity.

The simulation results produced three scenarios:

a) *Cold truck procurement scenario*: Simulation results in the Cold Truck Procurement Scenario as shown in Fig. 12.

Fig. 12. Cold truck scenario simulation results.

The simulation results (Fig. 12) indicate that although there is a decrease in cash in the 50th month due to the purchase of cold trucks, revenue increases. Investing in cold trucks is essential to maintaining the quality of frozen fish during distribution, preventing price declines. Despite the high initial cost, cold trucks are a strategic investment that supports long-term cash growth through revenue from selling high-quality fish. With five cold trucks, the model positively impacts long-term financial performance, despite the initial outlay. Cold trucks ensure stable fish temperatures during transportation from cold storage to markets or restaurants, mitigating quality issues that arise from unrefrigerated shipments, particularly for travel distances exceeding four hours. Without cold trucks, fish quality deteriorates due to temperature fluctuations, thawing, microorganism growth, and texture damage, all of which reduce the fish's selling value, lead to economic losses, and diminish consumer satisfaction and trust. The procurement of cold trucks helps preserve fish quality, increase selling prices, and improve consumer satisfaction, making it a key solution for the sustainability of TPI Karangsong and the efficiency of distribution.

b) *Cold truck and cold storage integration scenario:* Simulation Results of Cold Truck and Cold Storage Integration Scenario as found in Fig. 13.

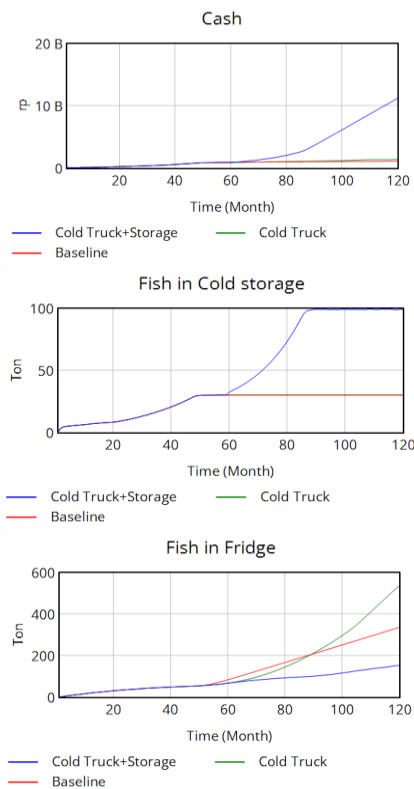

Fig. 13. Simulation results of cold truck and cold storage integration scenario.

This model illustrates how increasing cold storage capacity and using cold trucks for shipping can enhance storage efficiency, product quality, and revenue at TPI Karangsong. Expanding cold storage capacity and utilizing cold trucks are critical strategies for maintaining the quality of frozen fish during storage and distribution. Increased cold storage capacity

allows fish to be kept under optimal conditions for extended periods, minimizing the risk of quality degradation from temperature instability. Cold trucks, with their efficient cooling systems, ensure stable fish temperatures during transportation from cold storage to the final distribution point. The integration of cold storage and cold trucks ensures that frozen fish are stored and distributed under ideal conditions, preserving freshness and quality.

Key impacts of this strategy include improved product quality and safety, which are essential for consumer health and compliance with industry regulations. Revenue increases are driven by the higher selling value of high-quality products, boosting both income and profitability. Operational efficiency is also enhanced due to reduced product spoilage during storage and distribution, lowering damage-related costs. Customer satisfaction improves as well, evidenced by a decrease in return rates and higher satisfaction scores, resulting from consistent product quality. The integration of cold trucks and cold storage not only preserves product quality but also enhances operational efficiency and customer satisfaction, supporting business stability and profitability. Furthermore, this strategy strengthens TPI Karangsong's reputation as a high-quality fish provider, contributing to local fishermen's income and welfare.

c) *Cold truck, cold storage and fish catch drop integration scenario:* Fig. 14 is a simulation results of the integration scenario of cold trucks, cold storage, and fish catch drop.

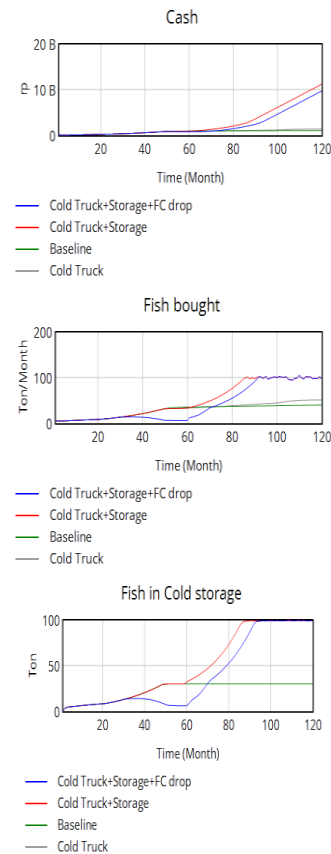

Fig. 14. Simulation results of the integration scenario of Cold Truck, Cold Storage, and Fish Catch Drop.

The simulation results indicate that a decrease in fish catch results in a decrease in the quantity of fish purchased, resulting in lower cold storage usage and reduced revenue. Although cash flow improved compared to the baseline, the increase was not as significant as it would be with stable fish catches. The integration of cold trucks and cold storage is a key strategy for optimizing the storage and distribution of frozen fish, ensuring product quality and safety from the point of catch to the final consumer. By increasing cold storage capacity, fish can be kept under optimal conditions for extended periods, minimizing the risk of quality degradation due to temperature fluctuations. Cold trucks maintain stable fish temperatures during distribution, preserving freshness and quality.

This strategy involves three main components: the fish catch drop, cold storage, and cold trucks. The fish catch drop refers to the initial phase where freshly caught fish are transferred to temperature-controlled facilities to slow spoilage. Cold storage maintains fish at low temperatures to preserve quality over time, reducing microbiological and enzymatic activity. Cold trucks ensure stable temperatures are maintained during transport, safeguarding product integrity.

While this integration enhances operational efficiency and product quality, the decline in fish catch still negatively impacts revenue and shipment volume. However, cash flow improved compared to the baseline, indicating that the strategy mitigates some of the negative effects of reduced fish catches, though overall revenue remains lower. The integration of cold trucks and cold storage is vital for maintaining product quality, improving supply chain efficiency, and enhancing consumer satisfaction, while also helping to reduce the impact of catch fluctuations on TPI Karangsong's revenue and operations.

B. Discussion

Additionally, this research highlights that the system dynamics model for the frozen fish supply chain generates several policy scenarios aimed at enhancing fish quality and improving fishermen's welfare. Policies should promote the effective, efficient, and sustainable utilization of all available natural resources within the country [30]. The policy scenarios are as follows:

1) *Scenario 1: Baseline:* Describes the current state without additional policies. It provides a picture of how variables develop without changes or interventions, helping to identify potential problems and the need for corrective action to achieve desired goals in the future.

2) *Scenario 2: Cold Truck Procurement:* The procurement of cold trucks is intended to maintain the stable temperature of frozen fish during transportation, ensuring the preservation of fish quality. With better product quality, the selling price of fish increases, and consumer satisfaction is ensured. Cold trucks are essential for transporting frozen fish from cold storage to markets, restaurants, or distributors. Trucks with a minimum capacity of 2.9 tons and a temperature range between -20°C and $+10^{\circ}\text{C}$ must be used for deliveries exceeding four hours, while non-refrigerated trucks are prohibited. Although this investment results in an initial cash reduction, it leads to increased revenue and maintains product quality, making it a

strategic decision. Routine maintenance is necessary to extend the lifespan of cold trucks to up to 10 years, ensuring sustainable operations.

The use of cold trucks is crucial for preserving product quality, reducing losses, and ensuring consumer satisfaction and trust.

3) *Scenario 3: Integration of Cold truck and Cold storage:* The integration of cold trucks and cold storage is a strategic policy in the distribution of frozen fish to maintain product quality and improve operational efficiency. This integration allows temperature stability from storage to delivery, reduces the risk of product damage, and increases customer satisfaction. Increasing cold storage capacity requires significant investment and government support. The use of cold trucks in distribution ensures that product temperatures are maintained throughout the supply chain, contributing directly to increased revenue and product sales value. Operational efficiency is improved through better coordination and integrated inventory management, reducing product transfer times and adjusting shipments to market demand. The success of this policy can be measured through increased revenue, reduced return rates, and customer satisfaction. In addition, this integration also reduces product damage, meets food safety standards, and improves business sustainability with better energy efficiency and supply chain management.

4) *Scenario 4: Integration of Cold Truck, Cold Storage, and Fish Catch Drop:* The integration of fish catch reduction, cold storage, and cold trucks aims to maintain optimal temperature and quality of frozen fish throughout the supply chain while enhancing operational efficiency and customer satisfaction. This policy combines all elements of the cold chain [45] to ensure product quality and safety from catch to consumer. The fish catch reduction strategy involves determining the timing and location of catches based on fish population data, along with using monitoring technology to improve catch efficiency. After processing, the fish are stored in cold storage at sub-zero temperatures, focusing on maintaining stable temperatures throughout the facility. Cold trucks are employed during distribution to preserve temperatures during transport, using efficient cooling systems and regular maintenance. Companies must also adhere to food safety standards at every stage. The success of this policy will be evaluated based on product quality, operational efficiency, return rates, and customer satisfaction.

This study offers significant advantages in supporting policy decision-making for the frozen fish supply chain. First, applying a system dynamics approach enables holistic and integrated analysis, capturing interactions among supply chain components, such as the impact of investment in cold trucks and cold storage on fish quality and income. Second, the proposed policy simulations provide insights into various relevant scenarios, including a baseline scenario without intervention for comparison and a scenario involving cold truck and cold storage investments, demonstrating the potential for increased income and selling prices through improved fish quality. Third, this

model facilitates predicting the long-term effects of policies, particularly in scenarios involving fish catch declines, aiding in understanding income stability challenges amid reduced catches. Additionally, the approach supports formulating evidence-based improvement strategies tailored to the needs of local fisheries stakeholders, contributing to sustainable solutions. By integrating simulation results with model-based decision-making, this study enhances its relevance in promoting the sustainability of the fisheries supply chain in TPI Karangsong and surrounding areas.

V. CONCLUSION

The study utilizes a system dynamics approach to simulate the frozen fish supply chain, the simulation results in several policy scenarios. The baseline scenario without intervention shows no significant changes. The cold truck procurement scenario increases income, despite requiring initial investment. Meanwhile, the integration of cold trucks and cold storage helps maintain fish quality and increases selling prices. In the final scenario, which combines cold trucks, cold storage, and a reduction in fish catches, fish quality is preserved, though the income is still affected by the catch decline.

Future research will explore the potential of new technologies, such as IoT for real-time temperature monitoring and blockchain for transparent tracking, to improve the supply chain model's accuracy. Additionally, the sub-models should be supported by a microservice-based IT roadmap, starting with small programs that evolve into larger modules.

Methodological Review of Social Engineering Policy Model for Digital Marketing

Wenni Syafitri, Zarina Shukur, Umi Asma' Mokhtar, Rossilawati Sulaiman
Center for Cyber Security-Faculty of Information Science and Technology,
Universiti Kebangsaan Malaysia, Bangi Selangor, Malaysia

Abstract—Social engineering attacks are recognized as human-based threats and continue to increase, despite studies focusing on prevention methods that do not rely on the human aspect. The impacts of these attacks are felt across various industries and organizations. To solve this issue, a social engineering policy model must be proposed for prevention in industrial settings, particularly emphasizing digital marketing activities, a crucial process in contemporary industries. However, hackers often exploit activities or information in these practices, necessitating an industry-specific policy to prevent these threats in digital marketing. As a result, a comprehensive review was conducted to identify critical methods for developing social engineering policy model. The review uses Bryman's method to determine effective approaches for designing a social engineering policy model tailored for digital marketing. Consequently, this review provided a method for crafting effective social engineering policy, providing valuable insights for enhancing digital marketing security.

Keywords—Digital marketing; social engineering attack prevention; review study; security policy model

I. INTRODUCTION

Social engineering attacks are often performed to expose private information through unauthorized actions [1]. Similarly, NIST describes social engineering attacks as a method of getting trust and confidence from victims [2]. Verizon defines social engineering as exploring human psychology and manipulating sensitive information to exploit people's vulnerability [3].

Various methods have been used to prevent social engineering attacks. For example, CISA recommends practices such as staying vigilant, verifying phone calls and emails, refraining from divulging private or organizational information, ensuring email safety for financial transactions, installing, and managing antivirus software, implementing email filtering and firewall protection, using anti-phishing features in emails and browser plugins, and using multi-factor authentication (CISA). SANS Institute also advocates for security awareness training to mitigate the impact of social engineering attacks (SANS). Moreover, it is crucial to be aware that the prevention methods proposed by CISA and SANS primarily address the technical aspects.

The term "social engineering" is applicable in the context of information security and marketing. Typically, marketing practices can be viewed as a form of social engineering [4]. In marketing, social engineering comprises applied methods for influencing social impact or change, signifying practices used

to influence people's decisions [5]. Consequently, activities in marketing can be termed social engineering [6].

The growing trend of organizations engaging in digital marketing to communicate with external parties makes organizational boundaries unclear. This complicates decisions regarding the information that can be shared with external partners [7]. For example, using social media for digital marketing, including advertising, introduces the risk of unintended information leakage.

According to the Weekly Threat Report dated April 12, 2021, published by NSCS, a data breach compromised 553 million social network users in 106 countries. This breach exposed private information such as IDs, gender, location, and date of birth (NSCS). Unauthorized individuals may exploit this information, manipulating human weaknesses to acquire more confidential data for financial gain. This deceptive tactic is executed through social engineering attack methods. The study conducted by [8] and [9] defined marketing studies based on the respective methods and scopes regarding social engineering. Unlimited exploitation of privacy can cause problems for both customers and companies, leading to a loss of customer trust and revenue when not properly managed by the company.

Cybersecurity policy has a significant influence in fostering cyber governance and cyber resilience in organizations [10], [11]. Some researchers try to build cybersecurity policies with several techniques, such as identifying appropriate security policies to be applied to cyberspace [12], identifying awareness of cybersecurity policies [13], and conducting comparisons between two countries in terms of governance aspects and security policies [14]. However, the policies are to be built by [12], [13], and [14] generalized against various attacks so that prevention against social attacks cannot be used. Therefore, [10] suggested that building policies against cyber-attacks should be specific, such as policies to prevent social engineering attacks.

Very few studies have built social engineering policies. The study in [15] examined recommendations for dealing with organizational members who fall prey to social engineering as an organizational policy issue. The results of this analysis showed that participants did not favor a punitive approach to security failures. Instead, they tended to favor education as a more pragmatic and humane solution. In contrast to [10], they combine the principles of raising security awareness and education in building a social engineering policy. The concept proposed by [10] requires organizational members to read and

learn how social engineering attacks work. In addition, social engineering attack awareness training is required to support the learning activities of organizational members, such as bringing in experts if they have the budget [16].

The studies in [15] and [10] specifically do not focus on building social engineering attack policies. They focus more on policies toward victims of social engineering attacks [15] and policies on how to enhance the social engineering knowledge of each member of the organization [10]. None of the researchers discussed how to build a social engineering policy. Therefore, to answer the gap that researchers have not resolved, this study propose a technical way to design a social engineering policy with a focus on digital marketing. The specialized policy aims to identify and implement relevant policy rules [10].

Developing and consistently updating information security policy is essential for enhancing an organization's security culture [17]. Numerous studies recommend adapting social engineering attack prevention methods at the organizational level by implementing robust social engineering attack policy. The study in [18] proposed the establishment of a strong information security culture through a policy aimed at preventing social engineering attacks. This implies that the crafted information security policy needs to anticipate recent trends in social engineering attacks [19]. Additionally, [15] advised focusing on content rather than just attack policy, taking into account factors such as avoiding harsh sanctions, providing employee education, offering incentives for positive behavior, and determining the appropriate timing for administering punishments.

A good organization should develop and evaluate security policy based on relevant standards and business processes to manage systems, applications, and information effectively. Implementation of social engineering policy by organizations can mitigate vulnerability to hacker attacks, thereby minimizing potential damage [20]. NIST SP 800-152 establishes a standard for Cryptographic Key Management Systems (CKMS), which categorizes security policy into two levels, namely a high-level policy for managing organizational information and a low-level policy consisting of rules to safeguard this information (NIST). CKMS standard is structured with three layers of security policy, including action management, information security, and cryptographic key management system security policy. NIST SP 800-53 Revision 4 defines security policy as a set of standards that support security services.

The search activity showed 31 studies on security policy, each categorized based on the security policy aspects. Each study used a unique method with the primary goal of developing a security policy, aiming to identify an appropriate phase for designing a security policy model to prevent social engineering attacks, particularly in digital marketing.

In the subsequent sections of this paper, studies on the security policy are explained in Section II. Meanwhile, Section III outlines the methodology, Section IV presents the results, Section V presents discussion and Section VI contains the conclusion.

II. RELATED WORK

This section explains some closely related studies, focusing on the topics, challenges, and recommendations relevant to the objective of this current study. The mentioned articles serve as references for designing a security policy model to prevent social engineering attacks in digital marketing. Consequently, the related studies are categorized into four sections as follows:

A. Social Engineering in Digital Marketing

Social engineering has a unique significance in digital marketing, where various marketing activities, such as content marketing, inbound marketing, influencer marketing, social media marketing, creative marketing, innovation marketing, customer journey marketing, conversational marketing, customized lifecycle marketing, performance marketing, and Marketing 4.0 & 5.0, are categorized as forms of social engineering [6].

Social marketing is loosely associated with various marketing methods (as shown in Table I), including non-profit marketing, charity marketing, cause-related marketing, public sector marketing, and government marketing. Additionally, it shares ties with more commercial activities including green marketing or branding for charitable causes, where a company aims to be recognized as a socially responsible entity [8]. When social marketing is used by governments, it does not carry the same negative connotation as totalitarian regimes' propaganda, even though it is a routine government activity [8]. Social engineering is often linked to the desired outcomes of a totalitarian state and is commonly associated with the oppression of citizens in the public perception [8]. Consequently, social engineering is typically viewed as unfavorable, while social marketing is seen as positive.

Digital marketing plays a crucial role in augmenting company income. However, improper use of digital marketing concerning information security can lead to substantial losses for the organization. [8] developed a conceptual model that described the factors related to social engineering and marketing. This model shows the effective and ineffective implementation of social engineering in government activities, such as education, policing, and funding. Similarly, [9] concluded that prioritizing privacy was a viable strategy for increasing hotel revenue. Hotels strategically use privacy measures to provide customers with appropriate services, such as spa and self-service amenities (mini-bars, vending machines, etc.), to enhance perceptions of room comfort and promote repeat visits.

Specific policies are required to address social engineering attacks in organizations, primarily in the aspect of digital marketing. These policies not only help protect sensitive data but also improve the overall effectiveness of marketing campaigns by fostering trust and security among consumers.

In addition, this policy will increase information security awareness as individuals can recognize the nature of cyber threats, how attacks are delivered, their impact on individual safety and business operations, recognize what behaviors can put organizations at risk, and what actions they need to implement when they are attacked [10].

TABLE I. RELATION BETWEEN SOCIAL ENGINEERING AND DIGITAL MARKETING COMPARISON OF A REVIEW STUDY

Term in digital marketing	Digital marketing activity	Related to social engineering activity
Personalization [21]	Marketers utilize browsing history, transaction history, and demographic information to build personalized ads that aim to increase competitive advantage.	Attackers make personalized message content contextually relevant to targets based on collected information [22].
Social Proof [23]	This technique utilizes feedback or ratings from other customers to influence customer decisions in purchasing a product or service.	Attackers create a false sense of security and collective behavior based on fake testimonials or statistics to increase credibility. In addition, the attacker may impersonate a trusted or respected figure in an organization and then say that his or her requests are in line with what everyone else is doing [24].
Scarcity and Urgency [25]	Marketers use the technique of conveying information on commodity unavailability or limited offer of a product in marketing activities.	Attackers using the scarcity principle refer to a persuasion approach using time-based constraints. This technique triggers feelings of anxiety about what will happen if no immediate action is taken.[26].
Storytelling [27]	Marketers create stories around products to create an emotional connection with consumers.	The attacker constructs a personalized story to get the attention of the target, such as a sad story or a victim of a crime or war [28].

Trust is paramount in digital marketing. A well-designed security policy will give customers the impression that the organization takes protecting customers from cybersecurity attacks seriously. The policy must contain an interactional approach to influencing user decisions through recommendations or responses from others as a preventive measure for social engineering attacks [29].

In addition, the social engineering attack policy that has been built is essential to be implemented in an organization. Regular training to raise awareness is an important aspect when implementing social engineering attack policies. Every organization must build social engineering policies carefully to reduce individuals becoming victims of social engineering attacks [15].

The social engineering attack policy should contain technical measures including incident management [30]. Every incident caused by social engineering must be immediately responded to by the organization, either automatically or manually, so as not to have a fatal impact on the management and finances of the organization [31]. Therefore, social engineering attack policies must contain incident management measures that are always up-to-date with social engineering attack patterns [32].

Therefore, building a social engineering attack policy is not only a preventive measure, but digital marketing aspects are an inseparable part of fostering customer trust, ensuring

compliance, and protecting the organization from evolving threats.

Very few researchers have modeled social engineering threats such as [33], [34], and [35]. One of the most famous social engineering attacks is phishing [34]. Threat modeling [33] is to build a phishing model consisting of the factors of threat detection, elaboration, phishing susceptibility, motivation to process, ability to process, and knowledge. Threat detection factors have a significant influence on reducing phishing attacks. Organizations should invest in mitigation measures that support users in detecting phishing threats [36]. In addition, the use of phishing threat modeling also has a significant impact on identifying and securing IoT device vulnerabilities during the initial design phase [34]. Reference [34] utilize detailed information about attacks from each stakeholder. After that, Authors in [34] built a Data Flow Diagram (DFD) to apply threat modeling techniques to identify potential threats in the underlying case using STRIDE threat modeling.

In contrast to [35], they predicted the occurrence of social engineering attacks based on data on the effectiveness of the modalities and principles of persuasion used in Social Engineering Threats (SETs). However, the prevention was carried out by [33], [34], and [35]. It is not fully maximized because it still focuses on technical prevention and evaluation of vulnerabilities that have the opportunity to be breached by social engineering.

Some researchers built threat modeling on social networks, such as Privacy Threat Modeling Language (PTMOL) [37] and DetThr model [38]. The study in [37] built PTMOL to model privacy threats in the Online Social Network (OSN) domain. PTMOL can be incorporated into software development during the design phase of OSNs [37] so that software developers can focus more on privacy protection when building OSNs. The DetThr model built by [38] uses the ThrNet semantic network. The study in [38] claimed that the DetThr Model performed very well in identifying threatening tweet messages. Similar to [33], [34], and [35], [38] and [37] have not been able to build a maximum prevention for social engineering attacks because they still focus on privacy and tweet threats technically.

Brand honesty, consumer trust, and economic security are all severely compromised by sophisticated cyberattacks targeting brand communication networks in today's digitally driven market [39].

Social engineering threats are increasingly dangerous today, but very few focus on prevention, especially in digital marketing. Some social engineering attacks that can be used by attackers in digital marketing are phishing, spear phishing, baiting, pretexting, vishing, smishing, and water-Holing [40]. Phishing utilizes human weaknesses such as time constraints, threats, and user habits to obtain important information by using emails that already contain malicious links. Similar to phishing, spearphishing is more targeted to potential victims; likewise, with vishing, phishing techniques utilize phone calls or the like to get victims, while smishing utilizes Short Message Service (SMS). Baiting utilizes the curiosity of potential victims, such as using a USB Stick with a specific

company logo that contains malicious code. At the same time, water-holing takes advantage of the weakness of an organization's website to insert malicious code to obtain important information when the victim accesses the website. Social engineering attacks can utilize digital marketing activities, as shown in Table II.

TABLE II. SOCIAL ENGINEERING WITH ATTACK VECTOR IN DIGITAL MARKETING

Social engineering attack	Attack vector	Potential digital marketing activity to exploit
Phishing	Email or message feature from Social Networking Sites contains a malicious link with a broader target	Email marketing, ads on social media, promotional landing pages, promotion-based instant messaging, Malicious SEO (Search Engine Optimization), Promotion in Online Groups or Forums, and QR Codes in Offline-Online Campaigns.
Spear Phishing	Email or message feature from Social Networking Sites contains a malicious link with a broader target	Personalized Offer Emails, Targeted Ads on social media, LinkedIn or Other Professional Platforms, Fake Events or Webinars, Targeted E-Commerce or Product Offers, Browsing Record-Based Phishing (Retargeting), Targeted Charity or Donation Campaigns, Surveys or Feedback Forms, Personalized WhatsApp or SMS Messages, and Use of Public Facts about Targets.
Vishing	Robocall or Malicious Call	Exclusive Promotional Offers by Phone, Fake Order Confirmations, Fake Charity or Donation Campaigns, Special Investment or Insurance Offers, Fake Surveys with Prizes, Customer Retention Scams, Lure of Prizes from social media or Online Contests, Confirmation of Changes to Customer Accounts or Data, Retargeting or Remarketing Based Scams, and Webinar or Online Event Registration Based Scams.
Baiting	Malicious USB Sticks or digital assets	Free Digital Content Promotions, Fake Giveaways, Fake Discounts or Coupons, Free E-Book or Educational Material Offers, Pop-Up Ads Offering Gifts or Services, Free Software or Plugin Offers, Fake "Try It Free" Campaigns, "Rare" or Exclusive File Promotions, Rewarded Surveys or Polls, and Rewarded QR Code Offers.
Smishing	The SMS contains a malicious link	Discount or Special Promo Offers, Order Confirmation or Package Delivery, Suspicious Activity Notifications on Accounts, Sweepstakes or Giveaway Winner Announcements, Surveys or Quizzes with Prizes, Service Upgrade Offers, Account Closure Announcements, Fake OTP Codes, Free Service Offers, and Personal Data Update Requests.
Water-Holing	Infected website with malicious code	Display Ads on Popular Sites, Manipulation of Affiliate or Partner Sites, Advertised Local Events or Events, and Attacks on Coupon or Discount Provider Sites.

Significantly few researchers have prevented social engineering attacks on digital marketing, such as preventing water-holing attacks by utilizing Remote Browser Isolation Technology [41] and building a Socio-Cyber-Physical System (SCPS) framework to protect digital marketing assets from the threat of cyber-attacks [39]. The study in [41] performs

isolation and protection of website security access by utilizing Remote Browser Isolation Technology. The concept proposed by [41] helps maintain customer trust, ensure data privacy, and protect brand reputation in the ever-evolving digital marketing landscape. In contrast to [41], [39] combines social behavior analysis, physical network monitoring, and powerful artificial intelligence to build a comprehensive and flexible security system to identify cyber-attacks in advertisements, such as phishing.

There was no one-size-fits-all solution for social engineering attacks, and not all mitigation or defense strategies were equally effective for every target. Therefore, methods for identifying and addressing differences in each target and existing social engineering attack models were needed to develop better prevention strategies [35].

B. Information Security Policy

Existing information security policies proposed by various studies and defined based on correlation topics among the policy and other scope include:

1) *General information security policy*: To build and implement an information security policy, [42] identified ten necessary elements, namely risk assessment, policy construction, implementation, compliance, management, employee support, and three input elements for policy development, including policy guidance standards, drivers, and current literature related to information security policy. Different elements proposed by [42] and [43] design information security policy to prevent insider threats in organizations. The study uses six elements, namely cyber threat intelligence, organizational commitment, security intelligence, information security investment, and misperceptions of information security. Meanwhile, [44] formulated information security policy to assist in organizational regulation and information system security. Information security forms consist of three main elements, such as archives of main directions or policy, standard aspects or policy elements, and activity procedures or technical directions. Additionally, [45] identified determining elements of information security policy, including policy components, objectives, actionable tools, consequences, educational concepts, general concepts, and additional sources. Similar to [45], [46] used seven elements, namely local, global, and integration elements, areas of information security policy expertise, ISP characterization, management, and critical player factors to build an information security model.

The elements proposed by [46], [45], [42], [44], and [43] shared a common relationship. However, a crucial step or procedure is more critical in the development of an information security policy [47], [48], [49]. Action methods, incorporating planning, action, and reflection are used to formulate information security policy in Small and Medium Enterprise (SME). The planning phase comprises identifying SME problems, the action phase consists of formulating an information system security policy, and the reflection phase assesses whether the policy is consistent with organizational

goals and resolves SME problems. This method was different from that of [49], which deployed a framework to realize information security policy for higher education. To safeguard an educational organization information asset from internal, external, intentional, or unintentional threats, an "Information Security Policy" must be developed [50]. The phases for elaborating information security policy, according to [49], include team development as a pre-development process, risk assessment, regulation drafting, validated policy documents, as a process of development, realization, control, and evaluation of policy as a utilization process.

Various studies adopted different perspectives when developing information security policy, such as ontologies and models. [51] used four stages to analyze the ontology, defining policy recognition to determine permission, obligation, or prohibition rules for users, determining action rules for accessible options in the system, identifying compliance factors with policy, and determining actors and accessors or recipients of information security policy practices. In comparison with [51], [52] used a policy-and human-oriented model consisting of three main factors, namely information security policy awareness, security training, and computer and security technology proficiency. Differing from the model proposed by [52], [53] used a formal model to determine security policy in companies by adopting the Chinese wall concept. Similarly, [54] developed a finite automaton policy model for implementation in network security systems. Meanwhile, [55] proposed a model discussing motivation mechanisms for employees to comply with the Information Systems Security Policy (ISSP). While studies presented various models to determine information security policy, no evaluation has been conducted on the proposed models in developing policy.

Numerous studies tried to assess existing information security policy to optimize development. Reference [56] scrutinized information security policy for implementing e-commerce in Saudi Arabia, while [91] explored the phases, context, and content of ISP information security policy development. Adjusting information security policy with business strategies is crucial for successful implementation, as identified by [57], which explored the assimilation of information security policy using a normative, mimetic, and coercive method. Evaluation of information security policy across various sectors, including business environments [58], education [59], and multiple entities in different countries [60], showed considerations such as non-compliance, promotion, management, policy updates, and biased policy areas. Recommendations for information security policy stem from risk analysis, industry guidelines, government legislation, and current organizational policy, yet [60] showed a lack of consistency in applying 'security controls' across policy.

Despite numerous studies on information security policy, several critical aspects require improvement. This includes the adoption of proposed policy applicable to various organizations, countries, and conditions, the evaluation of awareness surrounding developed policy, the lack of evaluation for policy acceptance, and the absence of technical procedures accompanying policy implementation.

2) *Information security policy in social engineering cases:* Social engineering is a cyber-attack with significant repercussions for organizations and individuals and has received limited attention in the aspect of information security policy. Reference [61] evaluated social engineering victims and provided policy recommendations for affected organizations. The study suggested that while education is highly appropriate for individuals affected by social engineering attacks, it may not suffice for members of organizations facing repeated attacks. The need for more suitable sanctions for organizational members was also discussed, advocating for a policy-based method to prevent social engineering attacks.

3) *Information security policy and formal model:* Reference [62] constructed a formal verification for information flow security with dynamic policy in a system. Furthermore, the study developed a general security model incorporating dynamic security policy, underscoring the importance of considering security policy in securing the flow of information.

In summary, various studies established diverse information security policies across different domains and scopes. Generally, investigation on information security policy has been developed based on unique methods and study scopes. However, no prior explorations outlined a social engineering security policy model for digital marketing, which is a gap the current study aims to fill.

C. Risk Assessment in Security Policy

Conducting risk assessments is recommended as a foundational step in developing information security policy. Social engineering arises due to hackers exploiting human vulnerability [63]. Therefore, risk assessments are necessary for organizations and individuals as an initial step in formulating policy to prevent social engineering attacks. [63] identified the nature and key factors of social engineering, conducted a risk assessment using a probabilistic model, and subsequently implemented mitigation strategies based on the assessment results.

Compared with [63], [64] verified the attack vector and prevention of social engineering using a formal model method. Risk assessment models prove valuable in situations characterized by high uncertainty and known facts [64]. The developed risk assessment model aids decision-makers in choosing the optimal solution for mitigating vulnerability and reducing risks.

D. Information Security Policy Evaluation

Previous studies proposed evaluating information security policy. For example, [65] described information security policy measurement using the readability factor. The study used sequential mixed methods to assess the readability of information security policy, although it did not delve into explaining the elements of information security policy. Similar to prior investigations, this study does not evaluate social engineering policy for digital marketing. The current review aims to address the gap in the existing literature by exploring a

security policy model to prevent social engineering attacks in digital marketing, an area that has received limited attention.

The study topic primarily focused on social engineering and information security policy as shown in Table III. It was observed that there was an absence of a study topic specifically addressing social engineering policy for digital marketing. Reference [8] determined the connection between social engineering and marketing, showing that social engineering could be used to reach customers in marketing strategies. However, it could not be directly applied to prevent the impact of social engineering in marketing activities. Addressing these gaps would be interesting to develop a social engineering policy model for digital marketing.

TABLE III. COMPARISON OF THE REVIEW STUDIES

III. METHODOLOGY

In this section, the research outlines the approach employed to formulate a security policy model aimed at preventing social engineering attacks within the domain of digital marketing. This analysis was organized following the findings presented in study [75]. The systematic and structured steps are outlined in three main stages, namely Planning, Conducting, and Reporting and Dissemination, as illustrated in Fig. 1.

In the planning phase, this research methodology was constructed based on the significant contributions found in this source. These references provide the theoretical foundation and key insights that guided the selection and evaluation of relevant articles. Therefore, the structure of this review acknowledges the significant contributions of this literature, which plays a critical role in shaping this study approach.

Moving into the conducting phases, this research involved a systematic and comprehensive exploration of the selected literature. This phase included a meticulous analysis of the identified articles to extract relevant information pertaining to the design and implementation of social engineering policy

models in the realm of digital marketing. Data extraction methods were employed to categorize and synthesize key findings, enabling a detailed understanding of the methodologies, challenges, and outcomes presented in the literature. Additionally, during this phase, this research applied rigorous criteria to ensure the inclusion of studies that align closely with research question and objectives. The conducting phases were crucial in assembling a comprehensive overview of existing insights, paving the way for a nuanced and evidence-based evaluation of social engineering policy models in the context of digital marketing.

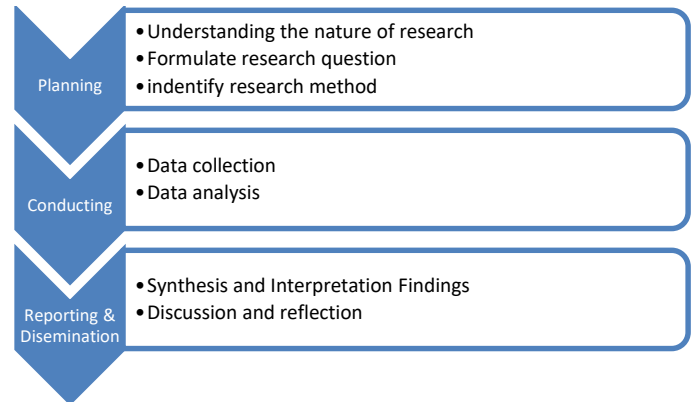

Fig. 1. The review study steps.

As this study transitioned into the reporting and dissemination phases, the focus shifted towards synthesizing the gathered information into a coherent narrative. This involved the compilation of a comprehensive report summarizing the key methodologies, findings, and insights obtained throughout the review. The report was structured to provide clarity and accessibility, ensuring that stakeholders and fellow researchers could easily comprehend the nuances of this study. Moreover, the dissemination aspect involved sharing research outcomes through appropriate channels, such as academic conferences, journals, and other platforms. This phase aimed to contribute to the broader scholarly conversation, fostering knowledge exchange and potentially influencing future research and practical applications in the field of social engineering policy models for digital marketing. Details of the criteria for the search, selection, and assessment process can be seen in Fig. 2.

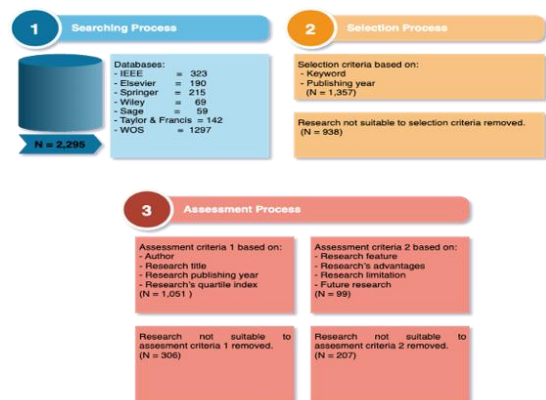

Fig. 2. Searching, Selection, and Assessment process.

A. Searching Process

The search process is a crucial component of this study, encompassing distinct selection and assessment phases. In the selection phase, the research objective was to identify and include studies that met predefined criteria essential to this study focus. Specific criteria, including aspects such as title, year of publication, and article type, were carefully applied to filter and include only studies relevant to this investigation.

To ensure a comprehensive exploration of the existing literature, the search was systematically conducted across nine renowned digital databases. These databases, namely ACM, Elsevier, Emerald, IEEE, Mdpi, Sage, Springer, Wiley, and the WOS index were selected for their prominence in hosting scholarly works related to the research domain. The inclusion of these diverse databases aimed to capture a broad spectrum of literature, enhancing the comprehensiveness and depth of this study.

Through this search process, this research sought to curate a robust collection of studies that would contribute meaningfully to understanding of social engineering policy models in the context of digital marketing. The emphasis on specific criteria and diverse databases ensures a rigorous and inclusive approach, allowing for a thorough examination of the available literature.

Aiming to address specific research question, “Which is the suitable method to design social engineering policy model for digital marketing?”, this study identifies, elucidates, and summarizes suitable methods. Article selection is based on specific criteria with relevant keywords such as social engineering, information security policy, risk assessment, and evaluation methods.

The outcome of the search process revealed 2,295 articles, including 323 articles indexed by IEEE, 190 articles indexed by Elsevier, 215 indexed by Springer, 69 articles indexed by Wiley, 59 articles indexed by Sage, 142 articles indexed by Taylor & Francis, and 1,297 indexed by WOS.

B. Selection Process

To ensure the inclusion of studies aligned with the research objectives, a meticulous selection process was undertaken. Specific criteria were defined, centering on keywords deemed relevant to the investigation, including social engineering, information security policy, risk assessment, and evaluation. These keywords were strategically chosen to encapsulate the essential components of research focus, allowing us to narrow down the pool of potential studies.

This comprehensive selection approach, which spanned multiple databases and publishers, aimed to capture a representative sample of the available literature, enriching the breadth and depth of this study. By adhering to specific criteria and surveying various databases, this study sought to ensure a thorough and well-rounded examination of the relevant studies in the field of social engineering policy models for digital marketing.

Articles were screened using criteria related to keywords and publication year, resulting in the identification of 1,357

articles during this phase. However, 938 articles did not meet the specified selection criteria.

C. Assessment Process

The next step involved assessment process, which was the final stage in this study. The process identified studies that were consistent with the objectives of this current study, using specific criteria and context. Furthermore, a matrix was developed to capture essential information such as author, title, publication year, quartile index, features, advantages, limitations, and potential future research.

This study employed two sets of assessment criteria. The initial criteria screened articles according to authorship, research title, publication year, and quartile index, yielding a total of 1,051 articles meeting these criteria. However, 306 articles did not align with the first set of assessment criteria and were excluded. The second set of criteria evaluated articles based on research features, advantages, limitations, and future research, resulting in the identification of 99 articles meeting these criteria. Additionally, 207 articles were deemed unsuitable based on the second set of criteria and were consequently excluded.

As a result, the selection process yielded a diverse set of results from various databases. Specifically, this study retrieved 2 papers from ACM, 13 from Elsevier, 9 from Emerald, 45 from IEEE, 1 from MDPI, 2 from Sage, 13 from Springer, 3 from Wiley, and 11 from other publishers indexed by the Web of Science (WOS). The results are presented in Table IV, encompassing the number of selected articles from each database.

TABLE IV. RESULT ASSESSMENT PROCESS

IV. RESULT

This study was categorized into three main areas with four subcategories, as shown in Table V. The primary contributions of the selected study for developing social engineering policy model for digital marketing comprised methods to building risk assessment based on qualitative methods models [63] or quantitative methods [64] and an evaluation method for information security policy before the release to users and stakeholders [76]. Finally, the selected study adopted different methods, aiming to develop information security policy or

prevent social engineering in the field of study, hence contributing to the development of a social engineering policy model for digital marketing.

TABLE V. MAPPING METHODOLOGY REVIEW

Methodology	Keyword	Study
Qualitative	Social Engineering	[7], [8], [18], [19], [29], [67], [68], [69], [70], [71], [72], [73], [77], [78], [79], [80], [81], [82], [83], [84], [85], [86], [87], [88], [89], [90], [91], [92], [93], [94], [95], [96], [97], [98], [99], [100], [101], [102], [103], [104], [105], [106], [107], [108], [109], [110], [111], [112], [113], [114], [115], [116], [117], [118], [119], [120]

	Risk Assessment	-
	Evaluation	-

V. DISCUSSION

The previous studies offered recommendations for designing security policy model to prevent social engineering attacks in digital marketing. Although various methods existed for designing security policy models to prevent social engineering attacks, this current investigation, according to [57], followed three phases, namely identifying security policy requirements, developing security policy model, and validating security policy model.

However, previous ones fell short of comprehensively addressing all three phases of designing security policy models to prevent social engineering attacks. It should be acknowledged that each study tended to concentrate on a specific part. For example, [118] exclusively discussed the user-centric model without covering other phases of designing security policy model for preventing social engineering attacks in digital marketing. Meanwhile, it overlooked the phases of developing security policy models, risk assessment frameworks, formal methods, and evaluation methods. This implies that future works are needed to design a comprehensive approach to model security policies to prevent social engineering attacks in digital marketing and to implement them in various organizations to see the effectiveness of the policies.

This study experienced several limitations, including acquiring methods to evaluate social engineering attack policy, particularly before and after policy implementation. Several studies solely concentrated on building information security policies to counter information security threats. Additionally, some social engineering explorations were limited to evaluating perceptions about information security policy and using formal models to identify essential processes in information security policy. While readability methods served as an alternative for assessing policy effectiveness, challenges existed in determining how to assess better readability in an organizational context. The aspect of digital marketing for social engineering is relatively new, yet numerous social engineering activities inevitably occur, particularly in information gathering. Even though the term "social engineering" in marketing carries a positive connotation, when the activity deviates, it could cause a threat to digital marketing activities without realization.

VI. CONCLUSION

This review successfully identifies methodologies that can be used to build Social Engineering Policy Models, especially Digital Marketing. This review categorizes quality articles into three methodologies, namely Qualitative, Quantitative, and mixed methods. Each article is categorized into social engineering, information security policy, risk assessment, and evaluation. Based on the review’s findings, many researchers only build policies to prevent social engineering attacks but do not validate the policies used, especially researchers who use mixed methods. Therefore, one of the directions of future research development is to ensure that every social engineering attack policy built must be validated or assessed. Validation and assessment can use formal methods and risk assessment techniques.

ACKNOWLEDGMENT

The authors also would like to show gratitude to Faculty of Information Science and Technology, and Universiti Kebangsaan Malaysia for their support.

Teknik Informatika-Fakultas Sains dan Teknologi, Universitas Islam Negeri Sultan Syarif Kasim Riau, Indonesia¹

Abstract—This study aims to conduct a comprehensive bibliometric literature review of chatbot research by examining key trends, frameworks, and influential applications across various domains. It seeks to map the evolution of chatbot technologies, identify influential works, and analyze how the research focus has shifted over time, particularly towards AI-driven chatbot frameworks. An expanded dataset was compiled from the Scopus database, and bibliometric analyses were conducted using n-gram reference analysis, network mapping, and temporal trend visualization. The analysis was performed using R Studio with Biblioshiny, allowing for the identification of thematic clusters and the progression from rule-based to advanced retrieval and generative language model paradigms in chatbot research. Chatbot research has grown significantly from 2020 to 2024, with rising publication volumes and increased global collaboration, led by contributions from the USA, China, and emerging regions, such as Southeast Asia. Thematic analysis highlights a shift from foundational AI and NLP technologies to specialized applications such as mental health chatbots and e-commerce systems, emphasizing practical and user-centered solutions. Advances in chatbot architectures, including generative AI, have demonstrated the field's interdisciplinary nature and trajectory towards sophisticated, context-aware conversational systems. The analysis primarily used data from Scopus, which may limit the breadth of the included research. Future studies are encouraged to integrate data from other sources, such as the Web of Science (WoS) and PubMed, for a more comprehensive understanding of the field.

Keywords—Chatbot research; bibliometric literature review; retrieval and generative; trend visualization

I. INTRODUCTION

Current technological trends indicate that chatbots are popular applications that use Artificial Intelligence [1], Machine Learning [2], Deep Learning [3], and Natural Language Processing [4]. They are used in various fields, including education, health, universities, schools, nursing, and business. Computers are becoming increasingly capable of performing tasks that humans perform. With artificial intelligence and machine learning technology, computer systems have become more compact and efficient in understanding voice and text interactions, leading to an effective speed [5].

Numerous prominent chatbots utilizing deep learning techniques have been created by major corporations, including ChatGPT by OpenAI, Alexa by Amazon, Siri by Apple, Google

Assistant by Google, Cortana by Microsoft, and Watson by IBM [6]. These chatbots serve as personal assistants in daily activities. They communicate through voice and integration with devices, such as smartphones, smartwatches, and cars. Owing to the rapid growth of chatbot applications, technical analysis methods are required, and a framework that is widely used in building chatbots today classifies chatbots into two distinct categories: task-oriented and non-task-oriented [7]. Task-oriented aspects operate according to human instructions, whereas non-task-oriented aspects have multiple objectives but cannot carry out specific activities. Non-task-oriented chatbot architectures can be classified into generative-based and retrieval-based. Chatbots are generally used to answer the questions asked by users. Typically, users initiate a conversation with this application and provide answers after analyzing the questions. Chatbot users must have convenient, flexible, and real-time access to ensure successful use [8].

This study investigates the trend of chatbot development, the sectors that use chatbots, and the frameworks and methodologies applied to chatbot development. Several research initiatives in the field of chatbots have used bibliographic analyses conducted by previous scholars. Io et al. [9] conducted an extensive bibliometric analysis of chatbot literature, emphasizing the growth of research beginning in 2015. This study suggests that future research should investigate new technologies and uses for chatbots, focusing on both user and business viewpoints to optimize chatbot functionality. The authors used traditional methodologies in chatbot development, focusing solely on Natural Language Processing techniques, such as natural voice, facial emotions, and body movements. Recent advances in deep learning require additional research to explore the potential applications of this cutting-edge technology for chatbot development across several domains.

Adomopoulou et al. [10] analyze the evolution of chatbots, focusing on their transition from simple rule-based systems to sophisticated machine-learning models. Researchers have critically analyzed various applications of chatbots in different domains, focusing on the importance of natural language processing and user interaction. It examines the current obstacles and potential future directions of chatbot technology, and suggests further research and development avenues to improve chatbot effectiveness and user satisfaction. The analysis conducted in this study reveals a persistent trend towards a high preference for basic authors. However, there is a

noticeable lack of comprehensive investigation into specific health topics, such as 'older people' or 'mHealth,' which are overshadowed by a broader emphasis on AI-based outcomes.

Pears et al.[11] conducted a bibliometric analysis to examine the increasing prevalence of chatbot applications in the healthcare sector. The increase in patient interactions has been attributed to advancements in AI and ML, particularly in NLP. Since 2016, there has been a substantial surge in research productivity, characterized by a transition from technology to studies centered around artificial intelligence and its practical applications. The research potential of advanced AI approaches has been emphasized by researchers who have specifically focused on developing user-friendly interfaces, tailored interactions, and integrating chatbots within various healthcare contexts. Furthermore, our analysis underscores the need to employ co-creation techniques that include stakeholders to enhance the efficacy of conversational agents designed for healthcare applications.

The objective of this study was to examine the trends and suggestions found in publications on chatbots, utilizing a bibliometric analysis approach. This study also presented visualizations of the current movement in chatbot development on different topics. The following research problems were addressed using data from the Scopus database.

RQ1: Who are the most prolific authors in chatbot, and what are their key research themes and topics?

RQ2: What are the most active countries in chatbot, and how does this vary across different regions and time periods?

RQ3: What are the prevalent keywords employed in the field of chatbots developed through bibliometric analysis?

RQ4: What research trends relate to chatbots (thematic and evolution trends), including journals, fields, countries, and universities?

RQ5: Which components, techniques, and frameworks are most widely used in chatbot development?

II. LITERATURE REVIEW

This literature review provides a comprehensive, updated overview of research developments in chatbot technology, focusing on recent innovations in AI, ML, NLP, and deep learning. This section surveys studies that address the expansion and application of chatbots across various domains, emphasizing the intellectual and social structures that shape current trends. By highlighting methodologies, frameworks, and analytical approaches from previous studies, this review aims to establish a foundation for understanding the gaps, advancements, and emerging directions in chatbot research, thereby framing the significance and context of the present study.

A. Historical Development

The history of chatbot development has evolved significantly from early rule-based systems to sophisticated AI-driven models. Over the years, advancements in machine learning, natural language processing, and neural networks have revolutionized chatbot capabilities. By the 2010s, major

companies such as Apple, Amazon, and Google had introduced intelligent virtual assistants—Siri, Alexa, and Google Assistant—that leveraged voice recognition and vast data processing to perform more complex tasks. These developments signaled a shift towards conversational AI with greater versatility, accuracy, and personalization. In recent years, deep learning and transformer models such as OpenAI's GPT series have marked significant milestones, enabling chatbots to generate human-like responses and comprehend contexts with remarkable accuracy. Studies often employ advanced research designs, such as bibliometric analyses, to map intellectual and social trends in chatbot development. This evolving landscape demonstrates a continued effort to optimize conversational agents for diverse applications, including healthcare, education, and customer service, with an emphasis on user-centric frameworks that balance functionality with ethical considerations.

B. Recent Development

Recent developments in chatbot research reflect a shift towards integrating emerging technologies, such as advanced NLP, deep learning, and transformer models, notably the architecture underlying OpenAI's GPT series. Researchers are increasingly examining chatbot applications in diverse fields, including healthcare, government, and education, where the demand for real-time, personalized, and secure interactions has grown. This expansion has led to new concerns, especially regarding data privacy and cybersecurity, because chatbots handle sensitive user data. In the healthcare sector, chatbots now assist in patient management and mental health support, whereas in the government, they provide accessible public service information. These applications underscore the importance of secure, efficient, and adaptable chatbot systems that can respond to domain-specific requirements. In terms of methodology, recent research has often used mixed methods, combining quantitative and qualitative data to capture user satisfaction and chatbot performance insights. Machine learning and NLP integration have become essential, enabling chatbots to process and understand complex queries more effectively. These trends indicate that future research will likely focus on enhancing chatbot trustworthiness, expanding their usability across contexts, and addressing ethical considerations in AI-driven interactions, ensuring that chatbot systems align with user expectations and privacy needs.

C. Previous Studies on Bibliometric Analysis

Previous studies on the bibliometric analysis of chatbots and conversational agents have primarily focused on mapping the field's growth, identifying prominent authors, and analyzing keyword trends. For instance, Io et al. [9]. conducted a bibliometric analysis that emphasized the rapid rise in chatbot research since 2015, focusing on NLP and AI advancements. However, their methodology is limited by its reliance on traditional NLP techniques, and the lack of integration of emerging deep-learning methods is now central to chatbot development. Similarly, Adomopoulou et al. [10] examined the transition of chatbots from rule-based to machine-learning-driven systems, highlighting applications across various sectors, but noting an underrepresentation of specific areas, such as health-related chatbots tailored for older adults.

Pears et al. [11] analyzed chatbots in healthcare and revealed the increasing role of conversational agents in enhancing patient interaction. However, further research on ethical considerations and patient data security is required. Collectively, these studies provide valuable insights into the evolution of chatbot research. However, they are limited by their focus on specific technologies or sectors and often overlook broader applications or recent AI advancements. Notably, there is a gap in the comprehensive frameworks that assess chatbot adoption across multiple domains. Future research could address these gaps by incorporating advanced bibliometric techniques, examining ethical implications in more depth, and exploring the diverse applications of chatbots in emerging fields, such as government services and personalized education.

Manigandan et al. [12] conducted a bibliometric analysis for mapping research landscapes across various fields. Chatbots, conversational agents, and virtual assistants were employed to identify publication trends, key research themes, and collaborative networks among authors and institutions. Recent studies have revealed a significant increase in chatbot-related research since 2018, highlighting its growing importance in business, management, and accounting. Common themes include chatbot design, customer experience enhancement, and business operations automation, although ethical concerns such as privacy and transparency remain underexplored. Despite increased interest, the field is characterized by limited collaboration among researchers and nations, underscoring the need for more inclusive partnerships. Future studies should

address underrepresented areas such as the ethical implications of chatbot use, user perceptions, and long-term organizational impacts. Expanding research into industries such as healthcare and education could also uncover the unique challenges and opportunities for chatbot adoption.

A similar study was conducted by Tawar et al. [13], who focused on the field of business management, although this research is rooted in computer science applications. Bibliometric analyses have proven valuable for systematically reviewing research trends, themes, and gaps across disciplines. In chatbot research, these analyses reveal the growing adoption and application of chatbots in areas such as customer service, marketing, and other sectors, showing their positive impact on customer engagement, trust, and business efficiency. However, significant limitations remain, including a focus on developed countries and insufficient exploration of ethical concerns such as privacy and transparency. Moreover, many studies rely on short-term data, lacking the longitudinal insights necessary to understand the evolving user behavior and technological progress. Addressing these gaps requires exploring cross-cultural contexts, developing ethical frameworks for chatbot use, and expanding applications in underexplored fields, such as healthcare and education. Future research integrating interdisciplinary theoretical approaches and longitudinal studies could deepen understanding and drive innovative developments in chatbot technologies. The summary of previous studies is presented in Table I.

TABLE I. SUMMARY OF PREVIOUS STUDIES

Author	Domain & Search Query	Objective of the Study	Total Document, Data Source & Coverage	Attributes Examined	Main Findings
Tanwar et al.[13]	The range of subject areas was restricted to “Business, Management and Accounting”, “Social Sciences”, “Psychology” and “Multidisciplinary”.	science mapping, performance analysis, and bibliographic coupling to identify significant trends and areas of research emphasis	798 articles from Scopus.	Publication Trends, Most Productive and Influential Countries, Most Prolific Authors, Most Prolific Contributing Institutions, Most Prolific Journals, Intellectual Structure of Chatbots.	Key areas of chatbot research include: applications of chatbots, behavioral and relational effects of chatbot use, and factors influencing chatbot adoption, including barriers. The United States leads in contributions, with the highest number of research articles and citations in this field.
Agarwal et al.[16]	Domain: Chatbots in Computer areas. Search Query: (TITLE-ABS-KEY (“chatbots” AND “virtual assistants”))	to examine the past research, to provide a conclusive mark, to explore the combination of keywords used in chatbots	130 articles from Scopus.	Theoretical contributions, Research implications, Managerial implications, Social implications.	The authors with maximum number of citations are Yan, Zaho, Bengio, Weizenbaum, Song, Zhou and Maedche with jointly 180 citations.
L et al. [12]	Domain: Chatbot in Business Management and Accounting	to identify key publication metrics, examine the intellectual structure, and explore the social structure of research in this field.	378 articles from scopus	number of publications and citations over time, productive authors, country productivity, h-index and intellectual structure	The keywords “Chatbot”, “conversational agent” and “virtual assistant” emerged as the most frequently employed terms in the majority of publications.
Io et al.[9]	consider the two terms “chatbot” and “conversational agent”	s to help researchers to identify research gaps for the future research agenda in chatbots	4,246 articles from wos and proQuest	Clustering keywords, co-occurrences.	The results of the analysis found a potential research opportunity in chatbot
Xia et al.[17]	Domain “AI Chatbo”	to offer bibliometric assessments of the expanding literature about AI chatbot services	571 article from scopus	the most influential work, authors, and co-cited authors on AI chatbots	based on the author’s cocitation analysis and the intellectual structure, Computer science is the most critical discipline regarding AI applications

III. METHODS

This Bibliometric Literature Review (BLR) utilized the bibliography analysis and meta-analysis approach. Bibliometric analysis is a crucial and effective method for comprehending the progression and patterns of research. Science mapping analysis is an integral part of bibliometric analysis that aims to provide a structured examination of trends periodically, studied themes, changes in fields of knowledge, and productive researchers [14], [15].

A. Search Strategy

Search Strategy: Explain how you identified the relevant literature for bibliometric analysis. This may include details such as the databases and search terms used, and any inclusion or exclusion criteria applied to the search results. The period covered in your analysis should also be described.

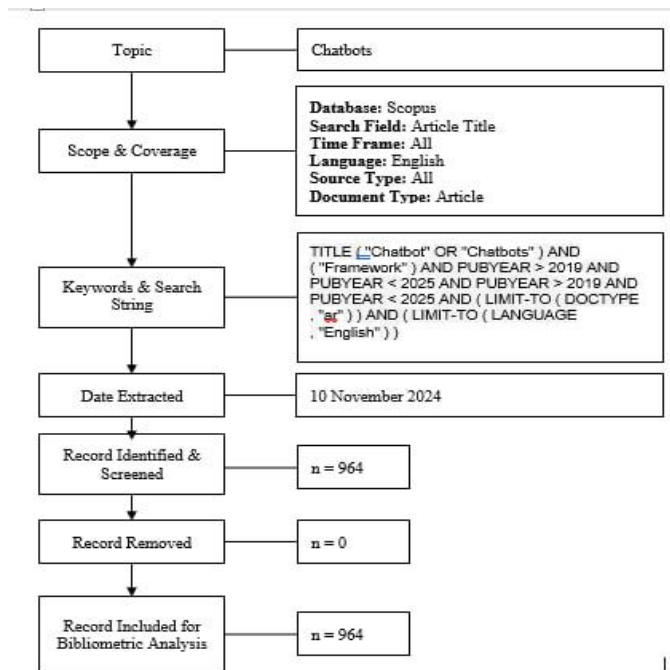

Fig. 1. Flow diagram of the search strategy.

Fig. 1 shows the stages in collecting data starting from topic and scope, keywords and search query, date extracted, record removed, record identified, and record included for bibliometric analysis.

B. Data Collection

The Search Strategy stages encompass distinct procedures: data extraction, identification, screening, record removal, and record inclusion in bibliometric analysis. We used Search Strategy stages to determine entries from the Scopus database by executing a query. The search yielded 964 documents.

C. Data Cleaning and Harmonization

To ensure the accuracy and consistency of the data imported into Biblioshiny, rigorous data cleaning was performed using the OpenRefine tool. The BibTeX file generated by Biblioshiny was exported to OpenRefine, and the dataset was verified to match the original source. Specific adjustments included standardizing

author data by converting them to lowercase data. The integrity of the dataset was validated through a series of analytical processes using OpenRefine, ensuring that it was clean and suitable for bibliometric analysis.

D. Tools

The Scopus database was used to obtain studies for a comprehensive evaluation of chatbot research. The identification process began with a well-defined search strategy that was used to query the Scopus database and retrieve relevant entries. Following data collection, the articles were analyzed using the Biblioshiny tool in R Studio, enabling a detailed bibliometric analysis and visualization of research trends.

IV. RESULTS

This section examines publications, research activities, journals, papers, and references, providing an analytical overview. Following the analysis, the findings are further explored and discussed to offer deeper insights into the subject matter.

A. Analysis of Publications

The main information from the article was entered into R bibliometric software for bibliometric analysis. From the analysis results, a significant increase in research in the field of chatbots was found from year to year. The growth of this research is depicted in the following Table II.

TABLE II. MAIN INFORMATION DATA

Main Information	Data
Publication Years	2010 - 2024
Total Publications	955
Annual Growth Rate %	60.28
Document Average Age	1.13
Average citations per doc	20.61
Keywords Plus (ID)	3061
Author's Keywords (DE)	2848
Single-authored docs	66
Co-Authors per Doc	3.91
International co-authorships	27.64

From 2010 to 2024, there were 955 publications with an impressive annual growth rate of 60.28%, indicating a rapidly expanding field. The average document age is 1.13 years, and each publication receives an average of 20.61 citations, reflecting substantial academic impact. Collaboration is prevalent, with 3.91 co-authors per document on average, and 27.64% of publications involve international co-authorships, highlighting the global nature of the research.

Fig. 2 shows Annual scientific production has grown consistently from 2020 to 2024, reflecting a substantial increase in research activity. Starting with 60 articles in 2020, the output increased to 98 articles in 2021 and 142 in 2022. This upward trend continues with 259 articles in 2023 and peaks at 396 articles in 2024, indicating an accelerating interest and investment in the field over the five-year period.

Fig. 2. Annual scientific productions.

TABLE III. AVERAGE CITATIONS PER YEAR

Year	Mean TCperArt	N	Mean TCperYear	CitableYears
2020	84.27	60.00	16.85	5
2021	49.37	98.00	12.34	4
2022	30.42	142.00	10.14	3
2023	15.67	259.00	7.84	2
2024	3.55	396.00	3.55	1

Table III provides information on the Mean Total Citations per article (MeanTCperArt), the number of articles (N of article), and the resulting Mean Total Citations per year (MeanTCperYear) for these years 2020 to 2024. In 2020, the mean total number of citations per article was 84.27, with eight articles contributing to a mean total number of citations per year of 18.85. Subsequently, there is a noticeable increase in the mean total citations per article per year in 2020, 2021, and 2022, followed by a significant decrease in 2023 and 2024. Measure an author's impact using the citation count, average citation rate, h-index, g-index, m-index, total citations, number of documents, and py_start, as shown in Table IV.

TABLE IV. AUTHORS' LOCAL IMPACT

Authors	h_index	g_index	m_index	TC	NP	PY_start
FØLSTAD A	6	9	1.200	286	9	2020
ZHU Y	6	10	2.000	235	10	2022
MOU J	5	5	1.667	305	5	2022
CHEN Q	4	5	1.333	145	5	2022
CHEN Y	4	4	1.000	201	4	2021
HOBERT S	4	5	0.800	156	5	2020
JEON J	4	7	2.000	220	7	2023
KIM H	4	5	0.800	146	5	2020
LI Y	4	5	2.000	34	7	2023
LIU Y	4	5	1.333	145	5	2022

Table IV provides an analysis of the top authors in chatbot-related research, based on bibliometric indices. FØLSTAD A and ZHU Y demonstrate the highest h-index scores (6), indicating consistent citation impact, with ZHU Y leading in g-index (10) and m-index (2.000), showcasing sustained

productivity and influence since 2022. MOU J stands out with the highest total citations (305) despite having a lower g-index (5), reflecting impactful but fewer publications. JEON J and LI Y show notable m-index values (2.000), suggesting rapid citation growth relative to their research duration, particularly with recent publications in 2023. Meanwhile, CHEN Q and LIU Y exhibit balanced productivity and citation metrics, while HOBERT S and KIM H display consistent contributions since 2020. Overall, the data revealed diverse patterns of research impact, emphasizing both sustained contributions and emerging influencers in the field. Meanwhile, the influence of countries contributing to this field is dominated by the USA and China, as shown in the picture of the country scientific production below.

Fig. 3. Countries' scientific productions.

The Fig. 3. highlights the regional distribution of publications on chatbot research, revealing significant contributions from the USA (372), followed by China (319), and India (155), demonstrating their leadership in the field. Notable contributions also come from the UK (134), Australia (110), and Canada (109), indicating strong engagement from English-speaking countries. Asian nations such as South Korea (97), Indonesia (56), and Malaysia (49) also feature prominently, showing increasing research activity in the region. European countries, including Spain (92), Germany (77), and Italy (50), have contributed substantially, reflecting their growing interest in the domain. While regions such as the UAE (38), Brazil (47), and Turkey (38) indicate moderate contributions, countries with emerging research activities such as Morocco (21) and Thailand (24) highlight the global expansion of chatbot research. Smaller contributions from nations such as Ethiopia, Zambia, and Fiji emphasize the nascent but widespread adoption of chatbot research across diverse geographical areas.

B. Analysis of References

In bibliometric analysis, the purpose of analyzing references is to examine and scrutinize citations in academic publications, aiming to uncover insights into the intellectual structure and progression of a specific field of study. By analyzing references, bibliometrics can identify the most influential works and authors in a field, track their evolution, and identify key research trends and collaborations. This analysis can help researchers and policymakers to make informed decisions regarding the direction of future research. In this article, the analysis of

references is divided into two analyses: the most relevant word and evolution trend analysis.

Using Biblioshiny, word cloud visualization was performed to examine the keywords commonly used in articles related to chatbots. In this study, the most relevant words were identified by analyzing the keywords listed in the author's section of each article. The word cloud generated from the top 20 words shows a broad spectrum of crucial terms in the realm of chatbots, covering pivotal areas such as "artificial intelligence," "natural language processing," "conversational agents," and "chatgpt," among others. It encompasses an extensive range of concepts, including "anthropomorphism," "machine learning," and "covid-19," reflecting the multidisciplinary nature and depth of subjects related to chatbot technology and human-computer interaction. Fig 4 shows the most relevant keyword descriptions.

Fig. 4. Word cloud by keywords.

By analyzing the titles of articles from the authors, the words frequently used were Artificial Intelligence, AI chatbots, Mental Health, Customer Service, Intelligence Chatbots, Generative AI, Mixed Methods, and Natural Language. The frequency of occurrence in the analysis using N-Grams (Bigrams) is shown in Table V.

TABLE V. WORD FREQUENCY

Word	2020	2021	2022	2023	2024
Artificial Intelligence	2	5	10	35	68
Ai Chatbots	1	2	10	14	101
Mental Health	1	4	11	17	26
Customer Service	0	2	4	11	19
Intelligence Chatbots	2	3	6	19	36
Generative Ai	0	0	0	1	16
Mixed Methods	0	1	4	6	16
Natural Language	1	2	5	10	18

This table illustrates the dynamic evolution of key research topics in chatbot-related studies from 2020 to 2024. "Artificial Intelligence" consistently leads the discourse, showing significant growth from 2 mentions in 2020 to 68 in 2024, reflecting its foundational role in chatbot development. Similarly, "AI Chatbots" demonstrates exponential growth,

particularly in 2024, with a sharp rise to 101 mentions, highlighting their increasing adoption and application. Emerging topics like "Mental Health" and "Customer Service" reveal a steady increase, emphasizing the diversification of chatbot applications in addressing user needs. "Intelligence Chatbots" and "Natural Language" also exhibited consistent growth, underlining advancements in chatbot sophistication and linguistic capabilities. Notably, "Generative AI" which appeared only recently, shows substantial growth in 2024, indicating a shift towards innovative frameworks and methodologies in chatbot research. These trends underscore the expanding scope and interdisciplinary nature of this field.

Meanwhile, the word "framework" is in the 31st position as the most frequently appearing word, and its occurrence has increased from year to year, two times in 2020, six times in 2021, 12 times in 2022, 18 times in 2023, and 33 times in 2024. Several types of framework have been used in chatbot applications. These include RASA, Microsoft Bot Framework, Google Dialogflow, Telegram, Facebook, Twitter, Whatsapp, Wit.Ai, IBM Watson, Line, BotPress and Streamlit. Table VI lists some frameworks used for chatbot development in this study.

TABLE VI. FRAMEWORK OF DEVELOPMENT CHATBOTS

Framework	Authors
RASA	Fauzia[18], Windiatmoko[19]
Microsoft Bot	M. Cont & A. Ciupe[20], L. Zhou[21]
Google Dialogflow	S. Valtolina, Jr. [22], Villanueva G.R.[23]
Facebook	Aina, Pashev[24] & Gaftandzhieva[25]
Wit.ai	Li C. [26], Chu E [27]
Twitter	Y. M. Çetinkaya[28], E. Alothali[29]
Telegram	Y. Wahyuni[30], W. Santoso[31]
Whatsapp	Mash[32], Paschetto[33]
IBM Watson	R. J. Moore[34], C. V. M. Rocha[35]
Line	AI Rasyid [36]
Botpress	Macanu B[37] ,
Streamlit	Kiangala K [38], Kothari S [39]

Interestingly, Streamlit was used in the 2023 and 2024 studies, where it was used as a generative AI chatbot using a large language model. The analysis and interpretation of research related to mental health dominate the health sector. Meanwhile, e-learning dominates the education sector and sales dominate the business sector. The top six fields where chatbots were developed are Health, Education, University, Financial, Industry and Tourism. Thematic evolution analysis was used to analyze chatbot trends in this study. Thematic evolution analysis was performed based on a co-word network and clustering. Using these diagrams, it can be shown that chatbot research changes yearly. The existing keywords indicate the direction of research changes. Fig. 5 shows a thematic evolution diagram of the Keyword Plus field.

Thematic analysis revealed a dynamic evolution in chatbot research trends from 2020 to 2024. During 2020–2022, broad foundational themes such as "AI" and "NLP" were central,

representing the underlying technologies for chatbot development. As research advanced, a notable shift occurred towards applied themes in 2023–2024, such as "e-commerce," "human-computer interaction," and refined chatbot designs. For example, the transition from "AI-2020-2022" to "chatbot-2023-2024" underscores the growing emphasis on creating specialized systems tailored to industry-specific needs.

Fig. 5. Thematic evolution.

From 2023–2024, the emergence of "e-commerce" chatbots (weighted inclusion index of 1.00) highlights their importance in enhancing online retail and customer interaction. Similarly, themes like "human-computer interaction" reflect an increasing focus on usability and user satisfaction, as chatbots evolve to provide more intuitive and engaging experiences. Additionally, "AI chatbot," which persisted across both periods, illustrates continuous efforts to improve conversational models, ensuring their adaptability and effectiveness in addressing real-world challenges.

The stability indices across themes revealed sustained interest in specific areas. While "e-commerce" chatbots exhibit relatively high stability (0.11), foundational themes such as "AI" and "NLP" show lower stability, reflecting their transformation into specialized applications. By 2024, research trends will clearly demonstrate a movement from broad theoretical discussions to practical implementations, with chatbots playing critical roles in domains such as retail, customer service, and user interaction design. This evolution highlights the increasing maturity and impact of chatbot technologies in various sectors.

V. DISCUSSION

Research Question 1. The analysis of prolific authors and their contributions to chatbot research revealed significant growth and diversification in the field from 2020 to 2024. Annual scientific production has increased substantially, with article outputs rising from 60 in 2020 to 396 in 2024, demonstrating an accelerating interest and investment in chatbot studies. Citation trends, as presented in Table III, highlight declining mean total citations per year over time, suggesting that while publication volume has grown, the citation impact of

individual articles may have been diluted because of the field's rapid expansion. As detailed in Table IV, the key contributors include FØLSTAD A and ZHU Y, which lead to h-index scores, reflecting a consistent influence. At the same time, ZHU Y and JEON J exhibited high m-index values, signifying rapid citation growth in recent studies. MOU J achieved the highest total citations (305), indicating a significant impact despite fewer publications. Emerging influencers such as JEON J and LI Y demonstrate rapid citation accumulation, with research starting in 2023. Additionally, country-level data underscores the dominance of the USA and China in scientific production, positioning them as central players in advancing chatbot research. Together, these findings highlight both the maturation of established contributors and the emergence of new voices in the evolving chatbot research landscape.

Research Question 2. The analysis of chatbot research activity across different countries and regions revealed a rapidly expanding global field, with a remarkable annual growth rate of 60.28% from 2010 to 2024, culminating in 955 publications. The research is highly collaborative, with an average of 3.91 co-authors per document, and 27.64% involving international co-authorships, underscoring its global nature. The USA has 372 publications, followed by China (319), and India (155), reflecting their dominance in advancing chatbot technologies. Significant contributions from the UK (134), Australia (110), and Canada (109) highlight the strong engagement of English-speaking nations. Asian countries, such as South Korea (97), Indonesia (56), and Malaysia (49), also show robust participation, indicating the region's growing focus on chatbot research. European nations, including Spain (92), Germany (77), and Italy (50), have contributed substantially, showcasing their increasing interest in this domain. While countries such as Brazil (47), Turkey (38), and the UAE (38) reflect moderate engagement, emerging players, such as Morocco (21) and Thailand (24), highlight the global diffusion of chatbot research. Small contributions from nations such as Ethiopia, Zambia, and Fiji demonstrate the field's expansion to diverse and underrepresented regions, marking a promising trajectory for future research collaboration and development worldwide.

Research Question 3. Utilizing R Biblioshiny, the study yielded significant findings regarding the dominant keywords in articles focused on chatbots through the creation of word cloud visualizations. The analysis uncovered a wide range of essential terms that influence the development of chatbot technology based on the keywords provided by the authors. The word cloud consists of the top terms that emphasize essential topics vital to chatbots, such as "artificial intelligence," "natural language processing systems," "conversational agents," and "machine learning." This provides a complete overview of the essential principles of the field. Furthermore, the incorporation of words such as "semantics," "reinforcement learning," and "user interfaces" user interfaces emphasized the interdisciplinary character of chatbot technology and its convergence with human-computer interactions. These results are different from those found by previous researchers, where the keywords that are widely used are natural processing language, big data, learning algorithm, language learning system, and user experience [16].

Fig. 4 illustrates the visualization that effectively displays the essential characteristics of the discovered keywords, highlighting an extensive range of issues within the chatbot field. Moreover, an analysis of article titles revealed frequent terms such as “Artificial Intelligence”, “AI chatbots”, “Mental Health”, “Customer Service”, “Intelligence Chatbots”, “Generative AI”, “Mixed Methods” and “Natural Language”. The continued presence of frameworks in these titles indicates their enduring significance and prominence in conversations related to chatbots. The keyword frequency analysis of article titles revealed a notable pattern: the topic of Mental Health Chatbots was the most commonly discussed compared to other domains. This finding underscores a significant inclination towards using chatbot technology for mental health purposes, signifying the growing acknowledgment of the significance of technology in augmenting overall well-being. Additionally, it underscores the expanding apprehension over trust and acceptance in employing technology to address mental health concerns.

Research Question 4. The findings illustrate a clear evolution in chatbot research, transitioning from foundational themes to specialized applications between 2020 and 2024. In earlier years, the focus was predominantly on developing underlying technologies, such as artificial intelligence and natural language processing, which laid the groundwork for subsequent advancements. By 2023–2024, the emergence of themes like “e-commerce” and “human-computer interaction” demonstrates a shift towards practical and user-oriented applications. This transition reflects the increasing demand for chatbots in sectors that require tailored, intelligent, and efficient communication systems, particularly in e-commerce and service-oriented industries.

The persistence and refinement of themes such as “AI chatbot” also highlight the continued need for innovation in conversational models. While foundational topics showed lower stability indices owing to their evolution into specialized areas, emerging applications demonstrated higher stability, underscoring their growing importance. These findings suggest the maturation of the field, with research increasingly addressing the real-world challenges. Future studies could build on this trend by exploring the integration of advanced chatbot systems into more diverse sectors, emphasizing ethical considerations, user satisfaction, and the long-term sustainability of these technologies. In contrast, previous research observed that chatbot trends have evolved from basic rule-based systems to advanced machine-learning models [10]. However, this study found that the machine learning trend has shifted towards reinforcement learning and knowledge-based systems.

Research Question 5. In chatbot architecture, key elements include the Question Answering System, The Environment, The Front-end System, Traffic Server, and Custom Integrations. This discussion delves into the methods employed within the Question Answering System components and the framework applied to the front-end system. The utilization of AI, particularly deep-learning technology, has emerged as a prevailing trend in chatbot development. This aligns with the findings of Caldarini et al. [40], who emphasized the future of chatbot development through NLP techniques and utilization of deep learning technology. This correlation is in agreement with

the thematic evolution analysis conducted in this research, revealing a prominent theme centered on deep learning.

Various techniques have been employed in chatbot development, each of which has its own strengths and applications. Rule-based systems rely on predefined rules and patterns to generate responses [41]. Meanwhile Kandasamy et al. [42] stated that Information retrieval-based systems focus on retrieving relevant information from a large text corpus. On the other hand, Ngai et al. [43] asserted that Knowledge-based systems use structured knowledge bases or ontologies to provide answers. NLP-based systems utilize NLP techniques to understand and generate context-aware responses [44]. Machine learning-based systems leverage supervised, unsupervised, or reinforcement learning to train models capable of answering questions [45]. Thus, the choice of development technique depends on the chatbot's specific requirements and goals.

There have been substantial advancements in the broader field of NLP. NLP encompasses the interaction between computers and human language. Recent developments in deep learning, particularly with models such as transformers, for example, bidirectional encoder representations from transformers (BERT), have led to significant breakthroughs in NLP applications such as sentiment analysis, machine translation, and question-answering [46]. Furthermore, NLP research spans various domains, including question-answering systems (QAS), summarization, machine translation, speech recognition, and document classification, each contributing to the overall evolution of NLP [47].

The chatbot architecture plays a crucial role in their functionality and effectiveness. Hwang et al. [48] research provided an overview of chatbot architecture, with components such as NLU, Intents/Entitas, Message Generator, Knowledge-Based database, and Respon. This architecture serves as the foundation for the design and operation of chatbots, encompassing various components and modules that enable them to interact with users and respond.

The need for external references and context becomes evident in open-domain Question Answering (QA), where the chatbot is expected to answer a wide range of questions. Researchers, such as Chen et al. [49] have developed frameworks such as the Retriever-Reader Framework. This framework allows chatbots to retrieve relevant information from documents and generate responses, thus enabling them to answer questions that require broader contextual knowledge.

Another approach to open-domain QA is the Retriever Generator QA framework, often called Generative Question Answering. This framework combines document retrieval systems with general language models such as BERT and GPT, as demonstrated by Petroni et al. [50] demonstrated in their research. This approach aims to leverage the strengths of both retrieval and generative methods to improve chatbot performance by providing comprehensive answers. The third model framework, known as the Generative Language Model, is associated with closed-domain QA, where a model, such as T5 Framework developed by Robers et al. [51] can generate responses to questions without requiring additional information or context. This approach is particularly valuable in scenarios in

which chatbots are expected to provide precise and concise answers without external references.

In summary, chatbot architecture is essential for their functionality, and researchers have classified chatbot QA models into different categories based on their capabilities. In open-domain QA, frameworks such as the Retriever-Reader Framework and Retrieve Generative Framework have been developed to enhance chatbots' ability to provide comprehensive responses. Closed-domain QA models, such as the Generative Language Model, excel in independently generating answers, making them suitable for scenarios where external references are not required. These developments in chatbot architectures and models contribute to the continuous improvement of chatbot performance and applicability in various domains.

VI. FINDINGS

Growth and Diversification in Chatbot Research: The field of chatbot research has experienced significant growth from 2020 to 2024, with annual publication output increasing from 60 in 2020 to 396 in 2024. Despite this growth, a decline in mean total citations per article was observed, indicating the potential dilution of individual article impacts due to the field's rapid expansion. Prominent authors, such as FØLSTAD A and ZHU Y, demonstrated sustained influence. Simultaneously, emerging contributors such as JEON J and LI Y exhibited rapid citation accumulation, highlighting the field's dynamic and evolving nature.

Global Research Collaboration and Regional Participation: Chatbot research has high collaboration rates, with an average of 3.91 co-authors per document, and 27.64% of papers involve international partnerships. The USA and China led global contributions, producing the highest number of publications, while countries such as India, the UK, and Australia also made substantial contributions. Emerging participation from Southeast Asia and Africa, particularly Indonesia, Malaysia, Morocco, and Ethiopia, signifies an expanding and inclusive research landscape.

Thematic Evolution and Practical Applications: Thematic analysis revealed a transition from foundational technologies, such as AI and NLP, to specialized applications in domains like "e-commerce" and "mental health chatbots" by 2024. Mental health chatbots have emerged as a critical focus area, reflecting the growing societal interest in leveraging chatbot technology for well-being. These findings underscore a shift towards practical, user-centered chatbot applications that address diverse real-world needs.

Advancements in Chatbot Architectures: The development of chatbot architectures has progressed significantly, incorporating sophisticated frameworks such as retriever-reader systems, generative QA models, and closed-domain QA models. These innovations enhance chatbot performance in open domain and domain-specific applications. The integration of reinforcement learning, user-interface design, and deep learning technologies demonstrated the field's interdisciplinary nature and trajectory towards advanced conversational capabilities.

Emerging Trends in Keywords and Research Focus: Analyzing keyword trends revealed a focus on topics like "artificial intelligence," "natural language processing," and

"machine learning," alongside newer themes such as "semantics," "user interfaces," and "reinforcement learning." Mental health applications, customer service, and generative AI are prominent themes, highlighting the diverse and evolving priorities of the field. This progression reflects the broadening scope and deeper specialization of chatbot research.

VII. CONCLUSION

This study provides a comprehensive examination of the evolution and diversification of chatbot research from 2020 to 2024, highlighting the rapid growth and global collaboration of the field. The rising annual publications and citations have significantly shaped this dynamic domain, as evidenced by prolific contributors and emerging researchers. Notable scholars such as FØLSTAD A and ZHU Y demonstrate sustained influence, while newer contributors such as JEON J exhibit rapid citation growth, reflecting fresh perspectives and innovative approaches. Geographically, countries like the USA and China dominate research output, whereas emerging contributions from regions such as Southeast Asia and Africa underline the global expansion and inclusivity of chatbot studies.

In addition to analyzing global research activities, this study highlights emerging trends and technological advancements. Themes such as "e-commerce" and "mental health chatbots" underscore the practical applications of chatbot technology, while the evolution of architectural frameworks illustrates advancements in conversational capabilities. The findings emphasize a transition towards sophisticated and user-centered applications from foundational AI technologies to specialized Generative AI. This trajectory provides promising opportunities for future research to address societal challenges, enhance user satisfaction, and expand chatbot utility across diverse domains. These insights collectively contribute to a deeper understanding of the evolving chatbot landscape and its potential transformative impact.

This research provides several recommendations for future research related to SLR in this area. This study used references from Scopus as the primary data sources. Although the Scopus database is the largest, it does not necessarily encompass all research related to chatbots. It is hoped that future reviews can incorporate literature from the WoS and PubMed databases to expand the findings on chatbots and achieve more complete results. This study focused on chatbot articles, including natural language processing, artificial intelligence, machine learning, deep learning, and neural networks. It is challenging to apply these concepts to existing subfields. Future research should focus on specific sub-fields, such as AI. It must also focus on existing health, education, industry, social, and political sectors.

ACKNOWLEDGMENT

We extend our sincere thanks to everyone who played a role in bringing this research to fruition. In particular, we are grateful to Universiti Pendidikan Sultan Idris (UPSI) for supplying the essential resources and backing for this investigation. Our work has been significantly improved by the valuable input and direction from our peers and reviewers, for which we are deeply thankful. We also recognize the scholars and researchers whose prior work laid the groundwork for our analysis, and we

appreciate the spirit of cooperation within the academic sphere. Finally, we want to thank our loved ones for their constant support throughout the course of this research endeavor.

School of Residential Environment and Design, Shijiazhuang Institute of Technology, Shijiazhuang, 050228, China²

Abstract—Due to the diversity of interior design, it is difficult for users to mine target data, so personalized recommendation systems for users are particularly important. Therefore, an optimized collaborative filtering recommendation system is proposed. Firstly, a random walk recommendation model based on category combination space is constructed, abandoning the traditional flat relationship connection and using Hasse diagram to achieve one-to-one mapping between items and types. The semantic relationship and distance are defined. Finally, a basic recommendation framework for random walks is established based on data such as jump behavior. Next, the potential semantic relationships between entities are explored, and a lightweight knowledge graph is proposed to define the social and explicit relationships between entities. Finally, the short-term features of the project are obtained using deep collaborative filtering technology, and a deep collaborative filtering temporal model based on semantic relationships is constructed. In subsequent validation, these experiments confirmed that under the vector dimension of 10, the average HR@K and NDCG@K were 6.9% and 12.9% higher than the other models. Therefore, the collaborative filtering recommendation model based on semantic relationships proposed in the study is reliable.

Keywords—*Semantic relationships; category combination space; random walks; collaborative filtering; temporal recommendations*

I. INTRODUCTION

The Internet has brought great influence to human society, which is not only a simple query tool, but also a method to tap the potential interests of users. This change is to adapt to the gradual increase in the amount of big data currently available, making it difficult for users to choose their preferences among the vast amount of information. At this time, the algorithm can build a recommendation model for users using previous preferences, and recommend relevant preference data and potential interest preference data for users [1]. Collaborative Filtering (CF) is the most commonly used recommendation algorithm at present. The key to this technology is searching for neighboring users and calculating similarity. However, the cold start and high computational dimension limit the improvement of recommendation performance. More researches focus on the introduced information. Project type is an important additional data, which can alleviate the sparse data. However, the limitation of its flattened organization is also one of the problems to be solved [2]. As a semantic network, knowledge mapping can construct semantic relations to connect entities,

which effectively solves the neglected explicit and implicit interactions between information in the traditional model [3]. In recent years, recommendation systems have made significant progress, from early CF algorithms to advanced technologies such as deep learning and graph neural networks. The accuracy and efficiency of recommendation systems continue to improve. However, traditional recommendation models often rely on flat relational connections and fail to fully explore the complex semantic relationships between items and types, resulting in insufficient recommendation accuracy and semantic understanding. Most studies often lack temporal considerations when dealing with dynamically changing user needs, making it difficult to adapt to real-time changes in user interests. Therefore, a deep CF recommendation system based on semantic relationship is proposed. It is expected to make significant contributions to the development of recommendation systems and provide more efficient and accurate tools for solving information overload problems. The innovation of this study lies in proposing a random walk recommendation model based on type combination space, which abandons the traditional flat relationship connection and uses Hasse diagram to achieve one-to-one mapping between items and types, providing a new perspective and idea for recommendation systems.

The research includes six sections. Firstly, the research status of recommendation system is introduced. Secondly, the designed CF recommendation system based on semantic relationship is described in Section III. Section IV verifies the recommendation model. Results and discussion is presented in Section V and finally, the paper is concluded in Section VI.

II. RELATED WORKS

In various current online platforms, personalized recommendation systems have gradually become a mainstream and necessary part. Gou L et al. believed that the marketing model in the communication field shifted towards socialization. Therefore, a recommendation model based on social analysis was proposed. Initially, a two-layer communication network for users and platforms was constructed through historical information, followed by a network of similar users and platforms using CF. Finally, a bipartite graph weighting method was used to achieve project recommendation, and the feasibility of the model was experimentally verified [4]. Wu et al. believed that knowledge maps had a good auxiliary effect on recommending a large amount of data content. Therefore, a

context aware algorithm based on Knowledge Graph (KG) was proposed, while gaining the advantages of both propagation and path-based technologies. The user preferences were represented through rules, and an automatic rule mining model was used in entity interaction. Finally, the performance of the model was further optimized through the local features in the neighborhood [5]. Yan et al. believed that the data density was the key factor affecting the CF recommendation performance. Therefore, a neighboring clustering method based on granular computing technology was introduced, and a CF optimization scheme based on coverage rough granular computing was proposed. The basic framework was built on user project scoring data, and local rough granularity sets were established through user preference thresholds, solving the data sparsity. The accuracy improvement in simulation experiments verified the reliability of the optimization model [6]. Miao et al. believed that the subjectivity of social networks has driven the improvement of their platforms. A recommendation algorithm based on user profiles was proposed and the user profile application model on short video platforms was described. These experiments confirmed that in four different platforms, the user satisfaction rate with recommended content was greater than 75% [7].

Liang et al. believed that the recommendation balance and trust of educational resources were generally poor. In response to this phenomenon, a trust relationship recommendation model was proposed. Firstly, support vector machines were used to classify educational resources and remove duplicate and useless data. Based on the remaining data, resource features were extracted. Finally, Kalman filtering was introduced to denoise and reduce the dimensionality of the features, constructing the recommendation model. These experimental data confirmed

that the equilibrium degree reached 96 [8]. Qi et al. proposed to apply graph neural networks to recommendation algorithms, using user historical data and second-order social data to learn user project feature representation. Multiple graph attention network modules were utilized to construct the model. Finally, simulation experiments were conducted to verify the effectiveness of the model [9]. Wang et al. believed that intelligent English has solved a large number of educational challenges. The Internet of Things serves as the technical foundation in this field and can effectively collect and manage information. An attention mechanism module was introduced to propose an educational resource recommendation algorithm, and a deep collaborative recommendation model was constructed. The effectiveness of the method was verified through experiments [10]. The summary of the research on recommendation models mentioned above is shown in Table I.

In summary, although recommendation models have received widespread attention from researchers, current recommendation models still have problems such as not delving into the complex semantic relationships between items and types, and requiring a large amount of data and computing resources. Therefore, this study introduces Hasse diagram, lightweight KG, and deep CF techniques to comprehensively consider the semantic relationships between items and types, as well as the social and explicit implicit relationships between entities. A semantic-based optimized deep CF algorithm is proposed to improve the accuracy and robustness of the recommendation system. This study has significant advantages over previous research in terms of the depth of recommendation models, semantic relationship mining, temporal considerations, and generalization ability.

TABLE I. SUMMARY TABLE

Researcher	Method	Insufficient
Gou L	Recommendation Model Based on Social Analysis	Not fully considering the semantic relationship and distance between projects and types
Wu C	Context Aware Algorithm Based on Knowledge Graph	Not delving deeply into the social and explicit implicit relationships between entities
Yan HC	Collaborative Filtering Optimization Based on Covering Rough Particle Computation	Not considering the complex semantic relationship between projects and types
Miao R	Recommendation Algorithm Based on User Profile	Lack of in-depth exploration of the complex semantic relationships between projects and types
Liang X	Trust Relationship Recommendation Model	Requires a large amount of data and computing resources
Qi W	Recommendation Algorithm Based on Graph Neural Network	Strong dependence on secondary social data
Wang F	Deep Collaboration Recommendation Model	Failed to fully explore the complex relationship between users and projects

III. APPLICATION OF CF OPTIMIZATION ALGORITHM INTEGRATING SEMANTIC RELATIONSHIPS IN INTERIOR DESIGN

The interior design data are relatively rich, making it difficult for users to accurately search for more types of preferences and to mine potential preferences. Therefore, it is necessary to optimize it to achieve more accurate user recommendations. The recommendation algorithm based on project types is a common personalized strategy. Traditional model building methods based on type similarity and preference types often overlook the relationship structure between types, which hinders the recommendation accuracy

[11-12]. This study proposes a random walk based recommendation model based on Category Combination Space (CCS), and introduces a temporal model based on semantic relationships to achieve final recommendations through deep CF.

A. A Random Walk Recommendation Algorithm Defined by Semantic Relationship

CCS is a collection of types contained in multiple projects, which Hasse diagrams to map projects and types one by one, including various relational structures such as up and down, same layer, and skip. Eq. (1) represents each element in space.

$$\begin{cases} U = \{u_1, u_2, \dots, u_m\} \\ I = \{i_1, i_2, \dots, i_m\} \\ C = \{c_1, c_2, \dots, c_m\} \end{cases} \quad (1)$$

In Eq. (1), $U/I/C$ represent a collection of users, projects, and types, respectively. The relationship between projects and types is one-to-many. CCS considers all types corresponding to each project as a whole and obtains a one-to-one correspondence diagram, as shown in Fig. 1.

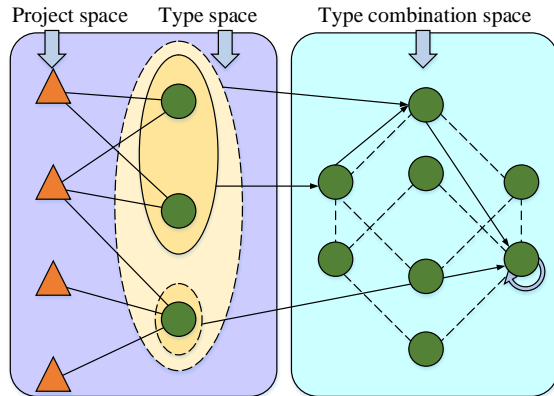

Fig. 1. Category combination space transformation structure.

CCS is essentially a partially ordered set of project types, belonging to an efficient Hasse graph. In actual operation, only some elements in the space are applied, and their project set is a subset of the partially ordered set. CCS achieves user preference mining through the jump sequence formed by user browsing behavior on nodes and the semantic relationship between jump nodes. Among them, the semantic relationships of browsing behavior include four categories, corresponding to the reduction, expansion, stability, and jump of user interests [13]. The qualitative description of relationships lays a solid foundation for mining dynamic preferences, while semantic distance further describes the preference change. This can be analyzed from two aspects: the true distance on the Hasse diagram and the changes in the number of basic and common elements [14]. Eq. (2) is the minimum distance between Hasse graph types.

$$d_L(\tilde{c}_i, \tilde{c}_j) = 2|\tilde{c}_i \cup \tilde{c}_j| - |\tilde{c}_i| - |\tilde{c}_j| \quad (2)$$

In Eq. (2), d_L is the link distance. This distance value represents the hierarchical span between types. If the span is small, the corresponding interests are stable. $(\tilde{c}_i, \tilde{c}_j)$ represents different types of combinations. Eq. (3) is the preference distance.

$$d_p(\tilde{c}_i / \tilde{c}_j) = \begin{cases} 0 & \tilde{c}_i = \tilde{c}_j \\ \frac{1}{|C|} & \tilde{c}_i \succ \tilde{c}_j \\ |\tilde{c}_j - \tilde{c}_i| & \tilde{c}_i \prec \tilde{c}_j \\ |C| + d_L(\tilde{c}_i / \tilde{c}_j) & \text{other} \end{cases} \quad (3)$$

The preference distance represents the changes in type combinations. There are four situations: the combination remains unchanged, the combination becomes larger, the combination becomes smaller, and the combination is located in different projects [15]. The last one has the highest preference distance and the most significant change in interest. User browsing graph $G = (\tilde{C}, E, A^E)$ is introduced to collect semantic relationships, distance sizes, and temporal features between types. \tilde{C}, E, A^E represent the vertex, edge, and edge feature matrix of the graph, respectively. PageRank based on random walk was introduced to construct an interest preference model. The core idea of this algorithm is to evaluate the importance of a page based on its quantity and quality of links in Fig. 2.

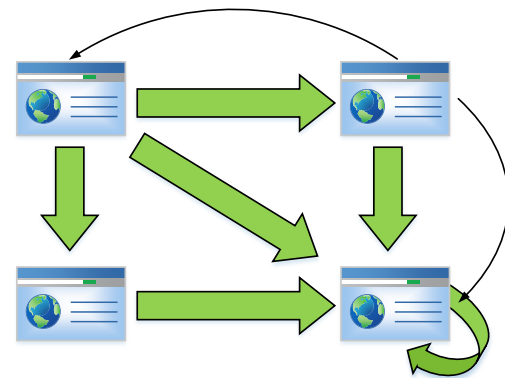

Fig. 2. Evaluation chart of the number of webpage links.

The number of times a webpage is linked is proportional to its importance, and its corresponding PageRank will also be improved. This transition probability design is the key to this method. The edge features of user browsing graphs contain a large amount of data such as node semantic relationships and preference distances [16]. The transfer matrix needs to transfer these data into probability, as shown in Eq. (4).

$$p_{ij}(\omega) = \frac{\omega^T a_{ij}^E}{\sum_j \omega^T a_{ij}^E} = \frac{\sum_k \omega_k a_{ijk}^E}{\sum_j \sum_k \omega_k a_{ijk}^E} \quad (4)$$

In Eq. (4), $p_{ij}(\omega)$ represents each element in the transition matrix. a_{ij}^E represents the edge feature vector. ω represents the weight of each edge. k represents the number of neighbors. The preference vector is the key to personalized random walk, as shown in Eq. (5).

$$q_u(i) = \frac{b_u(i)}{\sum_{k=1} |C| b_u(k)} \quad (5)$$

In Eq. (5), b_u represents the browsing vector of user u . The objective function can be obtained through the iterative process, as shown in Eq. (6).

$$\min_{\omega, \pi} (\omega^{(s)}, \pi^{(s)}) = \left\| \pi^{(s+1)} - \pi^{(s)} \right\|^2 \quad (6)$$

In Eq. (6), $\pi = (\pi_1, \pi_2, \dots, \pi_n)^T$ represents the scoring vector of the type combination. $\pi^{(s+1)}$ represents the iteration of a random walk. $\|\pi^{(s+1)} - \pi^{(s)}\|^2$ represents the loss function, and $\|\pi^{(s)}\| = 1$. The study introduces gradient descent method to minimize the objective function, while using cosine similarity to compare user similarity. Fig. 3 shows the overall CCS-based random walk algorithm.

Fig. 3. Random walk algorithm model based on type combination space.

B. Construction of Semantic Relationship Temporal Recommendation Model Based on Deep CF

KG based on semantic relationships can extend project data to mine deep relationships between project types. However, this also means that a large number of databases are required as support. Due to the limitations of mature and publicly available databases and the large volume of training features, the feasibility of actual operation is low. Moreover, using only semantic relationships as predictive information cannot mine the interactions between user items [17]. Therefore, a timing lightweight KG is proposed in Fig. 4.

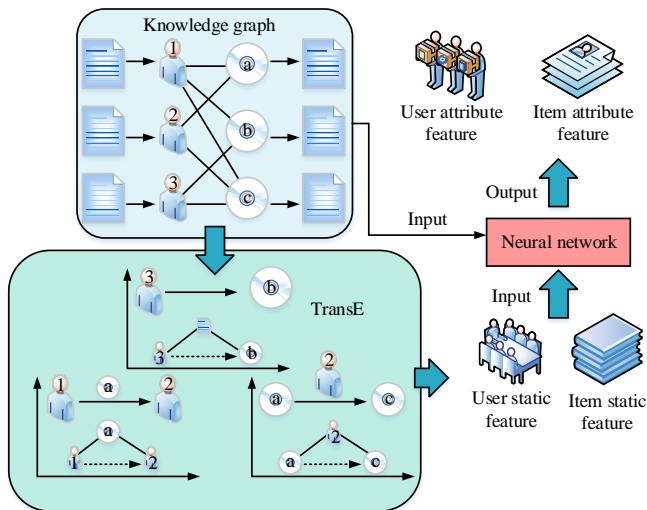

Fig. 4. Lightweight knowledge graph structure based on time series recommendation.

The model represents the explicit and implicit interactions between entities, users, and projects in KG by defining semantic relationships. The user rating of the project will create an edge between the two, and the attribute features of the two are linked to the corresponding entities [18]. The static attribute refers to the semantic feature representation vector of the two, which is obtained by associating the entity neighborhood with

According to Fig. 3, this model initializes the user preference vector through information such as rating matrix, user browsing graph, and weight parameters. Personalized preferences for each user are calculated based on their browsing data. Subsequently, the transfer matrix, objective function, and weight values are updated. When the scoring vector matches the iterative function, the final scoring prediction matrix is output.

the entity's first and second order neighbors. The attribute triplets of both are defined, including rating behavior, user relationships, project relationships, and attribute characteristics. Eq. (7) is the learning optimization probability of the rating behavior triplet.

$$P(u, r, v) = \sum_{(u, r, v^+) \in KG} \sum_{(u, r, v^-) \in KG^-} \sigma(g(u, r, v^+) - g(u, r, v^-)) \quad (7)$$

In Eq. (7), $\sigma(x) = 1/(1 + \exp(x))$ represents the sigmoid function. $g(\square)$ represents the energy function. The optimization probability $P(u_i, v, u_j)$ for user relationship triplets and project relationship triplets $P(v_i, u, v_j)$ are the same as Eq. (7). Eq. (8) is the energy function.

$$g(u, r, v) = \|u + r - v\|_{L_1/L_2} + b_1 \quad (8)$$

In Eq. (8), b_1 represents the bias constant. The attribute relationship between users and projects is essentially a bandit problem. Based on the representation vector, the neural network is selected for training. The optimization probabilities of user and project attribute triplets are expressed as $P(u, a, e) / P(v, a, e)$, and their definitions are similar. Eq. (9) is the calculation of the former.

$$P(u, a, e) = \sum_{(u, a, e^+) \in KG} \sum_{(u, a, e^-) \in KG^-} \sigma(h(u, a, e^+) - h(u, a, e^-)) \quad (9)$$

In Eq. (9), $h(\square)$ represents the classification function expressed by in Eq. (10).

$$h(u, a, e) = \|f(uW_a + b_a) - e_{ae}\|_{L_1/L_2} + b_2 \quad (10)$$

In Eq. (10), b_a, b_2 represent the learning parameter and bias constant, respectively. $f(\square)$ represents a nonlinear transformation function. e_{ae} represents the vector of attribute a . Due to the changing interests of users, popular elements can affect recommendation results, while static features do not change over time [19]. Therefore, short-term features of entities

are introduced for improvement. Model features can include static and attribute features based on KG semantic relationships, as well as short-term preference features generated by short-term browsing. The latter is implemented through Long Short-Term Memory (LSTM), which extracts popular items from the current browsing set. Taking the static and attribute features of the project as input, learning effectively reduces the computational pressure of the model in the attention mechanism. Finally, the recommendation is achieved through the long-term and short-term feature connections between entities in a multi-layer perception, as displayed in Fig. 5.

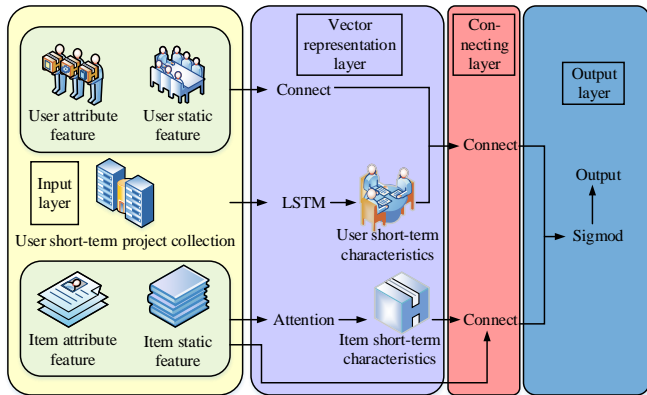

Fig. 5. LSTM recommendation model based on deep collaborative filtering.

The popularity of projects varies. A high level of popularity indicates that the project has a significant impact and requires learning through attention mechanisms. On the basis of maintaining sequential information, the attention mechanism extracts element relationships. The nearly 1-hour browsing sequence is used as input to match the entire project. The specific input data is the attributes and static features of the project. The weighted sum of each sequence is output, and Eq. (11) is the weight matrix.

$$T_i^t = z^T \tanh(W_c c_i + W_y y_i) \quad (11)$$

In Eq. (11), z^T, W_c represent vectors and matrices, respectively. W_y represents the learning parameter. c_i represents the training program at time t . y_i represents the i -th input item. The weight matrix also needs to be normalized in softmax to obtain S_i^t . The final short-term feature V_s needs to be output after iteration in Eq. (12).

$$\begin{cases} S_i^t = \text{soft max}(T_i^t) \\ V_s^t = \sum S_i^t y_i \end{cases} \quad (12)$$

The key to achieving the final recommendation lies in the model-based CF recommendation algorithm. It filters similar preferences in the neighborhood and recommends them to the target user through rating interaction between entities [20]. A multi-layer perception can perform deep CF recommendation, which combines to obtain diverse features in Eq. (13).

$$\begin{cases} q_1 = \phi_1(U_{s,a,r}, V_{s,a,r}) = \begin{bmatrix} U_{s,a,r} \\ V_{s,a,r} \end{bmatrix} \\ \phi_2(q_1) = a_2(w_2^T q_1 + b_2) \\ \dots \\ \phi_l(q_{l-1}) = a_l(w_l^T q_{l-1} + b_l) \\ \hat{y}_{uv} = \sigma(h^T \phi_l(q_{l-1})) \end{cases} \quad (13)$$

In Eq. (13), $U_{s,a,r}$ represents the combination of user dynamic preference U_s , attribute U_a , and static feature U_r . $V_{s,a,r}$ represents the union of corresponding characteristics of the project. w_x, b_x, a_x represent the weight matrix, bias vector, and ReLU activation function of the x -th layer perception, respectively. \hat{y}_{uv} represents the probability of interaction between entities. The model treats y_{uv} as a label. When there is already an association between the user and the project, the value is 1. On the contrary, it is 0. The probability range of entity interaction after training is [0, 1]. Eq. (14) is the final training objective function.

$$p(y, y^- | \Theta_f) = \prod_{(u,v) \in y} \hat{y}_{uv} \prod_{(u,v) \in y^-} (1 - \hat{y}_{uv}) \quad (14)$$

In Eq. (14), $p(y, y^- | \Theta_f)$ represents the objective function obtained through the probability function. Finally, a negative logarithmic likelihood loss function is obtained to minimize the optimization results in Eq. (15).

$$L = - \sum_{(u,v) \in y} \log \hat{y}_{uv} - \sum_{(u,v) \in y^-} \log(1 - \hat{y}_{uv}) \quad (15)$$

In Eq. (15), y^- represents negative instances, which are randomly generated by non-interacting items in the iteration and control the sampling probability of positive instances.

IV. PERFORMANCE TESTING OF CF OPTIMIZATION ALGORITHM MODEL BASED ON SEMANTIC RELATIONSHIPS

To verify the comprehensive performance of the recommendation model, simulation experiments are conducted, including two parts. The first step is to verify the feasibility of the CCS-based random walk basic framework. Subsequently, further validation is conducted on deep CF model based on semantic relationship to understand its excellent recommendation performance.

A. Performance Verification of the Basic Framework of a CCS Based-Random Walk

The study first validated the Optimized Random Walk (ORW) recommendation framework. Table II shows the experimental environment and parameters.

The experiment selected User-based CF (UCF), User-based CF by Genre Correlation (UBGC), Category Hierarchy Latent Factor Model (CHLF), and Genre to Classification model (GENC) for comparison with ORW. Firstly, the proximity

number of UCF was analyzed using Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) indicators in Fig. 6.

Fig. 6 shows the error impact of proximity number on UCF, respectively. In both MAE and RMSE, UCF tended to gradually decrease with the potential number, and there was a certain rebound phenomenon in the later stage. When the proximity number was 45, the MAE reached a minimum of

0.615. When the proximity number was 65, the RMSE reached a minimum of 0.785. Therefore, in subsequent experiments, the median value of 55 was chosen as proximity value. In further comparative experiments on various algorithms, precision, recall rate, F1 index, and Area Under Curve (AUC) index are selected for analysis. Conditions with 10 and 20 recommended lists belonging to the test set (i.e. different vector dimensions K) were selected for comparison, as shown in Table III.

TABLE II. EXPERIMENTAL ENVIRONMENT AND PARAMETER SETTINGS

Name		Parameter/Settings
Datasets		MovieLens: 1M
Data set total	User	6040
	Item	3952
	Review	1000209
Data sparsity rate		95.8%
Item type quantity		18
Number of combination types		301(Basic type: 6)
Verification method		5 fold cross verification
Training set: Test set		8:2

Fig. 6. Relation curve between proximity number and MAE/RMSE in UCF model.

According to Table III, the number of recommended lists that belong to the test set affects the performance of each model. For precision, all models reached their optimal values at Top@25. The difference between ORW and CHLF was relatively small, only 2.6% lower than the latter. Compared to UCF, UBG, and GENC, its precision has increased by 61.3%, 61.3%, and 77.3%, respectively. For the recall rate, all models reached their optimal value at Top@35. ORW performed the best, outperforming the other models by 57%, 59%, 6%, and 72.5%, respectively. F1 demonstrates a comprehensive performance of precision and recall. The performance difference between ORW and CHLF was minimal and almost negligible. Compared to UCF, UBG, and GENC, ORW was more than 55% higher. AUC represents the probability that the classifier outputs positive samples higher than negative samples,

which is a high value indicating good classification performance of the model. When it is not less than 0.5, it indicates that the classification effect is better than that of a random classifier. It also reached its optimal value at Top@35. The recommendation results of each model were superior to the random classifier, and the difference between the models was not more than 11%, indicating that these models were relatively excellent in recommendation performance. UCF, UBG, and GENC perform relatively poorly, with UCF performing the worst because the latter two use project-based associations, while the former uses user-based associations. ORW and CHLF are better because they both organize project types and obtain richer structural information. Fig. 7 shows the MAE and RMSE of each model.

From Fig. 7, CHLF performed the best, with MAE and

RMSE of 0.2 and 0.29, respectively. ORW was second only to CHLF, but its error was still much greater than CHLF, with MAE and RMSE of 0.6 and 0.79, respectively, an increase of 66.6% and 63.3%. In the comparison between ORW and other models, its MAE and RMSE were 25.9%/25.3% lower than UCF, 24.1%/45.6% lower than UBGC, and 31.6%/24.0% lower than GENC. CHLF outperforms all other models due to the used hierarchical type structures to construct entity-based implicit semantic models. Although the proposed model has CCS, it only performs a relatively simple similarity calculation on type numbering, which further demonstrates the necessity of introducing deep CF recommendations in the future.

TABLE III. COMPARISON OF THE COMPREHENSIVE PERFORMANCE OF EACH RECOMMENDED ALGORITHM

Index		ORW	UCF	UBGG	CHLF	GENC
Precision	Top@15	0.183	0.069	0.063	0.182	0.030
	Top@25	0.150	0.058	0.058	0.154	0.034
	Top@35	0.130	0.051	0.055	0.135	0.035
Recall	Top@15	0.075	0.029	0.024	0.065	0.012
	Top@25	0.117	0.049	0.044	0.108	0.026
	Top@35	0.149	0.064	0.061	0.140	0.041
F1	Top@15	0.107	0.041	0.035	0.095	0.017
	Top@25	0.132	0.053	0.050	0.127	0.029
	Top@35	0.139	0.057	0.058	0.138	0.037
AUC	Top@15	0.799	0.654	0.652	0.784	0.615
	Top@25	0.810	0.707	0.713	0.805	0.693
	Top@35	0.820	0.733	0.745	0.818	0.750

Fig. 7. Comparison of MAE/RMSE indicators of each model.

B. Performance Comparison Analysis of Semantic Relationship Temporal Recommendation Model Based on Deep CF

The study conducted performance validation analysis on the final model using a dataset. k in the triplet encoding Transe is 100. b_1, b_2 are 7 and -2, respectively. L_1 represents a regular term. The model operation framework and runtime platform are Keras and Python, respectively. To select the optimal Batch Size (S) and Learning Rate (R), this study used whether the test item was on the recommendation list and its position in the list as evaluation indicators, represented by HR and NDCG, respectively. The high value of both indicates excellent model performance. Table IV shows the experimental

results.

TABLE IV. HR/NDCG CHANGES UNDER DIFFERENT R/S SETTINGS

Index		HR@10	NDCG@10
R($\times 10^{-3}$)	0.1	0.681	0.405
	0.5	0.690	0.438
	1.0	0.700	0.451
	1.5	0.697	0.449
S	128	0.657	0.415
	256	0.701	0.452
	384	0.689	0.436
	512	0.674	0.428

In Table IV, when R increased, both HR and NDCG showed an initial increase followed by a slow decrease, with turning points of 0.001. Compared to the initial R of 0.0001, HR and NDCG were increased by 2.7% and 10.2%, respectively. Afterwards, HR and NDCG showed a gradually decreasing trend, but the decrease was smaller compared to the increase. In the testing of S, the change was the same as that of R, with a turning point of 256. Compared to the initial 128 batches, HR and NDCG were increased by 6.3% and 8.2%, respectively. As the S and R continue to increase, the proportion of test items in the recommendation list of the model changes relatively weakly, but the change in the position of the item in the list is relatively significant. When R=0.001 and S=256, the proportion of items in the recommendation list is higher, and their positions in the list are higher. Therefore, these parameters are selected as model settings for the experiment. CoupledCF, a Wide & Deep model based on logistic regression and feedforward deep neural networks, and a multi-layer perception NCF are compared with the Semantic Relationship Timing Recommendation model based on deep CF (SRT-DCF). SRT-DCF includes three types: user, item, and NCF. Fig. 8 shows the recommended results for TOP@10.

Fig. 8. Comparative analysis of HR_10/NDCG_10 performance of each model.

In Fig. 8, the difference among SRT-DCF_user, SRT-DCF_item, and SRT-DCF_NCF lies in the input of LSTM and the input of attention module. The inputs of SRT-DCF_user were the static and attribute features of recent projects learned from knowledge, as well as the onr-hot coding projects of the past hour. The inputs of SRT-DCF_item were onr-hot encoding item, as well as the static and attribute features of recent items

learned from knowledge. The inputs of SRT-DCF_NCF were static and attribute features of recent projects learned from knowledge. The combined performance of CoupledCF and SRT-DCF_item was the best, while the performance of SRT-DCF_user and SRT-DCF_NCF was the worst. The average values of HR₁₀ and NDCG₁₀ were 0.583 and 0.3705,

respectively. Compared to NCF and Wide&Deep models, the SRT-DCF_item had an average increase of 5.55% in HR₁₀ and 14.6% in NDCG₁₀. In summary, the research should select SRT-DCF_item as the final model. To further understand the impact of vector dimensions on various models, a comparative analysis was conducted in Fig. 9.

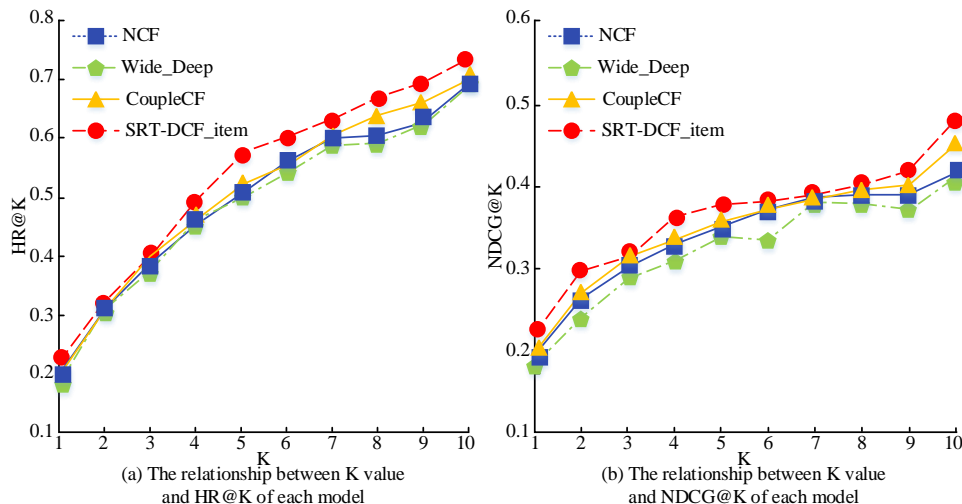

Fig. 9. Performance comparison of different models in different vector dimensions.

According to Fig. 9 (a), the HR@K change for each model was basically consistent, with the deviation node being K=5. At this time, the HR@K of the SRT-DCF_item model reached 0.583, which was 1.9%, 12.5%, and 1.8% higher than NCF, Wide&Deep, and CoupledCF models, respectively. When K was 10, the HR@K of other models was distributed around 0.67, while the HR@K of SRT-DCF_item reached 0.72, with an average increase of 6.9%. According to Fig. 9 (b), the NDCG@K variation was more tortuous. When K was 10, the values of each model were 0.493, 0.482, 0.409, and 0.397, respectively. Therefore, the average NDCG@K of SRT-DCF_item was 12.9% higher than that of other models. In summary, the proposed model has the best overall performance.

V. RESULTS AND DISCUSSION

To enhance the personalized recommendation function for users, a CF model based on semantic relationships is proposed. Firstly, a CCS based on random walk basic recommendation framework was constructed, and the semantic relationships between entities were defined. Then, the final deep CF temporal recommendation model was further constructed using semantic relationships. The recommendation algorithm proposed in study [7] mainly focuses on extracting and analyzing user features, and lacks in mining complex semantic relationships between items and types. This study achieved a one-to-one mapping between projects and types by constructing the Hasse diagram and the lightweight KG, and delved into the potential semantic relationships between entities, surpassing the recommendation algorithm proposed in study [7] in terms of semantic understanding ability. The trust relationship recommendation model proposed in study [8] has some

innovations in data preprocessing and trust relationship modeling, but it is slightly lacking in the depth and temporal considerations of the recommendation model. This study not only constructs a deep CF temporal model based on semantic relationships, but also fully considers the dynamic changes in user needs, thus outperforming the recommendation model proposed in study [8] in terms of recommendation accuracy and real-time performance.

The study conducted experimental verification according to the above two parts. In the experiments on ORW, compared to UCF, UBG, and GENC, the precision of the proposed method was increased by 61.3%, 61.3%, and 77.3%, respectively, but 2.6% lower than CHLF. The recall rate was 57%, 59%, 6%, and 72.5% higher than other models, respectively, but the average MAE and RMSE were higher than CHLF by 66.6% and 64.85%, indicating the importance of subsequent optimization. In the final model validation, R and S were first analyzed. When R=0.001 and S=256, the HR@K and NDCG@K of this model reached the maximum mean of 0.7 and 0.45. The experiment selected vector dimension 10 and analyzed each model. Compared to NCF and Wide & Deep, the SRT-DCF_item had an average increase of 5.55% in HR₁₀ and 14.6% in NDCG₁₀. In the validation of the impact on vector dimensions, HR@K and NDCG@K were on average 6.9% and 12.9% higher than other models.

VI. CONCLUSION

A semantic-based CF recommendation system was proposed to address the personalized user preferences in interior design, and its recommendation performance was tested. In summary, the proposed CF recommendation algorithm based on semantic relationships has excellent performance. However, this study still remains at a static level in constructing KG,

failing to fully capture the dynamic growth and evolution of information in actual situations. Therefore, in future research, real-time data stream processing technology should be further introduced to capture and process new information. Meanwhile, efficient dynamic update algorithms should be developed to update entities and relationships in the KG in real time.

Hybrid Clustering Framework for Scalable and Robust Query Analysis: Integrating Mini-Batch K-Means with DBSCAN

Hybrid Model for Complex Data Clustering

Abstract—Query clustering is a significant task in information retrieval. Research gaps still exist due to high-dimensional datasets, noise detection, and cluster interpretability. Solving these challenges will support large language models with faster and more efficient responses. This study aims to develop a hybrid clustering approach combining Mini-Batch K-means (MBK) and Density-Based Spatial Clustering of Application with Noise (DBSCAN) to cluster large-scale query datasets for information retrieval. The proposed method utilizes a preprocessing technique for data cleaning, extracts meaningful features, and scales all the features from the query dataset. The proposed hybrid clustering framework utilizes preprocessed data for clustering. The clustering algorithms MBK provide fast, scalable clustering, and DBSCAN delivers a precise, density-based refinement to efficiently process large-scale datasets while enhancing cluster boundaries to handle outliers. The proposed hybrid clustering framework effectively performs query analysis in information retrieval with a Silhouette score of 72.14 % and adjusted rand index of 78.23%. Thus, the hybrid clustering approach provides a robust and scalable solution for query analyzing tasks.

Keywords—Hybrid clustering; information retrieval; mini-batch k-means; query analysis

I. INTRODUCTION

Query analysis in a clustering framework is vital for understanding user intent and identifying behavioral patterns in information retrieval (IR) systems. Clustering is a group of objects that groups related objects into the same cluster and unrelated objects into diverse clusters. It is an analytical technique for grouping unlabeled data to extract meaningful information [1, 2]. People pursue information by asking queries on search engines. If the search engine generates unsatisfactory information, the users create another query by redeveloping the previous queries [3]. Query analysis in the clustering framework is discovering commonly asked questions and current popular topics on a search engine [4]. The clustering faces challenges in computational complexity, cluster refinement, high-data dimensionality, convergence speed, scalability, and evaluation measures [5].

Clustering is extensively utilized in pattern recognition, data mining, and query analysis, and different types of clustering algorithms have been proposed recently. The Spider

Optimization Algorithm with the Sequenced User Search Pattern Query Optimization (SOA-SUSPQO) improves the efficacy of the clustering query analysis and IR [6]. The Sampling-based Density Peaks Clustering (SDPC) algorithm minimizes the distance calculations in large datasets [7]. The hierarchical clustering, k-means, and Gaussian Mixture Models (DMM) on the Domain Name System (DNS) query dataset analyze and recognize the illicit activities in the domain names [8]. The centralized clustering procedure Low-Energy Dynamic Clustering improves the energy efficacy in query-based networks that target the cluster queries in a centralized way and supports the separation of clusters that match query targets [9]. The Machine Learning (ML) approach of K-means clustering classifies the data into K groups of similar examples for information retrieval [10]. However, traditional clustering algorithms face scalability, noise detection, and cluster interpretability challenges. The proposed model solves this issue by introducing hybrid clustering algorithms MBK and DBSCAN. The motivation for the proposed work is due to raising a few research questions.

- What are the limitations of existing clustering algorithms in handling large-scale, high-dimensional, and noisy query datasets?
- How can a hybrid approach combining Mini-Batch K-means and DBSCAN improve clustering scalability, accuracy, and outlier handling?
- What are the specific performance improvements in terms of clustering quality?

The major contributions of the proposed work are summarized as follows:

- The proposed methodology develops a hybrid clustering model combining Mini-Batch K-means (MBK) for fast, scalable initial clustering and Density Based Spatial Clustering of Application with Noise (DBSCAN) for precise refinement, addressing the limitations of each algorithm.
- In the proposed methodology, we design a two-phase clustering pipeline that leverages MBK's computational efficiency to reduce processing time for large datasets.

This is followed by DBSCAN for localized, detailed analysis.

- Address a significant gap in query clustering by proposing a hybrid approach that is both efficient and effective. This will set a benchmark for future clustering techniques that deal with dynamic, noisy data in real-world environments.

The remaining section of the paper is organized as follows: Section II analyses the existing clustering algorithms, Section III describes the proposed methodology, Section IV analyses the experimental results with an ablation study, and Section V concludes the paper.

II. LITERATURE SURVEY

This section reviews the performance of the existing clustering algorithms. Ates and Yaslam et al. [11] proposed a Graph-SeTES method that combines feature extraction and a decision network utilizing distance metrics and networks. The graph-based search task extraction addresses the challenges in search query logs. It improves the accuracy of short and misspelt queries, incomplete datasets, and limited labelled datasets. However, the model needed further improvements in quality embeddings. Shaik et al. [12] proposed graph-based and Machine Learning (ML) methods to improve the classification and clustering of incident ticket management systems using Resource Description Framework (RDF). The model faced limitations in scalability when utilizing a large dataset. Victor et al. [13] suggested integrated ML and PL/SQL tools to improve the database query performance. The model combined the Multi-Layer Perceptron (MLP) with k-means clustering to enhance the efficiency of the database response time.

Gong et al. [14] established a Query-Driven Clustering (QDC) protocol that leverages 5G infrastructure to improve energy efficiency and increase the network lifetime. However, the QDC algorithm required higher time complexity. To overcome this, Jia et al. [15] suggested a large-scale clustering model based on the Nystrom approximation to reduce the clustering complexity and enhance the clustering quality. Bashir et al. [16] proposed a proxy-terms-based query analysis by transforming true search queries into proxy queries that utilized the IR system, which preserves users' privacy. However, the model provided a query obfuscation only for the sensitive information contained in queries. Rehman et al. [17] suggested a Deep Learning (DL) based query response system to map farmers' queries to similar clusters. The system utilized a threshold-based clustering approach to group similar queries and enhanced the model's efficiency. The system faced difficulties with queries that had unclear meanings queries and included keywords in the dataset. Huang et al. [18] suggested a ML technique, K-means clustering, to identify the anomalous activities in the financial sector. However, the K-means clustering algorithms faced challenges in large datasets. Hartman et al. [19] developed a clustering algorithm for peptides to enhance the analysis of large spectrometry-based data that reduced the peptidomics dimensionality. The model needed further improvements in larger datasets. Zubair et al. [20] developed a model for improving the traditional K-means clustering algorithm, finding the optimal initial centroids to decrease the iterations and execution time.

Thus, the existing clustering works faced limitations in unclear and keyword queries, scalability, noise detection, large and high-dimensional datasets, and cluster interpretability. We proposed a hybrid clustering framework using the MBK and DBSCAN clustering algorithms to overcome these limitations.

III. PROPOSED METHODOLOGY

The framework of the proposed methodology is represented in Fig. 1.

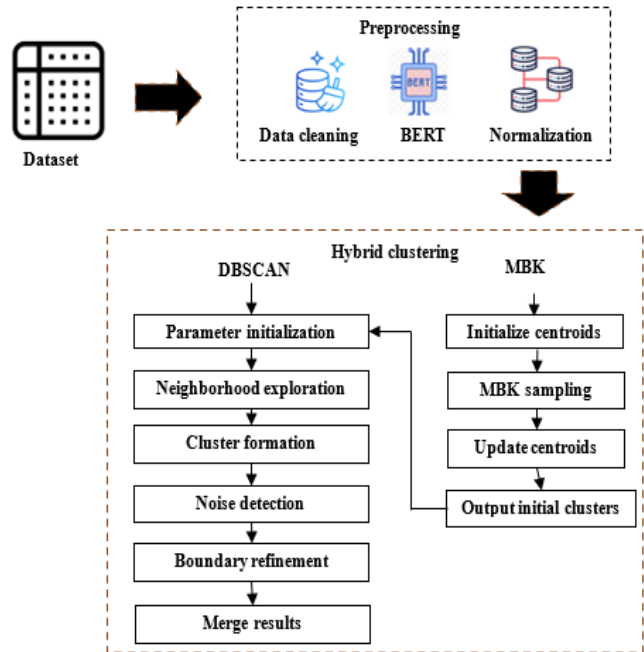

Fig. 1. Proposed hybrid clustering framework.

The proposed methodology utilizes an AOL User Session Collection 500K dataset to propose a scalable and robust query analysis framework. The query data preprocess using data cleaning, Bidirectional Encoder Representations from Transformers (BERT), and min-max normalization techniques. The data cleaning process removes the null values in the dataset, BERT extracts the meaningful features from the query data, and the min-max normalization technique scales all features in the dataset to ensure consistency across different feature dimensions. The proposed hybrid clustering algorithms MBK and DBSCAN evaluate the quality of the final clusters. The MBK clustering algorithm uses the pre-processed dataset to generate the initial clusters efficiently. The DBSCAN clustering algorithm processes each initial cluster independently to enhance cluster boundaries and detect dense regions and outliers. We utilize the hybrid clustering algorithms MBK for fast, scalable clustering and DBSCAN for precise, density-based refinement to efficiently process large datasets while enhancing cluster boundaries to handle outliers.

A. Dataset Description

The data were taken from the AOL User Session Collection 500K dataset [21]. The dataset covers 20 million web queries collected from 6,50,000 users over three months. A sequentially arranged unnamed user ID arranges the data. It provides real

query log data that is based on real users. The dataset includes four columns: AnonID, Query, QueryTime, ItemRank, and ClickURL. The AnonID contains the unnamed user ID number, the Query column contains the details of the user-issued queries, QueryTime represents the submitted time of the query, ItemRank denotes if the user clicks on a search result, the rank of the clicked item is listed, and the ClickURL listed the domain portion of the URL clicked. A query was NOT followed by the user clicking on a result item.

B. Preprocessing

Preprocessing enhances the quality of the query dataset. This research utilizes data cleaning, BERT, and min-max scaling normalization preprocessing techniques to improve the proposed query dataset.

1) *Data cleaning*: The data cleaning process removes the null values, such as queries with missing fields and keywords in the dataset. This process standardizes the format of the user's anonymous ID.

2) *Feature engineering*: BERT [22] is a language model that extracts meaningful query data features. BERT pretrains the query texts in the dataset. It breaks a sequence of tokens into characters, sentences, and words. The BERT language model pre-trained the queries in the dataset if the tokenizer did not identify the pretraining word, it split into sub words (eg: "Query"= "Que" and "ry") until the tokenizer found the sub word.

3) *Min-max normalization*: This research utilizes a min-max normalization [23] to scale all features in the dataset to a common range to ensure consistency across different feature dimensions. Min-max normalization performs linear transformations of the input data to generate a balance of value comparison between data after and before the process. The formulation of min-max normalization is expressed in equation (1).

$$Z_n = \frac{Z - \min(Z)}{\max(Z) - \min(Z)} \quad (1)$$

Where $\min(Z)$, and $\max(Z)$ denotes minimum and maximum values in the dataset, Z is the old value, and Z_n represents the new value from the normalized results.

C. Proposed Hybrid Clustering Algorithms

In this research, we propose a hybrid clustering approach that combines MBK and DBSCAN clustering algorithms that handle large-scale, high-dimensional datasets efficiently. The integration of the DBSCAN algorithm's ability to detect outliers with the MBK algorithm's computation speed to improve noise identification in large query datasets. In the first phase, the dataset is first clustered using the MBK algorithm. MBK uses mini-batches of data to update the centroids sequentially and ensure a good approximation of the clustering result. This helps speed up the process. The query dataset is first divided into a predetermined number of clusters by MBK. The overall computing load can be decreased by using this quick computation, particularly when working with big, high-dimensional query datasets. The DBSCAN algorithm is used in the second phase to refine the clusters after MBK has created the

initial clusters. DBSCAN is a density-based clustering technique that can effectively manage outliers and detect clusters of different sizes and shapes by concentrating on the local density of points. The clustering process is made better overall by DBSCAN's capacity to identify and separate noise or outliers, which results in more meaningful and cohesive clusters. Additionally, it improves cluster boundary definitions that may have been ambiguous in the MBK step. Although MBK is quick, DBSCAN addresses MBK's limitations when handling noise and irregular cluster forms by fine-tuning the cluster boundaries to ensure higher accuracy in the clustering results. A hybrid framework that is accurate and computationally efficient is developed by combining the speed of MBK with the density-based refining of DBSCAN.

1) *Mini-batch K-means clustering algorithm*: The MBK algorithm is unsupervised learning, an improved version of the K-means clustering algorithm. It resolves clustering techniques in mixed and large datasets. This research utilizes the MBK algorithm [24] to cluster the large-scale query dataset to enhance the scalability and optimize the clustering output. The MBK requires mini-batches as input, which are random subsets of the whole dataset. The MBK has a faster computation time than the k-mean algorithm. This clustering algorithm finds the set F of cluster centers $p \in R^S$ with $|F| = k$, to minimize over a set YD of examples $yd \in R^S$ the below objective function.

$$\min \sum_{yd \in YD} \|g(F, yd) - yd\| \quad (2)$$

In equation (2), $g(F, yd)$ returns the Euclidean distance of the adjacent cluster center $c \in F$ to yd . The problem is NP-hard, that gradient descent approach converges to the local optimum when seeded with an original set of k examples are drawn randomly from YD . The algorithm of MBK clustering is represented in pseudocode 1.

As shown in Fig. 2 MBK algorithm splits the dataset into smaller units known as mini-batches. MBK efficiently handles large datasets due to its fast computations by iteratively processing the mini-batches. In the MBK, centroids are placed as an initial marker; data points in each mini-batch are made reachable with the neighbouring centroid to locate their cluster. In the centre of the respective clusters, the centroids alter the changing distribution of data points. The final centroid generates a picture of the dataset's original clusters. Every data item fits into a certain cluster, which serves as an objective perspective for understanding, analyzing, and interpreting.

Fig. 2. Illustration diagram of the MBK clustering algorithm.

Pseudocode 1: Algorithm of MBK clustering phase

Objective: Initialize centroids for clustering

Input: $k, s \rightarrow$ mini-batch size m , iterations $i, YD \rightarrow$ data set.

Output: Set of clusters.

```

1: Initialize  $c \in F$  with  $yd$  select randomly from  $YD$ 
2:  $z \leftarrow 0$ 
3: for  $l = 1$  to  $i$  do
4:    $S \leftarrow m$  examples select randomly from  $YD$ 
5:   for  $yd \in S$  do
6:      $d[yd] \leftarrow g(F, yd)$ 
7:   end for
8:   for  $yd \in S$  do
9:      $c \leftarrow d[yd]$ 
10:     $z[c] \leftarrow z[c] + 1$ 
11:     $\eta \leftarrow 1/z[c]$ 
12:     $c \leftarrow (1 - \eta)c + \eta yd$ 
13:   end for
14: end for

```

2) *DBSCAN Clustering algorithm:* DBSCAN refers to a density-based clustering algorithm that efficiently processes the high-dimensional data and effectively distinguishes the noises in the clusters. This research utilizes the DBSCAN [25] clustering algorithm to cluster the high-density areas of target point data into clusters. It splits the data points into core, border, and noise points, as shown in Fig. 3, respectively, to the neighbourhood density points. This algorithm has neighbourhood ϵ and MinPts for density threshold parameters. The process of the DBSCAN clustering algorithm is denoted in pseudocode 2.

Fig. 3. Illustration diagram of DBSCAN clustering algorithm.

Pseudocode 2: Algorithm of DBSCAN clustering phase

Input: Initial MBK clustering with ϵ , MinPts

Output: Set of clusters

```

1: Randomly select a point  $P$ 
2: Regain all points from density reachable from  $P$ ,  $\epsilon$ , and MinPts
3: If  $P$  is a core point cluster formed
4: If  $P$  is a core point, no points are density reachable from  $P$  and DBSCAN visits the next point
5: Continue the process
6: All points are processed

```

IV. RESULTS

This section analyses the process and experimental results of the proposed hybrid clustering framework. The AOL User Session Collection 500K data preprocess using the data cleaning,

BERT, and min-max normalization techniques. The performance of the proposed model is evaluated using the metrics of the Silhouette score, Adjusted Rand Index (ARI), and Davies-Bouldin index, and a comparative assessment analyzes the effectiveness of the proposed clustering framework. The proposed hybrid clustering framework was executed in the Python 3.10 platform on a computer with Windows 10 Pro, Intel(R) Xeon(R) CPU E5-1650 v3 @ 3.50 GHz.

A. Performance Analysis of the Proposed Model

The proposed hybrid clustering framework is evaluated using the performance metrics of the Silhouette score, ARI, and Davies-Bouldin Index. Fig. 4 illustrates the proposed hybrid clustering framework performance. The silhouette score of 72.14 % estimates the quality of clustering algorithms, the ARI of 78.23 % calculates the similarity between the two partitions of a dataset and the Davies-Bouldin Index of 86.79 % estimate the quality of the clustering models.

Fig. 4. Performance of the proposed hybrid clustering model.

Fig. 5. Performance of the MBK initial clustering.

Fig. 5 illustrates the initial clusters generated by Mini-Batch K-means. The x-axis denotes the query time, and the y-axis represents the clusters in the query data. This represents the different clusters in distinct colors with centroids. In this clustering phase, the MBK includes various noises and outliers.

Fig. 6 demonstrates the clustering with centroids, which are represented in a group of different colours. In this graph, the x-axis signifies the query time, and the y-axis denotes the clusters in the query data. The outliers in the MBK clustering are denoted by red dots.

Fig. 7 illustrates the performance of DBSCAN clustering. It highlights DBSCAN's effect on refining clusters and detecting outliers. This graph shows how the proposed hybrid clustering algorithm efficiently reduces outliers in large-scale datasets.

Fig. 6. Clustering with noise outliers.

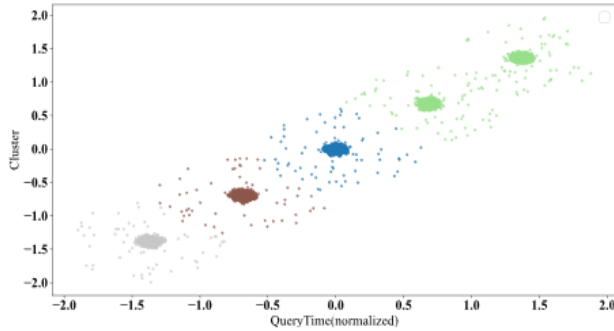

Fig. 7. Performance of the DBSCAN clustering.

Fig. 8 illustrates the performance of the queries in the dataset based on the execution time. This graph highlights the efficiency of the proposed hybrid approach. It shows that when the number of clusters increases at the same time, the execution time of the cluster also gradually increases. It is used to analyze the progression of clusters in the query data.

Fig. 8. Performance of the clusters based on the execution time.

Fig. 9. Elbow curve of MBK clustering algorithm.

Fig. 9 represents the elbow curve, which shows the optimal number of clusters (k) by plotting the Within-Cluster Sum of Squares (WCSS) against diverse values of k . The visualization of the plot and the location of the elbow joint indicate the most suitable number of clusters. The MBK clustering algorithm was applied to partition the dataset into distinct clusters. The obtained clusters are denoted in the above figure.

B. Ablation Study

The ablation study evaluates the model's performance with the MBK, DBSCAN, and hybrid clustering algorithms. It highlights the importance of the proposed hybrid approach, which significantly improves the clustering quality. The MBK clustering algorithm ensures the noise detection abilities of DBSCAN and reduces the execution time. Proposed model performance with ablation study is listed in Table I.

TABLE I. PROPOSED MODEL PERFORMANCE WITH ABLATION STUDY

Methods	Silhouette score (%)	ARI (%)	Noise (%)	Execution time (s)
MBK	0.65	0.72	4.5	1.2
DBSCAN	0.72	0.75	7.2	3.5
Hybrid clustering algorithms (mini-batch & DBSCAN)	0.7214	0.7823	6.0	2.3

C. Comparative Analysis of the Proposed Model with the Existing Approaches

Table II compares the proposed hybrid clustering algorithms with the existing K-means+GMM, GMM+DBSCAN, and KisanQRS approaches.

TABLE II. COMPARATIVE ANALYSIS OF THE PROPOSED VS EXISTING CLUSTERING APPROACHES

Model	Silhouette score (%)	Davies-Bouldin Index (%)
Shaik et al., 2024, K-means+GMM [12]	0.6569	0.4614
Shaik et al., 2024, GMM+DBSCAN [12]	0.6569	0.4614
Rehman et al., 2023, KisanQRS [17]	0.6218	0.4998
Proposed	0.7214	0.8679

V. DISCUSSION

The proposed model develops a hybrid clustering approach that overcomes the limitations of traditional clustering algorithms and achieves a balance between speed, accuracy, and noise handling. As represented in Table I, the MBK clustering algorithm attains a low silhouette score of 0.65%, and ARI of 0.72% with an execution time of 1.2 s. The DBSCAN clustering algorithm alone obtains a silhouette score of 0.72%, and ARI of 0.75% with an execution time of 3.5 s. This shows the proposed hybrid clustering framework performs better with a silhouette score of 0.7214%, and ARI of 0.7823% with an execution time of 2.3 s. The MBK clustering algorithm improves the framework's scalability by processing the query dataset into smaller batches. This algorithm processes the AOL User Session Collection large-scale data effectively but has limitations in

handling noised data, and its centroids approach is complex to outliers. As shown in Table II, the existing approach achieves a Silhouette score of 0.6569 %, 0.6569 %, and 0.6218 %, while the proposed model attains a better Silhouette score of 0.7214 %, which shows that the proposed model attains a better clustering performance. The DBSCAN clustering algorithm refines the clusters and identifies the outliers effectively. This algorithm's density-based approach effectively detects the noisy points in the clusters and improves the overall clustering quality. The Silhouette score, ARI, and Davies-Bouldin index performance metrics evaluate the clustering quality. The ablation study highlights the hybrid approach significantly improves the clustering quality. It proves the noise-handling capabilities of DBSCAN while reducing the execution time through the MBK clustering algorithm. This research demonstrates the significance of hybrid clustering algorithms for scalable and robust query clustering. Training was not required for the line query when $k = m$ because the number of clusters and data lines was equal, allowing for instantaneous data retrieval. The efficiency in the group query, $k = n$, where n is the number of clusters chosen, is determined by the training level: time is proportionately direct to k . After combining a few randomly chosen centroids, the data were obtained in the case of the whole query. The model's friction and fatigue ultimately serve as a representation of training consumption: friction for the k number and fatigue for the epoch amount specified in the parameters. Table III lists a few additional models that have been employed in various studies to determine the ideal k value.

TABLE III. QUALITY COMPARISON WITH OTHER SIMILAR MODELS

Ref	Model	Data	Epochs	K
[26]	Kmeans FE	50	N/A	N/A
[27]	Unsupervised Kmeans	400	11	k
[28]	Kmeans spherical	REST	N/A	k=6
Proposed	MBK and DBSCAN	100000	10	k=5

VI. CONCLUSION

In this research, we addressed the problem of clustering large-scale, high-dimensional query datasets. We proposed a hybrid clustering algorithm that provides scalable and robust noise-handling query intent detection in IR systems. The proposed methodology utilizes data cleaning, BERT, and min-max normalization techniques to extract meaningful features from the dataset. The proposed hybrid methodology begins with the MBK, which generates initial clusters by producing mini-batch sampling to handle large datasets. The DBSCAN refines the cluster boundaries and detects outliers in each cluster. The proposed hybrid algorithms overcome traditional clustering algorithms' limitations, enhancing their performance and interpretability. The experimental results demonstrate that the hybrid approach achieved superior clustering performance with a Silhouette Score of 72.14% and an ARI of 78.23%, making the model more suitable for developing LLMs. There are a number of directions for further investigation, even though the proposed approach offers notable advancements. First, advanced deep learning-based clustering methods such as deep embedded clustering may improve performance even further by taking advantage of latent feature representations. Second, real-time

clustering requirements in streaming data environments could be met by expanding proposed work to accommodate dynamic datasets that change over time. These possible paths provide chances to support advanced systems, improve clustering techniques, and create more effective models.

Modified Moth-Flame Optimization Algorithm for Service Composition in Cloud Computing Environments

Yeling YANG*, Miao SONG

College of Computer and Internet of Things, Chongqing Institute of Engineering, Chongqing, 400056, China

Abstract—Cloud computing service composition integrates services, distributed and diverse by nature, into an integrated entity that can meet a user's requirement with better effectiveness. However, some obstacles regarding high latency and suboptimal Quality of Service (QoS) still exist in a dynamic multi-cloud environment. This study addresses the limitations of traditional optimization algorithms in service composition, specifically the premature convergence and lack of population diversity in the Moth-Flame Optimization (MFO) algorithm. We propose the modified MFO algorithm with a new mechanism called Stagnation Finding and Replacement (SFR) to enhance the diversity of the population. It finds the static solutions based on a distance metric from globally optimal representative solutions and replaces them. MFO-SFR drastically improved all QoS metrics, such as response time, delay, and service stability. Empirical evaluations prove that MFO-SFR outperforms the baseline methods of multi-cloud service composition. It provides a computationally efficient and adaptive solution to cloud service composition problems, ensuring better resource utilization and higher user satisfaction in dynamic multi-cloud environments.

Keywords—Cloud computing; quality of service; service composition; edge cloud; moth-flame optimization

I. INTRODUCTION

Due to the growing demand for high-performance computing resources, the computing infrastructure has been transformed over the last several years [1]. Several new computational environments, ranging from cluster to grid and cloud computing models, have been created due to technological innovation [2]. As an architectural model, cloud computing provides users with shared computing capabilities available on-demand, with minimal Cloud Service Provider (CSP) interaction [3]. The main goal of this infrastructure is to consolidate geographically distributed resources to achieve greater efficiency, reliability, and performance [4]. Cloud computing facilitates the sharing of services and offers a diverse range of services that can be accessed from any location worldwide [5].

Cloud deployment models can generally be classified into four categories: public, private, hybrid, and community [6]. In public cloud deployments, multiple organizations subscribe to and utilize the exact cloud resources through a shared infrastructure model [7]. This method encourages cost-effectiveness as businesses only bear expenses for their particular resource usage. Private cloud deployments offer dedicated infrastructure environments for a single organization [8]. This model emphasizes heightened security and control as

it houses sensitive applications and data within the company's private cloud environment.

Hybrid cloud setups incorporate aspects of both public and private cloud designs. Companies can benefit from this method by having the flexibility to strategically place data and applications according to their sensitivity and processing needs [9]. Sensitive data that requires high security can be stored in the private cloud, while the public cloud can be utilized for cost-efficient and scalable computing operations. Community cloud deployments aim at a particular community of users with common interests or objectives [10]. These designs offer a shared infrastructure setting for numerous organizations in the community and may encourage cooperation and efficient use of resources.

Cloud computing services are broken down into three major classes: Infrastructure as a Service (IaaS), Platform as a Service (PaaS), and Software as a Service (SaaS) [11]. PaaS offers businesses and developers a robust platform for deploying and hosting software [12]. IaaS allows companies to monitor and control their network, storage, and servers using cloud computing [13]. SaaS involves the provision of software or applications as a service. External providers manage these programs [14]. Users can run applications and software through their web browsers without installing them on their devices.

As the said cloud service model evolves and expands worldwide, it can improve how services are delivered and controlled, allowing the CSP to respond to the different needs of the Cloud Service User (CSU). Service Level Agreements (SLAs) are essential in this situation as they define the desired level of service quality between the CSP and CSU. An SLA is a legally enforceable contract or formally negotiated agreement establishing the understanding and objectives between the CSP and the CSU. The document describes the specific terms and circumstances that govern the provision of services by the CSP.

Cloud computing relies on ensuring accessibility and efficient allocation of all necessary services [15]. There are two main challenges to overcome: first, it is difficult to anticipate the full range of potential service demands, particularly for software services. To solve this problem, complex services must be broken down into more straightforward, discrete, and essential components offered by different providers. Second, selecting the best combination of individual services from multiple providers with varying QoS attributes is an NP-hard optimization problem. Both challenges can be addressed through service composition. To guarantee user satisfaction,

this approach includes service selection from a diverse pool, adherence to composition constraints, identification of crucial QoS indicators, and accommodating the dynamism of services and network conditions.

The dynamic nature of cloud computing environments necessitates effective service composition strategies [16]. While heuristics, metaheuristics, and machine learning algorithms have been employed to address this challenge, each presents distinct advantages and limitations [17]. Heuristic approaches, often limited to single-objective optimization, may struggle with multi-objective problems [18]. Machine learning techniques, such as Deep Q Network (DQN), ADEC, and DQTS, have shown promise in solving multi-objective service composition problems [19]. However, their reliance on extensive training data can be prohibitive, particularly in complex scenarios. Metaheuristic algorithms, including evolutionary and swarm-based methods, offer a versatile and scalable approach to multi-objective optimization [20].

This paper proposes a novel service composition method for cloud computing environments enhancing the Moth-Flame Optimization (MFO) algorithm. By integrating a Stagnation Finding and Replacing (SFR) mechanism, the MFO algorithm addresses the common challenge of stagnation during optimization processes. This innovative approach dynamically detects and replaces stagnant solutions, effectively rejuvenating the search process and preventing the algorithm from converging prematurely on suboptimal solutions. Briefly, this research contributes to the following areas.

- We propose a novel service composition strategy designed explicitly for multiple-cloud environments. This strategy capitalizes on the distributed characteristics of service elements across multiple clouds to improve service quality.
- We introduce the MFO-SFR algorithm, a significant advancement over the traditional MFO algorithm. The MFO-SFR algorithm demonstrates demonstrably improved performance and diversification capabilities.
- A key innovation of our approach is the SFR strategy. This strategy dynamically detects and replaces stagnant solutions within the optimization process, leading to an overall improvement in performance.
- We incorporate an archive mechanism to enhance solution diversity further and ensure a more comprehensive search space exploration. This mechanism integrates both representative and globally optimal solutions encountered during the search process.

The rest of the paper is organized as follows. Section II presents related work on service composition and optimization techniques, identifying the gaps the current study intends to fill. Section III includes the simulation setup, results, and analysis to illustrate the efficiency of the proposed approach for improving key QoS metrics. Lastly, Section IV concludes the study with an overview of key results and contributions and suggests possible directions for further investigation.

II. RELATED WORK

Cloud computing environments demand real-time execution for quality-of-service conscious service composition. This entails maintaining coordination between achieving the best service configurations and ensuring efficient execution times for service composition. Prior research thoroughly examined combinatorial optimization methods to identify optimal service compositions within a specified time constraint. Nevertheless, the continuous expansion of cloud services results in a proportional increase in the problem's search space size. Consequently, these conventional methods are less effective at efficiently combining services within acceptable time limits.

As outlined in Table I, Karimi, et al. [21] suggested utilizing a genetic algorithm-based method to attain global optimization while complying with SLAs. Their methodology involves using service clustering to decrease the complexity of the search space and using association rule mining to improve service composition efficiency based on historical service consumption data. Experimental evaluations show that the proposed strategy is more efficient than comparable efforts.

TABLE I. OPTIMIZATION TECHNIQUES FOR SERVICE COMPOSITION IN CLOUD COMPUTING ENVIRONMENTS

Reference	Methodology	Key features	Limitations
[21]	Genetic algorithm with service clustering and association rule mining	Decreases complexity of search space; improves efficiency with historical data	Potential scalability issues with growing service datasets
[22]	The hybrid of the artificial bee colony and genetic algorithm	Two-stage optimization: GA for fitness, ABC for selection	High computational complexity
[23]	Capuchin search algorithm	Inspired by capuchin monkeys' social foraging behavior, focusing on both global and local optimization	It may require fine-tuning for different cloud environments
[24]	Honeybee mating optimization with trust-based clustering	Incorporates honeybee reproductive behavior; tackles trust issues	Underperforms in computational time for large-scale problems
[25]	Combining Aquila optimizer and particle swarm optimization	Hybrid approach; adaptive transition strategy	A complex implementation may be resource-intensive
[26]	Ant colony optimization with multi-pheromone mechanism and GA-inspired mutation	Addresses ACO's local optima issue; balanced exploration and exploitation	Potential risk of premature convergence without proper parameter tuning

Sefati and Halunga [22] used the Artificial Bee Colony and Genetic Algorithm (ABCGA) to generate optimal service compositions. This approach utilizes a two-stage optimization process. During the initial phase, a Genetic Algorithm (GA) determines potential services that satisfy particular fitness

requirements. Once the fitness function evaluation produces encouraging outcomes, these potential services are introduced to the Artificial Bee Colony (ABC) algorithm during the second step. The ABC algorithm enhances the service selection process by determining the service most closely matches individual user requirements. The effectiveness of the suggested ABCGA approach was assessed through experimentation utilizing the CloudSim simulator.

To tackle the task of enhancing service composition for multiple Quality of Service (QoS) metrics in cloud environments, Wang [23] introduced a new approach that utilizes the Capuchin Search Algorithm (CapSA). This algorithm mimics capuchin monkey social foraging patterns and exhibits its efficacy in addressing global and local optimization challenges. CapSA is chosen due to its inherent simplicity, reduced processing complexity, and well-rounded approach to exploration and exploitation. By conceptualizing service composition as an optimization problem, the proposed methodology seeks to reduce energy consumption and costs. According to empirical evaluations, the CapSA-based strategy substantially outperforms existing methods for achieving faster convergence and producing superior service compositions.

Zanbouri and Jafari Navimipour [24] investigated how Honeybee Mating Optimization (HMO) can address service composition in cloud computing environments. They focus on the connections between worker bees and the queen bee when choosing a new queen, utilizing knowledge from honeybee reproductive behavior. The optimization algorithm incorporates these biological inspirations to enhance the QoS. In addition, a trust-based clustering technique is used to tackle trust-related concerns specifically. The simulation results obtained from a C# implementation indicate that the suggested method outperforms existing algorithms, including GA, Particle Swarm Optimization (PSO), and the discrete best-guided ABC algorithm, for small-scale service composition problems. The enhancement results from the clustering method diminish the scope of the search and thus enhance the speed of response while also allowing for the choice of more dependable services. However, extensive simulations demonstrate that the computational time performance of the suggested method underperforms the average results of earlier studies.

Liu [25] developed a novel hybrid optimization technique known as the Integrated Aquila Optimizer (IAO), combining the functions of the PSO algorithm and Aquila Optimizer (AO). Hybridization addresses the inherent limitations of individual algorithms, such as their vulnerability to getting stuck in local optima and their limited ability to generate diverse solutions. The proposed IAO algorithm includes an innovative transition strategy for these difficulties. This method allows the AO and PSO algorithms to adjust their search operators flexibly. By employing this method, possible solutions are consistently improved. Utilizing both the AO and PSO algorithms can be a strategic move when each method reaches a standstill or when the range of possibilities decreases. This adaptive behavior improves the effectiveness and efficiency of the IAO approach. The proposed solution was thoroughly evaluated by testing in the CloudSim simulation environment. The numerical data indicate that the IAO technique successfully enhances

dependability, availability, and cost optimization within cloud computing.

Bei, et al. [26] discussed the composition of services in multiple cloud scenarios. They proposed an Ant Colony Optimization (ACO) algorithm to optimize QoS parameters, incorporating a multi-pheromone mechanism. This technique seeks to surpass conventional ACO constraints, which may become trapped in local optima. They incorporated a mutation operation influenced by the GA to improve the algorithm's exploration ability and avoid premature convergence. This hybridization approach promotes a more equitable and effective process of exploring and exploiting, resulting in the discovery of service compositions with superior QoS metrics, such as decreased latency and enhanced response times. Proposed method

A. Problem Definition and System Architecture

Cloud computing has made significant advancements in the past decade. Global infrastructure and market expansion have given rise to several cloud computing forms, including central and edge clouds. Central clouds are frequently utilized for extensive data analysis and deep learning training because of their robust processing and storage capacities. On the other hand, edge clouds are essential for collecting data, controlling processes in real-time, perceiving information intelligently, and making quick decisions at the outermost part of the network.

In contrast to centralized cloud infrastructures, edge computing provides users access to robust computational resources while mitigating the delay challenges inherent in remote data center interactions. This dramatically minimizes the data transmitted on the leading network and guarantees quick response times for upcoming services requiring minimal delays. As a result, the widespread use of these services in edge clouds is anticipated to grow prevalent.

This paper explores the architecture of cloud-edge devices, where service elements are mainly placed on a centralized cloud. Docker and other containerization technologies facilitate seamless and efficient migration to the cloud when consumers need a particular service component. This methodology enables the combination of services and the virtualization of resources (such as storage and computation) to meet users' requirements, as shown in Fig. 1. Docker containers are gaining popularity in cloud computing, as evidenced by their use in constructing genuine cloud environments for research purposes. Cloud services are highly advantageous in a dynamic cloud environment due to their effectiveness and ease.

The current service landscape is experiencing a significant change towards autonomous and loosely connected service designs, commonly called microservice architectures. Although service components can be spread out throughout different edge clouds, there is still a need to investigate and understand the current approaches for combining services in multiple-cloud setups. On the other hand, a multiple-cloud setup enables consumers to select from a range of services that perform better than single CSPs with limited computing capacity. In addition, multiple-cloud deployments provide built-in redundancy, which helps prevent equipment failures and improve the system's overall stability.

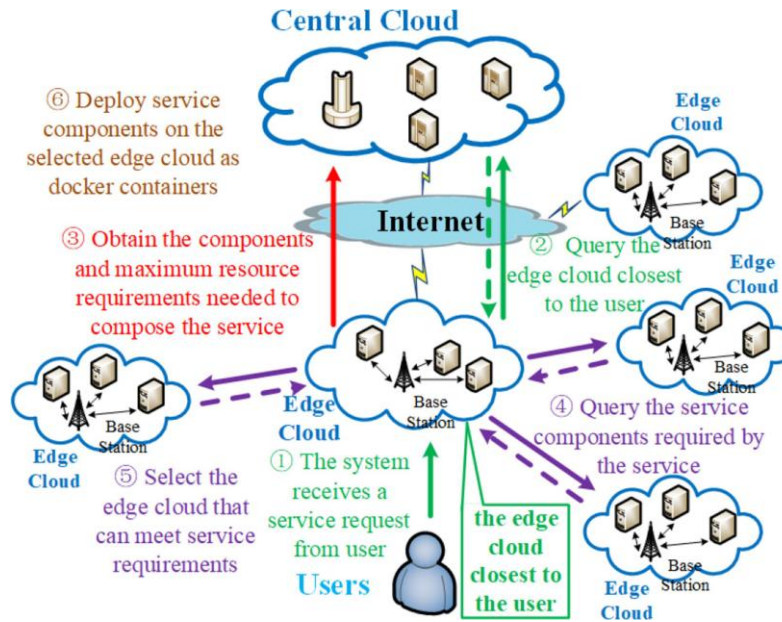

Fig. 1. Architecture of cloud-edge-devices integration.

This paper introduces a multi-cloud service composition architecture, depicted in Fig. 1, comprising M consumers, N edge clouds, and a central cloud. The central cloud is a repository for comprehensive service-related information and hosts a global network controller. Service components are distributed across an edge cloud infrastructure. User service requests are initially directed to the nearest edge cloud for preliminary processing. Each edge cloud maintains a local database containing information about neighboring edge clouds and available service components.

Table II is a crucial system component, providing essential network topology information. The index n_i varies from 0 to $N-1$, where N is the total number of edge clouds in the network. This ensures that all possible connections between edge clouds are considered. $path_i$ represents the optimal route linking the current edge cloud and another edge cloud in terms of the fewest hops. This information is crucial for routing data efficiently. hop_i quantifies the number of network hops between the current edge cloud and any other edge cloud within the network. A lower hop count generally indicates a more efficient communication path.

TABLE II. NETWORK TOPOLOGY INFORMATION FOR EDGE CLOUDS

Edge cloud count	Path	Hop
n_1	$path_1$	hop_1
n_2	$path_2$	hop_2
...
n_i	$path_i$	hop_3

Table III serves as a critical repository for service component metadata within the edge cloud environment. Service element names identify the service items available in the edge cloud and its neighbors. QoS attributes provide essential performance metrics for each service element, such as delay and reliability. The QoS attribute for the j^{th} parameter of

the i^{th} service element is represented as η_{ij} . This standardized notation facilitates data manipulation and analysis.

TABLE III. SERVICE ELEMENT DATABASE

Service element	Edge cloud count	QoS
$element_1$	n_1	η_1
$element_2$	n_2	η_2
...
$element_i$	n_i	η_3

Upon receipt of a service request, the proximate edge cloud initiates communication with a central controller to procure optimal computational resources, storage capacity, and network bandwidth. The service composition process proceeds in situ if the local edge cloud possesses sufficient residual capacity to fulfill the service's maximal requirements. Conversely, if resource constraints are encountered, the edge cloud embarks on a search for an adjacent edge cloud with minimal network hops. This iterative exploration continues until an edge cloud with ample resources to accommodate the service composition is identified.

Eq. (1) quantifies the resource demands (R_l) of service l . The set L encapsulates the services scheduled for orchestration on edge cloud i , while C_i represents the aggregate resource capacity of edge cloud i . These parameters constitute critical determinants in edge cloud service provisioning.

$$\sum_{l \in L} R_l \leq C_i, i \in N \quad (1)$$

Containerization virtualization has played a significant role in microservice adoption. Cloud computing can utilize containerization to flexibly install, migrate, or scale virtual machines under changing service demands. Containerization benefits conventional virtual machines by using the host's operating system kernel. This strategy minimizes the

administrative burden of delivering resources as needed and promotes optimal resource utilization. Containerized microservices typically involve the simultaneous creation of lightweight components within containers, which are then provisioned and scaled based on their requirements.

Expanding on these ideas, this method enables the quick and flexible deployment of service components by utilizing containerization technologies such as Docker in a multiple-cloud setting. This allows for deploying all necessary service components for composition onto respective edge clouds. A notification mechanism is built to guarantee real-time accuracy of records held in edge clouds and service components. Whenever one edge cloud stops serving customers or undergoes modifications to its deployed service components, it sends these updates to all connected edge clouds. Utilizing this broadcast technique allows for the timely updating of databases on other edge clouds, ensuring data consistency throughout the system.

B. QoS model

Services typically comprise k distinct groups, each containing abstract service component definitions with specific order requirements. Users seek a combination of services that fulfill user-specified requirements and QoS constraints to complete their desired operations during service composition.

The service composition process is divided into K steps according to the user's requirements. Every individual step, S_i , is linked to a particular service set. The algorithm chooses service components from each set S_i to fulfill the user's operation. The selection procedure yields numerous possible routes from the initial service component set (S_1) to the final set (S_k). The ideal combination of services is attained by determining the pathway that produces the most advantageous service combination.

When choosing a service, both the functional and non-functional aspects are considered. Functional attributes pertain to the explicit purpose and content offered by a service, whereas non-functional attributes encompass the overall quality of the service, as evaluated using QoS measurements.

Services are evaluated on the essential aspects of QoS, as described by internationally recognized standards organizations. QoS, as specified by these standards, includes non-functional features such as throughput, availability, response time, and dependability.

Ensuring high-quality service while combining multiple services is essential for distinguishing between the various components of the service. This optimization method assesses the QoS attributes of the constructed service. QoS parameters can be divided into two main categories: dynamic attributes, which include response speed, dependability, and availability, and fixed attributes, which include security, accuracy, and robustness.

This study focuses on throughput, reliability, delay, and response time. Throughput indicates the maximum rate at which data can be processed or transmitted successfully. Availability refers to the likelihood that service components are operational and ready for use in a particular environment. Delay

refers to the time it takes for data packets to travel between a server hosting a service component and a client.

Response time represents the time the service provider takes to respond to a user's service request. Table IV presents QoS attribute formulas for composed services. Calculations rely on j (number of service components chosen from service set i) and k (total number of service sets).

TABLE IV. QOS ATTRIBUTE FORMULAS FOR COMPOSED SERVICES

QoS parameters	Expression
Delay	$\sum_{i=1}^k L(\eta_{ij})$
Throughput	$\sum_{i=1}^k L(\eta_{ij})$
Availability	$\sum_{i=1}^k A(\eta_{ij})$
Response time	$\sum_{i=1}^k R(\eta_{ij})$

It is crucial to optimize various QoS parameters during service composition. However, it is equally essential to guarantee service stability and other relevant metrics. This study introduces a novel concept of QoS parameter stability, defined by the absolute value of each parameter across service elements. Eq. (2) represents the stability calculation for QoS parameter j within the service.

$$Sta_j = \sum_{i=1}^{k-1} \|\eta_{(i+1)(j+1)} - \eta_{ij}\| \quad (2)$$

Services with minimal cumulative absolute differences between their QoS parameters (QoS_i) are considered more stable. This approach mitigates significant fluctuations in QoS. Additionally, to prevent data size variations across service sets from skewing the final results, this paper incorporates a data normalization step for the QoS information associated with the service components. Following normalization, higher parameter values correspond to superior performance. Consequently, all subsequent references to QoS metrics (response time, availability, throughput, and delay) within this work will pertain to their normalized values.

This paper proposes a methodology that considers all four QoS criteria to determine the most effective technique for composing consumer services. This technique guarantees the optimization of these crucial parameters. The following section will explore an improved service composition technique based on the modified MFO algorithm. This approach has been specifically developed to boost the optimization of QoS.

C. Enhanced MFO algorithm

The MFO algorithm mimics the behavior of moths in nature. The unique navigational strategies of moths have generated considerable interest among researchers studying metaheuristics. Moths are nocturnal creatures that rely on lunar illumination for navigation Shehab, et al. [27]. Moth flight patterns can be mathematically modeled using the transverse orientation mechanism (Fig. 2). This strategy approximates a straight-line trajectory by maintaining a constant angular relationship with the moon. When faced with artificial light sources, moths divert from this path. When the moth is close to

the light source, it initiates a helical flight pattern that guides it towards the flame. Each moth symbolizes a potential solution, and every position is represented as a matrix of decision variables, as shown below.

$$X = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_N \end{bmatrix} = \begin{bmatrix} x_{1,1} & x_{1,2} & \dots & x_{1,n-1} & x_{1,n} \\ x_{2,1} & \ddots & \dots & \dots & x_{2,n} \\ \vdots & \dots & \ddots & \dots & \vdots \\ x_{N-1,1} & \dots & \dots & \ddots & x_{N-1,n} \\ x_{N,1} & x_{N,2} & \dots & x_{N,n-1} & x_{N,n} \end{bmatrix} \quad (3)$$

Fig. 2. Moth flight patterns model using transverse orientation mechanism.

In Eq. (3), N stands for the population size, equal to the total number of moths in the swarm. Also, n indicates the problem dimension, which measures how many variables are involved in the optimization process. The fitness of a particular moth is determined as follows.

$$Fit[X] = \begin{bmatrix} Fit[X_1] \\ Fit[X_2] \\ \vdots \\ Fit[X_n] \end{bmatrix} \quad (4)$$

Eq. (5) shows the flame matrix. Since all moths fly around a flame, the size must match the moth matrix previously defined.

$$FM = \begin{bmatrix} FM_1 \\ FM_2 \\ \vdots \\ FM_N \end{bmatrix} = \begin{bmatrix} Fm_{1,1} & Fm_{1,2} & \dots & Fm_{1,n-1} & Fm_{1,n} \\ Fm_{2,1} & \ddots & \dots & \dots & Fm_{2,n} \\ \vdots & \dots & \ddots & \dots & \vdots \\ Fm_{N-1,1} & \dots & \dots & \ddots & Fm_{N-1,n} \\ Fm_{N,1} & Fm_{N,2} & \dots & Fm_{N,n-1} & Fm_{N,n} \end{bmatrix} \quad (5)$$

Eq. (6) determines the corresponding fitness of the flame matrix.

$$Fit[FM] = \begin{bmatrix} Fit[FM_1] \\ Fit[FM_2] \\ \vdots \\ Fit[FM_n] \end{bmatrix} \quad (6)$$

The MFO algorithm relies heavily on two primary components: flames and moths. Moths fly through flames to achieve desired results. As shown in the equation below, the logarithmic spiral function is used to model the spiral movement of the moth.

$$X_i^{K+1} = \begin{cases} \delta_i \cdot e^{bt} \cdot \cos(2\pi t) + Fm_i(k) & i \leq N.FM \\ \delta_i \cdot e^{bt} \cdot \cos(2\pi t) + Fm_{N.FM}(k) & i \geq N.FM \end{cases} \quad (7)$$

δ_i represents the Euclidean distance between a moth's current position (X_i^K) and its corresponding flame (Fm_i). This value indicates the moth's proximity to a possible optimal solution. Spiral flight patterns of moths are determined by b and t , a uniformly distributed random number between -1 and 1. Moths and flames are attracted to each other based on these parameters, as shown in Fig. 3. The moth's trajectory towards the flame is depicted in Fig. 4. Throughout the optimization process, t gradually decreases toward a balance between exploitation (focusing on promising areas) and exploration (searching the entire search area). The mathematical representation of t is presented below, and Fig. 5 depicts the moth's next position.

$$r = -1 + Current_{iter} \left(\frac{-1}{Max_{iter}} \right) \quad (8)$$

$$t = (r - 1) \times k + 1 \quad (9)$$

The optimization process depends on three variables: Max_{iter} , k , and r . Max_{iter} specifies the maximum number of iterations, k indicates a uniformly distributed random number between 0 and 1, and r singularity ensures convergence. The value of r is linearly reduced throughout the optimization to balance exploration (searching the entire search space) and exploitation (focusing on promising regions).

Fig. 3. Attraction mechanism between moths and flames.

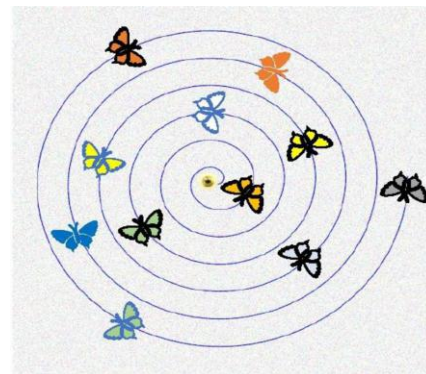

Fig. 4. Moth's spiral trajectory toward the flame.

Fig. 5. Decreasing parameter t for balancing exploration and exploitation in optimization.

During the optimization process, the moths with the highest fitness values continually move towards the most promising solutions, indicated by the flames. This phenomenon can be explained by the mechanism in which the number of flames (represented as $N.FM$ in Equation 10) gradually reduces with each cycle. This decrease in the number of flames efficiently focuses the search effort on the most favorable areas of the search space.

$$N.FM =$$

$$\text{round} \left(N.FM_{\text{Last iter}} - \text{Current}_{\text{iter}} \frac{(N.FM_{\text{Last iter}} - 1)}{\text{Max}_{\text{iter}}} \right) \quad (10)$$

A population of moths is represented by the matrix $X(t) = \{X_{1D}(t), \dots, X_{iD}(t), \dots, X_{ND}(t)\}$ in a D -dimensional search space at iteration t . Each element $X_{iD}(t)$ represents the position of the i^{th} moth within the problem space. The initial positions of all moths are generated randomly using a uniform distribution during the first iteration ($t = 1$). In subsequent iterations ($t \geq 2$), the SFR mechanism is used to update moth positions based on Eq. (11).

$$X_i(t+1) = \begin{cases} D_i^\alpha(t) \times e^{b\tau} \times \cos(2\pi t) + F_j(t) & \text{if } i \leq R(t) \\ D_i^\beta(t) \times e^{b\tau} \times \cos(2\pi t) + F_R(t) & \text{else} \end{cases} \quad (11)$$

SFR is characterized by its core components, represented by Eq. (12) and Eq. (13). The constant b determines the shape of

the logarithmic spiral employed by the moth, and τ indicates a random number uniformly distributed between -1 and 1 . $F_j(t)$ and $F_R(t)$ represent the positions of the j^{th} and the R^{th} flame, respectively. The parameter r is calculated using Eq. (8).

$$D_i^\alpha(t) = |F_j(t) - M_i(t)| \quad (12)$$

$$D_i^\beta(t) = \begin{cases} |F_j(t) - X_i(t)| & \varphi_i > 0 \\ \text{Select a random position form Arc} & \varphi_i = 0 \end{cases} \quad (13)$$

Eq. (14) calculates the mean distance, denoted by φ_i , for each moth. This distance is computed based on the individual dimensions (X_{iq}) of the i^{th} moth and the corresponding dimensions (F_{jq}) of its associated flame (j). The index j for each moth is determined using Eq. (15). This equation involves sorting the results obtained from Eq. (14) in descending order to identify the most "distant" moths and subsequently utilizing these indices as flame indexes within Eq. (13).

$$\{\varphi_1, \dots, \varphi_i, \dots, \varphi_N\} \leftarrow \varphi_i = \frac{1}{D} \times \sum_{q=1}^D |F_{jq}(t) - X_{iq}(t)| \quad (14)$$

$$\{\varphi_1, \dots, \varphi_j, \dots, \varphi_N\} \leftarrow \text{Sort}(\varphi_1, \dots, \varphi_i, \dots, \varphi_N) \quad (15)$$

The archive construction process serves a dual purpose: enhancing population diversity and accelerating convergence towards promising regions within the search space. This is achieved by storing representative flames and the best solutions encountered during optimization. The archive, denoted by Arc , is represented by the matrix $M = \{M_1, \dots, M_i, \dots, M_K\}$, where K signifies the predefined archive size. Each element $M_i = [m_{i1}, m_{i2}, \dots, m_{iD}]$ represents a vector position within the archive memory.

The construction of the archive involves two key steps: generating Representative Flame (RF) and archiving entries. The first step leverages the dual population ($dual_{Pop}$) and dual fitness values ($dual_{Fit}$) created based on the flame construction process outlined in Fig. 6. Eq. (16) calculates the RF position, representing the average of all flame positions. Here, C denotes the total number of moths considered, and F_{id} represents the d^{th} dimension of the i^{th} flame. Two new entries are added to the archive memory M : the global best flame position and the calculated RF position. If the archive reaches its total capacity (K), a random replacement strategy is implemented, replacing two existing entries with new entries.

$$RF_d(t) = \frac{1}{C} \sum_{i=1}^C F_{id}(t) \quad (16)$$

Input: X : the positions of moths, Fit : the fitness values of moths, F : the position of the flame, and OF : the fitness values of flames.

Flame construction in the first iteration when $t = 1$.

1. Sort the vector Fit in ascending order and extract the sorted index in $\{j_1, j_2, \dots, j_N\}$.
2. Construct the flame matrix $F(t) = \{F_1 \leftarrow X_{j1}, F_2 \leftarrow X_{j2}, \dots, F_N \leftarrow X_{jN}\}$.

Flame construction for the rest iteration when $t > 1$.

1. Construct matrix $dual_{Pop}$ by combining matrices $F(t)$ and $X(t-1)$.
2. Construct vector $dual_{Fit}$ by combining vectors $OF(t)$ and $Fit(t-1)$.
3. Sort the vector $dual_{Fit}$ in ascending order and extract the sorted index in $\{j_1, j_2, \dots, j_{2N}\}$.
4. Construct the flame matrix $F(t) = \{F_1 \leftarrow X_{j1}, F_2 \leftarrow X_{j2}, \dots, F_N \leftarrow X_{jN}\}$.

Fig. 6. Construction of representative flame and archiving entries.

III. SIMULATION AND RESULTS

A series of tests were performed on a Windows 8.1 computer powered by an Intel Core i5-460M processor at 2.53 GHz and 16 GB of RAM. This study employed a system model comprising 32 edge clouds and a primary cloud, as illustrated in Fig. 1. The Quality of Service for Web Services (QWS) dataset contained 2507 services, each characterized by nine QoS features: description, delay, best practices, consistency, reliability, throughput, availability, and response time. For this research, delay, throughput, availability, and response time were the primary QoS parameters, with their respective ranges and units detailed in Table V. A comparative evaluation was conducted to measure the proposed algorithm against traditional MFO, PSO, and WOA algorithms, evaluating fitness, stability, delay, and response time.

TABLE V. QOS PARAMETERS AND RANGES

Parameters	Dimensions	Unit
Delay	0.1-4500	ms
Throughput	0.1-50	Mbps
Availability	5-100	%
Response time	30-5000	ms

Fig. 7 and Fig. 8 compare the proposed algorithm and its counterparts regarding fitness and stability, respectively. To conduct this analysis, 100 to 1000 service instances were chosen at random extracted from the QWS dataset, with inclusion criteria limited to services comprising at least five components. Fig. 7 demonstrates the better fitness performance of the developed algorithm compared to its competitors. While fitness is a crucial metric, the ultimate objective is to maximize service QoS and maintain stability.

Fig. 9 and Fig. 10 illustrate the comparative performance of the algorithms in terms of delay and response time. All QoS parameters were normalized to mitigate the influence of varying parameter scales. Consequently, higher values indicate improved optimization outcomes. The results in Fig. 9 clearly reveal the superiority of the proposed algorithm in minimizing delay. Similarly, Fig. 10 reveals a significant advantage of the proposed algorithm in reducing response time compared to other methods.

Fig. 8. Stability comparison.

Fig. 9. Delay comparison.

Fig. 10. Response time comparison.

Fig. 7. Fitness comparison.

The experimental results distinctly demonstrate the superiority of the proposed algorithm over traditional optimization methods. From the fitness performance, it is obvious that the proposed algorithm constantly finds higher-quality solutions. This is mainly because the SFR mechanism can dynamically detect and replace the stagnant solution, making the search process more diverse and effective. Enhanced fitness will naturally provide better QoS outcomes,

crucial for service composition in multi-cloud environments. Moreover, the proposed algorithm outperforms others in service stability, which shows its robustness and adaptability to dynamic cloud scenarios.

The proposed MFO-SFR algorithm guarantees great efficacy when the delay and response time parameters are analyzed. A minimum delay shows how it may optimize the critical time-sensitive aspect of cloud service delivery, guaranteeing users' satisfaction with the service. On the other hand, the response times that could be retrieved by using this algorithm also promise to ensure that it may further enhance efficiency in the performance of any service. Therefore, the findings support the stated objectives of the study on QoS parameters in cloud environments and further indicate the practical relevance of the algorithm. Compared to traditional approaches, the proposed method yields better results in scalability and efficiency in solving complex service composition challenges in multi-cloud ecosystems.

IV. CONCLUSION

The swift advancement of cloud computing has led to the widespread growth of a wide range of cloud-based services. However, guaranteeing awareness of QoS during the construction of services is a substantial difficulty in cloud systems. Many individual services cannot handle complex requests and different needs that arise in real-world situations. Often, a solitary service may not be enough to fulfill the particular needs of consumers, therefore requiring the amalgamation of many services to attain the needed functionality. Due to its intrinsic NP-hard difficulty, service composition has been widely studied using various metaheuristic algorithms. This paper proposed an improved MFO algorithm with the SFR mechanism for the optimization of service composition in multi-cloud computing environments. Our approach overcomes the deficiency of early convergence in the traditional MFO by maintaining the diversity in the population with the aid of the SFR mechanism. It ensures that static solutions are identified and replaced with promising ones, which enhances the whole optimization process. The empirical results showed that our approach enhances significantly the QoS metrics such as stability of service, response time, and delay. We evaluated an algorithm using a realistic system model and the QWS dataset, considering the main QoS parameters. The comparative analysis confirmed the superior fitness and stability of our algorithm.

While the results are encouraging, many directions are open to future research: First, the proposed algorithm can be extended by allowing multi-objective optimization scenarios in which many QoS attributes can be optimized simultaneously. Second, exploring the integration of machine learning techniques and metaheuristics may lead to advanced adaptability and efficiency in service composition strategies. Third, using the MFO-SFR algorithm in other domains, like IoT-enabled edge computing, hybrid cloud environments, or real-time service orchestration, is a promising avenue for further exploration. Finally, real-world cloud deployments of the proposed approach can shed light on many practical feasibility and scalability issues.

Enhanced Task Scheduling Algorithm Using Harris Hawks Optimization Algorithm for Cloud Computing

Fang WANG

Computer School, Hubei University of Education, Wuhan 430205, China

Abstract—Amongst the most transformational technologies nowadays, cloud computing can provide resources such as CPU, memory, and storage over secure internet connections. Due to its flexibility and resource availability with guaranteed QoS, cloud computing allows comprehensive business and research adoptions. Despite the rapid development, resource management remains one of the significant challenges, especially handling task scheduling efficiently in this environment. Task scheduling strategically assigns tasks to available resources so that Quality of Service (QoS) metrics are effectively related to response time and throughput. This paper proposes an Enhanced Harris Hawks Optimization (EHHO) algorithm for scheduling cloud tasks to mitigate the common limitations found in existing algorithms. EHHO integrates a dynamic random walk strategy, enhancing exploration capabilities to avoid premature convergence and significantly improving scalability and resource allocation efficiency. Simulation outcomes reveal that EHHO minimizes makespan by up to 75%, memory usage by up to 60%, execution time by up to 39%, and cost by up to 66% compared to state-of-the-art algorithms. These benefits demonstrate that EHHO can optimize resource allocation while being highly scalable and reliable. Consistent performance over various stacks such as Kafka, Spark, Flink, and Storm further evidences the superiority of EHHO in handling complex scheduling challenges in dynamic cloud computing environments.

Keywords—Cloud computing; optimization; task scheduling; Harris Hawks Optimization; resource allocation; quality of service

I. INTRODUCTION

The Internet of Things (IoT) symbolizes change whereby many devices, from simple sensors and actuators to various everyday objects, are connected via the Internet to communicate and share information [1]. Objects like sensors and actuators form communication grids in healthcare, manufacturing, and smart cities. However, with the growth of IoT applications, volumes of generated data are huge and require immense processing and colossal storage. More importantly, real-time analytics implies vast demand [2]. Thus, cloud computing has become the backbone of IoT systems for extendable resources and rugged data management capabilities beyond IoT devices [3, 4].

Cloud computing enables customers to use the services with the help of the Internet on a pay-per-usage basis [5]. Cloud services include within their ambit a broad range of services, namely Software as a Service (SaaS), Platform as a Service (PaaS), Communication as a Service (CaaS), Data storage as a Service (DaaS), and Infrastructure as a Service (IaaS) [6]. These services allow cloud providers to provide utility-based resources whose usage supports diversified needs for IoT.

The physical servers and switches in the backbone layer of cloud computing are operated and scaled by the cloud service provider effectively as per user requirements [7]. It efficiently allocates hardware resources at a blistering pace. In terms of software, the supervisor runs these hardware resources, a hypervisor, middleware, etc. [8]. The operating system implements hardware functionalities and develops user and application communication [9]. It allows the hypervisor to create Virtual Machines (VMs) on cloud servers with specified hardware configurations and software stacks [10]. This, in turn, enables a further increase in service availability because virtualization facilitates easy service migration even during hardware failures. It is also accompanied by a tremendous rise in hardware utilization compared to the non-virtualized environment [11]. Recent advancements in reinforcement learning applications, particularly in mobile robotics, have showcased its ability to enhance decision-making and resource management in dynamic environments. Similarly, reinforcement learning's adaptive capabilities, as demonstrated in SLAM tasks, highlight its potential for optimizing virtualization and scalability in cloud computing infrastructures [12].

The middleware arranges the running and interaction of tasks on cloud servers transparently. The three fundamental types of software infrastructure are PaaS, SaaS, and IaaS [13]. IaaS allows users to create multiple VMs on servers as needed, enhancing computational resource utilization. SaaS permits users to store and access unlimited amounts of data in a minute on remotely located servers. PaaS provides secure, reliable communication services and an application development platform accessible via APIs. Lastly, the application tier enables the user to use applications stored in the cloud through the Internet, allowing quick and easy access without installation or updates locally.

Effective task scheduling is vital for managing resource allocation, execution time, and QoS in cloud-supported IoT environments. Scheduling can be classified into two types: static and dynamic approaches. In static scheduling, tasks are assigned to available machines based on a predefined strategy, whereas in dynamic scheduling, instantaneous conditions are considered to adjust resource allocations. Real-time scheduling techniques ensure priority tasks with tight timing constraints.

Task scheduling in cloud computing is complex and an NP-hard problem, directly influencing the system performance regarding resource utilization, response time, and energy consumption. In this regard, we propose an Enhanced Harris Hawks Optimization (EHHO) algorithm to optimize task scheduling problems in cloud environments. EHHO features a

novel dynamic random walk to reinforce exploration and avoid premature convergence issues, enhancing scalability, resource allocation, and energy management.

By integrating these enhancements, EHHO provides a high-performance solution for complex scheduling requirements in cloud-supported IoT systems, contributing to more efficient, reliable, and cost-effective service delivery. The following sections detail EHHO's methodology, implementation, and performance advantages over existing algorithms, underscoring its potential as a leading approach to resource management in cloud computing.

The remainder of this paper is arranged as follows: Section 2 discusses related research and highlights gaps in existing scheduling approaches. Section 3 presents the problem statement and explains the challenges of cloud task scheduling. Section 4 presents the proposed algorithm. Section 5 summarizes the experimental results and performance analysis. Section 6 discusses the practical implications and challenges. Finally, Section 7 concludes the paper and suggests future directions.

II. RELATED WORK

Shukri, et al. [14] formulated an Enhanced Multi-Verse Optimizer (EMVO) to optimize task scheduling in cloud computing contexts. The developed algorithm incorporates a new mechanism to reserve the most optimal solution from each iteration and inject it back into the population after a predefined interval to leverage better exploration and exploitation capabilities. The proposed approach minimizes task execution time and considers factors like task length, cost, and power consumption. The combination of local and global search and the core components of MVO has caused EMVO to overcome the weaknesses inherent in traditional task scheduling algorithms. Comparisons with the original Particle Swarm Optimization (PSO) and MVO have revealed the efficiency of the proposed EMVO in decreasing the makespan while improving resource utilization.

Natesan and Chokkalingam [15] developed a new Mean Grey Wolf Optimization (MGWO) algorithm to solve cloud computing scheduling issues. The study aims to optimize energy consumption. MGWO performance was evaluated using the Cloudsim toolkit under baseline workload conditions. From the simulation results, it could be revealed that MGWO substantially outperforms competing algorithms in optimizing these crucial performance metrics.

Mapetu, et al. [16] proposed a new binary PSO algorithm to cope with cloud computing load and task scheduling issues. The suggested technique embraces a formula that minimizes the overall difference in execution time between different VMs while keeping some optimization criteria. A dedicated particle position updating strategy was adopted for enhanced load balancing. The numerical evidence verifies that the algorithm performs better than the previous meta-heuristic and heuristic approaches for optimizing load balancing and task scheduling.

Liu [17] developed an effective task scheduling approach using an adaptive Ant Colony Optimization (ACO) algorithm in cloud computing contexts. Pheromone adaptation is introduced into the procedure to accelerate convergence; thus,

prematurity can be reduced. In the cloud environment, a multi-objective optimization function, which minimizes cost and time for task execution, reduces load imbalance and maximizes resource utilization, is implemented by optimized ACO. It has been proved by comparison analysis that, compared with traditional ACO, the proposed approach can always guarantee better performance in solution quality, convergence speed, and overall system efficiency, especially in handling large-scale task scheduling challenges.

Zhou, et al. [18] presented a hybrid task scheduling method based on an improved Genetic Algorithm (GA) combined with a greedy algorithm. This algorithm was designed to converge on optimal solutions in lower iteration numbers of the search process than compared approaches. It aimed at response time, completion time, and QoS performance metrics. Experimental results demonstrate that hybrid GA performs much better than existing algorithms in task-scheduling optimization than existing algorithms.

Abualigah and Diabat [19] proposed, incorporating the combination of Ant Lion Optimization (ALO) adapted to the concept of Differential Evolution (DE) to address many-objective task-scheduling issues in cloud computing settings. Elite-based DE enhanced ALO's exploitation and exploration capability, saving it from premature convergence. The effectiveness of the suggested algorithm has been tested on modeled and real-world datasets using the Cloudsim simulation environment. Additionally, experiments proved that the hybrid ALO method outperformed the other optimization algorithms regarding continuous convergence rate, especially for large-scale scheduling problems.

Panda, et al. [20] introduced a new multi-paired task scheduling algorithm for cloud computing by utilizing the Hungarian algorithm. With this approach, the logic efficiently resolves unbalanced workloads based on the pairing strategy for task scheduling. The algorithm outperformed the Hungarian Algorithm with Converse Lease Time, the Hungarian Algorithm with Lease Time, and First-Come-First-Served baselines in large-scale simulations.

Tamilarasu and Singaravel [21] proposed an Improved Coati Optimization Algorithm (ICOA) for critical challenges in cloud computing, namely lengthy scheduling times, excessive costs, and unbalanced VM loads. A task distribution and scheduling scheme involving VMs, time, and cost, was developed. A dual-objective fitness function is employed to optimize resource utilization and makespan. In the ICOA, an exploitation strategy has been incorporated to prevent the solution from converging prematurely and, hence, to enhance local search capabilities. Simulation results demonstrated the superiority of the ICOA over conventional metaheuristic task scheduling algorithms at improving makespan, success rate, turnaround efficiency, and overall system availability.

Abualigah, et al. [22] offered an enhanced hybrid optimization algorithm for cloud task scheduling, which combines Jaya algorithm strengths with Synergical Swarm Optimization (SSO) and a Levy flight. This new approach efficiently balances exploration and exploitation to accelerate and prevent premature convergence. In integrating the best of Jaya and SSO, this algorithm uses their complementary

analytics capabilities to drive an optimal assignment of tasks and allocate resources. The experimental investigation against existing methodologies confirmed the algorithm's superior scalability, convergence speed, solution quality, and performance.

Behera and Sobhanayak [23] proposed a hybrid meta-heuristic approach using GA and Gravitational Search Algorithm (GSA) for multi-target optimization of task scheduling in cloud computing. The authors addressed the NP-hard challenge of efficiently managing an exponentially growing search space while enhancing system performance. The proposed approach leveraged strengths from GA and GSA in improving the Quality of Service (QoS) measures: energy consumption, resource utilization, and makespan. As tested under CloudSim with standard, real-time, and artificial workloads, it improved degree of imbalance by about 12%, resource utilization by 9%, response time by 7%, and energy consumption by 6%.

Khademi Dehnavi, et al. [24] proposed a hybrid GA for efficient and dependable task scheduling across heterogeneous cloud computing environments. The method models an NP-hard optimization problem in scheduling to minimize costs, time, and failures. HGA introduces two novel mutation and crossover operators in global search. It also implements a localized "Walking around" step to improve solutions. Simulation runs on twelve scenarios revealed significant cost reductions compared to state-of-the-art techniques: a 14.1%

reduction in makespan, an 18.7% monetary cost reduction, and a 42.3% decrease in failure cost.

Gong, et al. [25] introduced the Enhanced Marine Predator Algorithm (EMPA) for the task scheduling challenges in the cloud computing environment. This approach incorporates the operators of the Whale Optimization Algorithm (WOA) operators, nonlinear inertia weight coefficients, and Golden Sine strategies to minimize makespan while optimizing resource utilization. Simulation runs using synthetic and GoCJ datasets showed that EMPA outperformed GWO, SCA, PSO, and WOA in makespan, resource utilization, and degree of imbalance, positioning EMPA as a very effective scheduling solution in cloud environments.

Pabitha, et al. [26] suggested a new scheduling algorithm, the Chameleon and Remora Search Optimization Algorithm (CRSOA), to tackle the task-scheduling issues arising in cloud environments due to uncertain user demands. In this proposed technique, the Chameleon Search Algorithm (CSA) is combined with the Remora Search Optimization Algorithm (RSOA) to deliver an efficient resource utilization approach that takes into consideration parameters like MIPS and network bandwidth to ensure load balancing while imposing minimal scheduling cost and, at the same time, reduced makespan. The experimental results show that the makespan reduction achieved by CRSOA is 18.9%, cost reduction is 22.1%, and the improvement in load balancing is 20.5% against baseline metaheuristic algorithms.

TABLE I. AN OVERVIEW OF RECENT TASK SCHEDULING ALGORITHMS FOR CLOUD COMPUTING

References	Algorithm	Pros	Cons
[14]	Enhanced multi-verse optimizer	Efficiently reduces makespan and improves resource utilization through enhanced exploration and exploitation mechanisms.	Limited focus on real-time dynamic scheduling challenges.
[15]	Mean grey wolf optimization	Optimizes energy consumption and makespan effectively under baseline workloads.	Does not account for task heterogeneity or scalability in large datasets.
[16]	Binary particle swarm optimization	Superior load balancing with tailored particle updating strategies reduces execution time variance.	Lacks emphasis on cost-efficiency and energy consumption.
[17]	Adaptive ant colony optimization	Enhanced convergence rate and solution quality; minimized cost, execution time, and load imbalance.	Limited applicability for large-scale dynamic task scheduling.
[18]	Hybrid genetic algorithm with greedy	Faster convergence with improved QoS metrics such as response time and completion time.	Focuses primarily on search process efficiency, with limited exploration capabilities.
[19]	Ant lion optimization with differential evolution	Enhanced convergence rates for many-objective problems; robust against premature convergence.	Complexity increases the computational costs for large-scale scheduling tasks.
[20]	Multi-paired task scheduling	Effectively handles unbalanced workloads; superior in minimizing layover times.	Limited applicability to multi-objective or heterogeneous scheduling scenarios.
[21]	Improved coati optimization algorithm	Dual-objective optimization improves makespan and system availability and prevents premature convergence.	No explicit consideration of energy efficiency metrics.
[22]	Jaya with synergistic swarm optimization	Balances exploration and exploitation; achieves high solution quality and convergence speed.	Performance under real-time or uncertain environments is not evaluated.
[23]	Genetic algorithm and gravitational search algorithm	Improves energy consumption, makespan, and resource utilization; suitable for QoS optimization.	Focus on standard workloads with limited scalability for heterogeneous tasks.
[24]	Hybrid genetic algorithm	Cost-efficient with significant reductions in makespan, monetary cost, and failure cost.	Limited application to real-time dynamic and heterogeneous scheduling problems.
[25]	Enhanced marine predator algorithm	Superior makespan reduction, resource utilization, and imbalance handling.	Lack of scalability for highly complex or real-time cloud scheduling tasks.
[26]	Chameleon and remora search optimization algorithm	Effectively minimizes scheduling costs and makespan under uncertain user demands.	High computational complexity for large-scale environments.
[27]	Horse herd-squirrel search algorithm	Demonstrates significant advantages in cost, energy, and makespan reduction.	Limited evaluation under multi-cloud or distributed cloud environments.

Parthasaradi, et al. [27] proposed a hybrid meta-heuristic for cloud computing task scheduling; the Horse Herd–Squirrel Search Algorithm (HO–SSA). This protocol combined SSA and the Horse Herd Optimization Algorithm (HOA) to increase cost efficiency, energy utilization, and scheduling performance. Furthermore, the proposed HO–SSA showed significant superiority and reduced up to 22.2% regarding tasks' cost scheduling costs, 9.68% regarding energy consumption, and makespan compared with SSA, HOA, and TSA.

As summarized in Table I, recent task-scheduling algorithms excel at optimizing specific metrics such as makespan, resource utilization, or cost. However, deficiencies remain in addressing scalability, real-time scheduling, and energy efficiency in heterogeneous and dynamic cloud environments. Although algorithms like EMPA have proven efficient in resource utilization, and huge cost reductions have been achieved in HO-SSA, few have provided a balanced approach to large-scale and multi-cloud comprehensive optimization problems for energy efficiency, load balancing,

and QoS. Furthermore, most of those methods lack real-time adaptability to uncertain user demands. Under such gaps, the proposed algorithm operates under an integrated dynamic exploration and exploitation strategy, aiming for optimal resource allocation scalability while enhancing performance in various cloud environments.

III. PROBLEM STATEMENT

Scheduling tasks in cloud computing environments is critical for effective and efficient execution, whereby resources are assigned according to user requests. Multiple layered architectures have been developed in cloud computing to offer these utility-based services. Fig. 1 depicts this kind of layered architecture. Each layer addresses specific functionalities, from data storage and processing to application development and communication support, and enables IoT applications to operate efficiently without major investments in local infrastructure. Table II provides a list of abbreviations and symbols used throughout the paper.

TABLE II. SYMBOLS AND DEFINITIONS

Symbol	Description	Symbol	Description
T	Cloud tasks	c_{ij}	Binary variable indicating task i assigned to virtual machine j
V	Cloud virtual machines	x_{ij}	Association between a virtual machine and a task
n	Total number of tasks	LB	Lower bound of the solution space
m	Total number of virtual machines	CT	Convergence time
VR	Collection of virtual machine resources	J	Randomization factor
$MIPS$	Millions of instructions per second capability of a CPU	$X_m(i)$	Updated position after applying random walk strategy
CU_j	Compute units capacity of the j^{th} virtual machine	$O(x)$	Objective function for optimization x
L_i	Task duration for the i^{th} task	$x(t+1)$	Position of a hawk in the next iteration
ET_{ij}	Execution time for the i^{th} task on the j^{th} virtual machine	$x_{random}(t)$	Random position of a hawk
BT_j	Busy period of the j^{th} virtual machine	$x_{rabbit}(t)$	Position of the prey
E	Rabbit's escaping energy	$x_{mean}(t)$	Average position of the hawk population
t	Current iteration number	UB	Upper bound of the solution space
Max_iter	Maximum number of iterations	c	Random walk deviation control constant
$\Delta x(t)$	Difference between prey and hawk positions	$rand$	Random number between 0 and 1

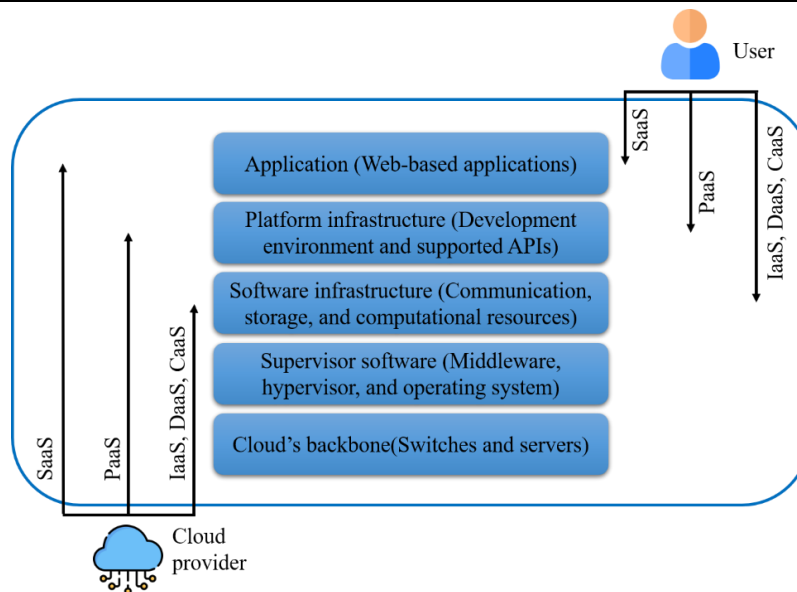

Fig. 1. Multi-layer design of cloud computing.

Fig. 2. Proposed framework for task scheduling.

The quality of the service will be directly affected by the following scheduling algorithm, affecting parameters such as execution time and operational costs. The existing frameworks comprise a cloud broker and Resource Information Servers (RIS) to ensure optimum scheduling and provide runtime information about resource availability and VM capabilities. While the above systems consolidate data from physical and virtualized infrastructures, significant research gaps exist in scheduling. A schematic of this framework is provided in Fig. 2.

Most traditional approaches fail to balance exploration and exploitation and thus lead to premature convergence or suboptimal resource allocation in a dynamic, real-time environment. In addition, most methodologies cannot adapt to heterogeneous workloads or consider uncertain factors such as fluctuating resource demand and VM performance. Other multi-objective optimizations, like minimal makespan, energy consumption, cost, and maximal resource utilization, have also been inadequately performed by most current strategies.

These gaps highlight the need for advanced algorithms capable of dynamic decision-making, enhanced exploration of solution spaces, and robust handling of diverse workloads. The EHHO algorithm addresses these challenges by integrating dynamic random walk strategies and stochastic adjustments to produce superior task scheduling performance, ensuring scalability and efficiency in complex cloud environments.

Cloud data centers feature an extensive range of actual machines containing functional VMs. The VMs function as the underlying infrastructure for the execution of user tasks. Tasks assigned to a particular VM are based on the task's requirements. Two alternative concepts of scheduling are common inside the cloud environment. The initial step involves identifying and allocating servers specifically intended for supporting VMs. The specific scheduling variant significantly enhances data center productivity, reduces power usage, and optimizes resource utilization. The impact of such a phenomenon is notably significant on cloud service vendors' operational activities.

On the other hand, the second classification of scheduling is concerned with assigning VMs for task execution. It is common

practice to divide large tasks into separate components and assign each one to a separate VM for execution under the virtualization setup. In the present scenario, the choice of VMs is contingent upon users' particular service requirements and the current condition of VMs. The implications of this specific scheduling method substantially affect the duration of job completion and the financial expenditure related to task execution. The scheduling paradigm exhibits a notable resonance among users, particularly concerning service quality and budgetary factors.

The responsibility for coordinating user tasks onto VMs based on user requirements and QoS factors usually falls on the data center broker and the cloud information service in a cloud computing environment. They are crucial in ensuring that user tasks are allocated to suitable VMs that meet the desired performance, resource availability, and other criteria. This coordination helps optimize resource utilization and deliver efficient cloud services. Users prefer minimizing costs associated with service expenses, whereas cloud providers strive to reduce energy consumption while maintaining optimal server performance and capacity utilization. These issues arise from the direct impact of these elements on the time of task performance.

As the duration of a task lengthens, there is a corresponding rise in cost expenditures and energy use. Therefore, the primary focus of this scholarly inquiry is the reduction of makespan. As has been previously analyzed, the complex issue of task scheduling is classified as one of the NP-hard issues. Despite the notable effectiveness of evolutionary algorithms in addressing NP-hard problems, their convergence rate tends to be prolonged due to the exhaustive examination of all probable, plausible solutions. As a result, the prompt achievement of convergence is regarded as a subordinate goal in this research. Given the presence of m VMs and n tasks within the environment, a set of tasks (T) and VMs (V) can be expressed by Eq. (1) and (2).

$$T = \{t_1, t_2, t_3, \dots, t_n\} \quad (1)$$

$$V = \{v_1, v_2, v, \dots, v_m\} \quad (2)$$

The assignment of these tasks to VMs produces a significant number of potential patterns, which can be expressed as nm possible scenarios. Suppose VR represents a collection of VM resources, indicated as $VR = (vr_1, vr_2, vr_3, \dots, vr_k)$. These features include the central processing unit's (CPU) capability to execute Millions of Instructions Per Second (MIPS), the availability of bandwidth, the capacity of Random Access Memory (RAM), and the capacity of storage. The task completion duration depends on the specific allocation of resources to the selected VMs. Cloud service providers utilize specific measurements known as Compute Units (CUs) to measure the capacity of VMs. For example, a solitary Amazon CU possesses processing capabilities that align with a frequency range of up to 1.2 GHz, similar to an Xeon and Opteron processor. The calculation of the duration of task execution and the projected operational expenditure for the workflow depends on CUs. Therefore, the execution time for the i^{th} task is given in the form of Eq. (3).

$$ET_{ij} = \frac{L_i}{CU_j} \quad (3)$$

Where i and j represent indices within integer numbers sets ranging from 1 to n and 1 to m , respectively. Here, CU_j corresponds to the computational unit associated with the j^{th} VM, whereas L_i signifies the execution time of the i^{th} task. The active time of a VM is defined as the interval during which tasks are being processed on the VM. Specifically, the phase of intense utilization throughout the active time of the j^{th} VM is represented by Eq. (4).

$$BT_j = \sum_{i=1}^n ET_{ij} \times c_{ij} \quad (4)$$

c_{ij} is limited to binary values, 0 or 1, x_{ij} represents the relationship between tasks and VMs, where 1 implies that task t_i is allocated to the j^{th} VM. Since VMs operate concurrently, the workflow's overall duration, or makespan, is calculated by the most prolonged time any single VM remains occupied. The makespan can be expressed using Eq. (5).

$$M = \max(BT_j) \quad (5)$$

Evolutionary algorithms aim to find the optimal solution by systematically navigating the problem domain. The time needed for the algorithm to converge depends on the solution space properties and the number of iterations executed. As the solution space expands, the convergence time increases. This relationship between convergence time and the solution space size can be expressed mathematically by Eq. (6).

$$CT \propto (l_x, k) \quad (6)$$

CT refers to the convergence time, k denotes the number of iterations necessary to identify an optimal solution, and l_x represents the length of the optimal solution x . The objective function O , used to determine the solution x , can be formulated based on Eq. (3) and (4) in form of Eq. (7).

$$O(x) = \min(M), \min(CT) \quad (7)$$

IV. PROPOSED METHOD

Harris Hawk cooperative hunting and tracking procedures inspire the HHO algorithm. These birds employ strategic tactics of surprise jumps and seven killings to capture their prey. In

cooperative attacks, some hawks coordinate in pursuit of a rabbit that has exposed itself after revealing its whereabouts for pursuit and quick capture. With hunting, however, there would be successive quick dives next to the prey, based on how it would react and the chance of its fleeing. Harris's hawks have various hunting techniques under their wings, each for different circumstances and different maneuvers of prey to evade them. If the top hawk in a hunting activity fails to track the rabbits, then another member of the team should replace that hawk and foil possible escape. It is here that the rabbit, once the hunt starts, cannot regain its defense mechanism, and the team's combined effort prevents it from escaping. The most experienced hawk makes the final catch of exhausted prey to share among the team members.

Fig. 3. HHO steps.

Fig. 3 visually represents the different phases of the HHO algorithm and reflects hawk predatory behavior: locating, circling, and ultimately capturing prey. HHO's mathematical formulation is structured accordingly, including the exploration, transition, and exploitation phases. Within this conceptual framework, each Harris's hawk symbolizes a possible solution to a particular problem, while the target prey symbolizes the ideal solution to be identified. Falcons use two exploration strategies to find prey. In the first strategy, hawks choose locations according to other hawks' positions and prey locations. In the second tactic, hawks sit randomly on tall trees. Eq. (8) mathematically models these two exploration methods with equal probability and uses random numbers to simulate their occurrence.

$$x(t+1) = \begin{cases} x_{random}(t) - r_1 |x_{random}(t) - 2r_2 x| & q \geq 0.5 \\ x_{rabbit}(t) - x_{mean}(t) - r_3 (LB + r_4 (UB - LB)) & q < 0.5 \end{cases} \quad (8)$$

Eq. (9) calculates the average position of the hawk population. The algorithm dynamically transitions between exploration and exploitation phases based on a metric termed 'rabbit energy,' defined by Eq. (10). When the rabbit's escaping energy $|E|$ exceeds 1, the hawks engage in a more extensive exploration of the search space; otherwise, the algorithm

transitions to the exploitation phase. Eq. (11) to (14) establish whether the hawks execute a soft siege or a hard siege, depending on the rabbit's energy level and its likelihood of escape. In a soft siege, the hawks simulate the rabbit's successful escape by performing repetitive diving maneuvers. Conversely, a hard siege employs a distinct computational strategy to model the scenario.

$$x_{mean}(t) = \frac{1}{N} \sum_{i=1}^N x_i(t) \quad (9)$$

$$E = 2E_0 \left(1 - \frac{t}{Max_iter}\right) \quad (10)$$

$$x(t+1) = \Delta x(t) - E|J \cdot x_{rabbit}(t) - x(t)| \quad (11)$$

$$\Delta x(t) = x_{rabbit}(t) - x(t) \quad (12)$$

$$J = 2(1 - random) \quad (13)$$

$$x(t+1) = x(t) - E|\Delta x(t)| \quad (14)$$

Eq. (15) to (18) regulate the rapid dives employed during the soft siege, employing Lévy movements to simulate the prey's evasive behavior. Eq. (15) and (16) mathematically model the hawks' actions during the diving phase. Subsequently, Eq. (17) and (18) define the characteristics of the

final rapid dives performed during the soft siege and the associated factors, k and z , utilized throughout the hard siege phase.

$$k = x_{rabbit}(t) - E|J \cdot x_{rabbit}(t) - x(t)| \quad (15)$$

$$z = k + RandomVector.L(dim) \quad (16)$$

$$x(t+1) = \begin{cases} k & \text{if } f(k) < f(x(t)) \\ z & \text{if } f(z) < f(x(t)) \end{cases} \quad (17)$$

$$k = x_{rabbit}(t) - E|J \cdot x_{rabbit}(t) - x_{mean}(t)| \quad (18)$$

The HHO algorithm incorporates four pursuit strategies during the exploitation phase to enhance exploration capabilities. While heightened exploration is beneficial in identifying diverse solution spaces, it can inadvertently precipitate premature convergence and local optima. To counteract this, standard stochastic strategies such as Gaussian random walk, Brownian motion, and Levy flight are often integrated into optimization algorithms. These strategies introduce controlled stochasticity, allowing the algorithm to balance exploitation with exploration. By generating random deviations, these methods keep the algorithm from becoming stuck in suboptimal solutions and boost its overall performance.

Initialize parameters:

- Generate an initial population of hawks with random positions.
- Define maximum iterations (Max_iter), iteration counter ($t = 1$), and necessary constants.
- Define the fitness function for the optimization problem.

Evaluate initial fitness:

- Calculate the fitness of each hawk in the initial population.
- Identify the prey position (the current best solution based on fitness).

While $t \leq Max_iter$, perform the following steps:**a. Calculate Rabbit Energy (E):**

Compute $E = 2E_0(1 - t/Max_iter)$, where E_0 is a random value in $[-1,1]$.

b. Determine phase:

- If $|E| > 1$, proceed with the exploration phase.
- Otherwise, proceed with the exploitation phase.

c. Exploration phase:

- Update the hawks' positions using:
 - Strategy 1: Update positions based on other hawks and the prey location.
 - Strategy 2: Allow hawks to perch randomly on tall trees.
- Use probabilistic rules (Equation 8) to determine the update strategy.

d. Exploitation phase:

- If prey escapes (soft siege):
 - Simulate evasive behavior using rapid dives with Lévy flights (Equations 15-18).
- Else (hard siege):
 - Aggressively update positions based on prey location (Equations 11-14).

e. Dynamic random walk (if fitness stagnates):

- Compute the deviation using Equation 19.
- Update the hawks' positions using Equation 20.

f. Update fitness and prey position:

- Recalculate the fitness for the updated hawk positions.
- Update the prey position if a better solution is found.

g. Increment iteration:

- Increase t by 1.

Output the results:

- Return the best position (prey) and its corresponding fitness value.
-

Fig. 4. Pseudocode of the proposed algorithm.

The paper proposes a dynamic random walk strategy to enhance the HHO algorithm. The pseudocode of the proposed algorithm is depicted in Fig. 4. The magnitude of the random walk deviation decreases over time. This ensures a balance between exploration (larger deviations in early iterations) and exploitation (smaller deviations in later iterations). The random walk is activated only when the fitness value of a hawk remains unchanged compared to the previous iteration. This indicates potential stagnation in the search process. The deviation is calculated using a time-dependent formula involving a random number and the present iteration relative to the maximum number of iterations. The proposed random walk strategy can be mathematically expressed using Eq. (19).

$$Deviation = (c \times rand - c/2) \times \cos(\pi/2 \times (t/T)) \quad (19)$$

Where *Deviation* is the value added to the hawk's position, *c* is a constant controlling the maximum deviation, *rand* is a random number between 0 and 1, *t* is the ongoing iteration, and *T* is the total number of iterations. Eq. (20) is used to model the process.

$$x_m(i) = X(i) + \left(c \times rand - \frac{c}{2}\right) \times \cos\left(\frac{\pi}{2} \times \left(\frac{t}{T}\right)^2\right) \times (X(i) - X_{rabbit}) \quad (20)$$

Experimental results indicate that a value of *c* equal to six yielded optimal performance. Applying the random walk strategy produces a novel position, denoted as $X_m(i)$. A subsequent greedy selection process, as formalized in Eq. (21), determines the most suitable position for the ensuing iteration.

$$X(t+1) = \begin{cases} X_m(t+1), & f(X_m(t+1)) < f(X(t+1)) \\ X(t+1), & f(X_m(t+1)) \geq f(X(t+1)) \end{cases} \quad (21)$$

V. RESULTS

The proposed algorithm (EHHO) algorithm was simulated using the CloudSim toolkit, which offers robust support for on-demand resource provisioning and versatile features, including multi-objective optimization, dynamic resource scaling, application modeling, and cloud deployment simulation. Kafka's built-in load-balancing mechanism was employed. To evaluate EHHO's performance, it was compared against ALO, GA, ACO, PSO, MGWO, and EMVO algorithms using metrics such as execution time, cost, memory storage, and makespan. Experimental parameters are detailed in Table III.

The platform selection for evaluating the EHHO algorithm, including Kafka, Spark, Flink, and Storm, was driven by their unique characteristics that align with the requirements of task scheduling in cloud environments. Kafka was chosen for its real-time reporting capabilities, enterprise-level security, and efficient cloud monitoring, making it ideal for scenarios requiring immediate feedback and load balancing. Spark's in-memory computation and scalability enable high-speed processing for large datasets, while Flink's event-driven architecture supports dynamic and continuous task scheduling. Storm, known for its low-latency processing, is particularly suitable for time-critical scheduling tasks. These platforms were selected to demonstrate EHHO's adaptability and performance across workloads, real-time requirements, and

resource management conditions, ensuring comprehensive evaluation in diverse cloud scenarios.

Tables IV and V show the execution time and cost results for different algorithms and platforms. EHHO consistently demonstrated superior performance, achieving the lowest execution time (610 ms) and cost (60) on the Kafka platform. Tables VI and VII summarize memory storage and makespan results, with EHHO again exhibiting optimal performance, recording minimum makespan values and memory consumption across all platforms. To ensure a fair comparison, all algorithms employed a maximum iteration of 100 and a population size of 100. Specific parameter settings for each algorithm are detailed below:

- EHO: alpha = 0.5, beta = 1, upper bound = 0.9, number of clans = 10, set elitism = 2, lower bound = 0.3.
- MGWO and EMVO: number of appliances = 12, coefficient vector = 1, TDR = 1, WEP = 0.2.
- PSO: maximum initial velocity = 15, minimum initial velocity = 5, alpha = 0.8, beta = 0.8.
- ACO: time factor = 2, saving matrix factor = 2, visibility coefficient = 3, pheromone concentration coefficient = 1.
- GA: mutation probability = 0.02, crossover probability = 0.60, number of demes = 6.
- ALO: number of dimensions = 5, lower bound = 0.1, upper bound = 0.8.

Kafka consistently outperforms other platforms regarding cost, execution time, makespan, and memory storage for all algorithms. Its real-time reporting capabilities, enterprise-level security, efficient cloud monitoring, and superior processing speed contributed to these results. Fig. 5 to 8 provide visual representations of the comparative performance of the algorithms as measured by cost, execution time, memory storage, and makespan, respectively. The simulations validate the superiority of the EHHO algorithm in optimizing resource allocation and performance across various metrics and platforms. Its ability to effectively balance workload and resource utilization resulted in significant improvements compared to traditional optimization algorithms.

VI. DISCUSSION

The EHHO algorithm demonstrates significant advancements in task scheduling within cloud computing environments. Integrating a dynamic random walk strategy has notably improved the algorithm's exploration and exploitation power, leading to superior performance in various metrics compared to other optimization algorithms. The experimental findings reveal that EHHO consistently achieves lower execution times, costs, memory usage, and makespan across multiple platforms, including Kafka, Spark, Flink, and Storm. These findings underscore the robustness and efficiency of EHHO in optimizing resource allocation and handling complex scheduling problems in cloud computing.

A key factor contributing to EHHO's success is its ability to avoid premature convergence, a common issue in traditional meta-heuristic algorithms. By incorporating stochastic strategies such as Gaussian random walk, Brownian motion, and Levy flight, EHHO maintains equilibrium between global exploration and local exploitation. This balance ensures that the algorithm can explore diverse solution spaces without falling into a local optimum, thereby enhancing solution quality. The dynamic adjustment of the random walk deviation over time further refines this balance, enabling EHHO to effectively adapt to different stages of the optimization process.

Moreover, the simulation results highlight the exceptional functionality of the Kafka platform concerning makespan, execution time, cost, and memory usage. Kafka's real-time reporting capabilities, enterprise-level security, efficient cloud monitoring, and superior processing speed contribute to these outcomes. These characteristics make Kafka a suitable environment for deploying EHHO, allowing it to fully leverage its optimization potential. The comparative analysis with other platforms reinforces the importance of selecting an appropriate infrastructure to maximize the benefits of advanced optimization algorithms like EHHO in cloud computing.

In summary, the EHHO algorithm effectively responds to the complex task scheduling challenges in cloud computing. Its enhanced exploration and exploitation mechanisms, coupled with the optimal performance on platforms like Kafka, position EHHO as a leading approach for efficient resource management. Researchers could explore ways to improve the EHHO algorithm, such as integrating additional stochastic strategies or refining the random walk parameters, to achieve even greater performance improvements. Additionally, investigating the algorithm's scalability and applicability to other optimization problems could expand its utility in broader contexts.

The EHHO algorithm can seamlessly integrate with popular cloud services such as AWS, Azure, and Google Cloud to optimize task scheduling and resource management. By leveraging these platforms' capabilities, EHHO can enhance the efficiency of IaaS by dynamically allocating VMs and managing compute resources. In PaaS, EHHO can streamline application deployments by optimizing workload distribution across scalable infrastructure. For SaaS, the algorithm ensures reduced latency and cost-effective resource utilization, improving overall service delivery. The ability of EHHO to

adapt to real-time cloud environments and balance workloads makes it a crucial component for maximizing the performance and scalability of cloud-based services, further solidifying its relevance in modern cloud computing ecosystems.

Despite its promising performance in task scheduling, the EHHO algorithm has certain constraints. Its reliance on predefined parameters, such as random walk deviation and iteration limits, may limit adaptability across varying real-time scenarios and dynamic workloads. Additionally, while EHHO demonstrates superior results on metrics like makespan, cost, and memory usage, its scalability to handle significantly larger task datasets or highly heterogeneous environments remains untested. The simulations, primarily conducted using the Kafka platform, suggest a dependency on specific infrastructure capabilities such as real-time reporting and efficient monitoring, raising concerns about performance consistency on less advanced platforms. Furthermore, while the dynamic random walk strategy improves exploration and exploitation, fine-tuning these adjustments for broader applications remains challenging. Addressing these constraints, particularly scalability and infrastructure independence, will be critical for maximizing EHHO's potential in diverse cloud environments.

VII. CONCLUSION

Effective task scheduling is paramount to the optimal performance of cloud computing systems. Unlike traditional computing environments, cloud-based task scheduling necessitates considering diverse parameters, including computational costs, processing capabilities, and task duration. In this research, we introduced the EHHO algorithm to tackle the complex challenge of task scheduling in cloud computing environments. Leveraging the CloudSim toolkit for simulations, EHHO demonstrated superior performance over traditional algorithms like PSO, ACO, GA, ALO, MGWO, and EMVO across critical metrics, including cost, execution time, makespan, and memory storage. Integrating a random walk approach significantly improved the algorithm's exploration capabilities, effectively preventing premature convergence to local optima and ensuring more efficient resource allocation. With its robust load balancing, high security, real-time analysis, and scalability, Kafka's platform further highlighted the algorithm's efficiency. Our findings underscore EHHO's potential for optimizing the operational efficiency of cloud computing systems, making it a viable solution for better task scheduling and resource management in diverse and dynamic cloud environments.

Future research on the EHHO could include focusing on its scalability and adaptability given real-time scheduling scenarios in highly dynamic cloud environments. By integrating adaptive random walk strategies, deviation parameters can dynamically change depending on task complexity and resource availability in real-time. The following extension of EHHO for multi-cloud or hybrid cloud infrastructures with cross-platform scheduling and resource allocation would increase its applicability. Testing its performance with more diverse and larger datasets and optimization of computational efficiency for real-world runtime applications may position EHHO as a more robust and versatile solution to complex challenges in cloud computing.

Abstract—With the rapid developments of measurement and monitoring techniques, massive amounts of in-situ data have been recorded and collected from the measurement system of combine harvesters in their working process and/or field experiments. However, the relationship between the operation parameters and the performance index such as clearing loss usually changes greatly in different sample subspaces, which makes it difficult for conventional prediction models to model the in-situ data, since most of them assume that the relationship is the same or similar throughout the whole sample space. Therefore, a polynomial chaos expansion-based bagging prediction model (PCE-BP) is proposed in this article. A polynomial chaos expansion-based decision tree is constructed to divide the sample space such that the relationship between the operation parameters and the performance index in the same part is more similar than the others, and bagging is used to ensemble the polynomial chaos expansion-based decision trees to reduce the perturbation and provide robust predictions. The experiments on the mathematical functions show that the proposed prediction model outperforms polynomial chaos expansion, polynomial chaos expansion-based decision tree, and the conventional bagging prediction model. The proposed prediction model is validated through two monitoring datasets from a combine harvester. The experimental results show that the PCE-BP model provides better cleaning loss and impurity rate prediction results than the other prediction models in most experiments, showing the advantages of sample space partitioning and bagging in the data modeling of combine harvesters.

Keywords—Combine harvester; data modeling; polynomial chaos expansion; decision tree; bagging

I. INTRODUCTION

A combined harvester is a critical type of agricultural machinery that has been widely used to harvest grain crops. In the working units of a combine harvester, the grain crops are divided into grains and other materials by cutting, feeding, threshing, and cleaning. Since the interactions between the working units (header, conveying trough, cleaning fan, and sieve) and crops are very complex, it is difficult to construct an accurate theoretical or simulation models to accurately describe the working process of combine harvesters [1], [2], [3], [4]. In recent decades, numerical simulation methods such as computational fluid dynamics have been used to predict and analyze the working process of combine harvesters, which provides useful advice and references for the design, analysis, and optimization of working units [5], [6]. However, the computational cost of numerical simulations is too high to be

accepted. For instance, the computational fluid dynamics simulation of a cleaning fan takes approximately four hours. If 100 simulations are conducted to obtain the mapping function between the design variables and the flow rate, it would take out 400 hours, around 17 days. In the past few years, the intelligent techniques of combine harvester since more operation parameters can be monitored and measured in the operation process and/or field experiments of combine harvesters. The interaction mechanisms and information among the working units and those between the crops and working units are involved in the measured data. In addition, the computational cost of the data-driven model is usually much lower than that of the corresponding numerical simulation. Therefore, the data-driven design, analysis, optimization, and control of combine harvesters are being the topics of interest in recent years [7], [8], [9], [10].

In the data mining tasks of combine harvesters, the first and most crucial step is constructing a prediction model for the response of interest, such as cleaning loss and grain impurity. Compared with hyperparameter prediction models (such as artificial neural networks and support vector regression), polynomial regression-based prediction models offer the advantages of lower computational cost and higher interpretability, which have been widely used in the data modeling of combine harvesters. For example, Zareei and Abdollahpour [7] applied polynomial regression to identify the primary factors influencing header loss and determined the optimal factor combination through experimental design. Mirzazadeh et al. [11] constructed a semi-threshed cluster prediction model using polynomial regression and then optimized the feeding rate, fan speed, and sieve open rate to reduce the impurity rate. However, the interplay between operational factors and the associated performance indicators often changes greatly in different sample subspaces, as the interactions between the working units and crops are very complex, as discussed above. Most conventional polynomial regression-based prediction models assume that the regression relationship is the same or similar throughout the whole sample space, so it is challenging to assess the complex relationship between the operation parameters and the performance index of combine harvesters. On the other hand, the conventional polynomial regression method lacks nonlinear learning ability [12]. To this end, we proposed a prediction method in this work, aiming to solve the first problem by sample space partition based on the interplay between operational factors and the associated

*Corresponding Author.

performance indicators and to solve the second problem by introducing a Gaussian stochastic process to polynomial regression (polynomial chaos expansion, PCE).

Many sample space partition methods have been proposed in the area of machine learning, such as decision trees [13], the k -means algorithm [14], and the fuzzy c -means algorithm [15]. Since the k -means algorithm and fuzzy c -means algorithm cannot provide the partition rules directly, the sample space partition strategy proposed here is developed under the framework of decision tree. In a decision tree, the sample space is recursively partitioned so that the samples in the same subspace at each leaf node have similar/identical classification labels (classification decision tree) or responses (regression decision tree). Decision trees for classification purposes play a prominent role in various applications, including fault detection and identifying patterns. Chaitanya and Yadav [16] proposed a fault identification and location approach for multi-terminal lines based on a decision tree. The proposed method has been applied and validated based on series-compensated transmission lines and double-ended transmission lines. Liu et al. [17] designed a void detection method to assist in the health monitoring of sandwich-structured immersed tube tunnels, where the void classifier was constructed using a decision tree based on the characteristics of impact elastic waves. Muralidharan and Sugumarán [18] used continuous wavelet transform to represent the vibration signals of monoblock centrifugal pumps and applied a decision tree to predict different types of faults. In a regression decision tree, the sample space is recursively partitioned so that the continuous responses in the same subspace are similar. The average response of the samples at the same node is considered as the predicted value for new points. Liang et al. [19] used a regression decision tree to predict the uniaxial compressive strength based on the material parameters and indicated that the regression decision tree outperformed multiple regression in most experimental cases. Waruru et al. [20] analyzed the near infrared diffuse reflectance spectroscopy data of air-dried soil and then used a regression decision tree to estimate the soil aggregation level based on the spectral data. Nieto et al. [21] collected the filter pressure drop data of a micro irrigation system and constructed a pressure drop prediction model using a regression decision tree. In addition, the importance of the input variables is ranked based on the nodes and splitting values of the regression decision tree. In conventional decision trees, the choice of the splitting input variable and the determination of the partitioning threshold for each node hinge on either the classification labels or the mean response exhibited by the samples. Put simply, within each leaf node's subspace, samples share identical classification labels or comparable responses, yet there's no consistent correlation between input variables and the output. The prediction performance of the decision tree frequently undergoes significant variations due to the perturbation in the splitting feature optimization process as well. To solve the first problem, a new decision tree based on polynomial chaos expansion is proposed here, in which the sample space at each node is divided according to the regression relationship of samples. Then, bootstrap aggregation [22], [23], [24], also called bagging, is used to improve the robustness of the prediction results to solve the second problem.

Here's how the remainder of this document is structured. In Section II, the related works of sample space partitioning and polynomial chaos expansion are reviewed, and the motivation and framework of the proposed method are discussed as well. The details of the proposed polynomial chaos expansion-based bagging prediction model are presented in Section III. In Sections IV, several mathematical functions and two in-situ datasets of a combine harvester are used to validate the proposed prediction model. Section VI summarizes the conclusions and viewpoints.

II. POLYNOMIAL CHAOS EXPANSION-BASED BAGGING PREDICTION MODEL (PCE-BP)

A. Polynomial Chaos Expansion

In this study, Polynomial Chaos Expansion (PCE) is employed to assess the correlation between operational parameters and performance indices. In a PCE model, the response of interest y is estimated as follows [25].

$$y = \sum_{\alpha \in N^n} \beta_{\alpha} \Psi_{\alpha}(\mathbf{x}) \quad (1)$$

where \mathbf{x} is the vector of input variables, $\alpha = (\alpha_1, \dots, \alpha_n)$ is an n -dimensional index, β_{α} is the coefficients, and Ψ_{α} is the tensor product of normalized univariate orthogonal polynomials as follows.

$$\Psi_{\alpha}(x) = \prod_{i=1}^n \Psi_{\alpha_i}^i(x_i) \quad (2)$$

Usually, only the p -degree is considered in Eq. (1) to reduce the computation cost, and the response of interest in Eq. (1) is revised as follows.

$$y \cong \sum_{\alpha \in A^{p,n}} \beta_{\alpha} \Psi_{\alpha}(x) \quad (3)$$

$$A^{p,n} = \{\alpha \in N^n : \alpha = \sum_{i=1}^n \alpha_i \leq p\}$$

Eq. (1) can be rewritten as

$$y = \Psi \beta \quad (4)$$

where, y is the vector composed of the responses for the n samples, Ψ is the matrix of Hermite normalized univariate orthogonal polynomials, and β is the vector of the polynomial chaos coefficients. Upon examining the aforementioned equation, it becomes apparent that acquiring knowledge of the coefficients β allows for the derivation of the PCE model. Notably, when the quantity of samples is at least as many as the model's degree, the coefficients β can be estimated utilizing the least squares approach, as outlined below.

$$\beta = (\Psi^T \Psi)^{-1} \Psi^T y \quad (5)$$

B. Proposed Prediction Model

As discussed in Introduction, we proposed a new prediction model based on polynomial chaos expansion, named the polynomial chaos expansion-based bagging prediction model (PCE-BP), in which the sample space is partitioned to enhance prediction precision, while bagging techniques are employed to bolster the stability of the prediction outcomes. In the proposed prediction model, m PCE-based decision trees are generated. The main difference between the proposed PCE-based decision tree and the conventional decision tree is that the node is split according to on the regression relationship, but not the

classification labels or the mean response. At all nodes, the samples (D_{train}) are categorized into the left subset $D_{train-L}$ and the right subset $D_{train-R}$. Based on D_{train} , $D_{train-L}$, and $D_{train-R}$, three PCE models are constructed, named PCE_t , PCE_L , and PCE_R . The training error before and after partition is used to calculate the splitting criterion S .

$$S = R_{after}^2 - R_{before}^2 + \theta$$

$$R_{before}^2 = 1 - \left(\frac{\sum_{i=1}^{n_t} (y_{i,t} - \bar{y}_{i,t})^2}{\sum_{i=1}^{n_t} (y_{i,t} - \bar{y})^2} \right) \quad (6)$$

$$R_{before}^2 = 1 - \left(\frac{\sum_{i=1}^{n_L} (y_{i,L} - \bar{y}_{i,L})^2 + \sum_{i=1}^{n_R} (y_{i,R} - \bar{y}_{i,R})^2}{\sum_{i=1}^{n_t} (y_{i,t} - \bar{y})^2} \right)$$

where $y_{i,t}$, $y_{i,L}$, and $y_{i,R}$ are the real responses of D_{train} , $D_{train-L}$, and $D_{train-R}$, respectively; \bar{y} is the mean response of D_{train} ; $\bar{y}_{i,L}$, $\bar{y}_{i,R}$, and $\bar{y}_{i,t}$ are the PCE predicted responses; n_t , n_L , and n_R are the sample sizes of D_{train} , $D_{train-L}$, and $D_{train-R}$, respectively; and θ is the adjustment coefficient. When $S > 0$, the current node is a leaf node. The construction process of the polynomial chaos expansion-based decision tree is summarized in Fig. 1. Utilizing the classification rules derived from the PCE-based decision tree, samples for prediction undergo classification until they arrive at leaf nodes, at which point the PCE models positioned as those leaf nodes provide the predictive responses.

A popular heuristic algorithm, the gray wolf optimizer [26], is modified to optimize the splitting feature at each node. In the modified optimization algorithm, the split input variable is first

transformed into a latent variable. Given d input variables, the latent variable represents each alternative splitting input variable through the following Table I.

After that, the new quantitative variable (q) and the division point (p_d) are combined into a vector $z = [q, p_d]$ and optimized as follows. In the optimization process, the solution with the best splitting criterion S is set as the alpha (z_α), the beta (z_β) and the delta wolf (z_δ) are worse than z_α , and the other wolves are omega wolves (z_ω). During each iteration, the solution will undergo an update as detailed below.

$$z(t + 1) = z(t) - a \cdot d \quad (7)$$

where $z(t + 1)$ is the updated solution, $z(t)$ is the current solution, a is a coefficient vector, and d is the motion of the wolf relative to the prey (z_{prey}), which is defined as follows:

$$d = |c \cdot z_{prey}(t) - z(t)| \quad (8)$$

where:

$$a = 2a \cdot r_1 - \tau \quad (9)$$

$$c = 2 \cdot r_2 \quad (10)$$

$$\tau = 2 - t \left(\frac{2}{T} \right) \quad (11)$$

TABLE I. THE INPUT VARIABLES AND LATENT VARIABLES

Input variable	1	2	...	$d - 1$	d
Quantitative variable	$[0, \frac{1}{d}]$	$[\frac{1}{d}, \frac{2}{d}]$...	$[\frac{d-2}{d}, \frac{d-1}{d}]$	$[\frac{d-1}{d}, 1]$

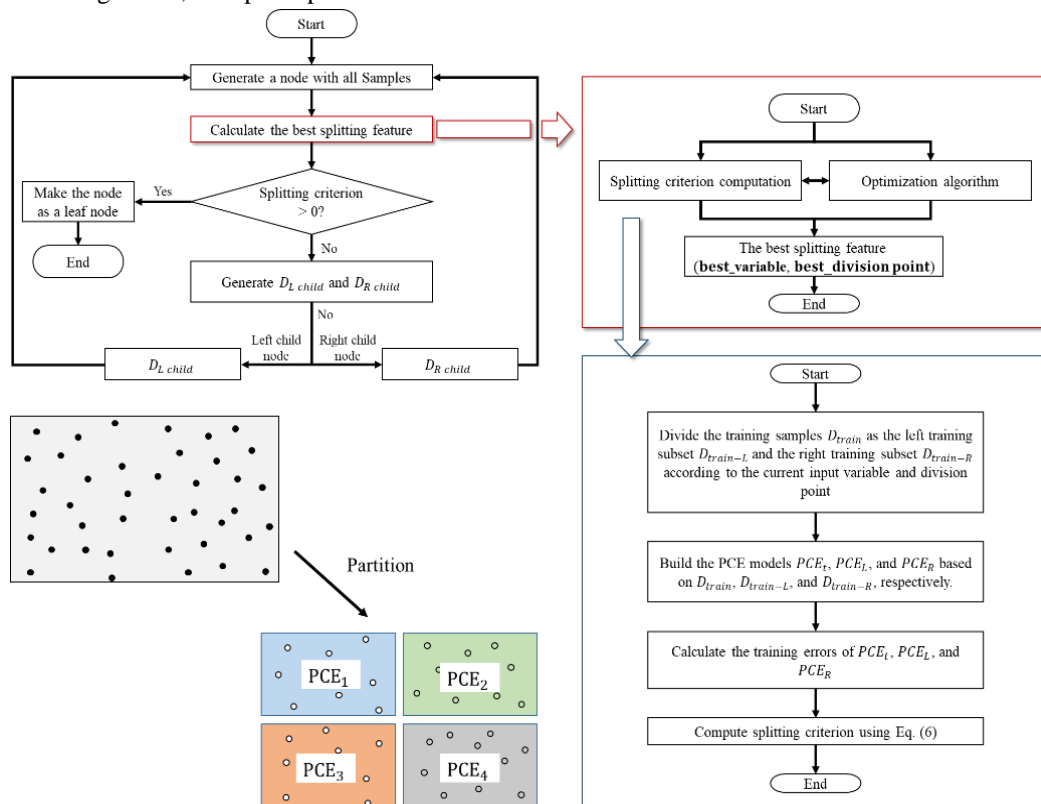

Fig. 1. Polynomial chaos expansion-based decision tree.

Where, T is the maximum number of iterations, and t is the current iteration. The positions of the other wolves (ω) are adjusted based on the three best solutions (z_α , z_β , and z_δ) as follows:

$$\begin{cases} d_\alpha = |c_1 \cdot z_\alpha(t) - z| \\ d_\beta = |c_2 \cdot z_\beta(t) - z| \\ d_\delta = |c_3 \cdot z_\delta(t) - z| \end{cases} \quad (12)$$

$$\begin{cases} z_1 = z_\alpha - a_1 \cdot (d_\alpha) \\ z_2 = z_\beta - a_2 \cdot (d_\beta) \\ z_3 = z_\delta - a_3 \cdot (d_\delta) \end{cases} \quad (13)$$

$$z(t + 1) = \frac{z_1(t+1) + z_2(t+1) + z_3(t+1)}{3} \quad (14)$$

The above process of Eq. (7)-Eq. (14) repeats until the termination criterion is fulfilled, and the z_α of the last iteration is considered the best splitting feature.

From the above equations, it can be found that the random generation of initial solutions have effect on the construction process of the PCE-based decision tree. In other words, the generated decision tree might be slightly different even if the settings are same. Thus, Bagging is introduced to solve this problem, in which where m PCE-based decision trees are generated simultaneously and the final prediction result is estimated by the generated PCE-based decision trees.

$$\widehat{y}^* = \frac{\sum_{i=1}^m \widehat{y}_i^*}{m} \quad (15)$$

Where \widehat{y}^* represents the final estimated response, and \widehat{y}_i^* refers to the response produced by the i -th decision tree based on PCE.

III. EXPERIMENTS ON MATHEMATICAL FUNCTIONS

The effects of the parameter settings including the number of trees (m) and the adjustment coefficient (θ) on the proposed PCE-BP model are studied through two mathematical functions. The proposed model (PCE-BP) is compared with PCE, PCE-based decision tree (PCET), and random forest. The effectiveness of the aforementioned methods is assessed using R -square (R^2), calculated as follows:

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - \widehat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2} \quad (16)$$

where y_i is the i -th real response, \widehat{y}_i is the corresponding predicted value, n is the number of testing points, and \bar{y} is the mean of the real responses. The closer R^2 is to 1, the better the performance of the prediction model.

A. Experiments on a Single Two-Dimensional Function

A two-dimensional function is utilized to validate the proposed PCE-BP model, maintaining consistency across the entire space. The function is defined as follows:

$$y = x_1^2 - 5\cos(2\pi x_2) \quad x \in [-1, 1] \quad (17)$$

The impact of the number of trees is examined first. For each number of trees (5, 10, 15, ..., 45, and 50), 20 experiments are conducted, where the parameter θ is set as 0.05. 100 samples are generated using Latin hypercube sampling, and another 2,000

samples are used to validate the prediction models. The obtained mean and variance of R^2 are shown in Fig. 2.

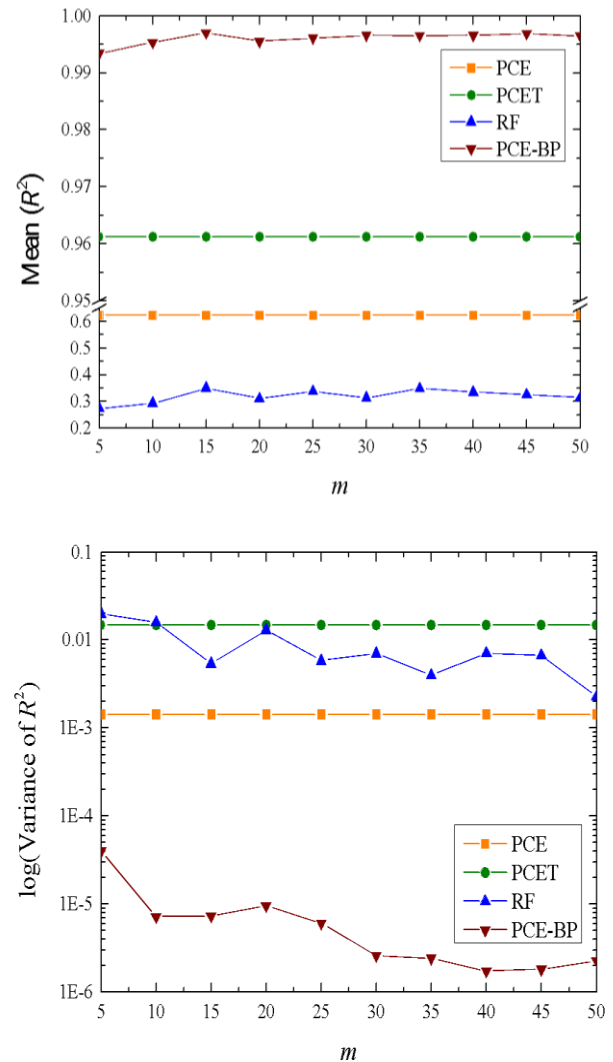

Fig. 2. The prediction results with different m .

From Fig. 2, it is found that the PCE-BP method outperforms the other prediction models in terms of the mean R^2 for all the values of m . The mean R^2 of PCET is higher than that of PCE, which is mainly because the PCET model partitions the sample space into several subspaces so that the regression relationship between the input variables and the response of interest is similar. Compared with the PCET model, the PCE-BP model produces better results with R^2 higher than 0.99. In each PCE-based decision tree, the sample space splitting at each node is influenced by the training samples and the randomly generated initial potential solutions for the splitting feature. The PCE-BP model uses bagging strategy to solve this issue, in which the predicted response is averaged by several PCE-based decision trees. The performance of the PCE-based decision tree varies greatly (the highest variance of R^2 for most experiments is shown in Fig. 2.), so its mean R^2 is smaller than that of the PCE-BP model. The PCE-BP model classifies the samples based on the regression relationship, but the RF model is based on the

mean responses. Thus, the PCE-BP model is also better than RF. The PCE-BP model is much better than the other three models in term of the variance of R^2 as well. The highest value is smaller than 0.0001, showing its robust prediction performance. With the parameter m increasing, the mean R^2 of the PCE-BP model first increases and then changes slightly when m exceeds 10. The variance of R^2 first decreases as parameter m increases and tends to remain stable. A larger m means that more PCE-based decision trees are generated in the PCE-BP model so that the perturbation brought by the splitting feature optimization is eliminated. As a result, the prediction accuracy is increased, as shown in Fig. 3. From the results and analysis above, it can be determined that the adverse effect of the splitting feature optimization is effectively reduced when m exceeds 25. In other words, the proposed PCE-BP model provides competitive prediction results for the single two-dimensional mathematical function tested here when the number of trees exceeds 25.

From Eq. (6), it can be found that the parameter θ is directly correlated with the splitting criterion, which would have an important effect on the prediction results of the PCE-BP model. The number of trees is set as 30, and the parameter θ is set as 0.04, 0.042, ..., 0.058, and 0.06. The mean and variance of R^2 over 20 experiments for each θ are presented in Fig. 3. The PCE-BP model is still better than that of the PCE, PCET, and RF models, showing the advantages of sample space partitioning and bagging. With the parameter θ increasing from 0.04 to 0.058, the mean R^2 increases and then tends to be stable. When the parameter θ is higher than 0.058, the mean R^2 decreases slightly. From Section III, it is known that the larger θ is, the higher the regression error before and after partitioning at each node. Samples within the same subspace show a more similar regression relationship between the input variables and the response of interest than those in different subspaces. The prediction accuracy of the PCE-BP model increases as parameter θ increases. However, when the parameter θ is too high, it is sample space is hard to be divided by the PCE-BP model, so the performance of the PCE-BP model decreases. The variance of R^2 decreases with increasing θ , indicating that the performance of the PCE-BP model is more robust. As a

conclusion, the PCE-BP model produces competitive prediction performance when the parameter θ is approximately 0.05.

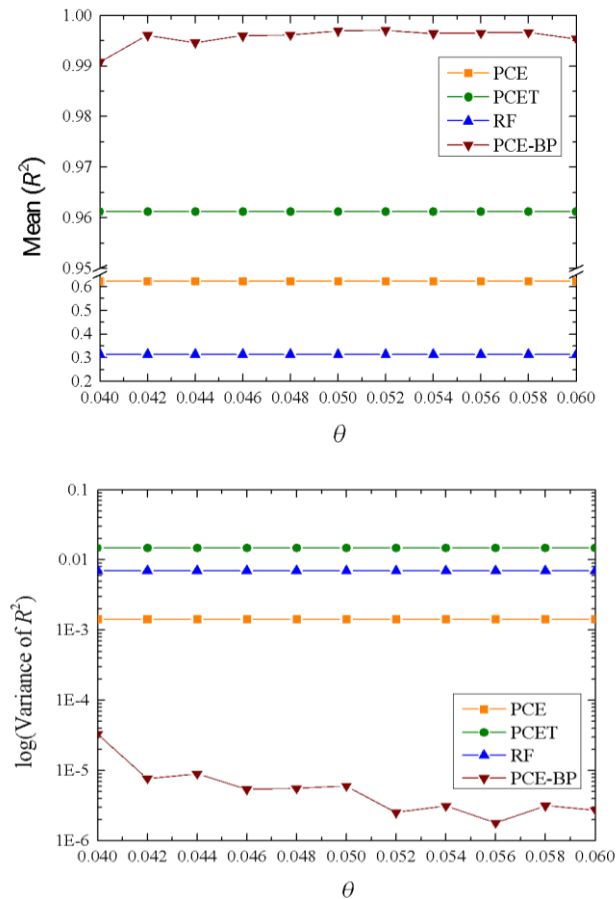

Fig. 3. The prediction results with different θ .

B. Piecewise Four-Dimensional Function

A piecewise four-dimensional function is used to validate the PCE-BP model, in which the mathematical function changes in different subspace, as defined as follows:

$$\begin{cases} y = \sin \sin (2\pi x_1) + x_2^2 + x_3 + x_4, x_1 \in [0, 0.5], x_2, x_3, x_4 \in [0, 1] \\ y = \cos \cos (2\pi x_1) + x_2 + x_3 + x_4, x_1 \in [0.5, 1], x_2, x_3, x_4 \in [0, 1] \end{cases} \quad (18)$$

The parameter θ is 0.05, and m is set as 5, 10, ..., 45, and 50. Two hundred points are generated for the prediction models, then then the model accuracy is validated through another 4,000 samples. The obtained mean and variance of R^2 for 20 experiments are shown in Fig. 4. The mean R^2 of PCET PCE-BP is higher than that of PCE in all experiments. With the help of sample space partition according the relationship between the input variables and the response of interest, the PCE models at the leaf nodes of the PCET and PCE-BP can accurately evaluate the relationship, and the overall prediction accuracy is improved as well. The PCE-BP model outperforms the RF model as well, indicating that the prediction model of each subspace of the PCE-BP model can accurately evaluate the relationship. In addition, the prediction accuracy of the PCET and PCE-BP models both surpass the RF model. The variance of R^2 of the

PCE-BP and RF models is smaller than those of the PCE and PCET models, which is mainly because of the introduction of bagging. With the parameter m increases, the average performance of the PCE-BP model increases and then tends to be stable. When m increases from 35 to 50, the variance of R^2 changes slightly. A larger m means that more PCET trees are generated in the PCE-BP model, so the perturbation brought by the splitting feature optimization can be more effectively eliminated. Thus, as m increases, the prediction accuracy increases, and the performance variance decreases, as shown in Fig. 4. When the parameter m is too high, the perturbation brought by the splitting feature optimization cannot be further reduced, so the mean and variance of the prediction results tend to be stable. Overall, the proposed PCE-BP model outperforms

the other three models and produces competitive prediction performance when the number of trees surpasses 25.

In the following experiments, the parameter m is set as 25; θ is set as 0.04, 0.042, ..., 0.058, and 0.060. The experiments are conducted 20 times for each value of θ , and the mean and variance of R^2 are shown in Fig. 5. From this figure, it is found that the proposed model outperforms the other models. With the parameter θ increasing from 0.040 to 0.046, the mean of R^2 of the proposed model increases, but the variance of R^2 decreases. As θ continuously increases to 0.06, both the mean and variance of R^2 change slightly. From the introduction of the PCE-BP model, it can be found that the initial space at the node is more likely to be partitioned when parameter θ is relatively smaller. In other words, the PCE-based decision tree is deeper, which results in the tendency of decision tree overfitting [13]. Thus, the prediction performance of the proposed model tends to be better when θ is larger. On the other hand, the variation brought by the splitting feature optimization is also reduced since the space at the node is more difficult to partition. Therefore, the variance of R^2 decreases as θ increases. The PCE-BP model provides competitive results for the piecewise four-dimensional mathematical function when θ is approximately 0.05.

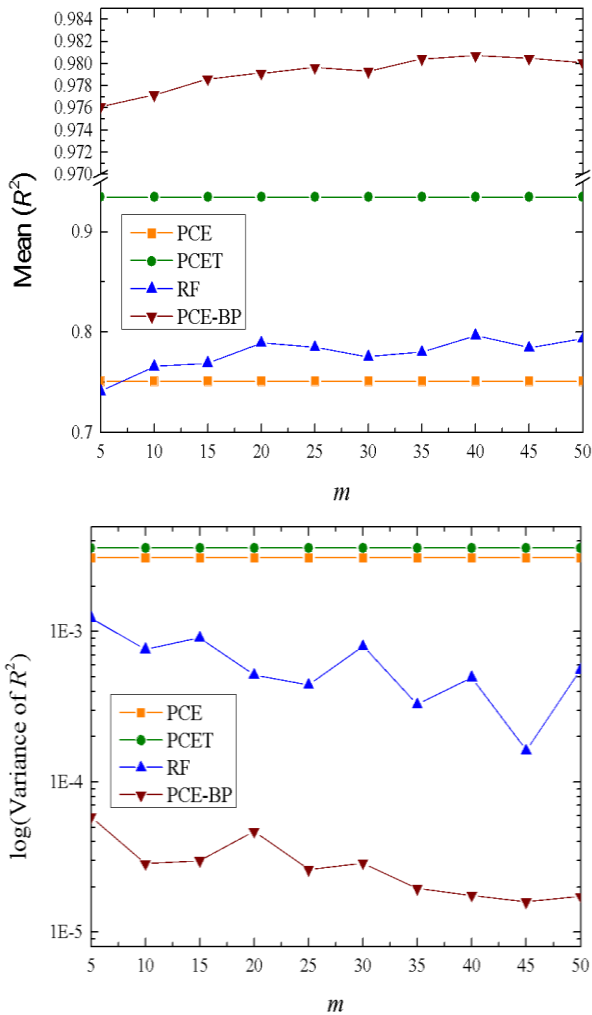

Fig. 4. The prediction results with different m .

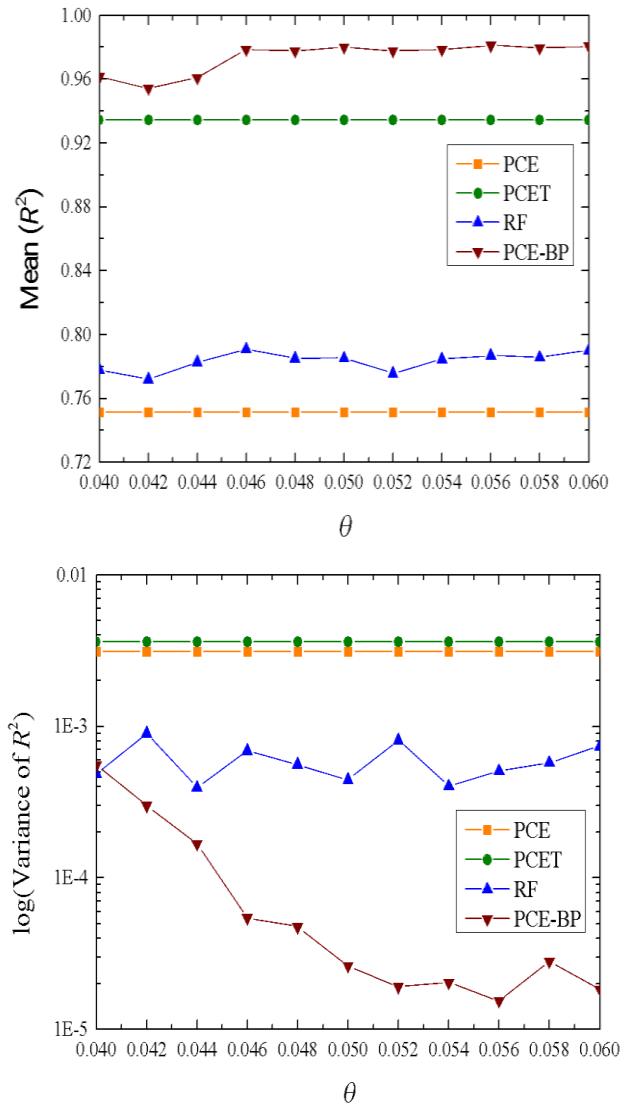

Fig. 5. The prediction results with different θ .

IV. VALIDATION BASED ON THE DATASETS OF A COMBINE HARVESTER

A. Case 1 (Cleaning Loss)

The PCE-BP model is applied to a while-feed combine harvester manufactured in Jiangsu, China (World Ruilong 4LZ-6.0A). The dataset used here comes from the field experiment (Fig. 6), containing 750 samples, including the header height, the open rate of the cleaning fan, the rotation speed of the cleaning fan, the open rate of the sieve, the angle of the guide plate, the rotation speed of the threshing drum, the gap of the threshing drum, and the cleaning loss. In each experiment, ten folds cross-validation experiments are conducted (in each experiment, a segment of the data serves as the basis for verifying the accuracy of the cleaning loss prediction models, whereas the remaining nine segments are dedicated to building the prediction model). The parameters m and θ of the PCE-BP model are set as 30 and 0.05, respectively. Fig. 7 shows the results of ten experiments.

Fig. 6. Field experiment of harvesting rapeseed.

Fig. 7. Experimental results of Case 1.

Fig. 8. Effect of parameters m and θ on the PCE-BP model.

It is found that the PCE-BP model is better than the other three models. The R^2 of the PCET model is higher than that of the conventional PCE model, where the PCET's average R^2 is 0.449 and PCE is 0.259. In the PCET model, the sample space is divided into different parts such that the relationship between the operating parameters and the cleaning loss in the same part is more similar than those in the other parts, thus improving the cleaning loss prediction accuracy. Similarly, RF is also better than the PCE model, which can be attributed to the sample space partitioning. With the help of the bagging strategy, the perturbation brought by the feature splitting in PCET is eliminated. Additionally, the RF model divides the sample space according to the mean responses. Thus, the PCE-BP model outperforms the PCET and RF models in all experiments.

The training and testing datasets in the tenth experiment are used to study the number of trees m on the proposed model. The parameter θ is set as 0.05, and the parameter m is set as 5, 10,

..., 45, and 50. Fig. 8 shows the experimental results. It is found that the prediction performance of PCE-BP increases as m increases from 5 to 25. A larger m means that more PCE-based decision trees are generated in the PCE-BP model, which means that the perturbation brought by the splitting feature optimization can be effectively reduced, thus increasing the prediction accuracy. As m continually increases to 50, the R^2 of the PCE-BP model changes slightly, which is mainly because the perturbation cannot be reduced further. The effect of the parameter θ is studied as well, and the results are shown in Fig. 8, where the number of tree is 30. It is observed that R^2 tends to increase and then decrease with increasing parameter θ . From the introduction of the PCE-BP model, it can be found that a deeper PCE-based decision tree would be constructed when the parameter θ is relatively smaller. The generated tree is easy to overfit, so R^2 tends to be lower. When the parameter θ is relatively larger, the space at the node is more difficult to partition, so R^2 is lower. Overall, the PCE-BP model can provide competitive performance for different values of m and θ .

B. Case 2 (Impurity Rate)

Another dataset is used here, which includes 337 samples with recorded operational parameters and impurity rates. Ten folds cross-validation experiments are conducted as well in this subsection. The parameters m and θ are set to 30 and 0.05, respectively. Fig. 9 shows the experiments. It is found that the PCE-BP model outperforms the PCE and RF models, which can be attributed to sample space partitioning based on the relationship between the input variables and the response of interest. The R^2 of the PCE-BP is higher than PCET in most experiments. In experiments 2, 3, and 9, the performance of the PCE-BP model is very close to that of the PCET model. From Fig. 10, it can be found that the mean R^2 of PCE-BP is 0.550, which exceeds those of the other three models, highlighting the benefits of sample space partitioning and bagging.

Fig. 9. Experimental results of Case 2.

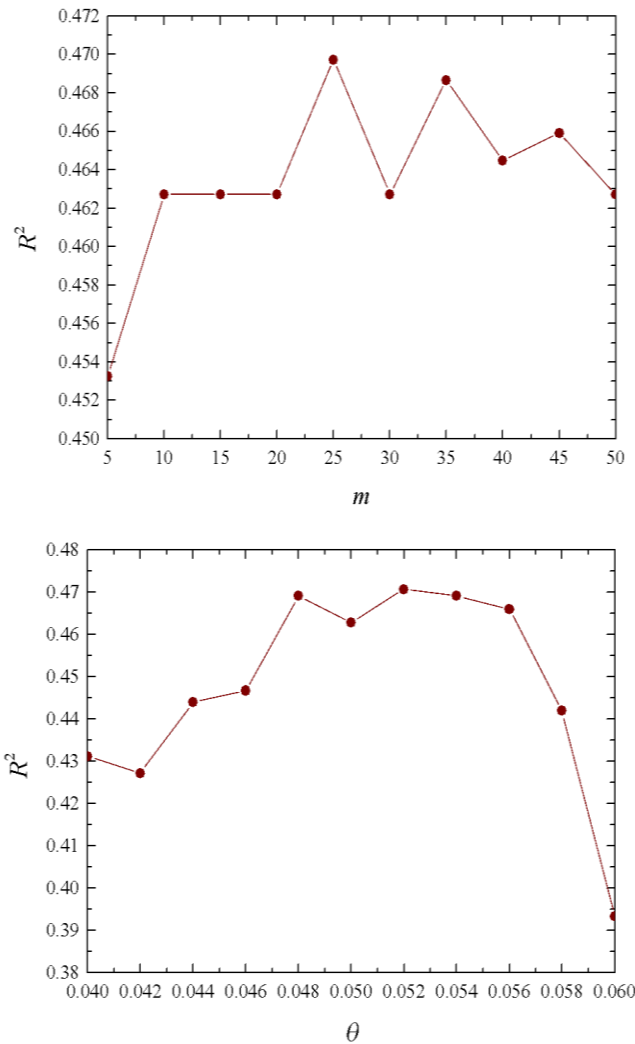

Fig. 10. Effects of parameters m and θ on the PCE-BP model.

The training and testing datasets from the tenth experiment are used to study the effects of the parameters m and θ on the PCE-BP model. The obtained results are shown in Fig. 10 (θ is set as 0.05). It is found that the R^2 with $m = 25\sim 50$ is higher than $m = 5\sim 20$. The parameter m is set as 30, the parameter θ is set as 0.04, 0.042, ..., 0.058, and 0.06, and the results are shown in Fig. 10 as well. R^2 first increases and then decreases as θ increases. When the factor θ is relatively small, a deeper PCE-based decision tree is constructed, which means that the prediction model easily overfits. On the other hand, when the parameter θ is relatively larger, the space at the node is more difficult to partition, so R^2 is lower as well. Overall, the PCE-BP model provides better results than the other three models for most values of parameters m and θ , as shown in Fig. 9 and Fig. 10.

V. CONCLUSION

In this paper, a polynomial chaos expansion-based bagging prediction model (PCE-BP) is proposed for modeling the field data of a combine harvester. In the proposed model, a polynomial chaos expansion-based decision tree is designed to partition the sample space, and bagging is used to ensemble the polynomial chaos expansion-based decision trees. The efficiency of the proposed prediction model is first validated through single and piecewise mathematical functions. The results show that the proposed prediction model outperforms polynomial chaos expansion, polynomial chaos expansion-based decision tree, and the conventional bagging prediction model functions. The proposed model demonstrates excellent prediction performance with 25 trees and the adjustment coefficient of 0.05. The proposed prediction model is further validated through two in-situ datasets of a combine harvester. The PCE-BP model provides more accurate cleaning loss and impurity rate prediction results than the conventional prediction models in most experiments. The experimental results show the advantages of sample space partitioning and bagging in the data modeling of combine harvesters.

From the results of the experiments, we found that the construction time of the proposed model is higher than that based on the conventional polynomial chaos expansion. In future work, the cost reduction of the proposed model will be our research topic. In addition, the other ensemble strategy such as boosting would be introduced into the proposed model as well.

Detecting Emotions with Deep Learning Models: Strategies to Optimize the Work Environment and Organizational Productivity

Cantuarias Valdivia Luis Alberto de Jesús, Gómez Human Javier Junior, Sierra-Liñan Fernando
Facultad de Ingeniería, Universidad Privada del Norte, Lima, Perú

Abstract—This study proposes the implementation of a facial emotion recognition system based on Convolutional Neural Networks to detect emotions in real time, aiming to optimize the workplace environment and enhance organizational productivity. Six deep learning models were evaluated: Standard CNN, AlexNet, VGG16, InceptionV3, ResNet152 and DenseNet201, with DenseNet201 achieving the best performance, delivering an accuracy of 87.7% and recall of 96.3%. The system demonstrated significant improvements in key performance indicators (KPIs), including a 72.59% reduction in data collection time, a 63.4% reduction in diagnosis time, and a 66.59% increase in job satisfaction. These findings highlight the potential of Deep Learning technologies for workplace emotional management, enabling timely interventions and fostering a healthier, more efficient organizational environment.

Keywords—Facial recognition; real-time emotions; convolutional neural networks; work environment; artificial intelligence in human resources

I. INTRODUCTION

Many companies today face the challenge of effectively managing their employees' emotions to improve the work environment. As noted in study [1], mental health is a state of well-being that allows you to manage stress and work effectively. In addition, a high percentage of workers suffer from work-related stress, which affects their mental health, performance and interpersonal relationships, generating significant economic and social costs [2]. This impact is linked to the “emotional sphere”, a model in which emotions influence group processes and outcomes [3].

In this way, it is [4] highlighted that positive socio-emotional interactions foster collaboration and teamwork. For its part, [5] it underlines that emotional management is a crucial skill for work success, since it allows regulating one's own and others' emotions. In Peru, job dissatisfaction is a growing problem, with 78% of Peruvians reporting burnout in 2023 [6]. This problem affects both the quality of life of employees and talent retention, since workers with high levels of stress are 4.5 times more likely to quit [7].

Traditional emotional management methodologies are limited, technologies such as facial recognition integrated with AI emerge as effective solutions to analyze emotions in real time and optimize organizational decisions [8]. Facial recognition has been integrated into multiple industries for its ability to authenticate identities and analyze emotions [9]. However,

identifying similar expressions such as fear, and surprise remains a challenge [10]. Since 55% of communicative information comes from non-verbal elements [11], these tools are essential to address emotional problems in organizations.

In this context, there is a need to implement an intelligent system for the detection of emotions in real time in controlled work environments. This approach seeks to optimize the identification of emotional states with high precision, contributing to the improvement of the work environment and the productivity of organizations.

The paper is organized as follows. Section II includes the literature review, where previous studies and key concepts are presented. Section III describes the methodology used. Section IV presents the results obtained from the experiment performed. Section V addresses the discussion of the findings. Finally, Section VI presents the conclusions and possible future work.

II. LITERATURE REVIEW

Facial recognition, based on computer vision and deep learning techniques, allows for the identification and analysis of emotional expressions with high precision. Artificial Intelligence (AI) algorithms are trained with large data sets to learn distinctive patterns, applicable in areas such as security, education, medicine and marketing [12], [13], [14]. In addition, its non-intrusive capacity and operational autonomy make it versatile technology for machine learning tasks [13].

Although effective, emotion recognition faces significant challenges, cultural differences and expression ambiguity are obstacles highlighting the need for high-quality data [15]. In [16], their DenseNet201 model showed the highest accuracy, with 86.85%, in detecting fake faces, outperforming other convolutional neural network architectures by using advanced transfer learning techniques and medicine benefits from AI to understand emotions [17], although they require advanced methods to address the complexity of facial expressions. Additionally, a BLTSM-based model based on attention mechanisms was shown to be effective in describing emotional attitudes and recognizing emotions [18].

Recent advances have greatly improved accuracy, for example, the “IPSOBSA-QCNN” was developed, a quantum neural network that achieves 98% success in emotion classification [19]. On the other hand, local binary patterns and extreme learning were integrated to maximize effectiveness on data sets such as CK+ and JFFE [20]. In addition, histograms of

oriented gradients (HOG) and fast networks were used [21], achieving 95.04% accuracy.

Specialized applications reinforce the potential of facial recognition, where the “EigenFaces” algorithm was used with libraries such as OpenCV and SKlearn to analyze emotions [22], emotional changes were detected from low-resolution images [23]. In addition, the effectiveness of convolutional neural networks to identify emotions in real time with an accuracy greater than 80% was highlighted [24], [25]; on the other hand, it was shown how scalable models allow the classification of seven emotions in video game, security and education applications [26].

Automatic recognition of facial emotions has seen significant advances thanks to convolutional neural networks (CNNs), which allow for highly accurate classifications. However, the effectiveness of these models largely depends on the quality and diversity of the data sets used for their training, highlighting the need for careful and representative data collection [27]. Recent advances in deep neural networks have

achieved accuracy rates above 90% in emotion classification, while future research aims to develop more robust models that adapt to diverse contexts and environmental conditions [28]. On the other hand, emotion recognition from visual data faces significant challenges due to the subjective nature of human emotions and the complexity of visual information, which has led to the use of convolutional neural networks to improve sentiment classification accuracy [29]; In addition, they have benefited from genetic algorithms (GA) [30] to optimize the hyperparameters of CNN models, achieving an accuracy of 76.11% in the third generation, consolidating the potential of the CNN-GA approach in facial emotion recognition [30].

In summary, these studies demonstrate that AI-based emotion detection has great potential across multiple sectors, although challenges remain related to cultural interpretation, data quality, and ethical applications. Table I compares recent studies on emotion detection using neural networks, highlighting their objectives, methods, datasets, and key results, along with the approach proposed in this work.

TABLE I. WORK RELATED TO EMOTION DETECTION USING DEEP LEARNING

Study	Goals	Method	Evidence	Results
[12]	Emotion detection in low-resolution images using residual networks	Residual network with voting	RAF-DB dataset (low resolution images)	Accuracy: 85.69%
[38]	Feature Extraction in Detection with EfficientNetB0	EfficientNetB0	FER2013 dataset	Accuracy: 95.82%
[31]	Real-time emotion detection for human-robot collaboration in smart factories	DeepFace	Industrial contexts (real-time testing)	High precision in real-time collaboration scenarios
[26]	Emotion recognition in low-resolution images	CNN	FER2013 dataset (low resolution images)	Accuracy: 66.85%
[19]	Quantum CNN for emotion detection in mental health contexts	Quantum CNN (QCNN)	Mental health context	Improved efficiency and reduced training times
Proposed	Real-time emotion detection in controlled work environments	Standard CNN, AlexNet, VGG16, InceptionV3, ResNet152, DenseNet201	Controlled work environment (real-time testing)	High precision in real-time emotion detection

III. PROPOSED METHODOLOGY

In this research, the CRISP-DM model was taken as inspiration as a basis to address the different stages of the project, from understanding to deployment, widely used as a

standard in data mining [32]. This framework, widely accepted in data analysis [33], stands out for its adaptability, allowing its application in areas such as medicine [34], signal processing [35], and the manufacturing industry [36], [37]. Fig. 1 shows the methodological graph that will be followed in this research.

Fig. 1. Diagram of the methodology.

A. Understanding the Business

The present study aims to optimize the work environment and productivity of the organization by implementing a facial

recognition system based on deep learning models. To achieve this, the following key business objectives were identified:

- Improve the emotional well-being of employees in real-time.
- Detect and address negative emotions that may impact team productivity.
- Provide technological tools that support data-driven decision-making.
- Reduce work stress and foster a healthier organizational environment.
- Increase job satisfaction through timely interventions.

Evaluation of the Current Situation: Employee dissatisfaction and stress impact performance. Traditional methods are subjective, requiring an automated solution.

Research Population: A sample of 17 workers was selected for relevant data collection, ensuring that despite constraints.

Expected Impact: Real-time emotion detection enables timely interventions, improving the work environment and decision-making.

B. Obtaining the Data

The development of the facial recognition system for emotion detection began with the collection of high-quality data, using the public Kaggle database where a dataset of 35,960 images of faces with the emotions required for training was found. In addition, special attention was paid to the diversity of the images, ensuring the representation of different demographic groups and emotional expressions (happiness, anger, sadness, surprise, fear, disgust and neutrality). Fig. 2 shows the dataset used in this study.

Fig. 2. Images of dataset.

C. Data Processing

In this phase of development, a series of essential steps were taken to ensure that the data collected from the dataset was suitable for training Deep Learning models, maximizing their effectiveness and precision. First, images were filtered, eliminating those that were of low quality or had characteristics that could hinder learning, such as insufficient resolutions or irrelevant elements in the background. This process made it possible to work with high-quality data.

Subsequently, image resizing was implemented, adjusting all images to a standard size defined for the models, which ensured consistency and homogeneity in the system input. Data normalization was then conducted, adjusting pixel values to a

uniform range, which facilitated processing and improved the model's ability to identify significant patterns during training.

Additionally, data augmentation techniques such as rotation, shifting and horizontal flipping were applied to increase the diversity of the dataset. These modifications helped simulate various capture conditions, increasing the robustness and generalization capacity of the model.

Finally, the processed images were transformed into tensors, ensuring that the emotional labels remained correctly aligned with each image. This set of steps established a solid foundation for efficient training of the models, minimizing errors and improving their predictive ability. Furthermore, the emotions were divided into folders as shown in Fig. 3.

Fig. 3. Organization of folders by emotions.

D. Deep Learning Algorithms

In the modeling stage, six deep learning models were developed and trained for emotion detection from facial images: standard CNN, AlexNet, VGG16, DenseNet201, ResNet152, and InceptionV3. Each model was selected for its characteristics and proven performance in classification and computer vision tasks, allowing the problem to be approached from different architectural perspectives.

The CNN model was implemented in this study to see its level of prediction. On the other hand, AlexNet, known for being a pioneer in the use of deep networks, was included for its ability to extract relevant features through efficient convolutional layers. Likewise, VGG16, with its architecture based on small convolutional layers, allowed capturing fine details of the images, benefiting from greater depth.

As for the advanced models, DenseNet201 stood out for its dense structure, which connects each layer to all the following ones, maximizing the reuse of residual features and redundancy

in learning. Meanwhile, ResNet152 used residual connections to mitigate the gradient vanishing problem, effectively training a deep network. Finally, InceptionV3 incorporated convolutions of multiple sizes in a single layer, capturing information at different spatial scales, making it especially robust against the complexity of emotional expressions. Fig. 4 illustrates the trained models divided by folders.

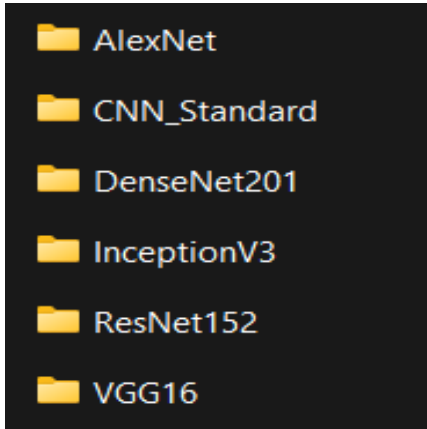

Fig. 4. Folder organization by trained model.

E. Evaluation Metrics

In this phase, the performance of the trained deep learning models for facial emotion detection was evaluated using the following quantitative metrics.

- Precision: Represents the percentage of correct predictions made by the model compared to the total number of predictions.

$$Precision = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

- Recall: Evaluates the model's ability to correctly detect positive instances, minimizing false negatives.

$$Recall = \frac{TP}{TP+FN} \quad (2)$$

- F1 Score: Combines precision and sensitivity in a harmonic average.

$$F1\ Score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (3)$$

Where:

- TP: True Positive
- TN: True Negative
- FP: False Positives
- FN; False negatives (False Negative)

F. Performance Evaluation Instrument

To evaluate the effectiveness of the models, an experimental instrument was designed in which the 17 individuals (sample) participated. Each participant performed specific tests in which they were asked to express emotions such as happiness, sadness, anger, surprise, fear, disgust and neutrality towards the system, while the system tried to recognize them. The predictions made by each model were compared with real emotions, generating a confusion matrix for each architecture. This approach allowed recording detailed data on the performance of the models in a controlled environment.

Precision, recall, and F1-score metrics were manually calculated from the results obtained using standard formulas. This procedure ensures that the calculations are accurate and reflect the real performance of the models under experimental conditions.

G. Desktop Application with the Best Performing Model

This section aims to present and analyze the results obtained after the implementation of the face recognition system based on convolutional neural networks. It was first based on a comparison of six main architectures: standard CNN, AlexNet, VGG16, DenseNet201, ResNet152, and InceptionV3; comparing their performance in terms of precision, recall, and F1 score. This comparison allows us to identify the most suitable model for the final implementation, based on its ability to classify emotions accurately and efficiently.

In addition to the comparison of models, the effects of the implementation of the selected system in the work environment were analyzed, which included metrics related to productivity, organizational climate, and diagnosis and data collection times.

Table II shows the results of applying the metrics to each model, with DenseNet201 being the best performing model.

TABLE II. MODEL COMPARISON

Model	Precision	Recall	F1 Score
CNN	78.59%	86.60%	82.45%
AlexNet	77.87%	88.64%	82.90%
VGG16	80.59%	90%	84.98%
DenseNet201	87.70%	96.30%	91.80%
ResNet152	82.79%	93.48%	87.81%
InceptionV3	81.15%	88.17%	84.51%

H. Confusion Matrices

Below are the confusion matrices for each model used. These matrices complement the global metrics presented in the comparison table, providing a more granular view of the classification. The confusion matrices reflect the individual performance of each model in classifying emotions. In each matrix, the balance between correct predictions (main diagonal) and errors can be observed, highlighting the relative precision of the most robust models. The matrices can be seen in Fig. 5.

Fig. 5. (a) Confusion Matrix of DenseNet201. (b) Confusion Matrix of ResNet152. (c) Confusion Matrix of InceptionV3. (d) Confusion Matrix of AlexNet. (e) Confusion Matrix of VGG16. (f) Confusion Matrix of CNN.

IV. RESULTS

A. About the Prototype

The emotion detection application was developed using Python and the Tkinter library to create an intuitive and functional graphical user interface (GUI). Tkinter allowed the design of a visual environment where users could interact with the system in real time. The best performing model, DenseNet201, was implemented, pre-trained, and integrated into the application using libraries such as TensorFlow and OpenCV. This combination allowed the predictions to be processed quickly and accurately, ensuring that the user experience was efficient and aligned with the system's objectives (see Fig. 6).

(a)

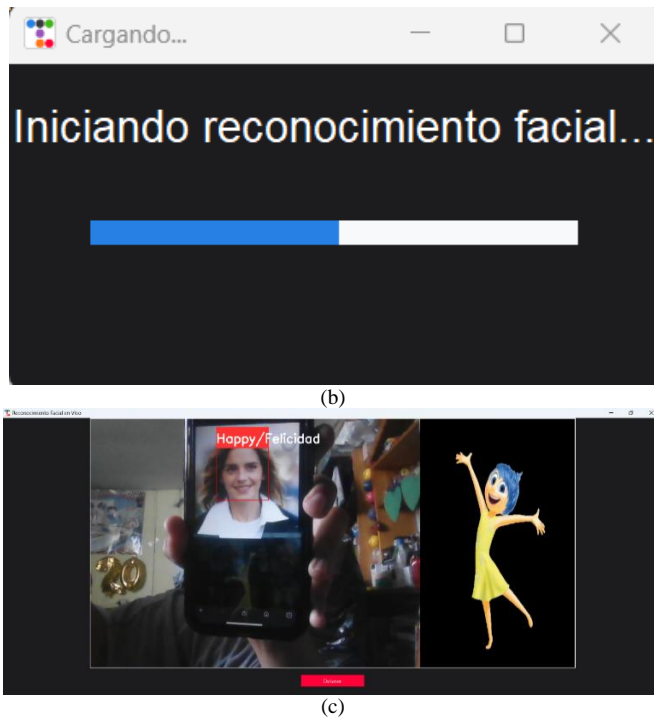

Fig. 6. (a) Startup interface (b) Progress bar (c) Running system.

B. About the Population

The research work approach is quantitative, so there was a population of 17 people, as specified in Table III.

TABLE III. WORKER'S POPULATION

Population	Number
Workers	17

In the present study, the samples require delimiting the population according to the available resources and the time allocated to conduct the research. For this reason, it was decided to use a non-probabilistic convenience sampling approach, which allows selecting participants intentionally, considering criteria such as accessibility, availability and ease of contact with them. This method is especially suitable in contexts where the total population is small. In this case, the same 17 people who make up the target population were selected, who meet the requirements to participate in the study, guaranteeing the obtaining of relevant data within the existing limitations, without compromising the validity of the analysis proposed in this document.

C. About the Indicators

This section presents the results obtained after the implementation of the facial recognition system based on deep learning, with the aim of optimizing the work environment and productivity in the organization. To evaluate the impact of the system, four key performance indicators (KPIs) were defined: i) Data collection time, ii) diagnosis time and iii) job satisfaction. These indicators were measured at two times: before and after the implementation of the system, using a pre-experimental design with a population of 17 workers. The results obtained reflect the effects of the system on operational effectiveness and

organizational well-being, providing empirical evidence on the contribution of emotional recognition technology in the workplace. Next, the results of each KPI are analyzed in detail, highlighting the most significant changes and their implication in organizational management.

1) *KPI - Data collection time:* The implementation of the automated facial recognition system has proven to be an effective solution to address the inefficiencies associated with manual emotional data collection. Before the intervention, the average time required for this process was 98.5 minutes, which implied not only a significant investment of time, but also a high dependence on human factors that could introduce biases and errors. With the integration of the proposed system, this time was drastically reduced to 27 minutes, which constitutes an improvement of 72.59%. This result demonstrates the transformative impact of AI-based technologies on organizational processes.

The optimization achieved is not limited only to time reduction; it also represents an advance in resource allocation, allowing staff to focus on strategic activities with greater added value. In addition, the automation of the process guarantees greater consistency and precision in data collection, eliminating variations derived from subjectivity or human limitations. This change not only improves operational efficiency but also strengthens the organization's ability to make informed decisions based on reliable data.

In terms of organizational impact, this reduction in data collection time has significant implications for overall productivity and responsiveness to emerging emotional issues. As illustrated in Fig. 7, the bar chart clearly compares the average times before and after implementation, providing a visual representation of the positive change achieved. This finding highlights how the adoption of advanced technologies can not only solve technical challenges but also contribute to the well-being of workers by freeing up time and resources to more effectively address their emotional needs in real time.

In summary, these results underline the strategic value of incorporating automated tools into organizational management. The ability to significantly reduce time, together with the improvement in the quality and consistency of the data collected, positions the facial recognition system as a key innovation to optimize both operational processes and the work environment in organizational environments.

Fig. 7. Before and after bar graph.

2) *KPI - Diagnostic time*: Following the implementation of the facial recognition system, a substantial improvement in the efficiency of emotional diagnosis was seen, with a reduction in the average time from 93 minutes to 34 minutes, representing a 63.4% increase in the speed of the process. This result not only optimized the workflow but also increased the precision in emotion detection by reducing the reliance on traditional methods, such as manual interviews, which are often subject to human bias and variability in results. Automation allowed for greater uniformity in diagnoses, which is key to addressing emotional problems more quickly and effectively.

Furthermore, this advancement directly contributed to operational efficiency by freeing up resources that can now be allocated to higher-value strategic organizational activities. Fig. 8 graphically shows this significant reduction using a bar chart, highlighting the positive impact of the system not only in terms of time, but also on the quality of diagnosis and the organization's responsiveness to complex emotional challenges. This finding underlines the transformative role of artificial intelligence in improving critical organizational processes.

Fig. 8. Before and after bar graph.

3) *KPI - Job satisfaction*: One of the key indicators evaluated was the impact of the facial recognition system on employee job satisfaction, which is considered crucial for emotional well-being and organizational climate. To measure it, questionnaires with a 5-point Likert scale were applied to a sample of 17 employees, before and after implementing the system. The 15 questions in the questionnaire addressed aspects such as communication, leadership and emotional support.

The analysis consisted of comparing the averages of the pre- and post-implementation responses, allowing the identification of quantitative changes in the workers' perception of their work environment.

The graph in Fig. 9 illustrates the general trends, where the orange line (after) reflects a high and stable perception compared to the blue line (before), which shows lower and less consistent scores. This graph highlights the positive impact of the system on the organizational climate and employee well-being. Furthermore, the figures show that, before implementation, employee responses were more diverse. After the changes, there was evidence of higher job satisfaction and uniformity in the aspects evaluated. The decrease in negative

perceptions suggests an improvement in emotional stability and trust in the work environment, with a 66.59% increase in satisfaction.

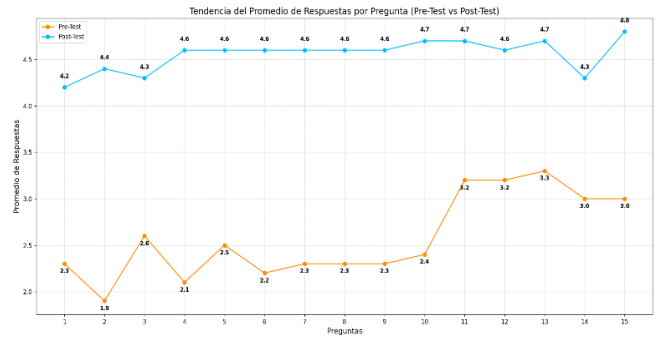

Fig. 9. Before and after response trends.

D. About the Survey and Expert Evaluation

To ensure the validity of the instrument designed to measure job satisfaction, the questionnaire was reviewed by three experts with experience in the development and evaluation of applied technological systems. The experts analyzed the structure, clarity and relevance of the questions, providing feedback to ensure that the instrument met the objectives of the study. This process allowed key adjustments to be made that strengthened the validity of the questionnaire, ensuring that the data collected accurately reflected the perception of the participants. Table IV presents the indicators that were used on the validity test approved by the experts. Where the following footage was graded:

- Poor (0 - 20%)
- Average (21 - 40%)
- Good (41 - 60%)
- Very Good (61 - 80%)
- Excellent (81 - 100%)

E. About the Methodology

The research was guided by the CRISP-DM model, recognized for its flexibility and focus on data mining and machine learning projects. This model divides the process into well-defined stages, allowing systematic progress from problem identification to the deployment of a functional solution.

The choice to take inspiration from CRISP-DM was based on its ability to adapt to the specific challenges of the research, such as handling large volumes of data and the need to train highly accurate deep learning models. Throughout this process, each stage was adapted to address key aspects of the project, such as the selection and preparation of the dataset, the training of advanced neural network models, and the implementation of a facial recognition system that meets the objectives of optimizing the work environment and productivity.

Table V presents the stages of the CRISP-DM-inspired methodology along with the activities carried out in each of them. This allows a clear visualization of how this approach was applied to ensure the effectiveness and reproducibility of the project.

TABLE IV. INDICATORS OF VALIDITY

Indicator	Criterion	Score		
		Expert 1	Expert 2	Expert 3
Clarity	It is formulated with appropriate language	80%	85%	90%
Objectivity	It is expressed in a coherent and logical manner	85%	85%	85%
Currentness	It is appropriate for advances in technology.	90%	85%	90%
Organization	There is a logical organization of variables and indicators.	80%	80%	80%
Sufficiency	It is coherent between indicators and dimensions	95%	90%	80%
Intentionality	It is appropriate to values and aspects related to the topic.	100%	82%	85%
Consistency	It is considered that the items used in this instrument are all and each one is specific to the field being investigated.	100%	90%	80%
Coherence	It is considered that the structure of this instrument is appropriate to the type of user to whom the instrument is directed.	85%	80%	90%
Methodology	The strategy responds to the purpose of the research.	85%	80%	85%
Relevance	It is appropriate to deal with the research topic.	80%	81%	85%

TABLE V. METHODOLOGY USED

Stage	Activity Completed
Understanding the Business	Problem identification: Job dissatisfaction and productivity; literature review to define objectives and approaches.
Obtaining the Data	Selection of the emotional images dataset (Kaggle), analysis of its structure and quality, initial data cleaning.
Data Processing	Normalization of pixel values, image resizing, data augmentation (rotation, flip, shift) and organization into folders according to emotions.
Deep Learning Algorithms	Training models such as standard CNN, DenseNet201, VGG16, ResNet152, AlexNet and InceptionV3.
Evaluation Metrics	Comparison of key metrics: accuracy, sensitivity and F1 score; analysis of confusion matrices to validate the effectiveness of each model.
Desktop App with the best performing model	Implementation of the DenseNet201 model in a functional prototype with a graphical interface, using Python and Tkinter.

This approach allowed theory to be integrated with practice in a structured manner, facilitating the achievement of the

research objectives and the validation of the results obtained. The table summarizes the essential steps that led to the success of the project, highlighting the rigor at each stage of the proposed methodology.

V. DISCUSSION

A. About KPI's

The results of this study show significant improvements in the operational efficiency of this company in the wholesale sector after the implementation of the facial recognition system based on convolutional neural networks. Significant reductions were recorded in data collection times with an improvement of 72.59%, emotional diagnosis with an improvement of 63.4% and job satisfaction with 66.59%, optimizing the company's internal processes. In addition, the analysis showed an increase in productivity, reflecting a positive impact on employee performance.

B. About the Models

This chapter analyzes the results obtained with the system implemented using DenseNet201, highlighting both productivity and work environment. The findings are compared with previous research, such as those that achieved 85.69% accuracy in RAF-DB using residual networks applied to low-resolution environments [12], and studies that achieved 85.82% accuracy with EfficientNetB0 on the FER2013 dataset [38]. Likewise, the integration of DeepFace in smart factories was explored, evidencing its ability to adapt to real-time scenarios [31]. In contrast, other research reported 66.85% accuracy with CNN in FER2013, highlighting the challenges associated with generalizing less-represented emotions [26].

On the other hand, the Bayesian CNN-LSTM model demonstrated outstanding performance on metrics such as accuracy, sensitivity, and F1-score, underlining its effectiveness in correlating emotions expressed in forums with the dropout rate in MOOCs [39]. Similarly, the model proposed in this study employs sequential and residual identity blocks, allowing for high-accuracy facial feature extraction, outperforming other state-of-the-art methods, especially in distance education contexts [40]. Furthermore, CNN-based architecture designed for gender and emotion classification have achieved accuracy levels above 98%, successfully addressing challenges such as emotional changes reflected in vocal features [41].

Finally, quantum convolutional networks (QCNNs) have shown significant improvements in the efficiency of emotional detection systems in mental health contexts [19]. These advances highlight the importance of factors such as controlled environments and robust computational resources to maximize the performance of these systems. Furthermore, recurrent neural networks (RNNs) have recorded 95% accuracy in classifying emotions in videos, evidencing their ability to capture complex temporal patterns in dynamic data [42]. Together, these studies illustrate how advanced technologies can transform emotional detection, successfully addressing the limitations and challenges present in this field.

C. About Limitations

First, the research was conducted in a controlled setting with a small sample size of 17 participants, limiting the

generalizability of the findings to larger populations. While the data set ensured multicultural representation, the system was evaluated within a single cultural context.

VI. CONCLUSIONS AND FUTURE WORK

In conclusion, the implementation of a facial recognition system based on convolutional neural networks (DenseNet201) in the context of a wholesale company has proven to be an effective tool to comprehensively address the challenges related to emotional management in work environments. This system allowed real-time monitoring of employees' emotions, which facilitated the early identification of negative emotions and enabled the implementation of timely interventions aimed at optimizing the organizational climate and promoting a healthier and more productive work environment.

A significant decrease was also observed in the time associated with data collection and emotional diagnosis, which translated into a substantial improvement in the efficiency of processes related to the management of workplace well-being. These findings highlight the transformative potential of AI-based technologies to promote more resilient, efficient and human-centered work environments.

Future studies could focus on evaluating the adaptability and applicability of this system in different sectors and work contexts, with the aim of validating its effectiveness and exploring new areas for improvement. Additionally, it is recommended that they can further enhance the system's capacity to address the dynamic challenges of emotional management in the organizational setting.

ACKNOWLEDGMENT

To our parents for giving us the opportunity to study and fulfill our dreams of becoming honest professionals with values; in addition to always being our guide in this difficult stage and always giving us the hope that the world can change if one is willing to give it there; to them, thank you very much.

To the Universidad Privada del Norte (UPN) for providing us with quality education during these five years of the computer systems engineering degree.

Sentiment and Emotion Analysis with Large Language Models for Political Security Prediction Framework

Liyana Safra Zaabar, Adriana Arul Yacob, Mohd Rizal Mohd Isa,
Muslihah Wook, Nor Asiakin Abdullah, Suzaimah Ramli, Noor Afiza Mat Razali*
Faculty of Defence Science & Technology, National Defence University of Malaysia, Kuala Lumpur

Abstract—The increasing spread of textual content on social media, driven by the rise of Large Language Models (LLMs), has highlighted the importance of sentiment analysis in detecting threats, racial abuse, violence, and implied warnings. The subtlety and ambiguity of language present challenges in developing effective frameworks for threat detection, particularly within the political security domain. While significant research has explored hate speech and offensive content, few studies focus on detecting threats using sentiment analysis in this context. Leveraging advancements in Natural Language Processing (NLP), this study employs the NRC Emotion Lexicon to label emotions in a political-domain social media dataset. *TextBlob* is used to extract sentiment polarity, identifying potential threats where anger and fear intensities exceed a threshold alongside negative sentiment. The Bidirectional Encoder Representations from Transformers (BERT) was applied to enhance threat detection accuracy. The proposed framework achieved an Area Under the ROC Curve (AUC) of 87%, with the BERT model achieving 91% accuracy, 90.5% precision, 81.3% recall and F1-score of 91%, outperforming baseline models. These findings demonstrate the effectiveness of sentiment and emotion-based features in improving threat detection accuracy, providing a robust framework for political security applications.

Keywords—Political security; large language models; sentiment analysis; emotion analysis; BERT; threat prediction

I. INTRODUCTION

Today, cyberspace has proven to be a very powerful tool and can impact national security. As new risks emerge, there is interest in developing more advanced defence strategies[1]. The current response to this problem is too limited, as it cannot capture the scale of information sharing that big data analyses. In this cyber arena, various platforms become addresses for various types of transactions including emotional transactions among the public [1]. These feelings can trigger great security concerns, such as the real-world example at the beginning of the Arab Spring, where the spread of false information online exacerbated negative attitudes and led to social instability that endangered national security[1], [2]. The events of the Arab Spring are one round of examples showing how emotions affect social and political stability. People are emotional creatures, and the emotion of anger or fear can mobilize people towards collective action, even disruptive to society. For example, anger has been demonstrated to lead more often to approach behaviour (increasing social movement participation), while fear leads most frequently to avoidance

[2]. Indeed, these emotional responses to political will unravel even relatively stable societies as seen in the Arab Spring protests. The collapse of stability in the Middle East and North Africa region caught almost all Western policy makers off guarded, but perhaps a paralytic counselling should be devoted to emotional matters within political and social regulation [3].

Many platforms accommodate a wide variety of different types of data exchange in cyberspace, including a wide range of public emotional expressions. These emotions can pose security risks, as evidenced by events like the Arab Spring, where negative sentiments were fuelled by misinformation online, which eventually led to societal unrest that threatened national security. As such, promptly detecting disruptive sentiments like these is essential for authorities to effectively manage crises. However, existing methodologies for emotional evaluation regarding national security are inadequate [9]. While most researchers explore various techniques for classifying human emotions, there is insufficient attention given to connecting these emotions to security threats and developing appropriate measurement mechanisms. Despite the capability of sentiment analysis methods to ascertain word polarity, their application in predicting threats remains largely unexplored, particularly in the realm of political security[5], [9].

Existing research on sentiment analysis largely focuses on hate speech and offensive content, with limited attention to detecting political security threats. While sentiment analysis effectively monitors public sentiment, it often fails to connect emotions like anger and fear to security threats within dynamic environments such as social media. Furthermore, traditional models struggle to capture the contextual and sequential dependencies necessary for identifying evolving threats. This study addresses these gaps by leveraging a BERT-based framework enhanced with the NRC Emotion Lexicon to improve the accuracy of political threat detection. By integrating advanced sentiment and emotion analysis, this research provides a robust model for enhancing political security prediction and contributes to bridging critical gaps in existing literature.

This paper is organized as follows: Section II reviews related work, establishing the relevance of the study and highlighting the contributions of the proposed approach. Section III describes the methods and materials, including details on the dataset, data preprocessing, word embedding

*Corresponding Author.

techniques, and the proposed BERT-based model for detecting political security threats. Section IV presents the results, offering a comparative analysis of the model's performance relative to existing approaches. Section V discusses the comparative findings and explores infrastructure requirements and future directions for deploying large language models in secure and efficient environments. Finally, Section VI concludes with the key findings and their implications for advancing political security threat prediction frameworks.

II. RELATED WORK

Authors in study [13] developed a global cyber-threat intelligence system using Conventional Neural Network and employed sentiment analysis techniques to detect global threats. In this study, the Bidirectional Encoder Representations from Transformers (BERT) model is used to address limitations inherent in traditional Recurrent Neural Networks (RNNs) and Long Short-Term Memory (LSTM) networks when capturing long-term dependencies in sequential data.

Traditional RNNs suffer from a vanishing gradient problem, in which gradients will diminish exponentially over time, making it difficult for the network to learn long-range dependencies [14]. While LSTMs mitigate this issue by introducing a memory cell with a sophisticated structure [12], BERT outperforms both RNNs and LSTMs by leveraging a transformer-based architecture that effectively models contextual relationships across the entire sequence, eliminating the constraints of sequential processing [15].

Emotions are known to have an important impact on human cognitive processes and decision-making [4]. Intelligence has been influenced by emotion, as they contribute for several underlying cognitive skills such as salience detection, decision making and adaptation in a critical way [4]. An interesting discovery is that non-compliant behaviour against security procedures can be influenced by emotions, with four main emotional traits in the field of information security domain including rage, trust fear and stress. Fear has been recognised as a foundational principle for keeping people using security measures. The emotion-based security threat detection is not meant to completely replace the traditional measures but can act as a complement strategy by providing an additional layer of intelligence and adaptability [5].

Recent studies highlight those emotions detected through sentiment analysis, specifically from social media, play an important role in identifying potential security threats. For example, the massive use of sentiment analysis on user-generated content such as tweets or Facebook posts has proven useful in monitoring public sentiment that may signal social instability, the spread of disinformation, or other factors that could threaten national security [6]. Emotional sentiment can be an early indicator of chaos, allowing authorities to intervene early before tensions escalate, as is the case in events such as the Arab Spring [7], [8]. Advances in sentiment analysis have leveraged machine learning and artificial intelligence (AI) technologies to not only detect emotional changes in social media content but also predict potential security concerns. By applying natural language processing (NLP) techniques, the

system can detect changes in emotional tone or intensity among a broad population, identifying issues such as anger, fear, or frustration that may lead to greater social threats [8].

Recent research has pointed out that emotions detected with sentiment analysis, especially those emanating from social media, become highly important in the process of identifying potential security threats. The high-volume applications of sentiment analysis on user-generated content such as tweets or Facebook posts have proven useful in the monitoring of public sentiments indicative of social instability, disinformation dissemination, and other factors that can threaten national security [6]. Therefore, it may be said that emotional sentiment can act as an early warning signal for chaos, and the authorities can intervene at an early stage before tensions escalate, as in events like the Arab Spring [7], [8]. Advanced sentiment analysis harnessed the power of machine learning and AI technologies to identify not only emotional changes in content on social media but also predict possible security concerns. Using the methods of NLP, it can observe changes in emotional tone or intensity of the greater population and pinpoint problems such as anger, fear, or frustration that might be a larger threat to society.

Negative emotions such as anger, fear, disgust and anxiety have been identified as potential indicators of security threats, especially when these emotions are widely expressed in public or digital spaces [9]. For example, anger is often associated with social discontent and can trigger collective actions such as protests or riots, especially in politically unstable contexts. According to studies, anger can be a trigger for aggressive behaviour when an individual or group feels marginalized or oppressed. This shift from emotion to action has been observed in many cases of social instability, where negative sentiment on social media is closely linked to violence or instability in the real world [8], [17].

Fear and related emotions such as extreme fear and anxiety also play an important role in predicting threats. While fear is not an immediate threat, it can cause destabilizing reactions, such as panic buying, mass evacuation, or rioting, especially when influenced by the spread of false information or rumours [18]. Studies in behavioural psychology and security frameworks emphasize that fear increases the perception of vulnerability, making it a useful tool for predicting crises and emergency response strategies [19]. Disgust, often fuelled by moral or ethical outrage, can also increase social division and instability, further contributing to security risks. Sentiment analysis tools, when used to monitor these emotions, have become increasingly accepted for predicting and mitigating threats before they escalate [5]. Author in [9] proposed that emotion is a key variable in determining an opinion or sentiment. Emotions such as anger, fear, disgust, fear, and anxiety can serve as emotional indicators in determining the existence of political security threats in text data. These emotions, as studies have determined, are closely related to the political security domain and have the potential to trigger political events such as riots, coups, terrorism, international wars, civil wars, and political elections, which can lead to negative sentiments or opinions. These opinions or sentiments can be analysed to predict threats in the political security domain [9], [20].

The selection of the proposed BERT-based framework is driven by its ability to overcome the key constraints of existing models, such as traditional RNNs and LSTMs, which face difficulties in addressing long-term dependencies and understanding of context. Unlike this approach, BERT uses a transformer architecture to effectively model data sequentially and capture more subtle relationships in text content. Additionally, while previous models primarily focused on general sentiment analysis or the detection of specific offensive content, they lacked the ability to link emotional intensity such as fear and anger to political security threats. By integrating Lexicon's NRC Emotion and sentiment polarity analysis, this proposed framework bridges the gap, providing better accuracy and adaptability for identifying threats. To prove the effectiveness of this framework, comprehensive verification measures and comparative analysis with existing methods were conducted, emphasizing its superiority in addressing the complexity of predicting political security threats.

III. METHODS AND MATERIALS

In our research, we developed the BERT LLM Political Security Model to predict various threats from online platforms. Our model comprises several key stages, including data pre-processing and cleansing, word embedding and threat classification and detection. In this stage, BERT is used for threat detection by adopting sentiment analysis method. Fig. 1 illustrates the Workflow of BERT LLM Political Security Model.

A. Dataset

In this experimental design, we used the labelled dataset provided by [9]. This dataset was originally created by manually gathering various Malaysian online news sources, such as The Star, New Straits Times (NST), and Free Malaysia Today (FMT), and more. The dataset comprises 250 texts from

online news sources. Out of these texts, 163 of them are categorized as positive, while the remaining 87 are categorized as negative. These positive and negative classifications serve as markers to ascertain the presence of threats within the sample texts.

B. Pre-processing

In Natural Language Processing (NLP), text pre-processing is a process that will enhance classifier performance and reduce feature complexity [10]. In this process, unnecessary elements such as punctuation, HTML codes, and symbols are removed, and the gathered text data is then transformed to lowercase and normalized. The normalization process consists of two main steps. First, the unstructured text dataset is converted into a structured word vector, and then, the feature vector's dimensionality is reduced by eliminating unwanted words and stemming them to their original forms. Stemming refers to reducing words to their roots, while lemmatization is the act of utilizing a lexical knowledge base to convert words to their base forms by rooting verbs. At the end of the process, words will be encoded into numerical formats [11].

C. Word-Embedding

Word embedding is a technique used in NLP and deep learning to represent words as dense vectors of real numbers [12]. It is a way to map words to vectors in a continuous vector space, where similar words are represented by similar vectors. This experimental layer carries max_words as an input dimension, with 50 as the output dimension (embedding size), and max_len as the input length. This layer creates a low dimensional vector that deals with each word in the input sequences and directly replaces them with their dense vector representation. These vectors are then multiplied from the embedding layer container and are then sent to the BERT layer for further processing.

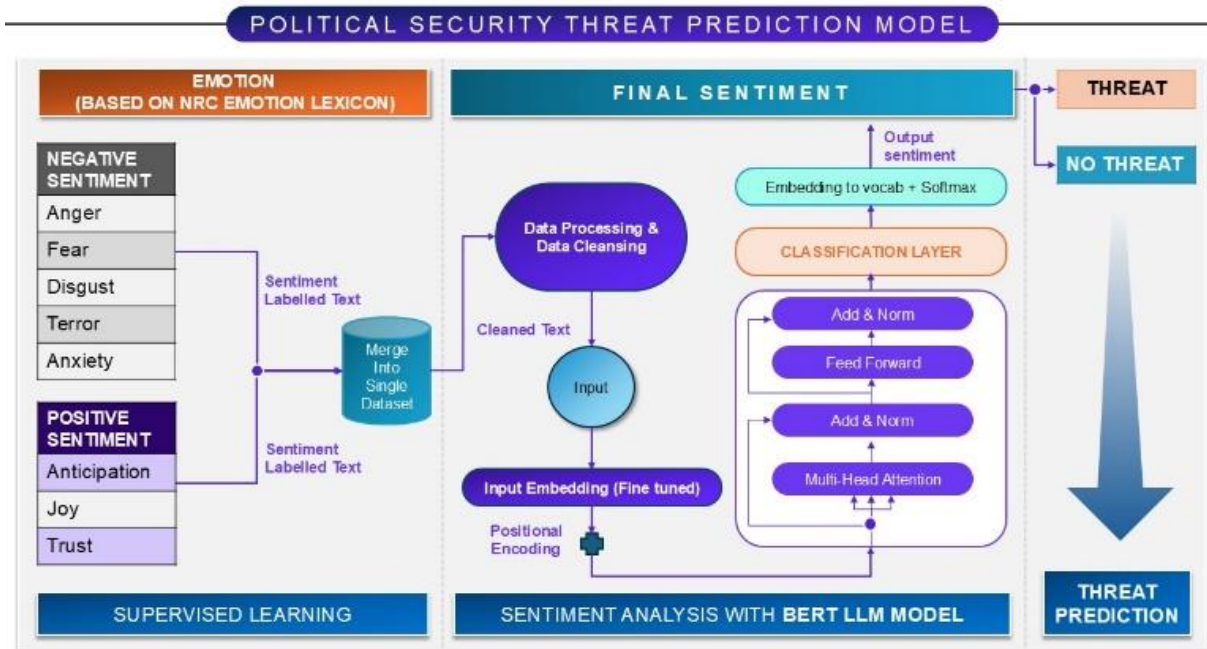

Fig. 1. Workflow of BERT LLM political security model.

D. Threat Prediction Using BERT

To validate our proposed model, an experimental analysis was conducted. The dataset for this research is constructed by collecting text data from various online news platforms, and the proposed model seeks to open new research avenues at the intersection of sentiment analysis and national security. The model will achieve this to enhance emotion measurement and threat prediction in cyberspace.

Fig. 2 illustrates the political security prediction model leveraging NRC Emotion Lexicon [15] and BERT [16] model for threat classification and prediction.

An experiment was conducted on a PC with an Intel® Core™ i7-8650U CPU @ 1.90GHz, 2.11 GHz, 8GB of RAM, a 64-bit OS, and an x64-based processor to test the developed model in Python 3.11.1 environment. 250 sentences from Malaysian online news sources were used as the main labelled dataset after the cleansing and data preparation process. To gauge the efficacy of our models, we compared them to the model developed by the researchers cited in reference [9]. We selected their model for comparison because it addresses the same task as our study, which is identifying threats in the political domain, and because it also utilizes the same dataset for evaluation, which is data that is derived from Malaysian online news.

The final phase of the research design is to validate the analyzed data. This study demonstrated a comparative performance evaluation to validate the proposed theoretical framework in this phase. The results of the evaluation test compare precision, recall, accuracy and F-measure [21]. The performance measure involves calculation of the accuracy, precision and recall value of the test dataset. The evaluation process commenced after the labelling of data into either

positive or negative classes, or the imbalance between the class proportions was addressed. A random subset of sentences was selected, to train and test it with the BERT transformer-based model. The employment of confusion matrix and the computation of accuracy, precision, and recall are the strong indicators to evaluate the performance of the chosen model based on the training data. The formula for accuracy, as shown in Eq. (1), is the proportion of correctly predicted opinions out of all input opinions to the classifier. This proportion is determined by true positive (TP), true negative (TN), false positive (FP), and false negative (FN) values.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

Precision is shown in Eq. (2) and is the percentage of true cases of an opinion (of an instance) among all the classified cases of the opinions (of all instances). To determine the accuracy, true positive rate (TP) was used, as shown in the formula below.

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

Recall is defined as the proportion of properly categorized occurrences of a polarity over the total number of correct instances of the polarity. The formula to calculate the recall values using TP and FN is shown in Eq. (3):

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

The F-score is calculated by dividing the number of true positives by the sum of true positives and false positives, as shown in Eq. (4).

$$F - score = \frac{2TP}{2TP+FP+FN} \quad (4)$$

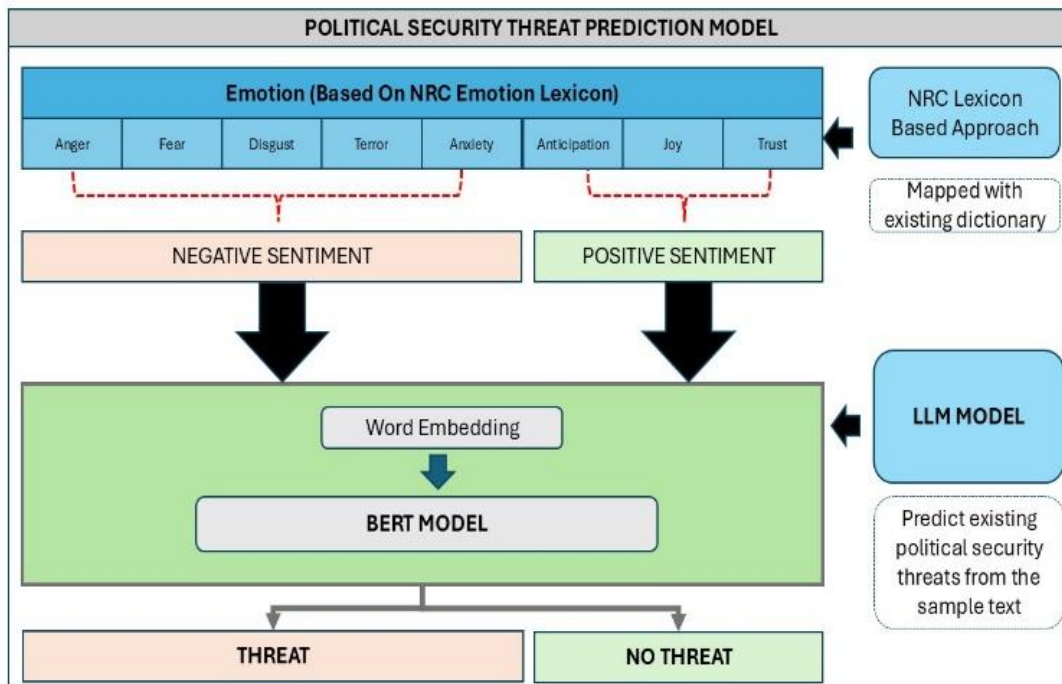

Fig. 2. Political security threat prediction model.

IV. RESULTS

A. Comparative Output and Benchmarking

The performance of the current model, BERT LLM, proposed model in political security domain, was benchmarked against the baseline hybrid model (Lexicon + Decision tree) by [9] as well as LSTM model. In Table I and Fig. 3, the BERT LLM model is compared to other currently existing approaches across key metrics: accuracy, precision, recall and F-score [22]. The findings indicate that the BERT LLM model surpasses the hybrid methods in performance, and that the LSTM model yields the least favorable results.

TABLE I. COMPARATIVE OUTPUT OF THE BERT LLM MODEL WITH OTHER METHODS

Methods	Accuracy	Precision	Recall	F-Score
Baseline Model (Lexicon + Decision Tree)	66.14%	98.86%	40.65%	57.62%
LSTM	81.30%	94.00%	71.80%	81.30%
BERT	91.00%	90.50%	81.30%	91.00%

Table I compares the performance of the BERT model with the Baseline Model (Lexicon + Decision Tree) and LSTM in terms of accuracy, precision, recall, and F-score. The BERT model outperforms both alternatives, achieving the highest accuracy (91.00%) and F-score (91.00%), demonstrating its superior ability to understand and classify threat effectively. While the Baseline Model shows high precision (98.86%), its low recall (40.65%) leads to a significantly lower F-score (57.62%), indicating limited generalizability. The LSTM model balances performance better, achieving 81.30% accuracy and F-score with substantial improvements in recall (71.80%) over the Baseline. However, BERT surpasses LSTM in all metrics, particularly in accuracy and F-score, highlighting its robustness in capturing contextual dependencies and delivering precise and balanced predictions.

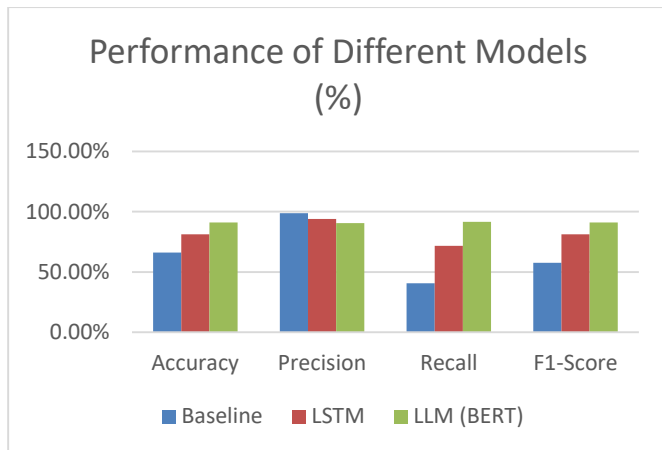

Fig. 3. Comparative performance of BERT LLM model and other methods.

V. DISCUSSION

A. Units Area Under Precision Recall (AUC-PR)

In Fig. 4, an AUC-PR of 0.87 indicates that there is high precision being recalled at different thresholds, suggesting that

the model performs well in separating positive classes from negative classes. The curve demonstrates a high area under the curve (AUC-PR = 0.87), which reflects BERT's ability to maintain a strong balance between precision (90.50%) and recall (81.30%). This high value indicates that BERT effectively minimizes false positives while accurately capturing true positives, even in scenarios with imbalanced datasets. The gradual decline in precision with increasing recall emphasizes the model's robustness in handling trade-offs between these metrics. The shaded region under the curve quantifies the AUC-PR, underscoring the superior contextual understanding and classification efficiency of the BERT model compared to the Baseline and LSTM methods. This result further highlights BERT's utility in tasks requiring precise and consistent predictions.

Fig. 4. Precision-recall curve of BERT-LLM model.

B. Training and Validation Loss Curve

The curves in Fig. 5 show the training and validation loss of the model. Validation Loss and Accuracy are calculated on a separate validation dataset and serve as indicators of how well the model generalizes unseen data [15]. The graph shown shows the train loss (red line) and validation loss (green line) over 100 epochs, which illustrates the model learning process.

The red line, which represents losses during training, decreases consistently, signifying that the model is getting better at understanding the patterns and characteristics present in the training data. This continued decline also indicates that the model is successfully reducing prediction errors on the training data, which is a sign that the model is learning well and becoming more efficient at performing predictions.

In addition, validation loss (green line) also shows a steady decline throughout the exercise. This decrease which is almost parallel to the train loss shows that the model not only learns well on the training data but also has good generalization capabilities on the validation data, which has never been seen

during training. The fact that these two losses are almost parallel indicates that the model does not suffer from overfitting, where it manages to avoid overlearning on training data alone, instead works well on the new data being tested.

Both lines show a good downward trend, and there is no significant difference between training loss and confirmation loss. This suggests that the model learns well without relying too much on training data alone. These results show that the model can be effectively used to make accurate predictions on new data. The model shows good generalizations, where it not only gives good results on the training data, but also on the validation data, which is important to ensure that the model does not fit too well with the training data alone.

Fig. 5. BERT LLM model loss curves.

C. Future Environment and Infrastructure to Support Large Language Models

This research was conducted in a low-performance environment, utilizing a labeled dataset containing only 250 texts. Given the high computational demands of large language models, it is recommended to leverage high-performance cloud infrastructure in the future.

The success of future Large Language Models approaches relies on a robust cloud infrastructure and stringent security measures to safeguard sensitive data. Consequently, Transformer-based model training, equipped with advanced optimizers, must be performed within high-performance cloud infrastructure. Ensuring the security of the cloud infrastructure, including the underlying bare-metal, firmware, and software technologies, is critical to maintain the overall integrity and resilience of the training environment [23]. A thorough understanding of cloud computing security implications is essential to safeguard data and systems and to ensure the accuracy and reliability of the training data [24], [25].

Cloud security challenges, such as access control issues and the integration of blockchain technologies, including decentralized access control frameworks, must be addressed [26]. The recent adoption of advanced technologies like blockchain for cloud access control through smart contracts also necessitates careful consideration [27]. Additionally,

human factors, such as the acceptance of cloud computing, should be considered to mitigate security risks and enhance the delivery of training and predictive analyses [28], [29]. Additionally, consideration should be given to the human perspective, including the acceptance and trust in cloud computing, to mitigate security risk factors that could affect the delivery of training and predictive analysis of threat [30].

VI. CONCLUSION

This research study shows that combining the transformer-based BERT model significantly enhances deep learning models' abilities to predict political threats. This model is not only capable of reshaping the political security threat prediction landscape but can also support researchers' future studies within the national security field. The synergy between the sentiment analysis, word embedding and BERT networks offers enhanced accuracy and robustness in national security scenarios by adaptively adjusting learning rates, while also capturing long dependencies that are essential in detecting evolving threats. To summarize, the transformer-based BERT model introduces new and effective ways to enhance the accuracy, efficiency, and versatility of political threat prediction, making it a significant advancement in the domain of national security.

Text-to-Image Generation Method Based on Object Enhancement and Attention Maps

Yongsen Huang, Xiaodong Cai, Yuefan An

School of Information and Communication, Guilin University of Electronic Technology, Guilin, China

Abstract—In the task of text-to-image generation, common issues such as missing objects in the generated images often arise due to the model's insufficient learning of multi-object category information and the lack of consistency between the text prompts and the generated image contents. To address these challenges, this paper proposes a novel text-to-image generation approach based on object enhancement and attention maps. First, a new object enhancement strategy is introduced to improve the model's capacity to capture object-level features. The core idea is to generate difficult samples by processing the object mask maps of tokens, followed by dynamic weighting of the attention map using latent image embeddings. Second, to enhance the consistency between the text prompts and the generated image contents, we enforce similarity constraints between the cross-attention maps and the attention-weighted mask feature maps, penalizing inconsistencies through a loss function. Experimental results demonstrate that the Stable Diffusion v1.4 model, optimized using the proposed method, achieves significant improvements on the COCO instance dataset and the ADE20K instance dataset. Specifically, the MG metrics are improved by an average of 12.36% and 6.55%, respectively, compared to state-of-the-art models. Furthermore, the FID metrics show a 0.84% improvement over the state-of-the-art model on the COCO instance validation set.

Keywords—Multi-object category; text-to-image generation; object enhancement; attention maps

I. INTRODUCTION

The rapid advancement of artificial intelligence has propelled text-to-image generation into the forefront of research at the intersection of computer vision and natural language processing. This emerging field aims to automatically generate visual content that aligns with natural language descriptions. Beyond its theoretical significance, this technology holds vast potential for application in diverse areas, including virtual reality, game design, artistic creation, and human-computer interaction. However, a major challenge persists: efficiently translating textual semantics into high-quality images while ensuring a high degree of consistency between the generated images and their corresponding textual descriptions.

Recent advances in deep learning have opened new avenues for text-to-image generation tasks. Generative Adversarial Networks (GANs) [1], as an early foundational technology, enabled the initial mapping from text to image via adversarial training between generators and discriminators. However, the quality and semantic alignment of the generated images still require significant improvement. The subsequent development of autoregressive and diffusion models has invigorated the field. Autoregressive models generate high-quality, semantically

consistent images through pixel-by-pixel synthesis but suffer from slow training and inference speeds. In contrast, diffusion models generate images through a process of iterative denoising, yielding not only high-quality images but also enhanced diversity, positioning them as the prevailing approach in contemporary research.

The objective of diffusion models can be summarized as reversing the gradual degradation process of data, which consists of a forward process that follows a Markov chain and a reverse diffusion process. In the forward process, noise is gradually added to the original data, causing it to degrade into nearly isotropic Gaussian noise, thereby corrupting the original data. In contrast, the reverse diffusion process utilizes a neural network to learn how to recover the original data from Gaussian noise. It is important to note that the input and output dimensions of the reverse diffusion process must remain consistent.

Although recent text-to-image diffusion models [2][3][4][5][6][7][8][9] have achieved notable progress in generating images with increasing levels of quality, resolution, realism, and diversity, a significant challenge remains in maintaining consistency between text prompts and the content of the generated images.

Several studies have addressed the challenge of generating images containing multiple objects. In 2022, Robin Rombach et al. [10] introduced Stable Diffusion, a high-resolution image synthesis method based on Latent Diffusion Models (LDMs), designed to overcome the computational inefficiencies of traditional diffusion models in high-resolution image generation. The model achieves diverse high-resolution image generation by integrating components such as variational autoencoders (VAE), conditional text encoders, and U-Net. In the same year, Liu et al. [11] proposed Composable Diffusion, a method leveraging multiple diffusion models to generate complex scenes by separately generating different objects, each handled by a specialized model. That same year, Liew et al. [12] introduced MagicMix, a technique that uses pre-trained, text-conditioned diffusion models to blend two distinct semantic concepts into a single image. The process begins by generating a rough semantic layout, followed by content matching the text description, and concludes by merging the semantic information of the two objects. In 2023, Chefer et al. [13] developed Attend-and-Excite, a method aimed at enhancing the semantic fidelity of text-to-image diffusion models. By optimizing the cross-attention mechanism, this approach ensures that the generated images better reflect the input text prompts. Directed Diffusion [14], also in 2023, introduced a novel approach to controlling the positioning of multiple elements in the image by manipulating attention maps at the word and word-position

levels, improving the model's focus on the relevant areas of the image. In the same year, Zirui Wang et al. [15] presented TokenCompose, a method that incorporates token-level supervision to improve performance in multi-object composition tasks and enhances the photorealism of generated images. More recently, in 2024, Tobias Lingenberg et al. [16] proposed DIAGen, an image enhancement method for few-shot learning scenarios. By combining generative models with text prompts, the method effectively increases the diversity of generated images.

However, most prior research has been limited to simple augmentation techniques, such as flipping, rotation, or basic enhancement operations on image data. These methods often fail to adequately capture the object features, leading to issues such as missing objects in the generated images.

Moreover, while much of the previous research has focused on the spatial layout of the cross-attention maps between text prompts and generated image contents during image generation, it has often overlooked the importance of enhancing the understanding of the spatial layout of the object cross-attention maps during the model's training phase.

To address the aforementioned issues, inspired by the literature [10] [15], this paper proposes a novel text-to-image generation method based on object enhancement and attention maps (TI-OEAM). By constructing difficult samples, incorporating a dynamic residual gating mechanism, and applying an attention maps guidance approach, this paper optimizes the model and significantly enhances the consistency between the text prompts and the generated images, leading to a substantial improvement in image quality.

The subsequent sections of this paper will provide a detailed exploration of this research. The TI-OEAM model section will describe the proposed method, focusing on the design and implementation of the object enhancement strategy, as well as how attention map optimization is employed to improve the consistency between text prompts and the generated image content. The experimental section will outline a series of experiments conducted to evaluate the effectiveness and performance of the proposed approach, including comparative studies with existing methods and ablation experiments. Finally, the conclusion section will summarize the key findings and contributions of this work, discuss its limitations, and propose directions for future research.

II. THE PROPOSED FRAMEWORK

A. An Overview of the Proposed Framework

As shown in Fig. 1, in the object enhancement module, the similarity between the object mask map and all other object mask maps in the image is first evaluated through a similarity calculation. Object mask maps with similarity values exceeding a predefined threshold are then filtered out. Gaussian noise is then applied to these selected mask maps to introduce random perturbations, generating difficult samples. Subsequently, latent noisy image embeddings with learnable parameters are utilized as dynamic residual weighting terms in the denoising U-Net, which are integrated into the model's training process. Building on this, attention map optimization is performed by imposing similarity constraints between the cross-attention map and the

attention-weighted masked feature map. Finally, the model is optimized using a loss function.

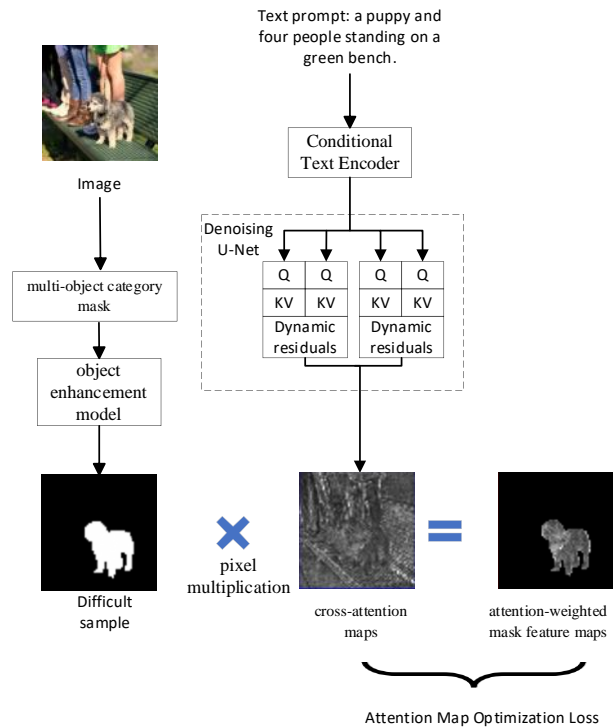

Fig. 1. TI-OEAM overall framework.

B. Object Enhancement Strategies using Masking and Residuals

To fully capture the diverse object feature information in images, a novel object enhancement strategy is proposed, consisting of two key steps. The first step involves constructing difficult samples, while the second step introduces a dynamic residual gating mechanism.

1) *Difficult sample generation*: In an image, multiple objects often exhibit similar visual characteristics, particularly when they belong to the same category or share similar appearances. Such similarities may hinder the model's ability to accurately distinguish between objects, potentially resulting in missed or incorrect generation of specific objects during image generation. To address this issue, we propose calculating the similarity between object masks and introducing noisy interference to highly similar masks. This approach forces the model to focus more on the subtle differences between similar objects. The interference thus encourages the model to learn how to differentiate and generate diverse features of similar objects, ultimately enhancing its capacity to generate objects across multiple categories more effectively.

Specifically, the first step involves designing an object enhancement module that calculates the pixel-level feature similarity between the object mask map in the image and all other object mask maps. Object mask maps with similarity values exceeding a predefined threshold are then filtered out. Subsequently, Gaussian random interference is applied to these mask maps to generate difficult samples.

The specific calculation process is as follows:

$$f = \frac{1}{G-1} \sum_k^{G-1} \cos(\mathbf{M}, \mathbf{M}_k) \quad (1)$$

Where \mathbf{M} denotes the object mask map in the image, G denotes the number of object mask maps the image contains, and f indicates the average pixel-level feature similarity between the object mask map and all other object mask maps in the image.

Then Gaussian random interference is applied to the object mask maps above the set threshold in the following process:

$$\begin{cases} \mathbf{M}' = \mathbf{M} + \Delta', f > \varphi \\ \mathbf{M}, f \leq \varphi \end{cases} \quad (2)$$

Where the threshold φ is set to 0.8, the added noise vector Δ' obeys $\|\Delta\|_2 = \delta$, and δ is a small constant. \mathbf{M}' is called the difficult sample, where Δ process is as follows:

$$\Delta = \omega, \omega \in \mathbb{R}^d \square U(0, 1e-3) \quad (3)$$

The incorporation of difficult samples encourages the model to focus on object mask maps that exhibit high similarity and are challenging to distinguish from other objects in the image. This strategy enables the model to more effectively learn the distinctive features of each object.

Dynamic Residual Gating: In this study, the definition proposed by Zirui Wang et al. [15] is adopted. For a given image $x \in \mathbb{R}^{H \times W \times 3}$ in RGB space, it is first processed by the encoder part of the VAE to obtain its latent image embedding $z_0 = \mathcal{E}(x_0)$. Subsequently, based on this potential image embedding, Gaussian random noise is injected with time t to obtain the potential noisy image embedding z_t containing the noise. Additionally, a conditional text encoder is employed to convert the text prompts y into an embedding $\tau_\theta(y)$ with the neural network parameter θ . Let $\mathbf{K} \in \mathbb{R}^{H \times L_{\tau_\theta(y)} \times d_k}$ represent the embedding of the text prompts corresponding to the token, where $L_{\tau_\theta(y)}$ denotes the length of the text prompts embedding $\tau_\theta(y)$. Let $\mathbf{Q} \in \mathbb{R}^{H \times L_{z_t} \times d_k}$ represent the latent noisy image embedding, with L_{z_t} indicating the length of the latent noisy image embedding. d_k denotes the dimension of \mathbf{K} . The cross-attention map of text prompts and images is computed as follows:

$$\mathbf{Q}^{(h)} = \mathbf{W}_Q^{(h)} \cdot \varphi(z_t) \quad (4)$$

$$\mathbf{K}^{(h)} = \mathbf{W}_K^{(h)} \cdot \tau_\theta(y) \quad (5)$$

$$\mathbf{V}^{(h)} = \mathbf{W}_V^{(h)} \cdot \tau_\theta(y) \quad (6)$$

$$\mathbf{A} = \frac{1}{H} \sum_h^H \text{soft max} \left(\frac{\mathbf{Q}^{(h)} (\mathbf{K}^{(h)})^T}{\sqrt{d_k}} \right) \cdot \mathbf{V} \quad (7)$$

Where $h \in \{1, \dots, H\}$ denotes each head in the multi-head cross-attention. $\mathbf{W}_Q^{(h)}$, $\mathbf{W}_K^{(h)}$ and $\mathbf{W}_V^{(h)}$ are the learnable projection matrices in the cross-attention layer in each head. $\varphi(z_t)$ denotes the function that flattens the 2D latent image embedding to 1D.

This study identifies a limitation in most current approaches, which directly use the output of the pre-trained U-Net model as the input for the VAE-generated images. This practice often results in insufficient learning of multi-category object information. To address this, the second step involves designing a dynamic residual gating mechanism.

In this paper, learnable parameters are employed to adjust the weights of the residual connections, thereby allowing the model to flexibly control the flow of information based on varying contextual conditions. This dynamic adjustment mechanism enhances the model's nonlinear learning capability, enabling more accurate representation of image features. By adopting this approach, the model can optimize the learning process during image generation in accordance with the specific characteristics of the image, thus mitigating the issue of insufficient feature capture that may arise when the weights of residual connections are fixed.

Specifically, the latent image embedding is used to preserve image features, thereby allowing the model to concentrate more effectively on these features. The residual cross-attention computation process is as follows:

$$\mathbf{A}' = \mathbf{A} + \alpha * z_t \quad (8)$$

Where α is the learnable parameter. The dynamic residual gating mechanism enhances and refines the cross-attention maps by dynamically adjusting the weights of the residual connections. This mechanism improves the model's ability to capture features, enabling it to more accurately learn the features of the data.

C. Optimization of Attention Map

Robin Rombach et al. [10] and Zirui Wang et al. [15] learned noisy features by using a denoising function, L_{DM} , which takes into account the lack of direct optimization correlation between tokens and image contents. To compensate for this deficiency, they introduced a token-level attention loss, L_t , which monitors the activation region of cross-attention. In addition, to prevent attention from being overly focused on certain sub-regions of the target region, they also propose a pixel-level attention loss L_p .

Inspired by the work of Robin Rombach, Zirui Wang, and others, we aim to better manage the spatial arrangement and interactions of multiple objects during the image generation process, ensuring that the generated image accurately includes

all specified categories and objects. In this paper, we propose a novel attention optimization method that constrains the similarity between the cross-attention map and the attention-weighted masked feature map. The objective is to improve the model's sensitivity to information within specific attention regions, without compromising its ability to capture global

context. Let i denote the noun token of a text prompt. Let A'_i represent the cross-attention map between the latent noisy image embeddings and the embedding of a token.

First, the attention-weighted mask feature map is computed as follows:

$$A'_{(i,u)} \square M'_{(i,u)} = A'_{M'(i,u)} \quad (9)$$

Where \square denotes the pixel multiplication. u is the spatial location of the cross-attention map. $M'_{(i,u)}$ denotes the object mask map of text token i at spatial position u . Let $A'_{(i,u)}$ denote the cross-attention map formed by the latent noisy image embedding of the i -th token at the spatial location u of $A'_i \in R^{L_{z_i}}$.

Subsequently, the cosine similarity function is calculated in accordance with the following procedure:

$$S(A'_M, A') = \frac{A'_{M'(i,u)} \cdot A'_{(i,u)}}{|A'_{M'(i,u)}| \cdot |A'_{(i,u)}|} = \sum_i^{L_{z_i}} \sum_u^{L_i} \frac{A'_{M'(i,u)} A'_{(i,u)}}{\sqrt{A'_{M'(i,u)}^2} \sqrt{A'_{(i,u)}^2}} \quad (10)$$

Where $S(A'_M, A')$ denotes the similarity between the cross-attention map and the attention-weighted mask feature map.

The two are then brought into closer alignment in the pixel domain using a loss function, which is calculated as follows:

$$L_s = 1 - S(A'_M, A') \quad (11)$$

Cosine similarity function $S(A'_M, A')$ measures how close the cross attention map is to the attention-weighted masked feature map in feature space. The loss function L_s effectively balances the learning of both local and global information, overcoming the limitations of traditional methods that tend to over-focus on the target region or neglect other areas of the image. This balance improves the alignment between text prompts and generated image content, thereby enhancing both image consistency and overall quality.

D. Loss Function

Finally, L_s and L_{DM}, L_t and L_p jointly trained and computed as follows:

$$L = L_{DM} + \sum_d^D (\gamma L_s + \eta L_t + \psi L_p) \quad (12)$$

Where η , γ and ψ are the scaling factors. In this paper, we set γ as 1e-3, η as 1e-3, ψ as 5e-5. The value of D represents the number of training layers.

III. EXPERIMENT

A. Datasets

In order to evaluate the effectiveness of the proposed model in the text-to-image generation task, this paper utilizes the COCO dataset [15] for training experiments. This dataset consists of 4,526 image-caption pairs and their corresponding binary mask maps. The choice of COCO is motivated by the relatively low ambiguity in its visual language and the rich diversity of object categories represented in each image, which effectively supports the task of learning and generating multi-category objects. To further assess the model's performance in multi-category instance combination, we conduct experiments on the COCO instance dataset [17], which includes 80 categories, and the ADE20K instance dataset [18][19], which includes 100 categories. Additionally, to evaluate the distributional differences between the images generated by the model and real images, we randomly sampled 10,000 image-caption pairs from the COCO instance validation set (C) and 1,000 image-caption pairs from the Flickr30K instance validation set (F) [20] for comparative analysis.

B. Evaluation Metrics

In this paper, we use the MULTIGEN [15] metric and the FID [21] metric to assess the ability of the model in combining instances of multiple categories and to analyse the distributional differences between the images generated by the model and the real images.

MULTIGEN is a challenging metric used to evaluate multi-category instance combinations. Specifically, given a set of N distinct instance categories, five categories (e.g., A, B, C, D, and E) are randomly selected and formatted into a sentence (e.g., "A photo of A, B, C, D, and E"). This sentence serves as the conditional input for the text-to-image diffusion model to generate the corresponding image. Subsequently, a robust open-vocabulary detector [15] is employed to assess whether the specified categories are accurately represented in the generated image.

Specifically, for each dataset, 1,000 text prompts were generated by randomly sampling 1,000 instances from each of the 80 COCO categories and 100 ADE20K categories, which were then used as inputs for the multi-category instance combinations. For each text prompt, 10 rounds of image generation were performed, resulting in a total of 10×1000 images for each dataset's category combination. Each generated image was subsequently analyzed using a detector to count the number of category instances present. Based on these detection results, the MG2 to MG5 metrics were computed for each round.

The mean and standard deviation (denoted in parentheses) of the MG2-5 success rates across the 10 rounds are presented in Table I.

TABLE I. COMPARISON OF EXPERIMENTAL RESULT OF VARIOUS MODELS

Method	Multi-category Instance Composition↑								Photorealism↓	
	COCO INSTANCES				ADE20K INSTANCES				FID (C)	FID (F)
	MG2	MG3	MG4	MG5	MG2	MG3	MG4	MG5		
SD	90.72 _{1.33}	50.74 _{0.89}	11.68 _{0.45}	0.88 _{0.21}	89.81 _{0.40}	53.96 _{1.14}	16.52 _{1.13}	1.89 _{0.34}	20.88	71.46
Composable	63.33 _{0.59}	21.87 _{1.01}	3.25 _{0.45}	0.23 _{0.18}	69.61 _{0.99}	29.96 _{0.84}	6.89 _{0.38}	0.73 _{0.22}	-	75.57
Layout	93.22 _{0.69}	60.15 _{1.58}	19.49 _{0.88}	2.27 _{0.44}	96.05 _{0.34}	67.83 _{0.90}	21.93 _{1.34}	2.35 _{0.41}	-	74.00
Structured	90.40 _{1.06}	48.64 _{1.32}	10.71 _{0.92}	0.68 _{0.25}	89.25 _{0.72}	53.05 _{1.20}	15.76 _{0.86}	1.74 _{0.49}	21.13	71.68
Attn-Exct	93.64 _{0.76}	65.10 _{1.24}	28.01 _{0.90}	6.01_{0.61}	91.74 _{0.49}	62.51 _{0.94}	26.12 _{0.78}	5.89 _{0.40}	-	71.68
TokenCompose	98.08 _{0.40}	76.16 _{1.04}	28.81 _{0.95}	3.28 _{0.48}	97.75 _{0.34}	76.93 _{1.09}	33.92 _{1.47}	6.21 _{0.62}	20.19	71.13
TI-OEAM	98.54_{0.19}	79.43_{0.91}	32.55_{0.96}	4.32 _{0.36}	97.91_{0.18}	79.39_{0.85}	37.13_{2.39}	7.04_{0.51}	20.02	71.94

The FID metric is used to assess the distributional disparity between two datasets: 10,000 image-caption pairs from the COCO instance validation set (C) and 1,000 image-caption pairs from the Flickr30K instance validation set (F), in comparison with the model-generated images.

C. Experimental Settings

The experimental setup is as follows: The operating system is Ubuntu 18.04.5 LTS; the hardware configuration includes an NVIDIA 3090 GPU; the deep learning framework used is PyTorch; and the programming language is Python.

The primary experiments in this paper are conducted using the Stable Diffusion v1.4 [22] model and the TokenCompose model. Stable Diffusion is a widely used text-to-image diffusion model for high-quality generation. AdamW is employed as the optimizer [23], with a global learning rate of 5e-6 and a total of 2400 steps. The image resolution is set to 512. Training was performed on a single GPU using a single batch and four gradient accumulation steps across the entire U-Net.

D. Experimental Results and Analysis

To validate the effectiveness of the TI-OEAM model, this study compares its performance with several representative text-to-image generation methods. These include Stable Diffusion (SD) [22], which addresses the high computational cost of traditional diffusion models in high-resolution image generation; Composable Diffusion [11], which generates complex scenes by combining multiple diffusion models; Layout [24], which manipulates the cross-attention layer in diffusion models to achieve precise spatial layout control; Structured [25], which enhances composability and attribute binding in text-to-image tasks by integrating linguistic structures with cross-attention layers; Attend-and-Excite [13], which improves semantic fidelity in text-to-image generation; and TokenCompose [15], which enhances text-to-image models through token-level supervision. The experimental results are presented in Table I, where MG, C, and F represent the MULTIGEN metrics, the COCO instance validation set, and the Flickr30k instance validation set, respectively.

The experimental results show that the baseline method, TokenCompose, achieves an average improvement of 12.8% over the Attend-and-Excite model across all the improved MG metrics. Since the FID metrics are reliable only when comparing 10,000 images, a comparison of the FID metrics on a dataset of

10,000 image-caption pairs sampled from the COCO validation set (C) shows a 3.3% reduction in the metrics of TokenCompose compared to the Attend-and-Excite model. The illustrative analysis results from the TokenCompose model further highlight the 12.8% improvement in MG metrics and the 3.3% reduction in FID metrics, representing substantial advancements in performance.

As shown in Table I, the proposed TI-OEAM model significantly outperforms all baseline methods across most evaluation metrics for these datasets. Compared to the state-of-the-art performance of current mainstream model, TokenCompose, on the COCO instance dataset, TI-OEAM achieves an average improvement of 12.36% on the MG2, MG3, MG4, and MG5 metrics. On the ADE20K instance dataset, TI-OEAM improves by an average of 6.55% on the same metrics. Additionally, TI-OEAM demonstrates a 0.84% reduction in the FID score compared to the 10,000 image-caption pairs in the COCO instance validation set. This performance enhancement is attributed to the model's efficacy, particularly its ability to learn information across multiple object categories through difficult sample construction and dynamic residual gating methods. Furthermore, TI-OEAM incorporates similarity constraints between the cross-attention map and the attention-weighted mask feature map, further improving the consistency between text prompts and the content of the generated images, resulting in significant gains across all performance metrics.

In comparison to the 1,000 image-caption pairs from the Flickr30K instance validation set, the FID metric for the images generated by the TI-OEAM model, as shown in Table I, is 71.94. The discrepancy in these experimental results can be attributed to the model's failure to pass the safety-checker detection during image generation based on the 1,000 captions. This issue led to the generation of a black image, which significantly affected the experimental outcomes.

E. Ablation Study

To validate the impact of the proposed OE and AN components on model performance, this paper conducts MG metrics ablation experiments on the COCO instance dataset and the ADE20K instance dataset, as well as FID metrics ablation experiments on 10,000 image-caption pairs sampled from the COCO instance validation set. Table II presents the experimental results, while Fig. 2 provides effectiveness analysis.

TABLE II. COMPARISON OF ABLATION EXPERIMENTAL RESULTS

Component	COCO INSTANCES			ADE20K INSTANCES			FID (C)
	MG3	MG4	MG5	MG3	MG4	MG5	
TI-OEAM	79.43 _{0,91}	32.55 _{0,96}	4.32 _{0,36}	79.39 _{0,85}	37.13 _{2,39}	7.04 _{0,51}	20.02
OE	77.62 _{1,08}	31.62 _{1,26}	3.93 _{0,46}	77.54 _{0,77}	35.82 _{1,30}	6.44 _{0,63}	19.90
AM	78.48 _{0,96}	31.44 _{1,62}	3.91 _{0,80}	79.18 _{0,79}	37.80 _{0,77}	7.62 _{0,84}	20.25

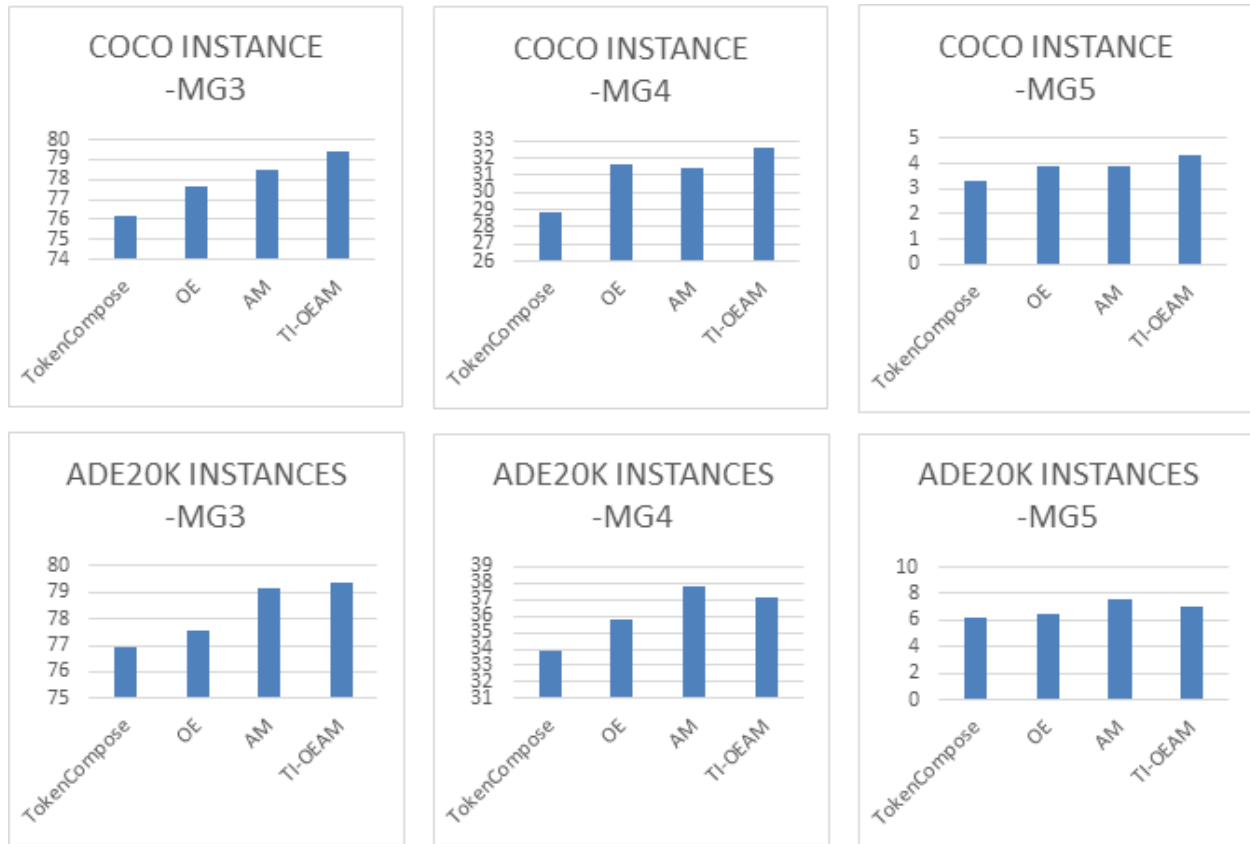

Fig. 2. Effectiveness analysis OE and AM.

Firstly, the OE module was independently validated, and the experimental results are presented in the "OE" section of Table II. Compared to the TokenCompose model, OE achieved improvements of 6.93% in the MG3, MG4, and MG5 metrics, respectively. This enhancement demonstrates that the OE module has made significant progress in extracting object features, thereby further enhancing the model's ability to learn object characteristics within the image.

Secondly, the AM method is validated in isolation, with the results presented in the "AM" section of Table II. Compared to the TokenCompose model, the AM method yields improvements of 11.41% in the MG3, MG4, and MG5 metrics. The AM method demonstrates significant improvements across all metrics, indicating that it enhances the model's understanding of the distribution of objects in images in alignment with text prompts. Furthermore, this method

improves the consistency between text and image content, resulting in images with greater object accuracy.

In conclusion, the OE and AM modules demonstrate significant improvements in the metrics associated with the text-to-image generation task.

F. Visual Presentation Analysis

To facilitate a comprehensive visual comparison between the proposed TI-OEAM model and the benchmark TokenCompose model, a set of six images was generated using identical text prompts by both models. The generated images are presented in Fig. 3 on the following page for direct comparison. In order to ensure the fairness and consistency of the comparison, the initial latent space values, which serve as the starting point for both models, were held constant across all experiments. This approach minimizes potential bias arising from variations in latent representations, thereby allowing for an objective assessment of the models' performance.

Fig. 3. Qualitative comparison between TI-OEAM and baseline.

To rigorously evaluate the quality and alignment of the generated images with the text prompts, this study involved a manual assessment conducted by 11 researchers from diverse fields, including natural language processing, big data, and computer science. The researchers were tasked with evaluating the consistency between the provided text prompts and the corresponding generated images, using a well-defined criterion to ensure objectivity. The results of the evaluation revealed that, out of the total 66 votes cast, 26 votes were in favor of the images generated by the TokenCompose model, while 40 votes were in favor of those generated by the TI-OEAM model. This indicates that the images produced by the TI-OEAM model demonstrated a significantly higher degree of consistency with the text prompts compared to those generated by TokenCompose, highlighting the effectiveness of the proposed model in faithfully translating textual descriptions into visual representations.

IV. CONCLUSION AND FUTURE WORK

This paper proposes a text-to-image generation method based on object enhancement and attention maps. The generation of high-quality images is achieved through the construction of challenging samples, the implementation of a dynamic residual gating mechanism, and the optimization of the model via an attention map guidance approach. These strategies work together to enhance the consistency between text prompts and generated images. Experimental results demonstrate that the

proposed method, which integrates difficult sample design, dynamic residual gating, and attention map optimization, yields more significant improvements than state-of-the-art models in both MG metrics and the consistency of text-image information for text-image generation tasks. Future work will continue to address the consistency issue between text prompts and image contents, with a particular focus on more complex text prompts. The aim is to provide practical solutions for this challenge in the field.

Abstract—Intelligent Transportation Systems (ITS) are crucial for managing urban mobility and addressing traffic congestion, which poses significant challenges to modern cities. Traffic congestion leads to increased travel times, pollution, and fuel consumption, impacting both the environment and quality of life. Traditional traffic management solutions often fall short in predicting and adapting to dynamic traffic conditions. This study proposes an efficient deep learning (DL) model for predicting traffic congestion, utilizing the strengths of an attention-based multilayer Gated Recurrent Unit (GRU) network. The dataset used for this study includes 48,120 hourly vehicle counts across four junctions and additional weather data. Temporal and lagged features were engineered to capture daily and historical traffic trends and categorical data were considered by employing feature embedding. The attention-based GRU model integrates an attention mechanism to focus on relevant historical data, improving predictive performance by selectively emphasizing crucial time steps. This model architecture, consisting of two hidden layers and attention mechanisms, allows for nuanced traffic predictions by handling temporal dependencies and variations effectively. The performance was evaluated using various error metrics. The results demonstrate the model's ability to predict traffic congestion with MSE of 0.9678, MAE of 0.4322, R² of 0.8686, MAPE of 6% offering valuable insights for traffic management and urban planning.

Keywords—Intelligent transportation system; traffic congestion; urban mobility; deep learning; gated recurrent unit

I. INTRODUCTION

Traffic congestion is a persistent and growing problem in urban areas globally. It leads to significant challenges that affect economic productivity, environmental sustainability, and the quality of life [1]. As cities continue to expand and urbanization accelerates, the demand for road space often surpasses the available infrastructure, resulting in slower traffic speeds, longer travel times, and increased vehicular queuing. Several factors contribute to this issue, including the rapid rise in vehicle ownership, insufficient public transportation systems, and inadequate urban planning. The surge in private vehicles, due to the rising incomes and population growth, places immense pressure on existing road networks, intensifying congestion, especially during peak hours. In many cities, the public transportation infrastructure is either lacking or inefficient, prompting people to rely heavily on private car. Additionally, poor urban planning—such as poorly designed

road networks, insufficient parking, and a lack of infrastructure for pedestrians and cyclists further intensifies traffic blocks [2].

The impacts of traffic congestion are wide-ranging and severe. Economically, it leads to significant costs, including wasted fuel, vehicle maintenance, and lost productivity as people spend more time in traffic. Businesses suffer due to delays in goods transportation and reduced employee efficiency [3]. Environmentally, traffic congestion contributes to higher emissions of greenhouse gases and pollutants, as vehicles emit more while idling in traffic jams than when traveling smoothly. This not only worsens air quality but also accelerates climate change. Socially, congestion reduces the quality of life, as long travels lead to stress, less time for personal activities, and overall frustration. The safety concerns are also notable, with increased stop-and-go traffic raising the likelihood of accidents and making roads more dangerous for both drivers and pedestrians. One of the most critical consequences is its impact on emergency services [4]. Congested roads can significantly delay ambulances, fire trucks, and police vehicles, potentially leading to life-threatening situations due to increased response times.

Addressing traffic congestion requires a multi-faceted approach. Enhancing public transportation is a key strategy, as efficient and reliable public transit systems can reduce the number of private vehicles on the road. Investments in bus transit systems, light rail networks, and better integration of transport modes can make public transport a more attractive option [5]. Additionally, traffic management schemes that use real-time data to enhance traffic flow, such as adaptive traffic signal controls, can alleviate congestion at critical points. Urban planning also plays a crucial role; cities need to adopt designs that encourage high-density, mixed-use developments that reduce the need for long shuttles. Promoting smart mobility solutions, such as ride-sharing, autonomous vehicles, and Mobility-as-a-Service (MaaS), can also help by optimizing road usage. Behavioral changes, supported by public awareness campaigns and incentives for carpooling or telecommuting, are essential in reducing the number of vehicles on the road during peak times [6]. In summary, while traffic congestion is a complex problem with significant impacts, a combination of improved infrastructure, smart technology, and policy measures can help mitigate its effects and create more sustainable and functional urban environments. A DL model for traffic congestion prediction is proposed in this study. The main contributions of the study are given below:

- To develop a DL-based traffic congestion prediction model.
- To compare the effectiveness of the suggested model with existing models.
- To evaluate the efficiency through various error metrics.

The remaining portion of the paper is organized as: Section II provides a comprehensive literature review emphasizing the need for the current research. Section III details the methodology and the deep learning model architecture for effective traffic prediction. Section IV presents the results and discussion, highlighting the potential of the suggested model. Section V concludes the paper by summarizing the key contributions.

II. LITERATURE REVIEW

Li et al. [7] introduced the AST3DRNet model, which incorporated a 3D residual network with a self-attention mechanism. This approach utilized a 3D convolutional module and employs a spatio-temporal attention module to dynamically adjust the impact of these relationships. Experiments conducted using a real-world traffic dataset from Kunming demonstrated that AST3DRNet outperformed existing baseline methods, achieving accuracy improvements of 59.05%, 64.69%, and 48.22% for short-term predictions at 5, 10, and 15 minutes, respectively. Despite its innovations, the model's dependency on convolutional neural networks (CNN) and residual networks was a limitation.

Tsalikidis et al. [8] evaluated various models for multi-step forecasting of traffic flow, particularly in areas with limited historical data. The methodology involved assessing a range of interpretable predictive algorithms, including Ensemble Tree-Based (ETB) regressors like Light Gradient Boosting Machine (LGBM) and comparing them with traditional deep learning methods. Results indicated that ETB models generally outperformed DL approaches, particularly for longer forecasting horizons, achieving high accuracy even at extended prediction steps. The study demonstrated that feature selection and engineering, incorporating temporal and weather data, improved model performance. The study was limited by its reliance on the statistical characteristics of the specific dataset, which could affect the efficiency of the algorithms. High data volume and complexity also posed challenges, impacting model training and performance.

Jiang et al. [9] introduced Congestion Prediction Mixture-of-Experts (CP-MoE) to improve prediction accuracy for dynamic traffic scenarios. The methodology involved developing a Mixture of Adaptive Graph Learners (MAGLs) with a sparsely-gated mechanism and congestion-aware biases, complemented by two specialized experts designed to identify stable trends and periodic patterns. This model was rigorously tested on real-world datasets, demonstrating its superiority over existing spatio-temporal prediction methods. Notably, CP-MoE was successfully integrated into DiDi's system, enhancing travel time estimation reliability. A key limitation identified was the utility of CP-MoE's application to other aspects of ride-hailing services.

Hao et al. [10] presented a fuzzy logic system based on the Greenshields model, designed to predict highway traffic congestion without requiring extensive training data. The methodology involved processing vehicle speed and traffic flow inputs using specified membership functions and applying fuzzy rules guided by Greenshields theory. The approach was validated through a comparative analysis with a polynomial regression model using real-world data from the Sun Yat-Sen Highway in Taiwan, demonstrating consistent prediction results. The fuzzy logic system proved effective in estimating congestion levels and adapting to various road conditions with minimal data preparation. A noted limitation was the potential for reduced precision in highly dynamic traffic scenarios where the fuzzy logic system's fixed rules not capture complex variations as effectively.

Zhang et al. [11] introduced a deep marked graph process (DMGP) model that combined a spatiotemporal convolutional graph network with a traditional point process model to predict congestion indices and occurrence times for large signalized road networks. This hybrid approach utilized the simplicity of the point process model and the advanced capabilities of graph neural networks to model the evolution of traffic congestion. Experiments using real-world traffic data demonstrated that the DMGP model outperformed existing baseline methods, achieving superior prediction accuracy and computational efficiency. While the model showed promise in supporting advanced traffic management and traveler information systems, a significant limitation was its reliance on high-quality citywide traffic data, which had not been available for all road segments.

Jasim et al. [12] analyzed the efficiency of several machine learning (ML) algorithms for congestion detection and prediction within Vehicular Ad hoc Networks (VANETs). The study focused on Support Vector Machines (SVM), Ensemble Learning classifiers, K-Nearest Neighbors (KNN), and Decision Trees (DT). The methodology involved training these algorithms with historical traffic congestion data and applying advanced feature engineering techniques. The study found that SVM, along with KNN and Ensemble Learning classifiers, achieved high classification accuracies. The study was limited by the dependence on precise feature selection and model optimization techniques, which required careful tuning.

Arabiat et al. [13] addressed the challenge of predicting traffic congestion using data mining and ML techniques. The study compared the performance of two open-source software tools, WEKA and Orange, in predicting traffic congestion in Amman, Jordan. Various classifiers, including SVM, KNN, Logistic Regression (LR), and Random Forest (RF), were tested using data from the Greater Amman Municipality for the year 2018. Results revealed that Orange excelled with high prediction accuracy. The study highlighted the superior performance of Orange over WEKA, particularly in handling different classifiers. A notable limitation was the reliance on specific data mining tools, which are not generalize across all types of traffic data or scenarios, potentially affecting the applicability of the findings.

Chahal et al. [14] tackled the challenge of traffic flow prediction using a hybrid model that combines Seasonal Auto-

Regressive Integrated Moving Average (SARIMA) with Bidirectional Long Short-Term Memory (Bi-LSTM) and Back Propagation Neural Network (BPNN). This approach aimed to address both linear and non-linear components of traffic data from the CityPulse EU FP7 project. The hybrid model demonstrated superior performance with the lowest MAE of 0.499 compared to single SARIMA, LSTM, and other models. The study was limited by the feature set considered, as the model did not account for external factors like weather or peak hours, which could affect traffic predictions.

Jin et al. [15] introduced a spatio-temporal graph neural point process (STGNPP) framework specifically designed to predict traffic congestion events that occur sporadically over time. The model incorporated a spatio-temporal graph learning component to efficiently capture long-term dependencies from historical traffic data and road network information. This information is then processed through a continuous GRU to model congestion evolution patterns, with a periodic gated mechanism enhancing the intensity function to account for periodic variations. Extensive experiments conducted on two large-scale real-world datasets demonstrated that STGNPP significantly outperformed existing methods in predicting both the timing and duration of congestion events. However, the model's reliance on historical data may limit its adaptability to sudden or unprecedented traffic disruptions.

Pan et al. [16] presented Ising-Traffic, a dual-model framework that employs the Ising model to address traffic management. Unlike conventional approaches that struggle with balancing algorithmic complexity and computational efficiency, Ising-Traffic combines two distinct Ising models: Predict-Ising and Reconstruct-Ising. Reconstruct-Ising utilized advanced Ising machines to handle traffic uncertainties with reduced latency and lower energy consumption, while Predict-Ising uses conventional processors to project future traffic congestion, requiring only 1.8% of the computational resources compared to existing methods. The proposed framework demonstrated an average speed up of 98 \times and a 5% accuracy improvement over conventional solutions when evaluated on real-world traffic datasets. A notable limitation of this approach was the dependency on specific hardware for Reconstruct-Ising, which affect its scalability and adaptability across different computational platforms.

Zhang et al. [17] explored urban traffic condition prediction and congestion control by integrating improved particle swarm optimization (IPSO) with radial basis function (RBF) networks and a fusion model of LSTM networks and SVM. The

proposed feature fusion model demonstrated superior performance in predicting traffic states, validated by experiments using regional traffic data from Shenyang Station, with the model achieving the lowest RMSE compared to other algorithms. For congestion control, a traffic allocation-based method was developed and tested using VISSIM simulation, showing effective congestion management. The primary limitation of the study was the reliance on simulation models to fully capture the complexities of real-world traffic dynamics and thus limit the applicability of the proposed methods in varied urban settings.

Wang et al. [18] addressed urban traffic congestion by developing a prediction model called Spatio-Temporal Transformer (STTF), which utilizes DL techniques. Traditional models struggled with the growing complexity of urban traffic networks, prompting the introduction of STTF. This model integrated traffic speed data, road network structure, and spatio-temporal correlations to enhance prediction accuracy. The STTF employed an information embedding module to convert both spatial and temporal data into feature vectors, which were then processed through spatial and temporal attention modules. The model was tested on real-world datasets, demonstrating substantial improvements in prediction accuracy compared to existing methods. Despite its advancements, the STTF model's main limitation was its dependence on comprehensive feature engineering and attention mechanisms, which increase computational complexity and impact its efficiency in real-time applications. Table I provides the summary of the existing traffic congestion prediction models.

While existing models, such as traditional spatio-temporal graph-based methods and hybrid approaches, have made significant strides, they often struggle with real-time efficiency and adaptability to rapidly changing traffic conditions. Additionally, existing approaches frequently lack the capability to adaptively weigh the importance of different time steps or traffic features, leading to suboptimal predictions. A critical gap in current traffic congestion prediction methods lies in the need for more advanced deep learning models that can seamlessly integrate and process complex spatio-temporal dependencies and dynamic factors. Deep learning models offer promising avenues for capturing intricate patterns in traffic data and improving prediction accuracy. Addressing these gaps requires the development of deep learning frameworks that can balance high accuracy with operational efficiency, effectively handling large-scale, dynamic data while being robust to varying traffic conditions and external influencing factors.

TABLE I. SUMMARY OF EXISTING TRAFFIC CONGESTION PREDICTION MODELS

Ref. No.	Works Carried Out in the Reference Papers	Advantages	Disadvantages
[7]	AST3DRNet model with a 3D residual network and spatio-temporal attention module for traffic prediction.	Achieved accuracy improvements of 59.05%, 64.69%, and 48.22% for 5, 10, and 15-minute predictions.	Dependency on CNNs and residual networks limits the scalability and adaptability of the model.
[8]	Ensemble Tree-Based (ETB) regressors (e.g., LGBM) compared with traditional DL methods for multi-step forecasting.	ETB models outperformed DL approaches, especially for long-term predictions; feature engineering improved performance.	Results relied on statistical characteristics of the dataset; complexity in high-volume data handling.
[9]	CP-MoE with Mixture of Adaptive Graph Learners and congestion-aware biases for dynamic traffic prediction.	Outperformed baseline methods; integrated into DiDi's system to enhance travel time reliability.	Limited applicability to other ride-hailing service aspects; utility depends on specific use cases.
[10]	Fuzzy logic system using Greenshields model for highway congestion prediction with minimal data preparation.	Consistent results; adaptable to various road conditions with minimal data.	Lower precision in dynamic scenarios with complex variations.
[11]	Deep Marked Graph Process (DMGP) combining spatiotemporal graph network and point process model for congestion prediction.	Superior prediction accuracy and computational efficiency.	Reliance on high-quality, citywide traffic data limits scalability to less monitored areas.
[12]	ML algorithms (SVM, KNN, Ensemble Learning, DT) with advanced feature engineering for VANET congestion detection.	High classification accuracy achieved with SVM, KNN, and Ensemble Learning classifiers.	Dependence on precise feature selection and careful optimization of models.
[13]	Comparison of WEKA and Orange tools for traffic prediction using ML classifiers like SVM, KNN, LR, and RF.	Orange achieved superior prediction accuracy over WEKA.	Limited generalizability across different traffic datasets and tools.
[14]	Hybrid SARIMA-Bi-LSTM-BPNN model for traffic flow prediction, addressing both linear and non-linear components.	Lowest MAE (0.499) compared to single models; superior performance on CityPulse EU FP7 data.	Did not account for external factors like weather or peak hours affecting predictions.
[15]	STGNPP framework with spatio-temporal graph learning and periodic gated mechanism for sporadic traffic event prediction.	Outperformed existing methods in predicting timing and duration of congestion events.	Limited adaptability to sudden or unprecedented disruptions due to reliance on historical data.
[16]	Ising-Traffic framework combining Predict-Ising and Reconstruct-Ising models for traffic management.	Achieved 98× speedup and 5% accuracy improvement; reduced latency and energy consumption.	Dependency on specific hardware for Reconstruct-Ising limits scalability.
[17]	IPSO-RBF network fusion model with LSTM and SVM for traffic prediction and congestion control via traffic allocation.	Superior performance in RMSE; effective congestion management in simulations.	Limited real-world validation; reliance on simulations restricts practical applicability.
[18]	Spatio-Temporal Transformer (STTF) integrating traffic speed, road networks, and spatio-temporal correlations.	Substantial accuracy improvements compared to existing methods.	High computational complexity due to feature engineering and attention mechanisms.

III. MATERIALS AND METHODS

Traffic congestion prediction is crucial for optimizing traffic flow and enhancing commuter experience by enabling more efficient traffic management and route planning. It helps reduce economic losses associated with delays, fuel consumption, and vehicle wear, benefiting both individuals and

businesses. Accurate predictions also contribute to minimize the idle time and slow-moving traffic, thereby supporting environmental sustainability. Additionally, it provides valuable data for urban planners to design better infrastructure and improve overall urban mobility. Thus, this study proposes an efficient DL technique for traffic congestion prediction. Fig. 1 shows the detailed block diagram of the proposed traffic congestion prediction model.

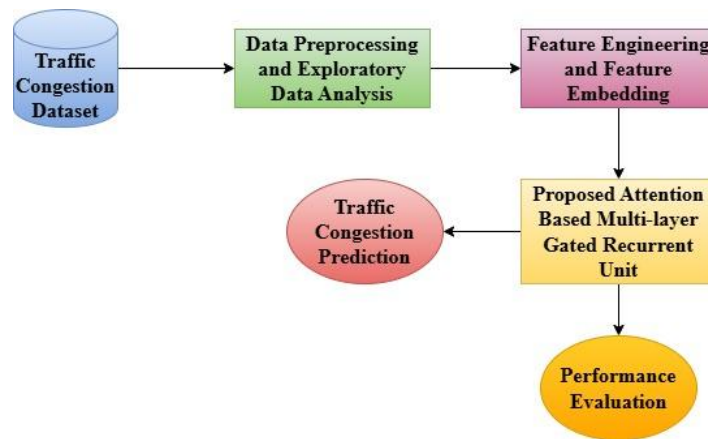

Fig. 1. Block diagram of proposed traffic congestion prediction model.

A. Dataset Description

The study utilized traffic data from Kaggle repository [19]. The dataset comprises 48,120 observations of hourly vehicle counts across four different junctions during the periods of November 1, 2015, to July 1, 2017, with observations distributed across different months and years. The data was collected by sensors placed at each junction, though these

sensors operated at different times, resulting in traffic data from various time periods. The extensive range of hourly traffic counts across multiple junctions provides a valuable resource for modeling and predicting traffic congestion. The key features in the dataset are tabulated in Table II.

TABLE II. KEY FEATURES IN THE DATASET

Features	Description
Date and Time	The specific date and time of the observation.
Junction	The identifier for the junction where the data was collected.
Vehicles	The number of vehicles counted at the junction during the specified hour.
ID	A unique identifier for each observation.

The study incorporated weather data [20] of same period of time for creating more accurate, responsive, and comprehensive traffic management systems. It helps in optimizing traffic flow, improving safety, enhancing emergency response, and supporting long-term infrastructure planning. By understanding how weather influences traffic patterns, cities can better prepare for and mitigate the impacts of both regular and extreme weather conditions on their transportation networks. The dataset provides the temperature alongside two types of radiation measurements: direct horizontal radiation and diffuse horizontal radiation. These metrics are essential for understanding the overall weather conditions, as direct radiation measures the sunlight that reaches the ground without scattering, while diffuse radiation accounts for sunlight scattered by the atmosphere.

specific range, allowing for easy identification of common traffic volume ranges and patterns. The plot also helps in detecting any skewness in the data, understanding the spread of traffic volumes, and spotting potential outliers.

B. Preprocessing and Exploratory Data Analysis

Preprocessing and EDA are crucial in the data analysis pipeline, with preprocessing ensuring the data is suitable for analysis and EDA providing insights and understanding of the data [21]. Fig. 2 provides the statistics of the data statistics.

The histogram in Fig. 3 provides a visual representation of the distribution of traffic volumes in the dataset. It displays how frequently different ranges of vehicle counts occur by dividing the data into 30 bins. Each bar in the histogram represents the frequency of vehicle counts falling within a

	Junction	Vehicles	ID
count	48120.000000	48120.000000	4.812000e+04
mean	2.180549	22.791334	2.016330e+10
std	0.966955	20.750063	5.944854e+06
min	1.000000	1.000000	2.015110e+10
25%	1.000000	9.000000	2.016042e+10
50%	2.000000	15.000000	2.016093e+10
75%	3.000000	29.000000	2.017023e+10
max	4.000000	180.000000	2.017063e+10

Fig. 2. Data statistics.

The line plot shown in Fig. 4 illustrates the average traffic volume over time by resampling the data on a daily basis. It shows how the average number of vehicles varies across different days, providing insights into daily traffic trends and fluctuations. The boxplots in Fig. 5 compare traffic volumes across different junctions, highlighting variations in vehicle counts. Each boxplot visualizes the distribution of traffic volumes for each junction, showing median values, interquartile ranges, and any outliers.

Fig. 3. Distribution of traffic volumes.

Fig. 4. Traffic volume over time.

Fig. 5. Traffic volume by junction.

The average traffic volume for each hour and each day of the week is visualized in Fig. 6, revealing variations in traffic patterns across different days. These visualizations help in

identifying peak traffic times and understanding daily and weekly traffic patterns.

Fig. 6. Average traffic volume for (a) hour of the day (b) day of the week.

The analysis involves identifying peak and off-peak hours for traffic management by calculating the average traffic volume for each hour and each day of the week, highlighting times of high and low traffic as in Fig. 7.

The trend component shows long-term changes in traffic volume, indicating periods of increase or decrease, but without providing conclusive trends due to its variability. The residuals, representing the noise after accounting for trend and seasonality, are scattered around zero with a few outliers. Using a correlation matrix in Fig. 9, the correlation analysis examines at the associations between traffic volume and variables like the day of the week and hour of the day.

Additionally, time series decomposition is performed to understand the underlying patterns in traffic volume data. By breaking down the data into trend, seasonal, and residual components, this approach reveals long-term trends, recurring seasonal effects, and irregular variations, providing a clear scenario of traffic dynamics over time as in Fig. 8. This comprehensive analysis supports better traffic management and planning by pinpointing peak traffic periods and understanding traffic behavior patterns.

The correlation matrix reveals that there is a moderate positive correlation between traffic volume and the hour of the day, indicating that traffic volume tends to increase with later hours. In contrast, the correlation between traffic volume and the day of the week is weakly negative, suggesting minimal variation in traffic volume across different days. The traffic flow variations throughout the week are illustrated in Fig. 10, which reflects patterns in commuter and commercial traffic.

The traffic volume analysis reveals a clear seasonal pattern with fluctuations that repeat on a weekly basis, suggesting regular peaks and troughs corresponding to weekly traffic

Fig. 7. Peak hour analysis.

Fig. 8. Time series decomposition.

Fig. 9. Correlation matrix.

Fig. 10. Average daily traffic rate.

The analysis of holiday effects on traffic volumes, shown in Fig. 11, aims to determine how public holidays impact traffic patterns compared to non-holidays. By marking specific public holidays and comparing the average traffic volumes on these days to those on regular days, the analysis identifies any significant differences in traffic flow.

For long-term trend analysis, monthly traffic volumes were examined to assess any significant changes over an extended period. The monthly average traffic volume data as illustrated in Fig. 12, indicates a general upward trend, suggesting that traffic has been increasing over time. An addition of a trend line to the plot confirmed this long-term upward trajectory.

This trend could reflect urban development, population growth, or other factors influencing traffic patterns. Such insights are valuable for traffic management and infrastructure planning, as they highlight the need for adapting strategies to handle increasing traffic volumes.

The junction comparison analysis in Fig. 13 highlights variations in average traffic volumes across different junctions. By grouping the traffic data by junction and calculating the average number of vehicles for each, the analysis reveals that Junction 1 consistently experiences the highest average traffic volume, significantly surpassing the other junctions.

Fig. 11. Holiday effect on traffic volume.

Fig. 12. Monthly average traffic volume over time with a linear trend line.

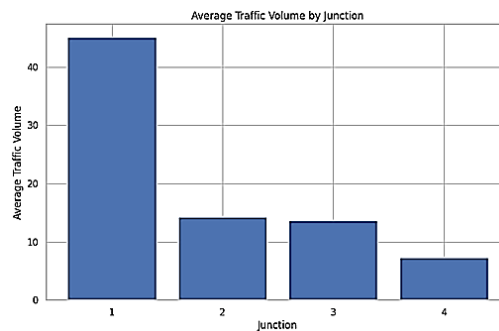

Fig. 13. Average traffic volume by junction.

The analysis of daily traffic volumes through Z-scores has identified specific dates with unusually high traffic levels. Z-scores quantify how far each data point deviates from the average, highlighting days with significantly above-average traffic. These elevated traffic volumes could be attributed to various factors. For instance, there have been special events, like concerts or sports games, that led to increased traffic on these days. Alternatively, temporary disruptions such as road construction or detours have redirected traffic through these areas, causing a spike. Additionally, seasonal patterns or local events also explain the higher traffic volumes observed.

Incorporating the weather data, the scatter plot in Fig. 14 shows that there is no evident correlation between temperature and the number of vehicles, suggesting that temperature has no significant impact on traffic volume.

The analysis of daily traffic volumes included the application of the Augmented Dickey–Fuller (ADF) test to assess the stationarity of the time series data. Stationarity is a critical property for time series analysis, as non-stationary data can lead to misleading results in forecasting models. The ADF test was employed to test the null hypothesis that the traffic

volume time series contains a unit root, which would indicate non-stationarity. The results of the ADF test revealed a significantly negative ADF statistic and a p-value much smaller than conventional significance levels. These findings strongly reject the null hypothesis, indicating that the traffic data is stationary. The Auto-Correlation Function (ACF) plot displays the correlation between the data and its lagged values over time, while the Partial Auto-Correlation Function (PACF) plot shows the direct correlation at specific lags, controlling for the effects of intermediate lags as in Fig. 15.

To complement this stationarity check, a Z-score analysis was performed to identify anomalies in daily traffic volumes. By calculating Z-scores, which indicate how many standard deviations a data point is from the mean, the analysis was able to identify days with significantly higher or lower traffic volumes compared to the average. These anomalies were then visualized on a line graph as in Fig. 16, with red dots marking the days where traffic volumes deviated notably from the norm. This visual representation provided insights into trends, potential seasonality, and outlier events that could be linked to external factors such as road closures, construction projects, or special events.

Fig. 14. Scatter plot of temperature vs. number of vehicles.

Fig. 15. ACF and PACF plot.

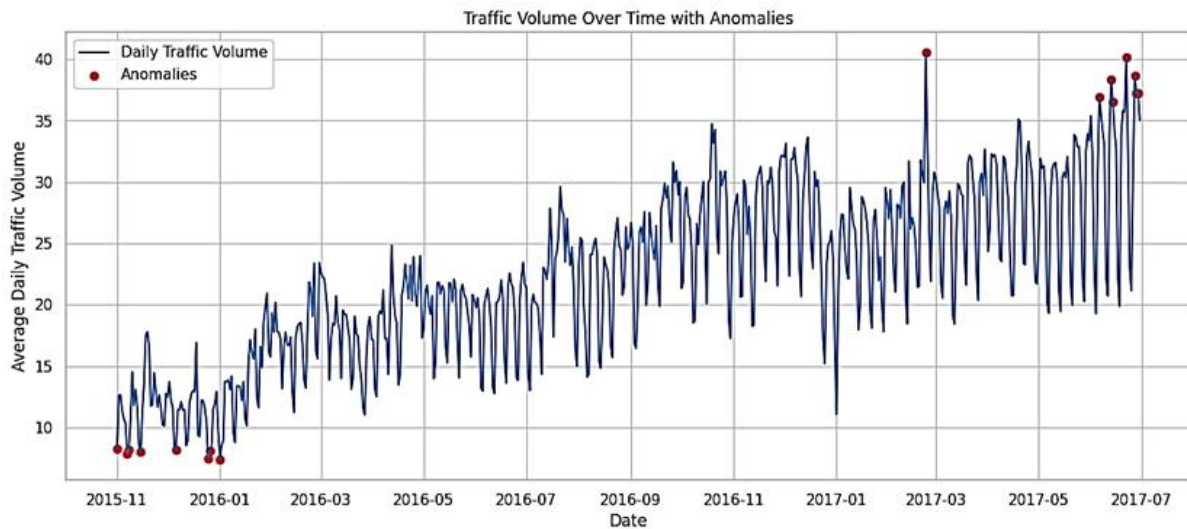

Fig. 16. Traffic volume over time with anomalies.

Additionally, the analysis involved checking for missing data, consistency of data reporting, and potential outliers. Missing timestamps were identified and accounted for, ensuring that the data was complete and accurately represented. The consistency of data reporting was verified by examining the number of records per junction and analyzing the time

intervals between records. This step ensured that data collection was uniform across different junctions and time periods. Outlier detection further refined the analysis by identifying traffic volumes that were unusually high or low as depicted in Fig. 17, which could distort the overall findings if not properly addressed.

Fig. 17. Box plot of vehicle count.

C. Feature Engineering and Embedding

Feature engineering is a crucial step in improving model performance by creating and transforming features to capture the underlying patterns in traffic congestion data [22]. One of the primary types of features engineered for this purpose is temporal features. These include the hour of the day (extracted from the timestamp) to capture daily traffic variations, the day of the week to distinguish between weekday and weekend traffic patterns, and the month to account for seasonal trends. Additionally, a holiday indicator is used as a binary feature to differentiate between holidays and regular days, which often

exhibit different traffic behaviors. In addition to temporal features, lagged features are introduced, such as the previous hour traffic volume, which helps in incorporating short-term historical trends into the model as represented by Eq. (1).

$$traffic_volume_lag_k = traffic_volume_{(t-k)} \quad (1)$$

where, k denotes the lags in hours, $traffic_volume_{(t-k)}$ denotes the traffic volume at time $t - k$, indicating the value of the traffic volume variable k periods before the current time t . This is particularly useful for predicting current traffic conditions based on recent patterns. Aggregated features like

the daily average traffic volume are also created by averaging traffic data over a day, which helps smooth out short-term fluctuations and captures overall daily trends as illustrated by Eq. (2).

$$daily_avg_traffic = \frac{1}{N} \sum_{i=1}^N traffic_volume_i \quad (2)$$

where N is the total number of observations. Furthermore, interaction features are engineered by combining different factors, such as the interaction between the hour of the day and weather conditions, to capture the combined effect on traffic patterns. Normalization standardizes the features by subtracting the mean and dividing by the standard deviation.

$$scaled_feature = \frac{feature_mean}{std_dev} \quad (3)$$

Feature embedding is particularly useful when dealing with categorical features that have a large number of unique values, such as Junction IDs in traffic data. By converting these categorical variables into dense vectors, feature embedding allows the model to learn complex relationships within the data. Junction IDs are categorical variables representing different traffic junctions. Temporal features are represented by time-based encodings. Using an embedding layer, each unique Junction ID is mapped to a continuous vector in a high-dimensional space as Eq. (4). This allows the model to capture similarities between different junctions.

$$Embedding\ matrix, E \in \mathbb{R}^{V \times d} \quad (4)$$

where, V is the number of unique junctions and d is the dimensionality of the embedding vector. Each junction i is represented by Eq. 5.

$$E_i \in \mathbb{R}^d \quad (5)$$

The embedding matrix E is initialized randomly and is learned during the training process. The embeddings are updated to minimize the loss function, allowing the model to capture relevant patterns in the data as Eq. (6).

$$embedded_vector = E_i \quad (6)$$

D. Proposed Traffic Congestion Prediction Model

The attention-based multilayer GRU model is designed to handle sequential data, such as traffic flow over time, by utilizing both the GRU for capturing temporal dependencies and an attention mechanism to focus on the most relevant time steps. This approach helps in improving the model's predictive performance by selectively concentrating on important historical data.

1) *Attention based multi-layer gated recurrent unit*: The GRU is a variant of Recurrent Neural Networks (RNNs) designed to handle sequential data effectively [23]. It employs update gates and reset gates to manage the flow of information through the network. Fig. 18 illustrates the GRU cell architecture.

Fig. 18. Cell structure of GRU.

In a GRU cell, a gate controller, represented by z, oversees the operation of both the input and forget gates. When z equals 1, the forget gate is turned off, enabling the input gate to function. On the other hand, when z equals 0, the forget gate is activated and the input gate is turned off. At every time step, the GRU cell maintains the memory from the previous time step (t - 1) while resetting the input for the current step. The operation of the GRU cell is governed by the following equations: Eq. (7) through Eq. (9).

Reset Gate (r_{ti}),

$$r_{ti} = \sigma(W_r \cdot [h_{ti-1}, x_{ti}] + b_r) \quad (7)$$

Update Gate (z_{ti}),

$$z_{ti} = \sigma(W_z \cdot [h_{ti-1}, x_{ti}] + b_z) \quad (8)$$

Candidate Activation (\tilde{h}_{ti}),

$$h_{ti} = (1 - z_{ti}) * h_{ti-1} + z_{ti} * \tilde{h}_{ti} \quad (9)$$

The GRU network is employed to forecast traffic congestion levels at 24 distinct time intervals, spanning from one hour to one day ahead, for model optimization. This GRU model features two hidden layers, with the input layer having 18 nodes and each hidden layer containing 13 nodes, as determined by the two-thirds rule applied to the input layer size and the inclusion of the output layer size. When predicting traffic congestion, extending the input sequence in a GRU network can reduce prediction accuracy because the model tends to equally weight all input variables despite their varying relevance to the forecasted outcomes. To mitigate this issue, an attention mechanism is incorporated, enabling the model to prioritize the most pertinent input variables.

The attention mechanism comprises an encoder that creates an attention vector from the input data and a decoder that generates a hidden state based on the encoder's output [24]. The encoder produces hidden states h_t for each time step t . These hidden states are segmented, and the encoder calculates an attention score $e_{t'}^t$ for each segment's hidden state using the hidden state from the preceding decoder segment. The attention score is calculated as specified in Eq. (10).

$$e_{t'}^t = \text{score}(h_{t'}, h_t) \quad (10)$$

This process creates an attention vector through a Softmax operation on the attention scores as given by Eq. (11).

$$\alpha_{t'}^t = \frac{\exp(e_{t'}^t)}{\sum_k \exp(e_{t'}^k)} \quad (11)$$

The context vector $c_{t'}$ is then computed as a weighted sum of the encoder hidden states as in Eq. (12), where the weights are the attention weights.

$$c_{t'} = \sum_t \alpha_{t'}^t h_t \quad (12)$$

This method ensures that the encoder concentrates on input variables that are closely related to the predicted value whenever the decoder generates an output. The decoder uses the context vector $c_{t'}$ along with its previous hidden state to generate the next hidden state and output as in Eq. (13).

$$h_{t'} = \tanh(W_h[c_{t'}, h_{t'-1}] + b_h) \quad (13)$$

To enhance the accuracy of traffic congestion predictions, the attention mechanism is designed to focus on highly correlated input variables. The size of the attention window is set to 96 for this specific model configuration. The attention based GRU model architecture is illustrated by Fig. 19.

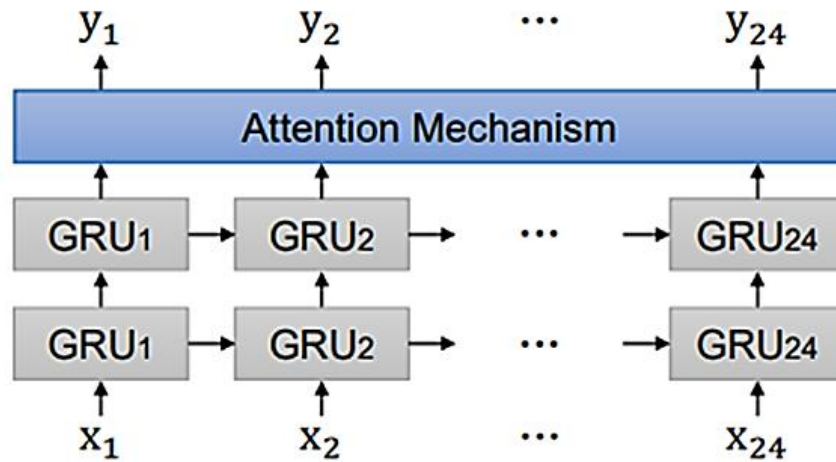

Fig. 19. Attention-based GRU model architecture.

Thus, the attention-based multi-layer GRU captures and processes the temporal dependencies in traffic data, the dense layer integrates and refines these features, and the output layer generates the final traffic prediction based on the transformed data.

E. Hardware and Software Setup

The experimental setup included an NVIDIA GeForce GTX 1080Ti GPU, an Intel Core i7 processor, 32GB of RAM,

and utilized python and the Keras library with TensorFlow as the backend. Keras' intuitive interface, combined with the computational power of Google Colab, enabled efficient model training with GPU support. The dataset was split for training and testing to ensure robust evaluation. Table III outlines the hyperparameters chosen for the training phase, which played a critical role in fine-tuning the model's performance on the traffic prediction dataset, ensuring both accuracy and rapid convergence.

TABLE III. HYPERPARAMETER SPECIFICATION

Hyperparameters	Values
Loss function	Mean squared error
Activation function	Sigmoid
Batch size	32
Epochs	150
Optimizer	Adam
Learning rate	0.001

IV. RESULTS AND DISCUSSION

The model's performance was assessed by means of various metrics, as detailed in Table IV. Table V shows the model

performance assessment using evaluation metrics for traffic congestion prediction.

TABLE IV. EVALUATION METRICS

Metric	Equation
Mean Squared Error (MSE)	$MSE = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$
Mean Absolute Error (MAE)	$MAE = \frac{1}{n} \sum_{i=1}^n y_i - \hat{y}_i $
Coefficient of Determination (R ²)	$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}$
Mean Absolute Percentage Error (MAPE)	$MAPE = \frac{1}{n} \sum_{i=1}^n \left \frac{y_i - \hat{y}_i}{y_i} \right \times 100$

n is the number of observations, *y_i* is the actual value, \hat{y}_i is the predicted value

TABLE V. PERFORMANCE ASSESSMENT USING EVALUATION METRICS

Evaluation metrics	Values
MSE	0.9678
MAE	0.4322
R ²	0.8686
MAPE	6%

The evaluation metrics demonstrate that the model excels in predicting traffic congestion with impressive performance. The MSE of 0.9678 indicates that the model generates predictions with minimal squared errors, reflecting a high degree of accuracy in capturing the nuances of traffic patterns. The MAE of 0.4322 underscores the model's strong predictive capability, with average deviations being relatively low and manageable. The R² of 0.8686 reveals that the model accounts for approximately 87% of the variability in traffic congestion,

showcasing its effectiveness in explaining the observed data. Additionally, the MAPE of 6% demonstrates that the model's predictions are, on average, within 6% of the actual values, highlighting its robustness and reliability. Overall, these results confirm that the model delivers highly accurate and reliable predictions for traffic congestion, marking it as an exceptional tool for traffic forecasting. Fig. 20 illustrates the predicted and actual values of the suggested attention based multilayer GRU model for traffic congestion prediction.

Fig. 20. Predicted vs. actual values of proposed model.

The attention-based multilayer GRU model showed considerable efficiency in predicting traffic congestion. The model demonstrated robust prediction accuracy and reliability, evidenced by an MSE of 0.9678, an MAE of 0.4322, and an R² value of 0.8686. A MAPE of 6% further demonstrates the model's resilience while processing real traffic data. The

integration of the attention mechanism within the multilayer GRU architecture enables the model to concentrate on the most pertinent temporal patterns and features in traffic data, enhancing prediction accuracy and ensuring effective capture of both short-term fluctuations and long-term dependencies in congestion patterns. The attention-based multilayer GRU

model is an exceptionally excellent method for predicting traffic congestion. An attention mechanism in a multilayer GRU aids in the prediction of traffic congestion by allowing the model to concentrate on the most important features and pertinent temporal patterns in the data. The attention mechanism, in contrast to conventional GRU models, gives significant time steps, ensuring that significant congestion-related occurrences or patterns are given priority during prediction. This enhances the model's ability to capture long-term dependencies while reducing the influence of irrelevant or noisy inputs. The multilayer GRU utilizes the attention mechanism to enhance prediction accuracy and interpretability, making it especially suitable for the intricate and variable nature of traffic congestion prediction.

V. CONCLUSION

The proposed attention-based multilayer GRU model offers a substantial improvement over traditional traffic management methods by addressing the dynamic and complex nature of traffic congestion. The model's ability to capture temporal dependencies and intricate traffic patterns through attention mechanisms enables more accurate predictions of traffic conditions and congestion levels. The model achieved a notable improvement in accuracy, with MAE and MSE values of 0.4322 and 0.9678, respectively. This enhanced predictive capability facilitates timely and efficient traffic management interventions, reducing travel times, minimizing fuel consumption, and lowering emissions. The effectiveness of the model in various urban scenarios demonstrates its potential to significantly improve overall traffic flow and urban mobility. Future research could explore integrating real-time data sources and extending the model's application to different traffic management systems to further enhance its effectiveness. Future studies should investigate transfer learning to adapt models for areas with scarce historical data and reduce dependence on computational resources. More thorough and useful solutions for traffic management systems will be ensured by integrating external factors like weather, road construction, and special events, as well as by creating reliable models for unexpected disruptions.

ACKNOWLEDGMENT

I would like to express my sincere gratitude to all those who contributed to the completion of this research paper. I extend my heartfelt thanks to my supervisor, my family, my colleagues and fellow researchers for their encouragement and understanding during the demanding phases of this work.

Robust Joint Detection of Coronary Artery Plaque and Stenosis in Angiography Using Enhanced DCNN-GAN

M. Jayasree^{1,*}, L. Koteswara Rao²

Department of ECE, Koneru Lakshmaiah Education Foundation, Aziz Nagar, Hyderabad, 500075, Telangana, India^{1,2}

Abstract—Timely detection and diagnosis of coronary artery segment plaque and stenosis in X-ray angiography is of great significance, however, the image quality variation, noise, and artifacts in the original image cause definitive difficulties to the current algorithms. These problems pose a challenge to meaningful analysis via traditional approaches, which compromises the efficiency of detection algorithms. To overcome these drawbacks, the current study presents a new integrated deep learning technique that integrates Deep Convolutional Neural Network (DCNN) with Generative Adversarial Network (GAN) in dual conditional detection. Detailed feature learning extracted from X-ray angiography images are performed through DCNN where it considers vascular structure and automatic pathologic regions detection. The use of GANs is to further enrich the dataset with synthetic images, distortions, and visual noise, which will make the model more immune to various conditions of images. Both approaches combined help in better classification of normal and pathological areas and less sensitiveness to quality of the obtained images. The proposed method therefore has shown an improvement of the diagnostic accuracy as a solid foundation for clinical decision making in cardiovascular systems. The efficacy of the suggested approach has been demonstrated by the following evaluation metrics: 97.9% F1 score, 98.7% accuracy, 98.2% precision, and 98% recall. The results prove higher sensitivity and accuracy of the plaque and stenosis identification comparing to the traditional methods, which confirms the efficiency of using the proposed DCNN-GAN method for considering the real-world fluctuations in the medical imaging. It reveals a decisive advancement in the ability to use algorithms for cardiovascular assessment by providing better results in difficult imaging environments.

Keywords—DCNN-GAN; angiography; coronary artery plaque; stenosis; joint conditional detection

I. INTRODUCTION

Correct detection of plaque formation together with stenosis severity enables the prevention of major cardiovascular health risks which lead to heart attacks and strokes. Timely interventions made possible by early diagnosis help minimize morbidity and mortality rates together with enhancing total patient outcomes. The accumulation of fat deposits in the arteries and the ensuing restriction of these essential blood channels are recognized as coronary artery plaque and stenosis, which are most important issues with cardiovascular fitness [1]. Plaque development starts a complex chain of activities inside artery partitions and is commonly made from ldl cholesterol, cell particles, calcium, and fibrin. These deposits may eventually

solidify and impede blood flow, which might reduce the amount of oxygen-wealthy blood that reaches the coronary heart muscle [2]. Simultaneously, this blockage is made worse by means of stenosis, or the narrowing of the arteries, which is regularly brought on via plaque build-up or the thickening of the artery partitions. The important results of those disorders for the health and properly-being of patients are highlighted via the huge upward thrust within the chance of cardiovascular occasions, together with heart attacks and strokes. X-ray angiography, which gives specific renderings of arterial structures, is one of the clinical imaging modalities this is most regularly utilized inside the clinical diagnosis of coronary artery plaque and stenosis [3]. Timely treatments and individualized treatment techniques are established on early diagnosis and specific evaluation of plaque load and stenosis severity. In order to improve diagnostic accuracy and prognostic capacities, modern research efforts are focused on building state-of-the-art imaging algorithms and computer models, inclusive of DL techniques and Bayesian frameworks [4]. Clinicians may additionally better manage and decrease the dangers related with plaque formation and stenosis with the aid of the use of these novel strategies to better understand and pick out coronary artery sickness, with a purpose to subsequently improve patient results and great of existence [5].

X-ray angiography image offer scientific personnel with a complete view of the artery machine, they may be vital for the identification and therapy of cardiovascular ailments [6]. With the usage of X-rays, this imaging technique highlights the anatomy and operation of blood arteries with the aid of taking real-time photos of them after a contrast agent injection [7]. X-ray angiography helps come across anomalies such as blockages, constriction, and aneurysms that would impair blood circulation to essential organs, mainly the coronary heart and brain, by way of carefully mapping the direction of blood float through arteries and veins [8]. Because those images can precisely pick out the location and diploma of artery blockages, they are helpful in helping to guide interventional treatments along with angioplasty and stent implantation. Moreover, X-ray angiography facilitates medical doctors make properly-knowledgeable judgments on endured affected person care by using allowing them to music the route of the ailment and compare the effectiveness of treatments [9]. The endured significance of X-ray angiography in modern medicine is proven via the truth that, despite the development of non-invasive imaging technology consisting of CT and MRI, this take a look at continues to be important for the prompt and particular

detection of acute cardiovascular crises and complex vascular issues.

Image analysis has gone through a revolution due to the fact that, the Deep Convolutional Neural Network, which automatically develop hierarchical representations from uncooked pixel records. Because this magnificence of neural networks is so desirable at figuring out small info and patterns in pictures, it is especially beneficial for tasks like segmentation, category, and object popularity [10]. Multiple convolutional filter layers are used by DCNNs to methodically extract regularly summary records from input photographs. Every layer has the ability to understand wonderful patterns, consisting of edges, textures, and complex systems, which enables the community discover minute versions that are essential for precise image interpretation. The generator and discriminator neural networks in an aggressive game framework make up a Generative Adversarial Network. While the discriminator learns to differentiate among produced and real facts, the generator learns to create synthetic data (together with pix and sounds) that mimic actual samples from a training dataset. GANs reach a pleasant stability thru iterative education: the discriminator becomes better at figuring out authenticity, at the same time as the generator receives more sensible output [11]. The outputs produced by means of this adverse learning process are highly sensible and can be unsuitable for real information. GANs have located programs in a wide range of disciplines, which includes pc vision, herbal language processing, and biomedical imaging. They have revolutionized jobs like picture synthesis, statistics augmentation, and anomaly detection [12].

The selection of DCNN-GAN model occurred because its image quality handling capabilities together with improved diagnostic verification and enhanced feature extraction satisfied the project requirements. The model's generation abilities increases dataset size while making the program resistant to artifacts and noise thus making it appropriate for plaque and stenosis detection in coronary arteries. The suggested study demonstrates a way to higher pick out coronary artery stenosis and plaque in X-ray angiography images by using utilising the complementing traits of GAN and DCNN. An energy of DCNNs is complicated function extraction from clinical snap shots, that's crucial for accurately identifying unwell illnesses. The DCNN element, skilled on annotated datasets, correctly identifies areas as both regular or suggestive of plaque and stenosis. In addition, GANs enhance the dataset by means of producing synthetic pictures that intently resemble real angiography scans. This improves the schooling information and makes the DCNN more resilient to changes in ailment presentation and photo excellent. Moreover, anomaly identity is made viable by way of the hostile education of GANs, which may also display subtle signs and symptoms of contamination development which might be neglected by way of conventional diagnostic strategies. The challenge intends to improve early intervention techniques, enhance diagnostic accuracy, and subsequently resource in more efficient medical selection-making in cardiovascular care by way of combining many technologies right into a single pipeline. Some of the important contributions of the proposed look at are:

- This method improves detection of the coronary artery narrowing and plaque by combining the GANs with DCNNs.
- The synthetic images created and added into the set by the GANs increase the range of inputs to be expected the DCNN model, for various patients' conditions and image differences.
- The diagnosis is made early and is accurate, two factors that help in early intervention by physicians and positive patient wellness.
- The method enhances the ability of medical practitioners to read X-ray angiography images thus enhancing diagnosis in clinical practices.
- The approach incorporated deep learning to solve difficult detection issues and improves medical imaging of the procedures hence improving clinical decision making.

The suggested work's section is organized as follows: Section III has the problem statement, while Section II contains associated initiatives. The methodology of the article is covered in Section IV, along with the suggested work, pre-processing, and execution. Section V presents the findings and discussion, while Section VI offers suggestions for more research.

II. RELATED WORKS

Rodrigues et al. [13] suggests using a two-step DL system to identify stenosis in X-ray coronary angiography pictures in a largely automated manner. The approach uses two separate convolutional neural network architectures to automatically detect and classify the angle of view and calculate the boundaries of the areas of interest in frames when stenosis is evident. To improve the system's performance, approaches including data augmentation and transfer learning are applied. The findings indicate that the LCA and RCA had 0.97 accuracy and 0.68/0.73 recall, respectively, in categorizing the LCA/RCA angle view and regions of interest. These results pave the way for an entirely robotic approach for determining the degree of stenosis using X-ray angiographies, and they compare favorably with earlier results achieved using analogous methodologies.

Ovalle-Magallanes et al. [14] offers a novel technique that uses transfer learning to automatically detect coronary artery stenosis in XCA images by employing a CNN that has already been trained. A common heart condition called coronary artery disease is brought on by abnormal construction of the coronary arteries. It ranks among the leading causes of death globally. XCA is the most standard imaging technique for diagnosing stenosis. The technique selects the best cut and fine-tuned layers using a network-cut and fine-tuning methodology after 20 alternative configurations. Three methodologies (actual data, purely fake data, and artificial and real data) were used to fine-tune the networks. The 10,000 photos in the synthetic dataset were created using a generative model. The findings demonstrated that pre-trained CNNs such as VGG16, ResNet50, and Inception-v3 performed better in stenosis identification than referencing CNNs.

Pang et al. [15] suggests using an object detection network-based technique called Stenosis-DetNet to automatically identify coronary artery stenosis in X-ray images. To optimize temporal information and produce precise detection results, the approach makes use of an order consistency alignment module and a series feature fusion module. The sequence feature fusion module merges all candidate box features, whilst the order consistency alignment module enhances preliminary results by merging a coronary artery displacement information and image characteristics of surrounding pictures. 166 X-ray picture sequences were utilized in the experiment for testing and training. Stenosis-DetNet outperformed the other three approaches in terms of precision and sensitivity, coming up at 94.87% and 82.22% higher, respectively. The suggested approach outperformed the approaches in suppressing false positive and false negative findings of stenosis identification in sequence angiography pictures.

Gil-Rios et al. [16] provides a strategy that overcomes several classification approaches and DL methodologies to automatically detect myocardial stenosis in X-ray coronary pictures. The approach selects features using the Univariate analysis Marginal Distribution Algorithm and compares metaheuristics statistically to investigate the computational cost of the search space. The approach is evaluated on two an X-ray image dataset containing coronary angiograms and compared with six other approaches currently in use. It is appropriate for clinical usage based on the accuracy rate of 0.89 and 0.88, the Jaccard Index of 0.80 and 0.79, and the average computing time of about 0.02 seconds, as demonstrated by the findings. The precision and Jaccard Index assessment metrics are used to assess the efficacy of the procedure.

Stralen et al. [17] recommended a study on coronary artery stenosis (CAD), a serious global health issue for which automatic diagnosis of the condition on X-ray images is essential. Atherosclerotic plaques and stenosis are the disease's causes; these conditions increase the workload of the heart and raise the risk of heart failure. In clinical practice, automated stenosis detection might be utilized as a second reader or for triage purposes. Deep neural networks are used to assess whether stenosis can be detected in X-ray coronary angiography pictures. Employing clinical angiography data from 438 patients, three potential object detectors were trained and evaluated. EfficientDet demonstrated a mean average accuracy of 0.67 in stenosis detection, supporting the notion that attention processes enhance convolutional neural networks' capabilities for medical imaging.

Ovalle-Magallanes et al. [18] enhances the identification of stenosis in X-ray coronary angioplasty using quantum computing. A quantum network is used to improve the performance of a classical network that has already been trained in a hybrid transfer-learning paradigm. Normalization features undergo processing in the quantum network after the classical data have been processed afterwards into a hypersphere utilizing a hyperbolic tangent function. A SoftMax function is used to obtain class probabilities. The data is divided into several circuits inside the quantum network using a distributed variational quantum circuit, which speeds up training without sacrificing detection performance. A small dataset of 250 image

patches from X-ray coronary angiography is used to assess the procedure. In terms of accuracy, recall, and -score, the hybrid classical-quantum network fared much better than the classical network, attaining 91.8033%, 94.9153%, and 91.8033%, respectively.

Han et al. [19] said that the diagnosis and treatment of coronary artery disease depend on the ability to recognize coronary artery stenosis in XRA images. Unfortunately, most methods suffer from poor spatiotemporal-temporal information use. To gather spatiotemporal features at the suggested level for an innovative stenosis detection method, a transformer-based component is provided. The proposal-shifted spatio-temporal tokenization approach gathers region-of-interest characteristics that the Transformer-based feature aggregation network utilizes to acquire knowledge a faraway spatio-temporal context for final constriction prediction, hence enhancing the ROI features. A remarkable score of 90.88% was attained, outperforming the results of 15 other detection techniques, as examinations on 233 XRA sequences, both qualitative and quantitative, validated the approach's effectiveness. This illustrates how well the technique can detect stenosis from XRA pictures.

Algarni et al. [20] suggested an ASCARIS model that conducts classification using the Attention-based Nested U-Net, optimizes maximum principal curvature to improve contrast, and eliminates noise pixels using a modified wiener filter. To improve segmentation accuracy, angle estimation is applied. Classifying X-ray pictures into normal and pathological classes is accomplished by extracting double characteristics from the segmented image using an architecture based on VGG-16. Using the simulation tool MATLAB R2020a, the model's performance was assessed and compared with previous methods in terms of segmentation accuracy, PSNR, Hausdorff distance, revised contrast to noise ratio, accuracy, sensitivity, specificity, mean square error, dice coefficient, Jaccard similarity, and ROC curve. The findings demonstrate that the suggested model works better than current methods, resulting in an optimum categorization of CAD. The technique enhances vascular anatomy and eliminates background artifacts.

To partially automate the process of detecting stenosis from X-ray coronary angiography pictures, a DL system has been presented. The system recognizes and categorizes the angle of view and areas of interest using two different convolutional neural network designs. To improve the system's performance, approaches including data augmentation and transfer learning are applied. The findings indicate that the LCA and RCA had 0.97 accuracy and 0.68/0.73 recall, respectively, in categorizing the LCA/RCA angle view and regions of interest. The technique selects the best cut and fine-tuned layers using a network-cut and fine-tuning methodology after 20 alternative configurations. For automated identification of coronary artery stenosis on X-ray images, the object detection network-based Stenosis-DetNet approach is suggested. The method uses a hybrid transfer-learning paradigm and quantum computing to improve stenosis detection in X-ray coronary angiography. The previous research had problems with the changes in angiography image quality is one of its drawbacks. The performance of the classifier may be impacted by irregular image quality, noise, or artifacts, which might impair the efficiency of the pre-processing and feature extraction processes.

III. PROBLEM STATEMENT

The application of XCA visuals to study arterial stenosis continues to provide significant challenges, partly because of shortcomings found in the currently used approaches. The primary problem is the potentially poor quality of the images, which may contain imperfections and noise that improve preprocessing and feature extraction functions while degrading the effectiveness of the classifier [13] [20]. Furthermore, the current methods, such as the one suggested by Han et al. [19], do not maximize the utilization of dynamical data, leading to suboptimal stenosis identification. Another significant problem is the failure to reliably classify both the LCA/RCA, as demonstrated through additional investigations, with consistent recall frequencies. Furthermore, even though quantum technology is used in combined transfer-learning and other DL-related applications. Additionally, despite the seeming promise of recent developments in DL, including a combined transfer-learning system using quantum technology [18], these technologies may be limited by the small datasets and computational demands, which may harm their application in practical. The lack of reliable methods to repeatedly manage the picture quality and patients' anatomical differences is a further significant problem, which adds to the complexity of accurately evaluating stenosis in various populations [17]. Current models face difficulties because they fail to handle variable image quality while dealing with inconsistent accuracy between different populations and demanding heavy computational processing. The inadequate management of noise and insufficient control of artifacts alongside limited dataset availability produce unreliable and inconsistent accuracy. In real-world medical settings the deployment of these methods

remains impractical because of challenges related to interpretability, manual preprocessing requirements and their limited adaptability. Because of the shortcomings of the previous method, new intelligent and flexible algorithms would be needed for the automated identification of stenosis in coronary arteries utilizing XCA pictures.

IV. JOINT CONDITIONAL DETECTION OF CORONARY ARTERY PLAQUE AND STENOSIS USING DCNN-GAN

Early detection and diagnosis of cardiovascular illness is crucial for the identification of stenosis and coronary artery plaque in X-ray angiography pictures. Conventional techniques frequently encounter image quality changes, including noise and artifacts, which might impair the detection algorithms' accuracy. To address these issues, providing a unique technique in this paper that combines GAN with DCNN. GAN are used in the augmentation of the dataset and DCNNs are used to extract features from X-ray angiography images, which enables in-depth examination of the vascular architecture and any anomalies that might be signs of stenosis and coronary artery plaque. Creating artificial images that mimic varying degrees of noise and visual artifacts. This improves the model's resilience to a range of image circumstances and speeds up the training process. With the help of the integrated DCNN-GAN architecture, joint conditional detection is made easier. In this process, the system uses learnt characteristics to classify regions of interest as either normal or pathological. Reducing the influence of changes in image quality on detection performance, this method seeks to greatly improve diagnostic accuracy and reliability and open the door to more efficient clinical decision-making in cardiovascular medicine.

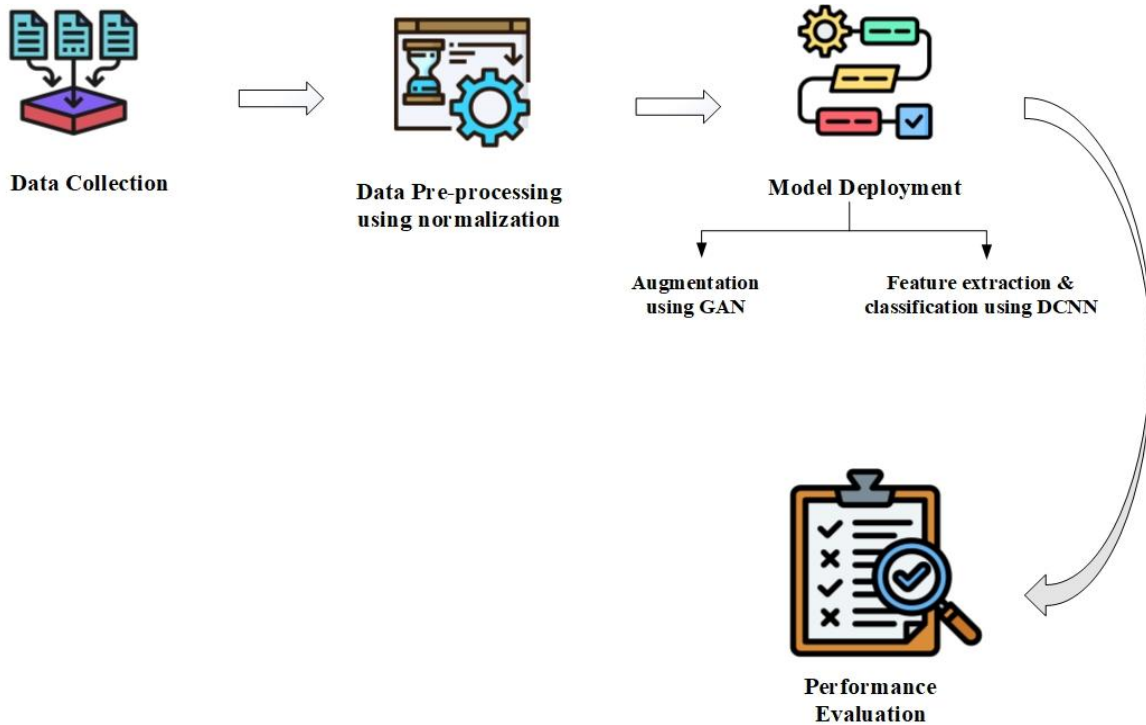

Fig. 1. Flow diagram of the proposed study.

The procedure of utilizing the DCNN-GAN approach to identify coronary artery plaque and stenosis in X-ray angiography images is shown in the Fig. 1. The first step in the procedure is data collection, which involves compiling an extensive collection of varied and high-quality angiogram images. The images are then enhanced and standardized for training using normalization during the Data Pre-processing stage. The core of the technique is DCNN-GAN, which combines Deep DCNN for in-depth extraction and classification of features with GAN for artificial picture generation to enrich the dataset and mimic various visual circumstances, hence boosting model resilience. Finally, performance evaluation to validate its effectiveness and reliability. The cycle process ensures continuous model improvement and robustness in real-world clinical scenarios while addressing the drawbacks of earlier methods for handling variations in picture quality.

A. Data Collection

The dataset Coronal Slices shows the MRI images that depict coronal slices taken from the torso's successive anteroposterior locations. A collection of 5000 X-ray angiography images was obtained from multiple clinical environments to deliver diverse patient population demographics for enhancing model training effectiveness and generalization ability. With its ability to provide a thorough vision of blood vessels and any anomalies inside the coronary arteries, X-ray angiography images are essential diagnostic tools in cardiovascular medicine. These images are produced by way of injecting a substance that contrasts into the bloodstream and acquiring X-rays whilst the agent flows through the heart and coronary arteries. X-ray angiography, that is commonly used to pick out illnesses such as coronary artery sickness, offers scientific experts high-decision images in actual time that display regions of stenosis (narrowing of the arteries), plaque formation, and other cardiovascular problems. When it comes to correctly interpreting those images and making selections about remedy, such as implanting stents or present process pass surgical procedure, their excellent and readability are crucial. In order to reduce radiation exposure and maximize photograph decision, present day X-ray angiography structures use modern generation, ensuring affected person safety and powerful prognosis. The goal of studies using X-ray angiography datasets is to create automatic strategies to improve detection sensitivity and performance. These techniques, which consist of DL algorithms like DCNN-GAN, will assist tailored treatment plans and early analysis in cardiovascular care [21].

B. Data Pre-Processing

The technique of converting unprocessed information right into a clear and on hand shape for research is referred to as statistics guidance. Making sure the data is prepared for ML designs, involves actions including resolving values that are missing, casting off outliers, normalizing or standardizing the records, and encoding specific variables.

1) *Normalization*: Data normalization is the technique of changing information in order that analytics and DL algorithms might also use it in a constant manner. It is typically used to convert raw statistics right into a layout higher suitable for DL techniques including logistic regression, neural networks, and linear regression. Normalizing facts in DL can help with data

simplicity for records this is numerical as well as express. The Min-Max Scaling technique converts statistics into a range among 0 and 1 by way of dividing the information by the difference between the best and least values, after which subtracting the minimum fee from each information factor. The normalization approach is useful in preventing the exceptions from severely affecting the data while working with exceptions.

$$m_o = \frac{m - m_{min}}{m_{max} - m_{min}} \quad (1)$$

In Eq. (1), m_{max} represents a feature's highest value, m_{min} its minimum value, and m_o its normalization value.

2) *Noise removal*: The process of reducing noise in images involves using filters in comparison to eliminate unwanted stochastic changes, or noise, which obscures key elements. A filter called Gaussian blur, which is a jointly-existing approach, aims to apply a function called Gaussian in addition to averaging pixels inside a certain area (to reduce noise). The following Eq. (2) defines the Gaussian blur [22]:

$$G(x, y) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2+y^2}{2\sigma^2}\right) \quad (2)$$

Whereas the Gaussian function is represented as $G(x, y)$, the pixel coordinates are represented by x and y , while the standard variation σ explains the level of uniformity. The filter's job is to reveal, by convolution, the Gaussian kernel with the image. This minimizes the high-frequency elements, or noise, while maintaining almost all of the boundaries.

C. GAN

Text, audio, and image data samples may be synthesized using generative models called GANs. Combining training a generator and discriminator neural networks at the same time is the basic idea behind GANs. While the discriminator learns how to discern between actual and phony data, the generator learns how to create synthetic data samples. Through adversarial training, where the generator tries to fool the ML algorithm and the discriminator tries to discern between genuine and fake samples, GANs are trained to generate realistic, high-quality data.

While the discriminator D seeks to discern between actual samples (from the true data distribution $P_{data}(x)$ and fraudulent samples created by G , the generator G seeks to make realistic data samples from random noise z (taken from a previous distribution $p_z(z)$). With θ_g as the generator's parameters, the generator network learns to map the input noise, z , to the data space, $G(z; \theta_g)$. Conversely, an input x is mapped by the discriminator, whose parameters are θ_d , to a probability $D(x; \theta_d)$ that x is a genuine sample.

A GAN must optimize two loss functions during training: one for the generator and one for the discriminator. While the generator is taught to trick the discriminator into believing bogus samples to be real, the discriminator is trained to optimize the chance of accurately categorizing actual and fake samples. The value function $V(G, D)$ may be used to structure this as a minimax game.

$$\min_G \max_D V(G, D) =$$

$$E_{x \sim P_{data}(x)}[\log D(x)] + E_{z \sim P_z(z)}[\log(1 - D(G(z)))] \quad (3)$$

In Eq. (3), D is stimulated to produce high probability for genuine samples by $E_{x \sim P_{data}(x)}[\log D(x)]$, which stands for the expected value of the discriminator's output logarithm for real data. On the other hand, $E_{z \sim P_z(z)}[\log(1 - D(G(z)))]$ stands for the anticipated value of the logarithm of one less the output of the discriminator for fictitious data, which incentivizes D to produce low probability for fictitious samples produced by G .

D and G are updated in turn throughout training. The discriminator is enhanced to more accurately distinguish true

from false data, while the generator is updated to offer accurate data that can trick the discriminator. In an ideal scenario, this adversarial process results in the generator generating extremely realistic samples that are identical to genuine data over time, reaching a Nash equilibrium where neither the discriminator nor the generator can operate better without altering the other. Because GANs can learn complicated data distributions and produce high-quality synthetic data, they are frequently employed in many different applications, such as image production, style transfer, and data augmentation.

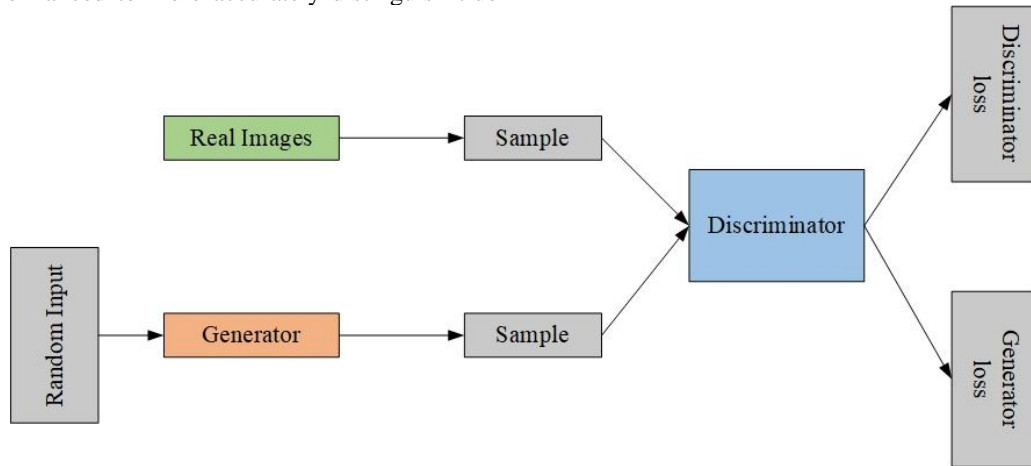

Fig. 2. Architecture of GAN.

The design and operation of a GAN are depicted in the Fig. 2. The generator and discriminator are its two primary parts. The generator, which converts random noise into a created image, is the first step in the process. Using the training dataset, this generator network learns to produce images that look authentic. The discriminator is then given both the produced and actual images from the dataset. It is the discriminator's job to determine if these images are authentic or not. It produces a likelihood that indicates if each image is artificially created or real. During training, both the generator and the discriminator are in competition with one another: the discriminator wants to distinguish between real and fake pictures with accuracy, while the generator wants to produce images that seem exactly like real ones to trick the discriminator. The discriminator sharpens its capacity to spot phony images, while the generator refines its output to trick the discriminator even more. Until the generator generates very realistic images that the discriminator can no longer accurately separate from real images, adversarial training will be conducted. Because of this dynamic process, GANs are able to produce practical statistics, which makes them effective tools for quite a few programs like information augmentation, photo synthesis, and the creation of original content.

D. DCNN

The circle of relatives of DL models called DCNN has tested magnificent overall performance in photo and video recognition programs due to its ability to mechanically generate hierarchical feature representations from unprocessed input records. Common layers seen in a DCNN design are convolutional neural networks, pooling, and fully connected layers. Crucial to the process are the convolutional layers, which use filters (kernels)

to convolve across the input image and create feature maps that emphasize certain elements like edges or textures. The convolution procedure may be mathematically represented in Eq. (4),

$$(X * W)(i, j) = \sum_m \sum_n X(i + m, j + n)W(m, n) \quad (4)$$

Output feature map, given by input X and a filter W . Taking small portions of the input into consideration, this process captures spatial hierarchies. Activation functions like as ReLU, which are defined as in Eq. (5),

$$ReLU(x) = \max(0, x) \quad (5)$$

are applied after the convolutional layers to induce non-linearity.

Pooling layers, often max pooling, substantially minimize the spatial dimensions of the feature maps while achieving spatial invariance and minimizing computation costs. The down sampled output is represented by Y , and the max pooling operation may be expressed mathematically in Eq. (6),

$$Y(i, j) = \max\{X(p, q) | p, q \in \text{poolinhregion}\} \quad (6)$$

More intricate and abstract information are learnt as the network becomes deeper, leading to fully linked layers that combine these features to provide predictions. A SoftMax function for classification problems is produced by flattening and feeding the output of the last convolutional or pooling layer into one or more fully connected layers.

$$\sigma(z)_j = \frac{e^{z_j}}{\sum_k e^{z_k}} \quad (7)$$

Eq. (7) is the formula for the SoftMax function, where z is the SoftMax layer's input vector and $\sigma(z)_j$ denotes the probability of the j -th class.

Backpropagation and optimization methods like stochastic gradient descent (SGD) are used during DCNN training in order to minimize a loss function, in this case, the cross-entropy loss for classification.

$$H(p, q) = -\sum_i q_i \log(p_i) \quad (8)$$

Eq. (8) is the definition of the cross-entropy loss for a true distribution q and a forecasted probability distribution p . Across a wide range of contemporary computer vision applications, from object identification and segmentation to facial recognition and autonomous driving, DCNN are essential for their automated and efficient extraction of pertinent information from high-dimensional input.

Fig. 3. Architecture of DCNN.

The two main phases of a DCNN architecture feature extraction and classification are shown in the Fig. 3. Several convolutional operations are performed on the input image during the feature extraction stage. These operations allow the filters to identify different features, such as edges and textures, and produce feature maps. After that, these feature maps are run via pooling layers, which achieve spatial invariance and lower computational burden by lowering the spatial dimensions of the feature maps by choosing the largest value from an area. During the category level, the final result of the remaining pooling layer is fed into fully linked layers after being compressed into a vector with one measurement. These layers combine the gathered features to generate the final categorization. The last layer typically makes use of a SoftMax activation function to generate an opportunity distribution over all possible lessons. DCNNs' design allows them to effectively apprehend and classify complex styles in the input records.

It is crucial for the activate detection and treatment of cardiovascular disorders to identify coronary artery plaque and stenosis in X-ray angiography images. Variabilities in picture excellent, which include noise and artifacts, pose serious hurdles to traditional tactics and may obstruct accurate detection. Suggesting a unique method that mixes GAN with DCNN to resolve this. Because of its skill in extracting complicated traits

from medical photos, DNN can identify diseased areas and examine vascular architecture in high-quality element. The DCNN successfully learns to categorize areas as regular or suggestive of plaque and stenosis through training on annotated datasets. In addition, GANs produce synthetic images that imitate actual angiography scans, including exclusive levels of noise and artifacts to decorate the education set. This ensures that the model is resistant to the many photo circumstances that get up in medical practice, further to improving the robustness of the DCNN. Joint conditional detection is supported by way of the integrated DCNN-GAN architecture, which complements diagnostic accuracy via permitting the gadget to regulate to and compare a variety of photo traits. Better affected person consequences are expected because of this strategy's primary upgrades to automatic cardiovascular diagnostics efficacy and reliability. Grad-CAM produces visual explanations which define fundamental areas that impact the model's prediction process. Visual interpretability enables healthcare professionals to both verify and trust the automated diagnosis process resulting in model acceptance for plaque and stenosis recognition tasks.

V. RESULT AND DISCUSSION

The outcomes of the proposed DCNN-GAN framework reveal widespread gains in the popularity of plaque and coronary

artery stenosis in X-ray angiography photographs. It has shown to a hit to mix GAN for statistics augmentation with DCNN for function extraction and classification. Using an NVIDIA RTX 3090 GPU allowed the proposed DCNN-GAN model to finish its training process within 12 hours. The model's optimized design achieves accelerated convergence while maintaining high diagnostic precision through more efficient operations thus allowing use in real-time clinical environments. The model can control image high-quality variations, consisting of noise and artifacts, that are frequently seen in scientific situations. As a result, the gadget has a huge potential to exactly discover and classify regions of interest, generating correct and dependable diagnostic consequences. These encouraging findings imply that the DCNN-GAN architecture can considerably enhance diagnostic overall performance, facilitating early cardiovascular sickness prognosis and intervention and improving patient care in popular in clinical exercise. The proposed work is implemented using python.

A. Experimental Outcome

Fig. 4. Coronary angiographic image with visible stenosis.

The Fig. 4 demonstrates the coronary angiogram which is a medical examination of coronary arteries. In this particular image, one of the coronary arteries has a condition called stenosis which narrowed. This narrowing can reduce the blood supply to the heart muscle and cause discomfort such as chest pain.

TABLE I. PERFORMANCE EVALUATION

Category	Accuracy	Sensitivity (Recall)	Specificity	Precision
3-CAT Prediction	0.98	0.97	0.96	0.98
2-CAT Prediction	0.96	0.95	0.94	0.96
3R-CAT Prediction	0.94	0.93	0.92	0.94
2R-CAT Prediction	0.92	0.91	0.90	0.92
Random Guessing	0.50	0.50	0.50	0.50

The Table I summarizes the performance of the DCNN-GAN model in predicting coronary artery plaque and stenosis across different categories. The 3-CAT Prediction (3 categories) achieves the highest accuracy (98%), sensitivity (97%), and precision (98%). The 2-CAT Prediction (2 categories) also performs well with 96% accuracy and 95% sensitivity. The 3R-CAT and 2R-CAT Predictions, slightly reduced versions, show strong but lower performance. Random guessing, included for comparison, shows much lower metrics, prominence the model's effectiveness.

Fig. 5. Performance of coronary stenosis classifications.

The Fig. 5 shows how various models of classification of coronary stenosis performed. The x-axis shows the different models, and the y-axis represents the performance metrics: sensitivity also referred to as recall, specificity and precision. In general, the 3-CAT (3 categories) such as normal, early and advanced prediction model demonstrates the highest accuracy as compared to the other models and also, the highest sensitivity as well as specificity. But the precision rate of 2-CAT (2 categories) prediction model is the highest among all the models. Random guessing makes the worst performance manifestation across each specified parameter.

Fig. 6. Distribution of finding labels.

The Fig. 6 represents the frequency of the different finding labels in the dataset and the figure reveals finding labels such as "Atelectasis", "Edema", "Pleural effusion", "Pneumonia", "Consolidation", and "Nodules" in patients with the listed pathologic conditions but this says that "Consolidation", "Nodules" among the listed pathologic conditions are rarely found.

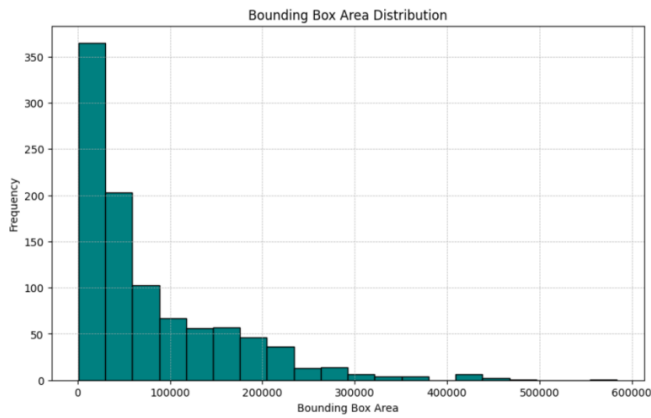

Fig. 7. Histogram.

The Fig. 7 indicates a histogram representing the distribution of bounding field areas. The x-axis suggests the location values, and the y-axis represents the frequency of occurrences. The histogram reveals that most bounding packing containers have regions between zero and 100,000 rectangular pixels, with some outliers having areas above 500,000 square pixels.

Fig. 8. Training and testing accuracy.

The Fig. 8 shows the Training and Validation Accuracy of the DCNN-GAN version's performance across one hundred epochs. Both accuracies rise quickly, suggesting that the model learned rapidly during the early epochs. Around the 20th epoch, schooling accuracy strategies one hundred%, demonstrating the model's right suit to the schooling set. Additionally, testing accuracy increases rapidly but exhibits slight fluctuations, suggesting a small amount of overfitting that eventually stabilizes. Both accuracies plateau and live comparatively regular after the twentieth epoch, with checking out accuracy carefully trailing accuracy, indicating robust generalization to formerly unknown facts. Effective regularization is seen by the small space between the 2 traces, which avoids considerable overfitting. This overall fashion suggests that the model may additionally acquire statistics and generalization from the preliminary dataset with great accuracy in each the validation and education tiers.

Fig. 9. Training and testing loss.

The Training and Testing Loss, shown in Fig. 9. Of the DCNN-GAN version's loss values across 60 epochs. Both losses start high at first, that's indicative of the version's early gaining knowledge of section. As a result of the version's adeptness at getting to know from the schooling information, the training loss drops off speedy, stabilizing around the 20th epoch and staying low. On the alternative hand, the testing loss has a greater complex pattern, first lowering after which experiencing a surge around the 20th epoch before stabilizing. This version indicates that the model had a few overfitting issues and made changes as training went on. The version correctly reduced errors on the training and testing datasets while, after the thirtieth epoch, both losses converge and hold low levels. When a version efficiently lowers mistakes and maintains stability, it is stated to have sturdy generalization overall performance and may produce accurate and dependable predictions whilst implemented to sparkling, untested data.

B. Performance Metrics

To assess a DL model's overall performance in figuring out artery plaques and constriction in X-ray angiography snap shots, essential factors to do not forget are precision, consider, precision, and F1 score. By calculating the percentage of correct high quality and accurate terrible forecasts among all forecasts, accuracy evaluates the version's ordinary correctness. Through expressing the ratio of proper positives to the overall of actual and fake positives, precision suggests how dependable the superb predictions are. Recall, that's often referred to as sensitivity, quantifies the degree to which a model is capable of as it should be pick out actual high-quality scenarios. The ratio of genuine positives to the entire of proper positives and false negatives is used to calculate it. The F1 score strikes a stability between the 2 variables to produce a single statistic that debts for false positives in each case and false negatives: the harmonic average of accuracy and recollect. Collectively, these metrics provide a comprehensive assessment of the version's efficacy, showcasing its accuracy and electricity in diagnosing cardiovascular conditions.

1) *Accuracy*: Accuracy is a measure of the way regularly a ML model predicts a result successfully. Accuracy can be calculated through dividing the entire number of estimates by means of the quantity of accurate forecasts.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (9)$$

2) *Precision*: Precision is a metric that quantifies how regularly a ML model efficiently predicts the nice magnificence. The amount of particular superb forecasts (genuine positives) divided via the whole range of favorable predictions (false and actual fine) that the model properly anticipated can be used to calculate accuracy.

$$Precision = \frac{TP}{TP+FP} \quad (10)$$

3) *Recall*: Recall is a statistic used to describe how often a ML model correctly identifies positive instances, or real positives, out of all the genuine positive examples in the dataset. By dividing the total number of positive instances by the number of true positives, recall may be calculated. The latter includes both true positives (patients who are successfully found) and false negative results (missed cases).

$$Recall = \frac{TP}{TP+FN} \quad (11)$$

4) *F1 score*: The F1 score, often called the F-measure, is the harmonic mean of the accuracy and recall of a classification model. Because both measures have the same weight in the score, the F1 measure appropriately depicts the reliability of a model.

$$F1\ score = 2 * \frac{Precision \times Recall}{Precision + Recall} \quad (12)$$

In Eq. (9), Eq. (10), Eq. (11), and Eq. (12), TP and TN represent true positive and true negative. Whereas, FP and FN represent as False negative and False positive.

TABLE II. PERFORMANCE METRICS

Metrics	Efficiency
Accuracy	98.7%
Precision	98.2%
Recall	98%
F1 score	97.9%

The DCNN-GAN model exhibits remarkable performance metrics in Table II with respect to the detection of heart plaque and stenosis in X-ray angiography pictures. The model predicts outcomes with a 98.7% accuracy rate, which is quite good. With an accuracy of 98.2%, the version detects genuine positives with few false positives. Because the version is so exact at figuring out authentic positives, its excessive take into account charge of 98% ensures that just a few genuine positives are neglected. The model's potential to manipulate inaccurate consequences and false negatives by using balancing accuracy and don't forget is confirmed by way of its F1 rating of 97.9%. Together, those measures show the version's extremely good outcomes and its capacity to substantially boom diagnostic accuracy and

dependability for the identity of cardiovascular illness in scientific settings.

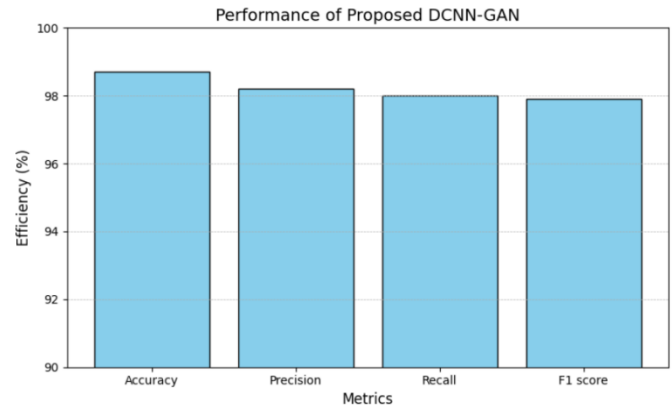

Fig. 10. Performance efficiency of the proposed model.

Fig. 10 shows the effectiveness metrics for a version that recognizes artery plaques and stenosis in X-ray angiography photographs. The 4 number one performance metrics displayed inside the graph are accuracy, precision, consider, and F1 score. The simulation is the maximum accurate forecaster normal, with a 98.7% accuracy fee. The accuracy of 98.2% suggests that the model well recognizes actual positives with a low range of false positives, demonstrating the reliability of the advantageous predictions. The model's keep in mind, which stands at 98%, is quite lower and indicates its accuracy in figuring out actual wonderful instances. The model's capacity to deal with fake positives and false negatives is validated by the F1 rating, which stands at 97.9% and moves a compromise between accuracy and bear in mind. These measures, taken together, highlight the model's strong and remarkable performance and in efficiently figuring out and categorizing cardiovascular illnesses from X-ray angiography images.

TABLE III. PERFORMANCE EVALUATION

Methods	Accuracy	Precision	Recall	F1 score
RCNN	78.3%	78.1%	77.5%	77%
RNN-LSTM	88.4%	88.1%	88%	78.5%
3D-CNN	90%	89.5%	89.2%	88.8%
SVM	82.8%	82.3%	82%	81.5%
Proposed method	98.7%	98.2%	98%	97.9%

The performance parameters of several techniques for detection of coronary artery plaque and stenosis in X-ray angiography pics are shown in Table III. The proposed DCNN-GAN approach performs appreciably higher than the opposite methods. Its famous excellent basic accuracy with an accuracy charge of 98.7%. Its effective ability to discover certainly ideal facts is meditated in a take into account fee of 98%, and an accuracy of 98.2% indicating a very good prediction with a relatively reliable F1 score of 97.9% indicating consumption fake positives and negatives are dealt with correctly with a stability of remember and accuracy. In contrast, 78.3% accuracy is done through RCNN, 88.4% by using RNN-LSTM, 90.0%, and 82.8% by using SVM, all of which aren't reached by using

the proposed method a low F1 score, accuracy, and keep in mind, which confirmed that the proposed technique performs well in those parameters. This suggests that the DCNN-GAN system appreciably improves the sensitivity and efficiency of cardiac diagnosis in addition to presenting extra correct and reliable insights.

Fig. 11. Performance comparison.

The Fig. 11 indicates 4 measures of the efficacy of the diverse strategies in detecting pulmonary fibrosis and fibrosis. The proposed DCNN-GAN approach performs significantly higher than the other techniques. It achieves the very best universal values of round 98.7% accuracy, 98.2% accuracy, 98% recollect and 97.9% F1 score. All measures hover approximately 78%, with RCNN being the worst in evaluation. RNN-LSTM does better but still fall short, its metrics are around 88%. SVM scores approximately 82%, whereas the 3D-CNN approach performs competitively with nearly 90% for all measures. When compared to conventional approaches, the suggested method's evident superiority shows how robustly and correctly it can detect cardiovascular problems, greatly increasing diagnostic effectiveness. This demonstrates how the suggested approach may enhance clinical results in the identification and treatment of cardiovascular disease.

C. Discussion

Previous research on X-ray angiography-based coronary artery plaque and stenosis identification has encountered problems with noise, artifacts, and image quality, all of which harm the effectiveness of classifiers and accuracy in diagnosing [23]. These difficulties frequently cause the extraction of features and methods for preprocessing to be less successful, producing less dependable findings. These drawbacks are addressed by the suggested DCNN-GAN methodology, which incorporates deep learning methods to improve data robustness and framework dependability. While the DCNN product is extraordinary in correct function extraction, the GAN product offers artificial pix with varying quantities of noise distortion. This combined method gives the approach's potential to deal with optical differences so its use in diverse situations in medication is extremely good [24]. The technique retains outstanding results regardless of low-quality inputs since it was trained on a wide dataset of artificial and high-quality pictures. Subsequent research has to cognizance on increasing the adaptability of the DCNN-GAN machine to exclusive scientific settings and imaging modalities. Analysis of multidimensional data integration in essential modalities (e.g., combination of X-

rays with CT or MRI) and improvement of methods that can potentially modulate noises in energetically may also be vital to boom manner readability and doctor recognition and self-belief. Adoption and improvement of the machine may be based on partnerships with healthcare centers to provide greater range of statistics, promote computerized cardiovascular ailment, and beautify results for patients.

VI. CONCLUSION AND FUTURE WORKS

This proposed DCNN-GAN framework seems to perform very well in identifying the statuses of coronary artery plaque in X-ray angiography images, solving the problem of previously used approaches. Since, DCNN is optimal for function extraction and GAN for data augmentation the model is able to handle fluctuations in image quality, presence of noise and artifacts which is usual in medical images. The performance measurements, including the test accuracy that is 98.7%, precision 98.2% and recall 98%, corroborates the model productivity in providing accurate diagnostic results to further improve cardiovascular diseases diagnosis and early diagnosis. Besides enhancing the ability of doctors to diagnose their patients more accurately, this approach enhances the reliability and dependability of automatic systems being used in clinical practice.

Further, there is significant possibility for the development of DCNN-GAN model for other imaging modality like CT-MRI and by the application of the more comprehensive multiple dimension data for diagnosis. More studies could be conducted on the novel methods of dealing with dynamic noise levels and image distortions in real-time that would make the model more flexible for implementation in different clinical settings. Further cooperation with healthcare centers would be important in order to gather more varied and exhaustive information about patients, to let the model perform better throughout different individuals and diseases. Also, improved understanding of processes that enable real-time decision making and diagnostic accuracy through further enhancing of the model can contribute to widespread adoption of automated cardiovascular diagnostics into practice, which will benefit patient outcomes and decrease the time lapse before diagnosis. Implementation of such systems would dramatically change management of cardiovascular diseases with an ability to intervene at an early stage and potentially address heart diseases on a much bigger scale.

Abstract—In the current research, the application verification of traditional algorithms in actual accounting management is insufficient, and deep learning data processing capabilities need to be fully optimized in complex accounting scenarios. Given the challenges of efficiency and accuracy faced by the current accounting industry in the context of big data, this study creatively combines the swarm intelligence algorithm and deep learning technology to design and implement an efficient and accurate accounting automation management system. The research aims to investigate the potential of swarm intelligence algorithms and deep learning techniques in developing an automated accounting management system, with a focus on improving efficiency, accuracy, and scalability. Key research questions include exploring the optimal configuration of swarm intelligence algorithms for accounting tasks and assessing the performance of deep learning models in automating various accounting processes. Through experimental verification, the system is tested with the financial data of a large enterprise for three consecutive years. The results show that the system can significantly shorten the time of financial statement generation by 65%, reduce the error rate to less than 0.5%, and increase the accuracy of abnormal data recognition by as much as 90%. These data not only reflect the significant improvement of the efficiency and accuracy of the system but also prove its great potential in early warning of financial risk, providing intelligent and automated solutions for the accounting industry.

Keywords—Swarm intelligence algorithm; deep learning; accounting; automation management

I. INTRODUCTION

In today's wave of digital transformation, the accounting industry faces unprecedented challenges and opportunities [1, 2]. Traditional accounting processes, including data entry, account reconciliation, financial statement generation, etc., often rely on manual operations, which are time-consuming, labor-intensive, and prone to errors [3]. With the rapid development of big data, artificial intelligence, and other technologies, the emergence of accounting automation management systems provides new ideas and possibilities for solving these problems. Among them, the integration and application of swarm intelligence algorithms and deep learning technology are becoming a research hotspot in accounting automation management, opening up a new path for realizing the intelligence and automation of accounting work [4, 5].

Swarm intelligence algorithms, such as the ant colony algorithm and particle swarm optimization algorithm, are optimization algorithms that imitate the behavior of biological swarms in nature and have strong global search ability and robustness [6, 7]. In accounting automation management, swarm intelligence algorithms can effectively deal with complex decision-making problems, such as financial forecasting, cost control, etc., and find the optimal or approximately optimal solution by simulating the collaboration and competition of swarms [8]. Deep learning, as an essential branch of artificial intelligence, can automatically learn features from massive financial data through its powerful data processing and pattern recognition capabilities, realize automated account classification, anomaly detection, and other functions, and significantly improve the efficiency and accuracy of accounting work [9, 10].

However, there are still many challenges in applying swarm intelligence algorithms and deep learning technology to design accounting automation management systems [11]. How to design a reasonable algorithm model to adapt to the complexity and diversity of accounting data; How to ensure the stability and robustness of the algorithm and avoid decision-making errors caused by data fluctuations; How to realize the effective use of data on the premise of protecting data privacy is an urgent problem to be solved [12, 13]. In addition, developing and applying an accounting automation management system also involves compatibility with existing accounting software, user interface design, system security, and other issues, which require interdisciplinary knowledge and skills [14]. While there has been significant progress in the development of accounting automation systems, there are still several challenges and limitations that remain unaddressed. For instance, existing systems often lack the flexibility and scalability to handle complex accounting tasks and large datasets efficiently. Additionally, many systems rely on traditional rule-based approaches, which may not be well-suited for the dynamic and unpredictable nature of accounting data. In this paper, we propose a novel accounting automation management system based on swarm intelligence algorithms and deep learning techniques that aims to address these limitations and fill the existing gap in the field. Our system leverages the strengths of swarm intelligence for optimization and deep learning for pattern recognition, enabling it to handle complex accounting tasks with high accuracy and efficiency.

The purpose of this study is to deeply explore the key technologies and methods of accounting automation management system design based on swarm intelligence algorithm and deep learning and propose an efficient, intelligent, and safe accounting automation management solution through theoretical analysis and empirical research to provide theoretical guidance and practical reference for the digital transformation of the accounting industry. This research will focus on the following contents: First, analyze the application potential and limitations of swarm intelligence algorithm and deep learning in accounting automation management; The second is to design and implement the prototype of an accounting automation management system based on swarm intelligence algorithm and deep learning, and evaluate its performance and effect; The third is to put forward the algorithm optimization strategy according to the characteristics of accounting data to improve the intelligence level of the system; The fourth is to discuss the challenges and countermeasures of accounting automation management system in practical application, and provide direction for future research and practice.

The design and research of accounting automation management systems based on swarm intelligence algorithms and deep learning is not only an essential direction of technological innovation in the accounting field but also a key force in promoting the digital transformation of the accounting industry. Through this study, we expect to provide new ideas and methods for developing and applying accounting automation management systems, promote the intelligence and automation process of the accounting industry, and provide more powerful and intelligent tools for enterprise financial management and decision support. In the following part of this article, we will delve into the design and implementation of an accounting automation management system based on bee colony intelligence algorithms and deep learning technology. In Section II, we will first introduce the theoretical background and the research related to the research on accounting automation management strategy based on swarm intelligence algorithm, and then describe in detail the system architecture and method we propose in Section III. In Section IV, we will present the results of the experimental evaluation, demonstrating the effectiveness and efficiency of our system. Finally, in Section V, we will discuss the significance of our findings and suggest directions for future research. The paper is concluded in Section VI.

II. RESEARCH ON ACCOUNTING AUTOMATION MANAGEMENT STRATEGY BASED ON SWARM INTELLIGENCE ALGORITHM

A. Ant Colony Algorithm

Social insects in nature, such as ants, show strong adaptability and flexibility and cooperate to complete tasks such

as foraging and nesting by releasing up to 20 kinds of pheromones. These pheromones provide a means of navigation and communication for ants with limited vision, especially playing a key role in finding pathways back to the nest and dividing labor and cooperating [15]. Inspired by the social behavior of ants, scientists have developed ant colony algorithms, which provide new ideas for solving complex problems by simulating the action mechanism of pheromones. Years of studies have shown that ants can secrete a substance that affects the environment, promotes mutual communication or perceives environmental changes, namely pheromones. This discovery has deepened our understanding of ants' environmental interaction mechanisms [16, 17].

Imagine an ant facing two paths around obstacles. Because there is no former pheromone to guide it, it chooses randomly. During walking, ants release pheromones, which provide a selection basis for subsequent ants. Subsequently, ants are more inclined to choose the path with high pheromone concentration and supplement pheromone at the same time, and the pheromone concentration will naturally decay with time [18, 19]. Through the continuous selection and pheromone update of colony ants, pheromone space is formed to guide ants in making decisions.

The ant colony algorithm is based on an abstract model, which is shown in Fig. 1. Ants communicate and obtain environmental information through pheromones and perform tasks independently. The model assumptions include the following: environmental changes have feedback on ants; Pheromone is a medium for ants to communicate and obtain environmental information; Except for pheromones, behaviors are independent of each other and are not directly affected by other ants. The primary challenge of applying an ant colony algorithm is to transform the problem into an understandable form of an ant colony; that is, the problem needs to be properly described. After the description, an algorithm model based on the pheromone decision mechanism is developed. As the basis of ant communication and organization, the pheromone must simulate the use of the pheromone in the algorithm to guide ants' exploration path, just like real ants foraging and obstacle avoidance [20]. Renewal of pheromones directly controls ant colony behavior.

In applying the ant colony algorithm, heuristic information is defined as the basis of ant decision-making, which usually reflects prior knowledge. For example, in the traveling salesperson problem, the heuristic information is the reciprocal of the path distance. The longer the path, the smaller the information value, which affects the ant transition probability. Its calculation formula is shown in Eq. (1). In network problems, heuristic information correlates delay, bandwidth, and packet loss rate to guide the algorithm in finding the path that conforms to the network characteristics.

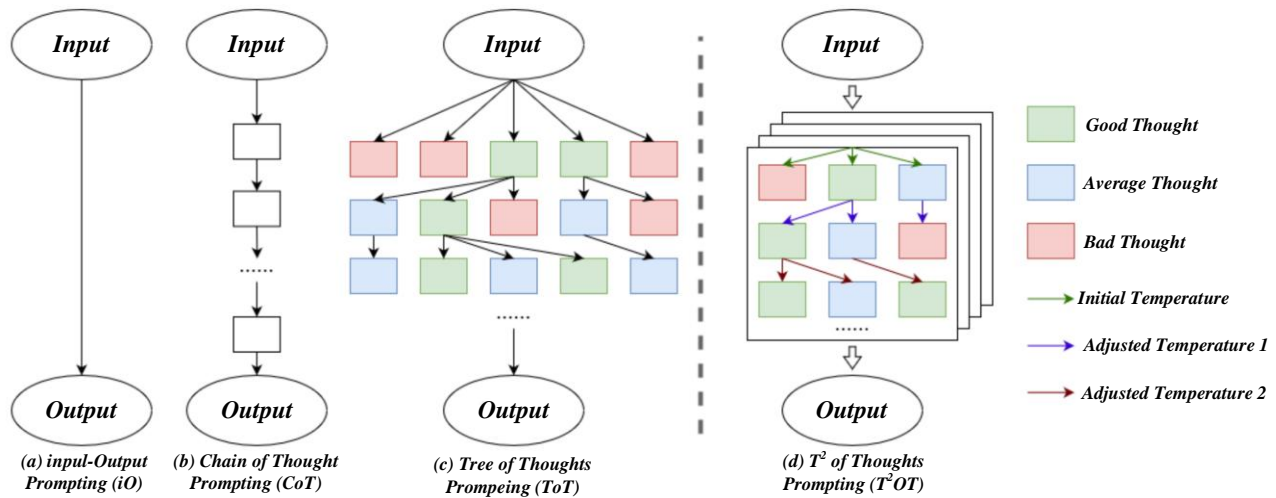

Fig. 1. Ant colony algorithm model.

$$p_{ij}^k = \begin{cases} \frac{[\tau_{ij}]^\alpha [\eta_{ij}]^\beta}{\sum_{j \in allowed_k} [\tau_{ij}]^\alpha [\eta_{ij}]^\beta}, j \in allowed_k \\ 0, otherwise \end{cases} \quad \Delta\tau_{ij}^k = \begin{cases} Q / L_k & Ki \text{ to } Kj \\ 0, & other \end{cases} \quad (5)$$

In Eq. (1), η_{ij} represents the heuristic information of the link (i, j) , τ_{ij} represents the pheromone concentration of the link (i, j) , and $allowed_k$ represents the set of nodes that ant k can transfer to in the next step, α and β have the influence coefficients representing the pheromone concentration τ_{ij} and the heuristic information η_{ij} of network link (i, j) , respectively. At the initial time, the pheromone concentration between each path is the same, and $\eta_{ij}(t)$ of the molecule is the heuristic information from node i to node j . Its expression is $\eta_{ij}(t) = 1/d_{ij}(t)$, where d_{ij} is the Euclidean distance between node i and node j , and the expression is Eq. (2):

$$d_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \quad (2)$$

(x_i, y_i) is a heuristic factor representing the relative importance of pheromone concentration; (x_j, y_j) is the visibility heuristic factor. The ant determines the next position by calculating the path transition probability and applying the wheel gambling method. After completing a round of searching, the path length is evaluated, and the shortest path is identified. Subsequently, the pheromone is updated according to the principle of "volatilization-release," as shown in Eq. (3) and Eq. (4).

$$\tau_{ij}(t+1) = (1-\rho) * \tau_{ij}(t) + \Delta\tau_{ij}^k \quad (3)$$

$$\tau^k = \sum_{k=1}^m \Delta\tau_{ij}^k \quad (4)$$

Where ρ is the pheromone volatilization factor, and the value range is $\rho \in [0, 1]$; m represents the number of ant colonies. Equation (5) represents the amount of pheromone left by all ants in the current search process, where the pheromone left by each ant in the current iteration process can be expressed as:

Among them, Q is a constant, which represents the total amount of pheromone that can be released in one search process of ant pheromone; L_k represents the total length of the path traveled by ant k in this cycle, and K_i to K_j represents a range sequence.

B. Drosophila Algorithm

Set the population size (popsize) and the maximum number of iterations (maxgen). Among them, $(X_{axis}; Y_{axis})$ represents the two-dimensional coordinates of each individual in the fruit fly community, LR represents the position range of the fruit fly population, and the mathematical expression of the initial position is as follows (6)-(7):

$$X_{axis} = rand(LR) \quad (6)$$

$$Y_{axis} = rand(LR) \quad (7)$$

$rand$ is a function used to generate random numbers. When individuals in the community search for food, their flight direction and distance are random. The following expression represents the new position when the fruit fly i flies to the next moment, as shown in Eq. (8)-(9):

$$X_i = X_{axis} + rand(FR) \quad (8)$$

$$Y_i = Y_{axis} + rand(FR) \quad (9)$$

FR denotes the range of a single flight, and $axis$ refers to the straight line in the coordinate system. Because the specific location of the food source is unknown, first use the following formula to calculate the distance $Dist_i$ of the individual fruit fly from the origin:

$$Dist_i = \sqrt{X_i^2 + Y_i^2} \quad (10)$$

Then, the taste concentration determination value S_i is calculated by the following Eq. (11):

$$S_i = 1 / Dist_i \quad (11)$$

Fitness refers to the quality or quality measure of a solution. The taste concentration value $Smell_i$ of each individual in the current population is expressed by the following Eq. (12):

$$Smell_i = fitness(S_i) \quad (12)$$

C. Ant Colony Algorithm for Path Preprocessing of Drosophila Algorithm

When the traditional ant colony algorithm searches the path, the node traversal probability is equal, leading to a blind search in the initial stage [21]. In order to solve this problem, the Drosophila algorithm is introduced to pre-plan the path, which is transformed into the pheromone required by the ant colony algorithm, and the ant colony algorithm is guided to avoid blind search, reduce node traversal, and shorten the running time [22]. After pre-planning, the ant colony algorithm optimizes the search on this basis.

According to the requirements, FOA (Fruit Fly Optimization Algorithm) is first used for path preprocessing, and then the preprocessed path is converted into a pheromone, which is imported into the ant colony algorithm (ACO). The calculation formula is shown in Eq. (13).

$$\tau(i, j) = \tau^s(i, j) + \Delta\tau^B(i, j) \quad (13)$$

Where $\tau(i, j)$ represents the pheromone concentration from node i to node j , $\tau^s(i, j)$ is the original pheromone from node i to node j , and $\tau^B(i, j)$ refers to the pheromone increment from node i to node j converting the results of FOA search.

The ant uses the roulette method and selects the next node according to the formula. After the algorithm is finished, the pheromone is updated, and a portion is added and volatilized. After each generation of ants iterates, the paths are compared, and the shortest path is determined when the set number of iterations is reached.

III. DESIGN OF ACCOUNTING AUTOMATION MANAGEMENT SYSTEM BASED ON SWARM INTELLIGENCE ALGORITHM AND DEEP LEARNING

A. Deep Learning Neural Network Technology

In the study, the performance and effectiveness of the accounting automation management system were evaluated in depth, and the comprehensive functionality, data accuracy and operational efficiency of the accounting automation management system were compared with popular accounting and financial software solutions in the market (such as QuickBooks, Xero, SAP, Oracle Financials and Kingdee, which may include other software) in order to fully verify the performance of the system in the real financial environment. To achieve this assessment, the accounting automation management system was systematically integrated with the above-mentioned software and extensive testing and data analysis were implemented. In terms of text processing of accounting sheets, special attention is paid to text records

containing complex information such as equipment numbers, timestamps, exception reports, etc., and through preprocessing (including text segmentation, data cleaning, format standardization) and feature extraction (using bag-of-word model BoW, word frequency-inverse document frequency TF-IDF, N-gram model and word embedding technology, etc., the word embedding technology effectively solves the problems of dimensional disaster, data sparsity and semantic loss caused by high-dimensional data by mapping words or phrases to real low-dimensional vectors [25]), which successfully extracted critical information, which was critical for subsequent root cause analysis and ticket recommendations [23, 24]. In addition, the autoencoder (AE) deep learning technology is introduced to compress the high-dimensional input data into the low-dimensional feature vector space by using its powerful feature extraction ability [26], and the applications of denoising autoencoder (to enhance the robustness of the model), sparse autoencoder (to improve the compression ratio and learn the data structure), and variational autoencoder (to maximize the probability of data sample union, optimize the model parameters and hidden variables a posteriori, and endow the model generation ability and latent distribution simulation ability) are explored.

Neural network attention is introduced into the design of an accounting automation management system, which makes the network automatically focus on crucial information and improves its performance and interpretability. It is divided into three categories: soft attention (global), intricate attention (local), and self-attention (internal attention) [27, 28]. Soft attention calculates the weights based on similarity, utilizing all the input information, but it is computationally heavy. Intricate attention focuses on local areas, reduces computation, and conforms to visual characteristics but may ignore critical information. Self-attention considers inter-input and inter-output relationships and enhances long-distance dependency and structure capture. Principle of attention mechanism: When generating output, the model selectively focuses on relevant parts of the input according to the context, assigns different weights, optimizes information coding, and improves accuracy and robustness. The steps include calculating weights, such as dot product, additivity, self-attention, etc.; Apply weights to the weighted average or splice the inputs; Update the output, direct output, or further process.

In order to optimize the feature extraction capability, this study applies convolution operation to graph structure to realize graph data feature learning and classification. Unlike CNN in regular grid processing, GCN (Graph Convolution Networks) is good at unstructured graph data. The advantages are that it deals with complex graph structures and has good interpretability and visualization. The adjacency matrix expresses the graph structure, vectorizes node and edge features, and updates the features by convolution. Through the operation of the adjacency matrix and node feature matrix, feature aggregation and transfer are realized, and local features are extracted by convolution, similar to CNN. GCN also contains pooling operations for dimension reduction and feature abstraction of graph data.

B. Model Building

Automated accounting analysis aims to quickly and accurately identify and solve system failures and improve

system stability and reliability. Analysis methods are divided into traditional and machine learning categories. Traditional methods rely on manual system performance analysis or use tools such as FMEA to identify anomalies. However, their ability to process large-scale data and quickly locate anomalies is limited and error-prone [29, 30]. The machine learning method builds a model by analyzing the system structure and historical data and automatically identifying anomalies' root causes. It has the advantages of processing massive data, quickly analyzing, and automatically adjusting the model to improve accuracy and real-time response, significantly superior to traditional manual methods.

The model is shown in Fig. 2. First, the preprocessed node data is vectorized for model training. The words in the node are split into characters, and a 70-dimensional hot encoding represents each character. The encoding table contains 26 letters, ten digits, 33 unique characters, and line breaks. Each node is transformed into a matrix of 70. Excessively long characters are truncated, and more characters should be filled with zero vectors. The encoding order starts from the last character, which is convenient for the weight association of fully connected layers. The vectorized node data is input into the model training. The model contains nine layers of neural network: 6 one-dimensional convolutional layers and three fully connected layers. A maximum pooling layer follows the first, second, and last convolutional layers. In the model, the kernel size of the first two convolution layers is 7, the core size of the last four layers is 3, each layer has 256 kernels, and the size of the pooling layer is 3. The node data outputs a 1008×256 feature map through the first convolutional layer. After the first pooling layer, the feature map size is 336×256 .

Text feature extraction only uses work order data, ignoring the relationship between nodes. GCN model can handle graph structure, learn nodes and relationship features, and be used for root cause analysis. GCN training requires node features and an adjacency matrix. The feature extraction method is the same as before, and the top 200 high-frequency words are selected. The adjacency matrix represents the node relationship, and the weight is the number of occurrences of dependent paths in the historical work order description. GCN consists of two graph convolutional layers and a fully connected layer. Node features and adjacency matrix input convolutional layer, activated by ReLU, and fully connected layer and SoftMax output node features. The node features and graph features extracted from the text are used to match the abnormal root causes of the work

order. Preprocess the exception description of the current work order, convert it into a character-level vectorized representation, and obtain the work order feature vector. By calculating the comprehensive similarity between the work order and the node, the node with the highest similarity is selected as the abnormal node. The root cause analysis is output by classification, and the similarity between the work order and each node is given, and the probability of abnormal nodes is calculated accordingly.

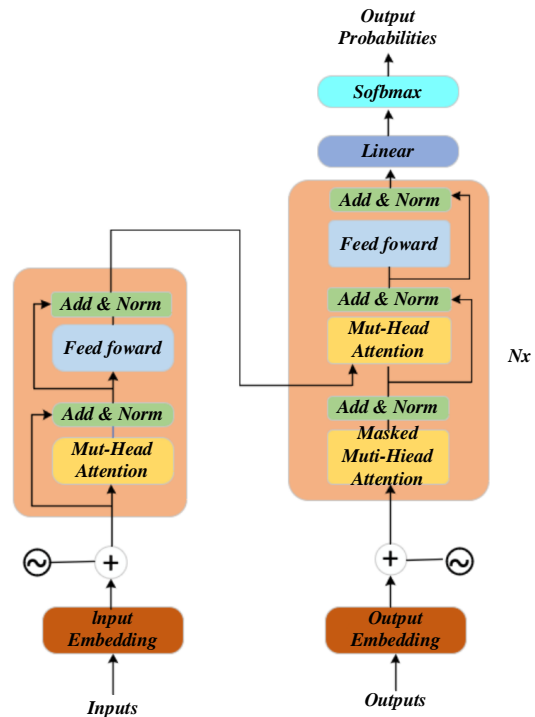

Fig. 2. Input data processing model.

IV. EXPERIMENTAL RESULTS AND ANALYSIS

Fig. 3 compares the algorithm's performance at a confidence level of 90%. The model based on swarm intelligence algorithm and deep learning performs outstandingly in two-thirds of the dimension of ROC, thanks to its utilization of second-order difference information, which improves search efficiency. The algorithm also has advantages in the extreme dimensions of ES and entropy. The model continues to show competitiveness at higher confidence levels (95%, 97.5%, 99%).

Fig. 3. Model results.

Fig. 4. Results at different confidence levels.

In Fig. 4, the HV value based on the swarm intelligence algorithm and deep learning model is the highest, and the second-order differential evolution operator effectively broadens the frontier of the Pareto solution set and enhances the extensibility of understanding. Table I shows that GBDT is the best among traditional methods but not as good as deep learning. CharCNN-based TicketRCA is better than CNN and RNN models. Due to the lack of a timing series of work order data keywords, models such as TextCNN are limited. CharCNN character-level representation is better. After the combination of GCN, TicketRCA root cause analysis is significantly improved, proving that the graph model is adequate. Although TicketMining and NetSieve are better than traditional machine learning, they are not as good as TicketRCA, indicating that deep learning can better extract text features.

In Fig. 5, Four strategies construct the anchor node table: the top 100 is selected by degree sorting, the top 100 by PageRank sorting ($d = 0.9$), and 100 is randomly selected. The joint

strategy combines the top three in a ratio of 4: 4: 2 (degree sorting 40, PageRank 40, random 20). Experiments show that the accuracy of degree ranking and PageRank strategy is similar. The stochastic strategy also performs similarly, and the joint strategy has the highest accuracy, indicating that the combination of centrality and random noise is beneficial to improve the node classification performance.

In the ablation experiment, the joint strategy is used to construct the anchor node table and generate the subgraph sequence. Fig. 6 shows that the complete model samples ten anchor nodes and distances, three neighbors and relationships, one self-node, and a self-ring edge. The ablation model does not sample anchor nodes, neighbors, self-nodes, and self-ring edges. The complete model is better than the Transformer, which samples the whole graph. In ablation, unsampled anchor nodes have the most significant influence, followed by neighbors, and self-nodes and self-ring edges have less influence.

TABLE I. MODEL COMPARISON OF RESULTS

	Accuracy	Precision	Recall	F1-score
SVM	0.3311	0.2717	0.3311	0.2706
DecisionTree	0.3872	0.2519	0.3872	0.2904
RandomForest	0.3971	0.3014	0.3971	0.3179
GBDT	0.5214	0.4488	0.5126	0.4642

Fig. 5. Comparison of node classification accuracy of anchor node sampling methods based on different strategies.

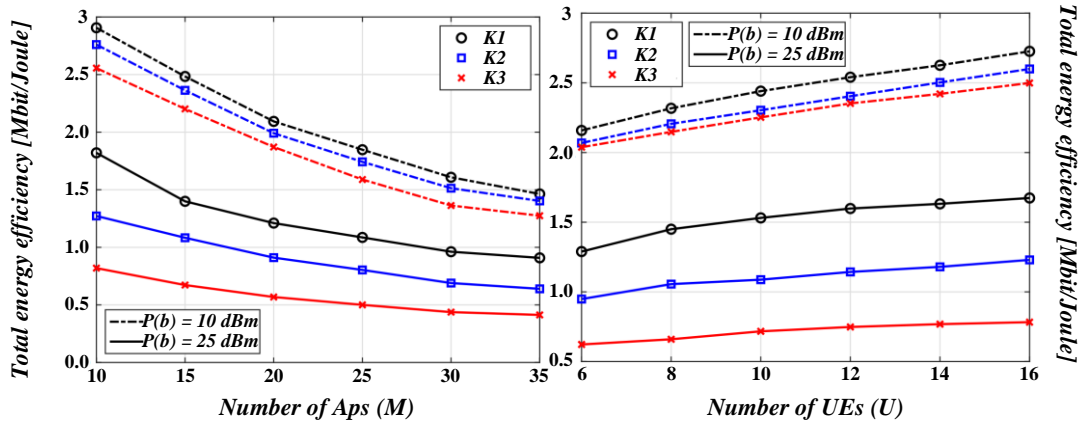

Fig. 6. Comparison of node classification accuracy based on different sampling objects.

The hyperparameter analysis is shown in Fig. 7. The data set performs best when the anchor node table size is 100 and 10 anchor nodes are sampled. Increasing the number of anchor nodes usually improves accuracy, but performance degrades after more than 10-20. The performance is optimal when the anchor node table size is 100. In order to improve system performance, more anchor nodes are needed to cover a wide range of knowledge fields due to the vast number of entities and relationships. When using large and complex data sets, it is necessary to build a larger anchor node table, sample more anchor nodes, and select appropriate strategies to ensure representativeness and improve model performance and robustness.

Fig. 8 shows the impact of the number of convolution kernels on predictive analysis. Using a data set with rich relationship types, its 237 relationships are denser. The results support the conjecture. more convolution kernels and high-dimensional relational embeddings improve performance. Since 128-dimensional embeddings cannot fully describe features, high-dimensional embeddings require broad convolution support.

Fig. 9 shows that on the sparse graph, the experimental results decrease by 5% and 9%, respectively, highlighting the improvement of the method in prediction accuracy. Removing both mechanisms significantly decreased accuracy. The embedding quality may only depend on the relationship

embedding of small graphs near the target node. One-hop relationship is more important than neighbor nodes. Rich relationship types generate more combinations and provide nodes with more expressive subgraph features. Two-dimensional convolution and Transformer encoder fuse relationships and node embeddings. Therefore, compared with FB15k-237, which has 20 times more types of relationships, the performance degradation of WN18RR is more evident without these two modules.

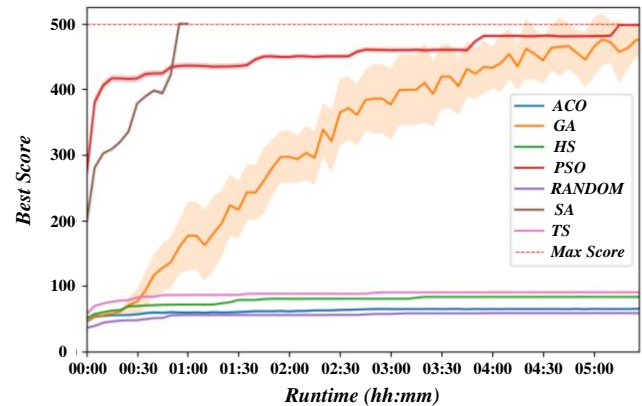

Fig. 7. Hyperparameter analysis.

Fig. 8. Effect of the number of convolution kernels on predictive analysis.

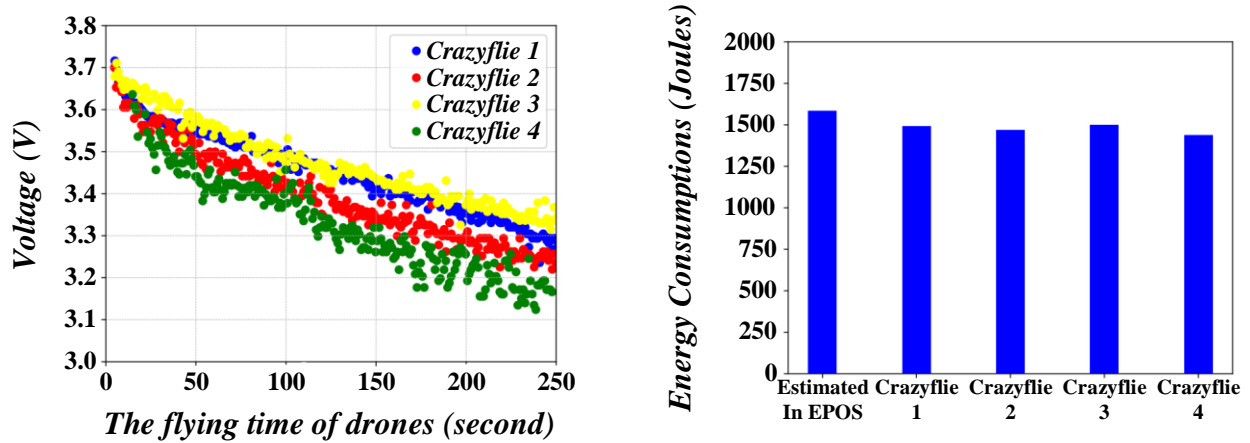

Fig. 9. Experimental results of sparse graph.

Fig. 10 shows that the AUC values of all models exceed 0.5, indicating that the prediction is better than a random guess and has data fitting ability for M&A prediction. The linear regression AUC value is high, but the F1 score is lower than that of decision tree regression, reflecting its foundation and low robustness. The logistic regression AUC reached 0.65, which was the best performance, thanks to the non-linear fit. The decision tree regression AUC was only 0.551, which was poorly fitted. AdaBoost boosts AUC but is limited by weak classifier performance. Through high-dimensional mapping and the kernel trick, the AUC of SVM is 0.014 higher than AdaBoost's. The overall effect of the machine learning method is not good, mainly due to insufficient capture of M&A data distribution information. Baseline performed the worst among the deep learning models, with an AUC of about 0.5. LSTM is significantly improved, AUC super logistic regression 0.04, good at long sequence data, capturing data connections. The model proposed in this paper has an AUC of 0.721, the best

ACC and F1Score, which are 0.071 and 0.031 higher than logistic regression and LSTM, respectively, indicating that it can effectively fit the prediction data and achieve accurate prediction.

Fig. 11 shows the loss curve of the ablation experimental model, which intuitively reflects the prediction accuracy. The AUC value of AttDNN was 0.721, with the largest area of the ROC curve, followed closely by LSTM, with a difference of 3.1 percentage points in AUC values. Logistic regression AUC is higher and marked yellow. The AUC of linear regression, decision tree, AdaBoost, and SVM are low, the prediction effect is poor, and the ROC curves almost coincide. As the basic algorithm of deep learning, the Baseline lacks a regularization layer and attention mechanism training. Its ROC curve is close to the (FPR = 1, TPR = 1) connection of random guess, and the prediction effect is equivalent to random.

Fig. 10. Results of ablation experiment.

Fig. 11. Loss curve of ablation experimental model.

V. DISCUSSION

Our results demonstrate the effectiveness and efficiency of our proposed system in handling complex accounting tasks and large datasets. However, there are still several challenges and limitations that need to be addressed in future work. For instance, while our system has shown promising performance in controlled environments, its robustness and scalability in real-world scenarios remain to be tested. Additionally, there is a need for further research on the integration of our system with existing accounting software and platforms to facilitate seamless adoption and use. In conclusion, our work represents a significant step forward in the field of accounting automation, and we believe that it provides a solid foundation for future research and development efforts.

VI. CONCLUSION

In the context of the digital transformation of the accounting industry, this study creatively combines a swarm intelligence algorithm with deep learning technology to design and develop an intelligent accounting automation management system that aims to address the limitations of traditional accounting management in big data processing.

By applying swarm intelligence algorithms and deep learning technology to accounting automation management, this study significantly improves the efficiency and accuracy of accounting work and enhances the ability to detect early warnings of financial risk. Experimental data show that the system's efficiency in processing financial statements has increased by 65%, mainly due to the optimization path of the swarm intelligence algorithm and the intelligent analysis ability of deep learning, which significantly shortens the data processing cycle.

This study provides an intelligent and automated solution for the accounting industry, and the accuracy rate is greatly improved. The error rate is reduced to less than 0.5%, indicating that the system can effectively identify and reduce human errors when processing complex financial data, significantly improving the accuracy of data processing.

Through continuous training of deep learning models, the system's recognition accuracy of abnormal data has reached

90%, providing strong technical support for financial risk early warning and effectively reducing potential financial risks.

This study designed an accounting automation management system based on swarm intelligence algorithms and deep learning, which is expected to improve accounting processes' efficiency and accuracy significantly. However, this study has limitations: the system was only tested in a controlled environment, and the experimental dataset cannot cover all accounting task scenarios. Subsequent research requires more extensive testing in real-world scenarios, using more diverse datasets and further exploring integration with existing accounting software platforms to develop complex swarm intelligence algorithms and deep learning models to enhance system performance.

Enhancing Road Safety: A Multi-Modal Drowsiness Detection System for Drivers

Guirrou Hamza¹, Mohamed Zeriab Es-Sadek², Youssef Taher³

ENSAM, Mohammed V University Rabat, Morocco^{1,2}

Centre of Guidance and Planning of Education Rabat, Morocco³

Abstract—Driver drowsiness is a major contributing factor in road accidents, emphasizing the need for enhanced detection measures to improve car safety. This paper describes a multi-modal fatigue detection system that uses data from an internal camera, a front camera, and vehicle factors to reliably assess driver alertness. The technology outperforms traditional methods in terms of detection accuracy by utilizing powerful machine learning algorithms. Simulation and real-world tests show considerable improvements in reliability and performance. This integrated strategy offers a promising alternative for reducing the dangers associated with driver weariness and improving overall traffic safety.

Keywords—Component; fatigue detection; drowsiness monitoring; ADAS

I. INTRODUCTION

The rising number of traffic accidents due to driver drowsiness poses a significant threat to worldwide vehicle safety. Drowsiness decreases reaction times, alertness, and decision-making abilities, potentially leading to serious consequences. According to World Health Organization study, drowsy drivers cause up to 30% of road accidents [1]. Despite advances in car safety systems, detecting and reducing driver drowsiness remains a major concern. Existing systems frequently rely on a single data source, such as driver monitoring cameras or vehicle behaviour analysis, which may not provide a complete picture of the driver's state.

This study overcomes this limitation by creating a multi-modal sleepiness detection system that combines data from an interior camera, a front camera, and a variety of vehicle factors. The inside camera catches the driver's facial expressions and eye movements, which provide direct indications of weariness. The front camera detects the vehicle's position relative to road markings and other cars, providing contextual information about the driving environment. Furthermore, vehicle data, such as steering patterns, speed variations, and lane deviations, contribute to a thorough evaluation of driver behavior and potential sleepiness signs.

By combining these disparate data streams, the proposed system intends to improve the accuracy and reliability of sleepiness detection, thus enhancing overall traffic safety. This paper describes how the integrated system was designed, implemented, and evaluated. It begins with an overview of sleepiness labeling and monitoring technologies, followed by data collection and specification in accordance with norms and regulations. Next, the system architecture and feature extraction algorithms are given. The report also explains the detection

algorithms used to process data and generate alerts, as well as the system integration and real-time operation techniques.

The system's performance is confirmed by simulation and real-world testing, which show considerable gains in detection accuracy over typical single-modality systems. The findings highlight the system's potential to improve automobile safety and enable better driving experiences. Finally, the consequences of these findings for vehicle safety are examined, and ideas for further research are suggested.

II. INSTRUMENTATION AND DATA COLLECTION

A. Drowsiness Labeling

Drowsiness is classified in a variety of ways, including subjective and objective measures. The Karolinska Sleepiness Scale (KSS) is the most commonly used tool. Participants rated their drowsiness on a scale of 1 (very awake) to 9 (extremely drowsy, fighting sleep). The KSS is known for its simplicity and rigorous validation, making it a dependable tool in both research and therapeutic settings. Another popular subjective measure is the Stanford Sleepiness Scale (SSS), which asks people to score their sleepiness on a scale of 1 (feeling active and vital) to 7 (no longer fighting sleep, sleep onset imminent) [2].

Other scales are the HFC Drowsiness Scale, Epworth Sleepiness Scale (ESS), Johns Drowsiness Scale (JDS), Observer Rating of Drowsiness (ORD), and Subjective Drowsiness Rating (SDR). The HFC sleepiness Scale, ORD, and SDR use external labelling methods, in which an observer assesses the subject's sleepiness based on observable behaviors and physical indications. In contrast, the ESS is a self-administered questionnaire that assesses an individual's proclivity to fall asleep in a variety of scenarios, providing a total score indicative of general daytime drowsiness. The JDS is unique in that it relies on physiological signs, such as eye movements, blink rate, or brain activity, to objectively quantify drowsiness.

The KSS was chosen as the major instrument for sleepiness labelling in this study because of its ease of use and solid validation record. The KSS allows participants to easily and reliably self-assess their state of drowsiness, giving a strong and trustworthy indicator to support the study's aims.

B. Drowsiness Monitoring

Driver sleepiness detection strategies include a wide range of physiological [3], behavioral [4], and vehicle-based approaches [5], each with differing levels of intrusion and accuracy. Physiological approaches such as

electroencephalography (EEG), electrocardiography (ECG), electromyography (EMG), and electrooculography (EOG) are highly accurate because they detect early signs of drowsiness. In this study, ECG data will be collected with self-reported participant assessments to provide precise baseline measures of sleepiness levels in a controlled environment. This combination provides an excellent paradigm for evaluating drowsiness using both subjective and objective inputs.

The fundamental goal of this research is to combine behavioral and vehicle-based detection algorithms to increase overall accuracy and solve edge circumstances that may be difficult for a single modality. Eye movements, facial emotions, and head position are among the indications used in behavioral analysis. Although these procedures are less physically intrusive than physiological measures, their relationship with monitoring raises issues about psychological intrusiveness. Typically, behavioural detection uses cameras and deep learning algorithms to diagnose sleepiness states based on data including blink duration, blink frequency, percentage of eyelid closure (PERCLOS), yawning, and head posture. Eye movement-based tests are especially effective because of their high association with tiredness.

Vehicle-based approaches are used in addition to behavioural detection to capture driving information such as lane position, steering wheel movements, acceleration patterns, and pedal usage. Steering wheel movement and lane-keeping performance are commonly investigated measurements, with conflicting results about their relative accuracy in diagnosing drowsiness. Vehicle-based procedures are most effective in locations with clear road markings and favorable weather conditions, but they are often less dependable than physiological or behavioral measures when used alone.

The combination of behavioral and vehicle-based methods takes advantage of the strengths of both approaches. Behavioural methods provide extensive, real-time insights into the driver's state by continuously monitoring facial and ocular traits, whereas vehicle-based methods provide a practical, non-intrusive way of evaluating driving performance. By combining these modalities, the proposed method improves the resilience and diversity of sleepiness detection while balancing accuracy, intrusiveness, and practicality. This hybrid technique is intended to provide a comprehensive solution fit for real-world applications, effectively tackling a wide range of scenarios and edge cases.

C. Data Collection

To improve data collecting for sleepiness detection, a comprehensive technique was used to gain a holistic picture of driver alertness. ECG was used to monitor participants' heart

rate and heart rate variability, providing important information about their physiological status. Participants used the KSS to self-report their sleepiness levels, allowing subjective fatigue ratings to be correlated with physiological data.

Front and interior cameras were carefully placed to capture the vehicle's position in the lane, as well as facial expressions, eye movements, and head posture, allowing for thorough behavioral analysis. Furthermore, vehicle data were tracked via the Controller Area Network (CAN) technology, which captured crucial driving metrics like steering wheel movements, lane deviations, and pedal usage. The obtained data is utilized to train the model, validate it, and calculate the system's performance.

D. Norms and Regulations

To maintain safety and dependability, drowsiness and distraction detection systems in the automotive sector must meet high standards. Euro NCAP (European New Car Assessment Program) [6] is a major regulatory body that provides rigorous methods for evaluating the performance of advanced driver assistance systems (ADAS). Euro NCAP evaluates these systems on their ability to detect and reduce risks associated with driver fatigue and distraction, which plays an important part in establishing vehicle safety ratings. These studies include extensive assessments of the system's response to real-time sleepiness signs, accuracy in detecting distractions, and overall reliability under varied driving scenarios.

Furthermore, the European Union's General Safety Regulation 2 (GSR2) mandates all new vehicles to have driver monitoring devices that can identify both tiredness and distraction [7]. GSR2 requires that these systems meet high precision, reliability, and user data protection standards in order to improve road safety.

We created software and system requirements in accordance with the automobile safety standard ISO 26262 [8] and the applicable regulation. Furthermore, we measured performance and validated it in accordance with the defined requirements and applicable norms.

III. OPERATIONAL DECISION MODEL

A. System Architecture

The suggested multi-modal sleepiness detection system is intended to use the strengths of several data sources to deliver a complete assessment of driver weariness. The system architecture is separated into four major components: data collecting, processing, analysis, and alarm production. Each component is critical to guaranteeing the accuracy and reliability of the sleepiness detection procedure. Fig. 1 depicts the major components of our multi-model driver drowsiness detection system (DDAS):

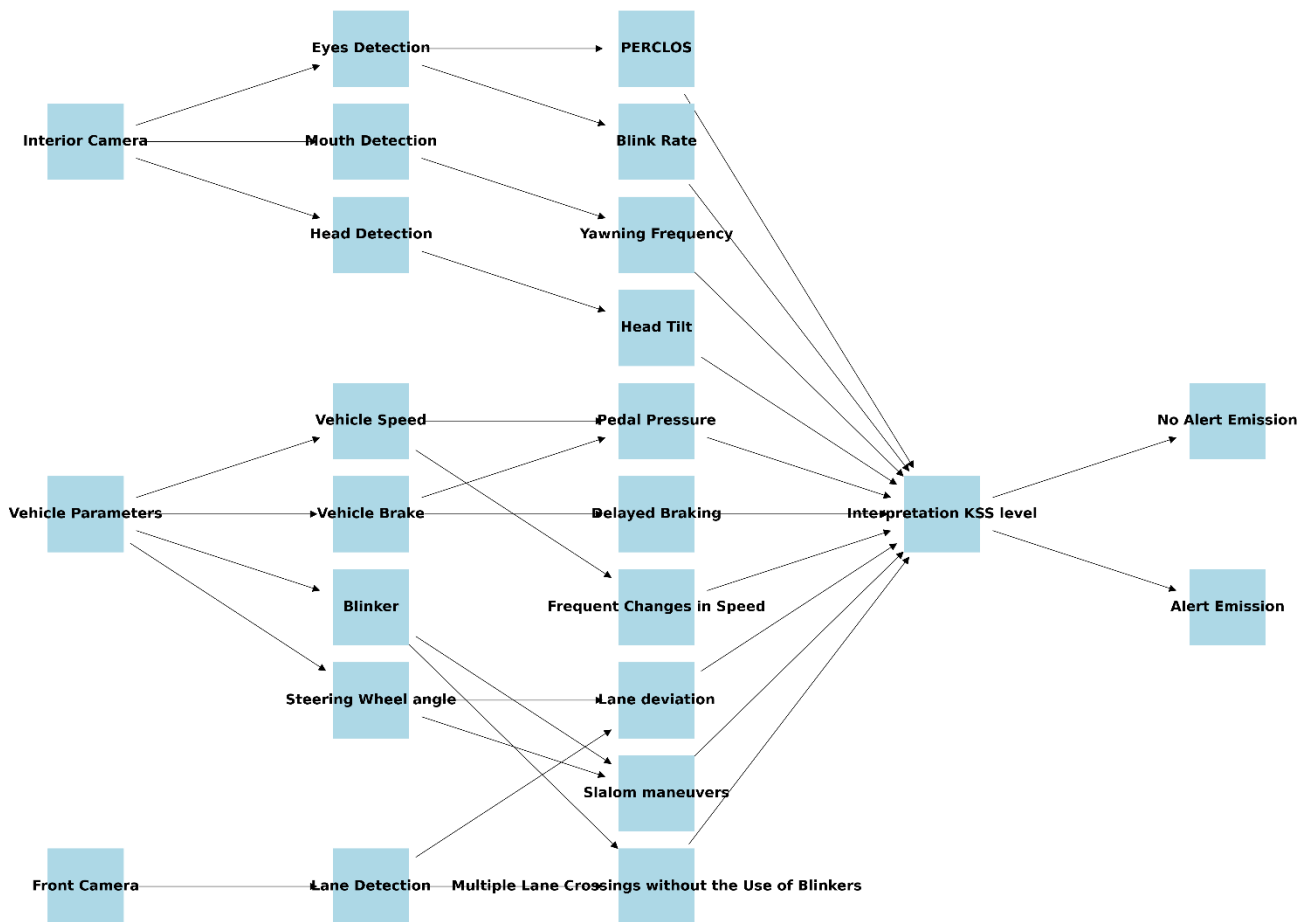

Fig. 1. Multi-modal driver drowsiness detection system framework.

The data acquisition device uses three basic sources: an internal camera, a front camera, and vehicle parameters. The interior camera is set up to capture the driver's facial expressions and eye movements. The front camera, positioned behind the rearview mirror and facing the road, captures real-time imagery of the road ahead. Vehicle parameters are obtained from the CAN network.

Data processing entails extracting and identifying unique properties from each data source. The internal camera identifies face landmarks such as eyes, mouth, and head orientation. These traits are identified and tracked using methods such as facial recognition and feature point detection. The front camera identifies lane markers and the vehicle's relative distance to the lane, while line detection algorithms track lane deviations and headway distance. Meanwhile, the vehicle parameters subsystem gathers information on steering wheel movements, speed variations, brake pedal pressure, and acceleration patterns.

The data analysis unit examines the retrieved features to determine the driver's state. Blink frequency, duration of eye closure (PERCLOS), and yawning frequency are all examples of fatigue indicators in interior camera footage. High blink rates and prolonged eye closures are clear signs of tiredness. The data

from the forward-facing camera is utilized to calculate lane deviation frequency, time-to-lane crossing, and headway. Frequent lane drifting, crossing lines, without indicating and maintaining a low headway distance can all indicate a lack of attention. Vehicle parameters are examined to identify slalom motions, speed abnormalities, and erratic braking. Sudden steering wheel movements, irregular speeds, and abrupt brakes all indicate driver weariness or inattention. To process these features and identify drowsiness-related patterns, an advanced machine learning technique called support vector machine (SVM) is used. These models are trained using annotated datasets to distinguish between normal driving behavior and indicators of weariness.

When drowsiness is identified, the system issues relevant alerts to the driver. These alerts include both voice notifications and visual cautions on the dashboard. These warnings are intended to catch the driver's attention and encourage them to take a rest.

B. Features Extraction and Decision Making

1) *Lane detection and deviation:* The front camera identifies lane deviations, indicating irregular driving behavior.

The video stream is preprocessed to determine the road's region of interest (ROI), then edge detection is performed using the Canny edge detector:

$$G(x, y) = \sqrt{G_x^2 + G_y^2}$$

where, $G(x, y)$ is the gradient magnitude at pixel (x, y) , and G_x, G_y are horizontal and vertical gradients, respectively. The identified edges are converted into line segments using the Hough Transform:

$$\rho = x \cos \theta + y \sin \theta$$

where (x, y) are edge points in the image, ρ is the perpendicular distance from the origin to the line, and θ is the line's angle.

Lane position deviations are measured as the Standard Deviation of Lane Position (SDLP):

$$SDLP = \sqrt{\left(\frac{1}{n} \sum_{i=1}^n (\rho_i - \bar{\rho})^2\right)}$$

where ρ_i is the lateral position of the vehicle at time i , and $\bar{\rho}$ is the average lane position across the observation window [9].

2) *PERCLOS (Percentage of Eye Closure)*: PERCLOS quantifies the proportion of time that the eyes are closed during an observation session:

$$PERCLOS = \frac{N_{closed}}{N_{total}}$$

Where:

The term N_{closed} = Number refers to the number of frames with an Eye Aspect Ratio (EAR) below the threshold, which indicates closed eyes.

N_{total} is the total number of frames captured during the observation time.

The Eye Aspect Ratio (EAR) for each frame is determined as:

$$EAR = \frac{dist(p_2, p_6) + dist(p_3, p_5)}{2 \cdot dist(p_1, p_4)}$$

Where:

p_1, p_2, \dots, p_6 = Coordinates for eye landmarks [10].

3) *Blink rate*: Blink rate is the number of blinks per minute, calculated as:

$$Blink Rate = \frac{N_{blinks}}{T} \times 60$$

Where:

N_{blinks} = Number of detected blinks during the observation period.

T = Duration of the observation period in seconds [11].

4) *Yawning frequency*: Yawning frequency refers to the number of yawns each minute:

$$Yawning Frequency = \frac{N_{yawns}}{T} \times 60$$

Where:

N_{yawns} is the number of yawns identified throughout the observation time.

T represents the duration of the observation period in seconds. [12]

5) *Head tilt*: Head tilt angle (θ) is measured by measuring the vertical and horizontal distances between specified facial landmarks:

$$\theta = \arctan\left(\frac{dist(p_{nose}, p_{chin})}{dist(p_{eye_corner_left}, p_{eye_corner_right})}\right)$$

Where:

p_{nose} = Landmark for the tip of nose.

p_{chin} = Chin landmark.

$p_{eye_corner_left}$ and $p_{eye_corner_right}$ = Landmarks for the outer corners of the left and right eyes [13].

6) *Slalom*: To identify slaloming using steering wheel angle ($\alpha(t)$), examine the rate of change ($\alpha'(t) = \frac{d\alpha}{dt}$) for sudden adjustments. Calculate the frequency of oscillations (f_{steer}) using the Fourier Transform of $\alpha(t)$.

we calculate the amplitude of oscillations ($A_{steer} = \frac{1}{T} \frac{d\alpha}{dt} \int_{t_0}^{t_0+T} |\alpha(t)| dt$) to reflect the magnitude of steering changes. A composite Slaloming Index (SI) comprises the following metrics:

$$SI = w_1 \cdot f_{steer} + w_1 \cdot A_{steer}$$

High SI values indicate slaloming without using the blinker, indicating erratic steering that could be attributed to fatigue [14].

7) *SVM-Based model*

a) *Feature vector*: The feature vector x combines all necessary parameters for detecting tiredness:

$x = [\text{PERCLOS}, \text{Blink Rate}, \text{Yawning Frequency}, \text{Head Tilt}, \text{Pedal Pressure}, \text{Delayed Braking}, \text{Frequent Change in Speed}, \text{Lane Deviation}, \text{Slalom Maneuver}, \text{Multiple Lane Crossings without Blinker}]$

b) *SVM decision function*: The SVM decision function is defined as follows:

$$f(x) = w \cdot x + b$$

Where:

$W = [W_1, W_1, \dots, W_{10}]$ Weight vector for the features.

b : Bias word.

$f(x)$: A decision score that indicates the possibility of drowsiness.

Classification Rule

The categorization choice depends on the sign of $f(x)$:

$$Y = \sin f(x)$$

Where:

Y = +1 indicates Non-Drowsy.

Y = -1 indicates Drowsy.

c) *Mapping to KSS level*: The decision score $f(x)$ is mapped to the KSS level using the mapping function $g(f(x))$:

$$K = g(f(x))$$

Where:

KSS levels range from 1 (high alertness) to 9 (high drowsiness).

d) *KSS-based decision outcomes*: The system action is based on the KSS level K:

$$\text{State} = \begin{cases} \text{No Alert, if } K < 7 \\ \text{Alert, if } K \geq 7 \end{cases}$$

e) *SVM training objective*: The SVM is trained by minimizing the following objective function:

$$\min_{w,b,\xi} \frac{1}{2} \|w\|^2 + C \sum_{i=1}^n \xi_i$$

subject to:

$$y_i(w \cdot x_i + b) \geq 1 - \xi_i, \quad \xi_i \geq 0$$

The regularization parameter C is used to balance the trade-off between maximizing margin and minimizing misclassification errors.

ξ_i : Slack variables for misclassified data points [15][16].

C. Operational Phases of DDAS

1) *Initialization of DDAS*: The DDAS is activated under the following conditions: the engine is turned on, the driver is present with the door closed and the seatbelt buckled, and no malfunctions are identified in the monitored parameters.

2) *Learning phase*: The DDAS learning phase occurs once every driving session, assuming the sleepiness function is engaged. This phase begins immediately upon system activation and lasts one minute, during which the system assesses the driver's sleepiness level. If a driver change is detected, the system resets and begins a new learning period. After completing the learning phase, the system moves on to the monitoring phase.

3) *Monitoring conditions*: The learning phase is reset every time the vehicle is started or a driver change is detected. To accurately detect tiredness, the vehicle must travel at a minimum speed of 50 km/h.

4) *Monitoring phase*: Following the learning phase, the DDAS enters the monitoring phase, which continues until the engine is turned off. During this phase, notifications are disabled in certain situations, such as when the vehicle's speed falls below 50 km/h. The technology continuously detects the driver's fatigue level.

IV. VALIDATION AND PERFORMANCE ANALYSIS

A. Simulation Based Result

The proposed DDAS's performance was evaluated through a series of video simulations that analyzed video footage acquired during the data collecting phase to detect sleepiness occurrences based on predetermined thresholds and metrics. To evaluate the system's usefulness and accuracy, a confusion matrix was created, which provided a detailed breakdown of the system's classification.

The video simulations included a diverse collection of lighting conditions, face angles, and subject sleepiness levels. The system's outputs were recorded and compared to the ground truth labels. The system's overall detection accuracy was assessed to be 92%, proving its capacity to discern between drowsy and alert states. In particular, the system properly identified alert states (True Negatives) in 94% of cases while accurately detecting drowsiness (True Positives) in 86%. However, it misidentified alert states as drowsy (False Positives) in 8% of cases and failed to detect drowsiness (False Negatives) in 6%. Fig. 2 displays the confusion matrix based on a huge dataset injected:

Fig. 1. DDAM confusion matrix.

The system demonstrated great sensitivity in identifying drowsiness, which is crucial for timely intervention and accident avoidance. The relatively low False Negative rate demonstrates its effectiveness in reducing unnoticed drowsiness. However, the False Positive rate, while acceptable, implies that further refinement in feature extraction and threshold tweaking could help eliminate unwanted warnings, hence improving user experience.

The system's performance was further tested under difficult conditions. Due to limited visibility of facial landmarks in low-light conditions, accuracy dropped somewhat to 88%. Under severe angles, accuracy remained stable at 90%, thanks to improved preprocessing and feature normalization. During rapid head movements, there was a modest decrease in True Positive detection, indicating an area for improvement in motion compensation.

B. Real-Condition Testing

Real-world testing in operating settings was carried out to validate the suggested sleepiness detection system. The

technology was placed in a vehicle and tested with drivers doing typical driving tasks. The scenarios included changing lighting (daylight, dusk, and night), different road surroundings (urban and highway), and dynamic driver behaviors. During these experiments, the system tracked and evaluated the driver's facial expressions, blinking patterns, and head movements to detect drowsiness in real time. The real condition testing findings are reported in the confusion Table I below:

TABLE I. REAL TIME DRIVING RESULTS

Predicted \ Actual	Drowsy	Alert
Drowsy	TP: 82%	FP: 12%
Alert	FN: 10%	TN: 88%

The system had an overall detection accuracy of 85%. It recognized drowsiness (True Positives) in 82% of cases and accurately identified alert states (True Negatives) in 88% of cases. However, it misclassified alert states as drowsy (false positives) in 12% of cases and failed to detect tiredness (false negatives) in 10% of cases.

C. Results, Discussion and Future Work

The testing findings show that the suggested DDAS works reliably under both simulation and real-world settings. The system's exceptional sensitivity in detecting drowsiness provides quick intervention, which is crucial for avoiding accidents. Furthermore, the comparatively low False Negative rate demonstrates its usefulness in reducing undetected drowsiness, an important feature of driver safety systems. The system's overall accuracy, especially in difficult settings like low light and severe facial angles, demonstrates its durability and adaptability to real-world applications.

These favorable results suggest that the system meets the safety and performance requirements stipulated in the GSR2 regulatory frameworks and Euro NCAP standards. Compliance with these standards demonstrates the system's ability to greatly improve driver safety and reduce traffic deaths. Its capacity to identify tiredness with high reliability is consistent with the growing emphasis on integrating advanced driver monitoring systems into vehicle safety regulations.

While the system worked effectively, there is still room for improvement. Future work should focus on lowering the False Positive rate in order to improve the user experience and reduce unwanted notifications. Advanced techniques, such as deep learning-based facial analysis, multi-modal data integration, and feature extraction method improvement, may improve system performance. Furthermore, further field testing with a more diversified driver population would help generalize the system's usefulness across different demographics and driving circumstances.

The positive results demonstrate the system's suitability for real-world deployment, assuring compliance with international

safety standards while providing a dependable solution for improving driver safety and contributing to the growth of intelligent vehicle technology.

V. CONCLUSION

This study introduces a multi-modal detection system that combines interior and front cameras with vehicle parameters to improve drowsiness detection accuracy. Using powerful machine learning, the system achieves 92% accuracy in simulations and 85% in real-world tests, consistently diagnosing fatigue under varied settings.

Abstract—Face attribute estimation has several applications in computer vision, biometric systems, face verification /identification and image retrieval. The performance of face attribute estimation has been improved by using machine learning algorithms. In recent years, most algorithms have addressed this problem in multiple binary problem. Specifically, CNN-based approaches, which we can divide them into two classes; shared features and parts-based approaches. In shared features approach, the model uses two types of CNNs: one for feature extraction succeed by another one, for attribute classification. In the parts-based approaches, the approaches split the face image into multiple parts according to the geometric position of each attribute and train a CNN model for each part of the face. However, the shared features approach can handle attributes correlation but ignored attribute heterogeneity and gain in training time. On the other hand, the parts-based approaches can handle attributes heterogeneity but ignore attributes correlation and need more time in the training set compared with a shared feature approach. In this work, we propose a face attribute estimation method, which combined shared features and a parts-based approach into one model. Our model splits the input face image into five parts: whole image part, face part, face upper part, lower part, and nose part. In the same manner, the face attributes are subdivided into five groups according to the geometric position in the face image. We train shared feature model for each part, and we proposed an algorithm for feature selection task followed by AdaBoost algorithm to handle attribute classification task. Through a set of experiments using the LFWA and IITM Face Emotion datasets, we demonstrate that our approach shows higher efficiency of face attribute estimation compared with the state-of-the art methods.

Keywords—Face attribute estimation; biometrics; Convolutional Neural Network (CNN); face verification; computer vision

I. INTRODUCTION

The face recognition systems are the most attractive topics in the biometrics systems because of their convenience, hygiene, and low cost. Specifically, the face as the objective signal can be acquired in a contactless manner without requiring any special equipment. Moreover, due to the multiple advantages provided by the face recognition system, these kinds of systems are the

most used in industry, combined with fingerprint-based systems as personal authentication for smartphones, security gates, payment services, computer human interaction, etc. In addition, the explosive development of Convolutional Neural Networks (CNNs) models, Graphic Units Process (GPU) material and opensource frameworks (e.g, Keras, PyTorch, Caffe, Dlib, etc), the Convolutional Neural Networks (CNNs) have replaced most traditional methods for face recognition problems. To further illustrate the versatility and application of convolutional neural networks (CNNs) in various domains, it is noteworthy to mention recent advancements in related fields. For instance, the work on automatic translation from English to Amazigh using transformer learning [1] demonstrates the adaptability of deep learning models in language processing tasks. Similarly, the recognition of Tifinagh characters using optimized convolutional neural networks [2] highlights the effectiveness of CNNs in character recognition tasks. These studies underscore the broad applicability and potential of CNNs, reinforcing their relevance in face recognition systems as well. To address the great demand for face recognition on face retrieval systems [3], video surveillance environments [4], and criminal investigation protocols [5]. There are multiples studies aimed at improving the performance of face recognition by improving the face attribute estimation.

For improving the face attributes task, the research community provides a number of face databases with their attributes like: CelebA [6] and LFWA [7] datasets, at each dataset, we have a number of face attributes (40/73 attributes) that describe the biological characteristics of the face (e.g ; color, shape and texture) or give information about a subject, weather it is wearing ornaments such as glasses or earrings or not. In addition, the works in study [8] and [9] make an assumption about relationship between face attributes based on the co-occurrence probabilities of two attributes in some databases. To illustrate, the attribute ‘Male’ has a high probability of attributes such as ‘Goatee’, while ‘Female’ has high probability of attributes such as ‘Heavy Makeup’ and ‘Wearing Lipstick’. On the contrary, the lower probability of occurrence for some attributes, the more likely those attributes are to be heterogenous. In the same manner, the works [10], [11], [12] and

[13] show that the relationship between attributes is based on the face parts. For example, 'Black Hair' and 'Blond Hair' are attributes related to 'Hair', which has a position in the upper face part and 'Big Nose' with 'Pointy Nose' are attributes related to 'Nose', which has a position in middle face part, where 'Double Chin' and 'Goatee' are attributes related to the low face part.

In general, face attribute estimation approaches consist of three processes: face detection, feature extraction and attribute classification. Among these processes, feature extraction and attributes classification are the most important, since they have the greatest impact on the estimation accuracy. To deal with the challenging problem of feature extraction and attribute classification, multiple works have been published about this object. In all published works, specifically CNN-based methods, they have a significant impact on feature extraction in terms of accuracy. Some works like in [14] and [10], use the same features for estimating multiple attributes without considering the attribute heterogeneity, and some others are limited to estimating a single attribute [15], or training a separate model for each face attribute without considering the attribute correlation [3]. Although, all previous works have a challenging problem when dealing with non-frontal face images, low image quality, occlusion, and pose variations. The region of interest (ROI) is often suitable and it may cover only a small part of the image, while the face image is dominated by the effects of position pose and viewpoint. Since then, Part-based methods in [5], [10], [11] and [16] have recently become the most popular approaches to dealing with pose variation, occlusion and low image quality.

In this paper, we present a novel method which combined three principal approaches; multi-task, part-based and attributes relationship to achieves better results on face attributes estimation. However, the contributions of this research aim to present;

- 1) Image denoising and online data augmentation with a specific technic, which get the experimental condition close to real-world scenarios.
- 2) Data balanced process to handle the challenge of minority class in databases.
- 3) Face split process combined with attributes subgrouping to handle respectively; head pose and attributes heterogeneity in same task.
- 4) An algorithm to handle feature selection step, followed by Adaboost classifier to addressed the attributes correlation and achieved the final estimation of each attribute.

The remainder of this paper is organized as follows; Section II gives a brief overview of the related work on face attributes estimation. The proposed approach with the baseline networks is outlined in Section III. Section IV displays the different experiments that have been conducted to achieve better results than competing methods. A discussion of the results is addressed in Section V. Finally, we conclude our work in Section VI.

II. RELATED WORK

A. Multi-Tasks Learning Approaches

Multi-task learning (MTL) in facial attribute estimation consists of training a model to achieve multiple attribute

prediction using, in some cases, shared representation approaches. For instance, the work in study [6], proposes two CNNs; LNet and ANet; the first one is pre-trained for face localization and the second one is pre-trained for attribute prediction. Those two CNNs are succeeded by an SVM classifier for attribute classification. Also, the approach in study [16] proposed Deep Multi-task Learning (DMTL) network consists of learning a modified AlexNet with a batch normalization (BN) layer inserted after each Conv Layer for the shared part of model, followed by, a category-specification block for attributes estimation. This method can handle heterogeneous information about attributes. In addition, this shows superior performance compared to state-of-the-art methods on public benchmarks. Moreover, another architecture is designed in study [9], where a ResNet50 Network is adapted as the backbone architecture, they take the first 46 layer as Shared Layers succeed by Task-specific Layers consist of two branches res5C1 and res5C1 corresponding to smile and gender prediction (res5C1and res5C2 are two Residual Blocks of ResNet50). Those two branches are passed by attention block (coined as Att_C) to represent the dependency between smile and gender attributes. Furthermore, two novel approaches have been proposed in study [8], the first one called HyperFace uses AlexNet as backbone of model, while the second one called HyperFace-ResNet is based on ResNet-101. Those two architectures perform well in the face detection, landmarks localization, pose estimation and gender recognition on various public available unconstrained datasets, those approaches show a novel hypothesis about fusing the intermediate layers of the backbone structure. In other words, the introduction of multi-tasks learning approaches in CNN-based models shows better results compared with single-task learning approaches in the terms of attribute correlation.

B. Parts-Based Approaches

In parts-based approaches, the object image and face image are split into small parts and each part is taken as input of the feature extraction process. For example, the work in study [10], proposed Pose Aligned Networks for Deep Attribute Modeling (PANDA), which divide person image into small parts coined as Poselets and each one is passed by a trained CNN. The top-level activations of all CNNs are concatenated to obtain a pose-normalized deep representation and then Linear SVM classifier is trained for attribute classification. In some recent works, the facial attributes are clustered in many groups according to their location in facial parts and relationship in terms of correlation and heterogeneity, before the process of feature extraction and attribute classification. However, in study [5] they split the 40 face attributes into six or nine groups, and they proposed a multi-task deep CNN (MCNN) combined with an auxiliary network (AUX) to achieve the final estimation for each attribute group. Based on the MCNN-AUX model, the study [11] proposed Partially Shared Multi-task CNN (PS-CNN), since they split all the 40 attributes into four attribute groups including Upper, Middle, Lower, and Whole Image. Then the attributes classification of each group can be considered as individual attribute learning task. This method shows the promise results on two databases CelebA [6] and LFWA [7]. In short, parts-based approaches still the better approaches to addressing heterogenous attributes and face parts occlusion.

C. Attributes Grouping

Inspired by the fact that information contained in a face image is geometrically distributed on face parts like; eyes, nose, mouth, etc. For this reason, many recent works are based on this assumption. They have been adding attribute grouping approach as pre-processing step before feature extraction in attribute estimation process. For example, the work in study [8] split 40 attributes of LFWA and CelebA dataset into six subgroups based on attribute color and texture. This approach shows better results compared with other work like PANDA [10] with more than 10% of improvement in term of accuracy detection. Besides, in [5] the attributes have been separated into nine groups; Gender group, Nose group, Eyes group, Face group, AroundHead group, FacialHair group, Cheecks group and Fat group, each one contains a number of attributes according to their facial parts. Furthermore, the Faceness-Net approach proposed in study [12] separate attributes of CelebA dataset into five groups, similarly to [5] and [8]. This work proposes: Hair group, Eye group, Nose group, Mouth group and a Beard group. Each group is represented by branch in the model, those branches was summed into a face label map, which clearly suggests face's location in the image. Moreover, The Faceness-net approach shows better results compared to state-of-the-art methods in term of face detection problems (near 98.05 % AP = average precision on AFW dataset and 92.11 % AP on PASCAL dataset). Therefore, in [6] the subject face in dataset has been split into 14 parts and in the same manner, the 40 face attributes have been separated into 14 subsets. Each part of the face has a subset of attributes based on the visibility value of this attributes in this part of face (visibility value $> \tau$ = visibility threshold). In short, the attribute grouping step handles the attribute correlation and reduces model training time and hyperparameters, but still handles the attribute heterogeneity. On the other hand, in study [17] the group of attributes is subdivided into four groups based on attribute categories (nominal, ordinal, holistic and local). The approach trains four sub-network types according to each subgroup of attributes. This approach can handle attribute heterogeneities compared with the previous works in studies [5], [6], [8], [12], [16], and shown better results on average accuracy reach 93% on CelebA dataset and 86.3% on LFWA dataset. In conclusion, all the previous works prove that the attributes grouping step as pre-processing step can guide the model to achieve expected results, in terms of attribute relationship.

On the whole, the goal of this work is to combine an attribute grouping approach, parts-based approach and multi-tasks learning in order to make a novel model that can handle attribute correlation and heterogeneity at the same time and reach better results compared with state-of-the-art methods.

III. PROPOSED METHOD

In the majority approach's, the first step consists of taking the crop face from image and normalized it based on facial landmarks or splitting it to small parts before attacking CNN structure. In two cases, the crop face has less information about some attributes like; Wear Hat, Bald and 5 O 'Clock Shadow. Since, we propose an approach consists of five CNNs models, one of them, specifically design to extracted the information about Hair, Face background and Neck, at the same time, the

other fours CNNs are specialized in facial details. More details about the proposed approaches are giving in following sections.

A. Face Split and Attributes Grouping

To split face image into three parts, we have used the position of facial keypoints return by MTCNN method presented in [17] (as shown in Fig. 1). The segmentation of face image and face attributes are pre-processing step of input image before it has been processed by CNNs models, those three parts are coined in this work as UP for upper-part, LP for lower-part and NP for nose-part indicated in Fig. 1, respectively, by (A), (B) and (C). (E) represent the face part.

In this approach, we have five CNNs coined as UP-Net (for upper part convolutional neural network), LP-Net (for lower part convolutional neural network), NP-Net (for nose part convolutional neural network), FP-Net (for face bounding box convolutional neural network) and WI-Net (for whole face image convolutional neural network). Each CNN take a specific input image to predicts a subset of specific attributes. Therefore, UP-Net take upper part of face as input and predict their corresponding attributes (attributes with index number #2, #4, #6, #13, #16 and #24), LP-Net take lower part of face as input to predict the attributes with index number (#7, #17, #22, #23, #25, #32 and #37). Where, NP-Net predict the attributes with index number (#8 and #28) according to nose part of face and FP-Net predict the attributes with index number (#5, #19, #20, #21, #26, #27, #30 and #40) which contain the information about face region. Finally, WI-Net receive whole face image as input and given the prediction of attributes with index number (#1, #3, #10, #11, #12, #14, #15, #18, #29, #31, #33, #34, #35, #36, #38 and #39). The label of each index number is described in Table I.

Indeed, certain segments are more effective at predicting a subset of attributes than others. For example, we can expect that upper-part (UP) would contain information about the person being bald, wearing hat or having certain types and color of hair. Therefore, this part of face can still predict attributes related to eyes, eyebrows and hair, at the same time, the lower-part (LP) can predict attributes related to mouth, goatee and moustache. Where, nose-part give information about nose. In short, we join each part with their corresponding attributes.

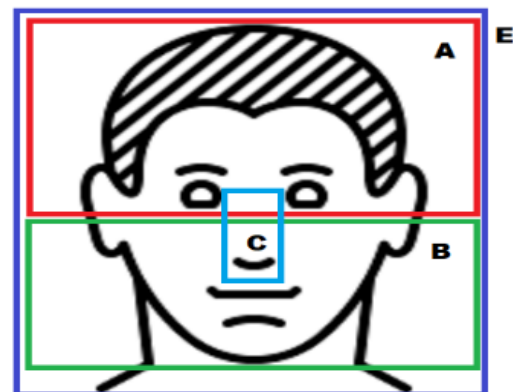

Fig. 1. The face image is divided into four parts; (E) face part, (A) upper part, (B) lower part, (C) nose part. The segmentation of face has been made based on keypoints return by MTCNN method in [17] (Best viewed in color).

TABLE I. FACE ATTRIBUTE LABELS DEFINED IN LFWA [7] DATASET

Index	Attribute	Index	Attribute
#1	5 O 'Clock Shadow	#21	Male
#2	Arched Eyebrows	#22	Mouth Slightly Open
#3	Attractive	#23	Mustache
#4	Bags Under Eyes	#24	Narrow Eyes
#5	Bald	#25	No Beard
#6	Bangs	#26	Oval Face
#7	Big Lips	#27	Pale Skin
#8	Big Nose	#28	Pointy Nose
#9	Black Hair	#29	Receding Hairline
#10	Blond Hair	#30	Rosy Cheeks
#11	Blurry	#31	Sideburns
#12	Brown Hair	#32	Smiling
#13	Bushy Eyebrows	#33	Straight Hair
#14	Chubby	#34	Wavy Hair
#15	Double Chin	#35	Wearing earrings
#16	Eyeglasses	#36	Wearing Hat
#17	Goatee	#37	Wearing Lipstick
#18	Gray Hair	#38	Wearing Necklace
#19	Heavy Makeup	#39	Wearing Necktie
#20	High Cheekbones	#40	Young

B. Attributes Correlation and Heterogeneity

The face verification and image search fields are the first methods has been introduced image attributes as descriptor. They used a subset of 40 binary attributes to describe each face in dataset (see Table I). They later extended the number of attributes with addition ones to achieve 73 binary attributes. In the recent years, more approach's shown attributes dependency and non-dependency [5] to improve accuracy of attributes detection. Further, as shown in the Fig. 2, the attribute with clear color square shown strong positive correlation between their two corresponding attributes respectively, in x-axis and y-axis. On the other hand, attribute with dark color square shown low correlation (heterogeneity). To draw the image in Fig. 2, we have been calculated co-occurrence matrix of each attribute index in LFWA dataset and each square in co-occurrence matrix present the probability to have a specific two attributes in same image. For example, the attribute No_beard (#25) has a strong correlation with Heavy_Makeup (#19), Wearing_Earrings (#35) and Wearing_Lipstick (#37) which has a probability more than 90% (shown by clear color square in Fig. 2) even though the attribute No_beard (#25) has weak correlation with Mustache (#23) which has a probability near 0% (shown by dark color square). In short, the proposed approach is motivated by previous assumptions and it has been introduced in the task specification process which well be detailed in following sections.

C. Network Architecture

Different parts of the face may have different signals for each attribute and sometimes signals coming from one part

cannot infer certain attributes accurately. For example, the information about nose like Big_Nose (#8) (in the Nose Part of face) cannot give information about Wearing_hat (#36) (in the top of head, Whole image part). Therefore, based on these assumptions, we have been explored the advantages of part-based approach to handle the non-dependency of attributes in the shared feature process of our network and we have been explored paire-wise co-occurrence matrix of attributes to handle dependency attributes in task specification process.

Fig. 2. Pair-wise co-occurrence matrix of the 40 face attributes (see Table I) provided with the LFWA [7] database (Best viewed in color).

Inspired from the works in [8] and [16], we have chosen to work with AlexNet as base structure of our model because it has a good result in the term of accuracy on challenging database and faster than GoogleNet and has a small structure compared with VGG and ResNet models. However, the AlexNet consists of five convolutional layers, three max pooling layer and the three Full connected layers. Based on work in study [18], we have been inserted a batch normalization layer after each convolution layer to avoiding overfitting problem. The original and modified AlexNet are shown in the Fig. 3.

Inserting Batch Normalization Layer to AlexNet model. Regularization stands out as an effective technique to combat overfitting issues. Incorporating Batch Normalization (BN) [14] between convolution layers can enhance model stability and regularization. The BN layer normalizes the output from the preceding activation layer by subtracting the mini-batch mean and dividing by its standard deviation. Essentially, this normalization process adjusts the means and variances of layer inputs by introducing two trainable parameters per layer. Additionally, BN reduces the network's sensitivity to the initialization of individual layers, enabling the use of higher learning rates. In our approach, we set a fixed learning rate of 0.001. The Fig. 3 shown more details about original and modified AlexNet model used in this work. The batch normalization layers add into AlexNet model are motioned in Fig. 3 by blue square. C shown the number of attributes returned by AlexNet block according to input facial part. The numbers denote the kernel size, cardinality and features maps for given layer.

Overall structure. The proposed approach consists of denoising process followed by image splitting process to get five parts (deemed as WI, FP, UP, LP and NP). Those five parts are resized into 224x224 size image whose have been taken as input of five subnets (coined as WI-Net, FP-Net, UP-Net, LP-Net and NP-Net). Each subnet of them has a modified AlexNet described in Fig. 3 as base structure.

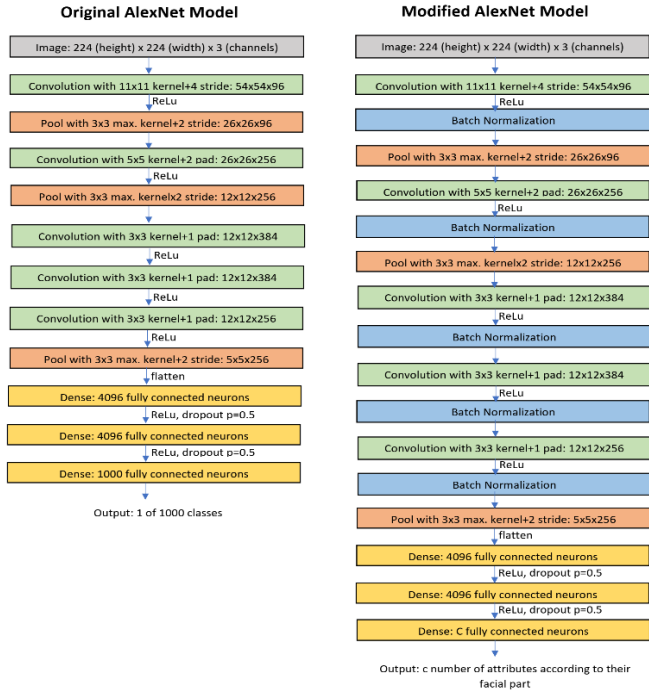

Fig. 3. The original and modified AlexNet used in backbone of our structure (Best viewed in color).

Since, the batch normalization (BN) layers add into AlexNet backbone adjusted the means and variations between the Conv. layers and make the main structure more stable in the learning process. Moreover, at the output of each subnet, we have a specific number of face attributes see Subsection A for more details (17 face attributes for WI, 8 for FP, 6 for UP, 7 for LP and 2 NP). To show the correlation between attributes, we have been proposed a coding algorithm repose on occurrence matrix to handle face attributes correlation see subsection E for more details. The feature selection has been followed by Adaboost classifier to achieve the final estimation for each attribute, see Fig. 4 to have an overview of our proposed method.

D. Simulation of Real-World Scenarios by Data Augmentation

In real-world, there are no universal patterns for facial attributes across all individuals and all datasets present in the literature are limited and don't accurately mirror real-world scenarios based on this assumption, a more realistic attributes estimation system should be trained on dataset prepared with data augmentation process to achieve real-world conditions.

Data augmentation, as discussed in study [19] and study [20], serves as a regularization technique by introducing synthetic images to the neural network, simulating more realistic conditions and viewpoints. This approach helps mitigate

overfitting issues stemming from limited datasets. Various transformations can be applied to create additional modified images, including translation, zooming, brightness adjustments, and more. These subtle variations enable the model to generalize better to unseen data and enhance its robustness when exposed to slightly altered images. In our study, we adopted online augmentation, applying transformations to images as batches are processed during training. This approach accelerates the training process and eliminates the need to store augmented data alongside the original dataset in memory, as required in offline augmentation as per the protocol in study [19]. Specifically, our data augmentation involved shifting image appearance by 0.2 of the image height, adjusting brightness within a range of values between 0.1 and 0.2, and applying zooming. Fig. 5 illustrates the results of the data augmentation process on an image from the LFWA [7] database. The image in the left side of Fig. 5 is the original image after denoising process which loaded from LFWA [7] dataset and the group of images in right side are the data augmentation images after different transformation functions.

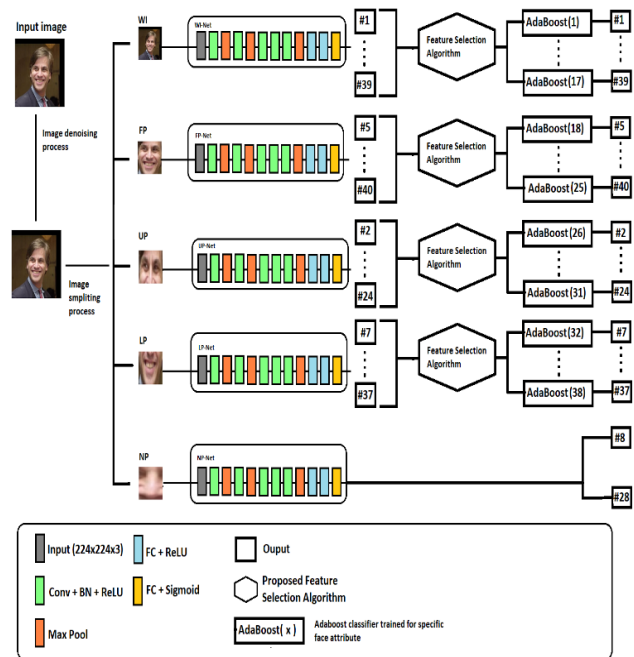

Fig. 4. Overview of the proposed architecture. (Best viewed in color).

Fig. 5. Data augmentation process of each image in dataset (Best viewed in color).

In addressing this aspect of our methodology, we utilized the Keras ImageDataGenerator class, which offers a convenient and efficient method for image augmentation. This class provides a range of augmentation technics, including standardization, rotation, shifts, flips, brightness adjustments, and more. However, the primary advantage of employing the Keras ImageDataGenerator class is its capability for real-time data augmentation. This means it generates augmented images on-the-fly during the training phase of your model. In short, by utilizing this class, images are loaded in batches, which means saving more memory in training process.

E. Task-Specification Process

To achieve task-specification process, many approaches has been shown in the literature. For example, in study [6] an automatic attributes grouping method has been proposed which take columns of weights matrix returned fully-connected layer ANet as a decision hyperplane to partition the negative and positive samples of attribute. By sample applying k-means to these vectors, the clusters show clear grouping patterns. These are used as system features which passed by SVM to achieve final attribute detection. Furthermore, the work in study [21] used Multi-Kernels Maximum Mean Discrepancies (MK-MMD) proposed in study [22] to show the correlation between features returned by MNet and TNet. Another approach shown with PANDA [10] which take a signal returned by each poselet as pose normalization of each image part and used a linear classifier (Logistic Regression in this case) to achieve a Task-specification process. In addition, FaceTracer [15] used SVM algorithm which deemed by Attribute-Tuned Global SVM to achieve final attribute detection. In short, the task-specification process consists of two steps feature selection combined with an algorithm of classification.

In contrast with the previous approaches, we have been proposed an encoding algorithm for features selection step and AdaBoost algorithm to achieve final prediction of each attribute. The proposed algorithm has been presented in the following section and the based co-occurrence matrices of FP-Net, UP-Net and LP-Net have been presented respectively, by (a), (b) and (c) in Fig. 6. The proposed Algorithm used those matrices to achieve feature selection step.

Algorithm 1: LPBT ← (find list of attributes with probability greater than specific threshold)

```
Initialize
I ← Specific attribute
M ← Matrix of occurrence
T ← Threshold
N ← Number of rows in M
Compute
For i ← 0 to i ← N-1 do
  Update
  Update and analyze
  If M[I][i] >= T then
    L[C] ← i
    C ← C + 1
  End
End
End
```

Algorithm 2: CAGT ← Calculate the margin of error between list attributes return by subnet and ground truth

```
Initialize
I ← Specific attribute
L ← List returned by Algorithm 1 (LPBT function)
N ← lent of L list
T ← Matrix values return by subnet (WI-Net, FP-Net, UP-Net or LP-Net)
P ← Matrix of ground truth values of attributes group according to each subnet.
R ← Number of rows in T matrix
C ← Number of columns in T matrix
Compute
For i ← 0 to i ← N-1 do
  Update
  Update and analyze
  If M[I][i] >= T then
    L[C] ← i
    C ← C + 1
  End
End

For i ← 0 to i ← N-1 do
  Update
  Update and analyze
  TV[i] ← T[:,L[i]]
End

For i ← 0 to i ← R-1 do
  Update
  Update and analyze
  For j ← 0 to j ← C-1 do
    Update
    Update and analyze
    If TV[i][j] == 0 then
      TV[i][j] ← -1
    End
  End
End

For i ← 0 to i ← C-1 do
  Update
  Cpt ← 0
  Update and analyze
  For j ← 0 to j ← R-1 do
    Update
    Update and analyze
    Cpt ← Cpt + TV[j][i]
  End
  CV[i] ← Sigmoid(Cpt)
End
End
```

Algorithm 3: we have in output of this algorithm the list shown the relationship between attributes.

```

Initialize
M ← Co-occurrence matrix in the output of each subnet (WI-Net, FP-Net, UP-Net or LP-Net)
T ← Matrix values return by each subnet
P ← Ground truth matrix for each subnet
R ← Number of rows in T matrix
Compute
For i ← 0 to i ← R-1 do
Update
    Update and analyze
    Accu ← 0
    For j ← 0 to j ← 9 do
Update
        Update and analyze
        S ← j/10
        CO ← LPBT(i, M, S) /* Algorithm 1 */
        If Accu < CAGT(i, CO, T, P) then
            Accu ← CAGT(i, CO, T, P)
            Find ← CO /* Algorithm 2 */
        End
    End
    F[i] ← Find
End
End
    
```

Effectively, in the training set, we have been taken the output of each subnet and we have been applied this algorithm to show the correlation between face attributes. See Table II for more details.

TABLE II. ATTRIBUTES IN FORT CORRELATION WITH EACH ATTRIBUTE RETURNED BY PROPOSED ALGORITHM FOR FEATURE SELECTION STEP IN OUR MODEL

Attribute index	Attributes in correlation	Attribute index	Attributes in correlation
#1	#1, #29, #31, #33, #39	#21	#21, #26, #27
#2	#2, #4, #6, #13, #16, #24	#22	#22, #25, #32
#3	#3, #33, #34, #35, #38	#23	#7, #17, #23
#4	#4, #13, #24	#24	#4, #13, #24
#5	#5, #21, #26, #27	#25	#22, #25, #32
#6	#2, #6, #24	#26	#19, #21, #26, #27
#7	#7, #22, #25	#27	#19, #21, #26, #27, #40
#8	#8	#28	#28
#9	#3, #9, #33, #35, #38, #39	#29	#1, #14, #15, #18, #29, #31, #33, #34, #39
#10	#1, #3, #9, #10, #11, #12, #14, #15, #18, #29, #31, #33, #34, #35, #36, #38, #39	#30	#5, #19, #20, #21, #26, #27, #30, #40

#11	#11, #12, #29, #33, #34, #35	#31	#1, #31, #39
#12	#3, #12, #33, #35, #38	#32	#22, #25, #32
#13	#4, #13, #24	#33	#1, #9, #14, #15, #18, #29, #33, #38, #39
#14	#14, #15, #33	#34	#3, #34, #38
#15	#14, #15, #29, #33, #39	#35	#3, #35, #38
#16	#13, #16, #24	#36	#14, #33, #36, #39
#17	#7, #17, #23	#37	#7, #22, #25, #32, #37
#18	#18, #29, #38	#38	#3, #35, #38
#19	#19, #26, #27, #40	#39	#1, #15, #29, #33, #39
#20	#19, #27	#40	#19, #21, #26, #27, #40

Finally, the results returned by Algorithm for each attribute has been passed in the followed step by Adaboost classifier to achieve the final estimation.

Fig. 6. The matrix of co-occurrence for each subnet in LFWA dataset. (Best viewed in color).

IV. EXPERIMENTAL RESULTS

In the experimental section, we have been shown all the experimental steps provide in this work. In first time, we have

been presented Evaluation Metrics used in this work (subsection A). In the followed subsection B, we have been described the databases used in this work to made training, validation and testing steps. The data pre-processing has been presented in subsection C, which contains image denoising, splitting and database balanced. Further, we have been shown the process to determine the values of some specific parameters of our networks in the subsection D. Finally, the performance of our approach for 40 face attributes, gender recognition and smile estimation have been shown in the subsection E.

A. Evaluation Metrics

The most common metrics for attributes estimation is Accuracy, Precision, Recall and Fi-score. Those metrics can be more representative than others metrics in du literature to evaluate the attributes estimation system, since it can be shown the difference between the estimated value and their ground truth in the statistics manner. Those metrics can be mathematically defined as following:

$$Accuracy = \frac{TP+TN}{TP+FN+TN+FP} \quad (1)$$

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

$$F1 - score = \frac{2*Precision*Recall}{Precision+Recall} \quad (4)$$

Where:

- True positive (TP): An instance for which both estimated and ground truth values are positive.
- True negative (TN): An instance for which both estimated and ground truth values are negative.
- False Positive (FP): An instance for which estimated value is positive but ground truth value is negative.
- False Negative (FN): An instance for which estimated value is negative but ground truth value is positive.

B. Datasets

LFWA dataset [7] is a large-scale face attribute database with 13143 images of 5.749 subjects in unconstrained environment. Each image is annotated with 40/73 attributes (see Table I more description). The images in this dataset are in color space and contain large variations in pose, expression, race, background, etc., making it challenging for face attribute estimation. Moreover, the split protocol suggested by dataset is 6263 for training and 6880 for testing. Some images from the dataset have been shown in Fig. 7.

Fig. 7. Samples from LFWA dataset (Best viewed in color).

More descriptions about LFWA dataset have been illustrated in Fig. 8.

Fig. 8. Details about data distribution in LFWA dataset (Best viewed in color).

Strating from the Fig. 8, the LFWA dataset suffer from large imbalanced in data distribution. For example; number of man subjects in data reach 4727 when female subjects equal to 2153, which make gender estimation task harder for female subjects in compared with man subjects. In the same manner, smiling people in train part of dataset equal to 2687 when no smiling people reach 4193, which make this task hard in the training process. To deal with this problem, we have adopted SMOTE [23] algorithm to balance a training data for each subnet (WI-Net, FP-Net, UP-Net, LP-Net and NP-Net). More details have been described in the followed Subsection C.

The IITM Face Emotion dataset [24] originates from the IITM Face Data and comprises 1,928 images from 107 participants, including 87 males and 20 females. These images have been captured in three distinct vertical orientations (Front, Up, and Down) and has been featured six different facial expressions: Smile, Surprise, Surprise with Mouth Open, Neutral, Sad, and Yawning. The original IITM Face dataset includes additional attributes such as gender, presence of facial hair like mustaches and beards, eyeglasses, clothing, and hair density. For this study, the IITM Face dataset was adapted to focus on facial expressions across different orientations. The IITM Face Emotion dataset features only the facial region segmented for each subject, with all images resized to fixed dimensions of 800 x 1000 pixels, maintaining an aspect ratio of 4:5. This resizing approach ensures consistent scaling across various facial positions for each subject. Some images from the dataset have been shown in Fig. 9.

Fig. 9. Samples from IITM Face Emotion dataset (Best viewed in color).

C. Data Pre-processing

Despite of the approaches in the literatures, we have been intruding denoise process as a data pre-processing step. The method has been used to denoising face image is the method called Non-Local Means proposed in study [25] which based on a simple principle: replacing the color of a pixel with an average of the colors of similar pixels. But the most similar pixels to a

given pixel have no reason to be close at all. It is therefore licit to scan a vast portion of the image in search of all the pixels that really resemble the pixel one wants to denoise. Thus, we have split each image into five parts and we resize them into 224x224 resolution to be compatible with our modified AlexNet input layer. To resize images, we have used Cubic Interpolation algorithm. In short, for denoising and rescaling images, we have been used the implementation of Cubic Interpolation and Non-Local Mean algorithms available in OpenCV library. The face bounding box detection has been achieved by Haar-like detector present in study [26].

Fig. 10. Example of pre-processing steps for each image in LFWA datasets (Best viewed in color).

Furthermore, we have been processing to cross-validation approaches to predict the skill of our subnets.

In general, cross-validation is a statistical technique employed to assess the performance of machine learning models. When you have both a machine learning model and data at hand, you aim to determine its capability to fit the data. One common approach is to divide the data into training and test sets, training the model on the former and evaluating its performance on the latter. However, a single evaluation may not be sufficient to ascertain whether a favorable outcome is due to genuine model efficacy or mere chance. By conducting multiple evaluations through cross-validation, you can gain greater confidence in the robustness and design of your model.

The method involves a parameter known as 'k,' which denotes the number of subsets the data sample will be divided into. Hence, this technique is commonly referred to as 'k-fold cross-validation.' When a particular value is selected for 'k,' it can replace 'k' in the model reference; for example, setting k=10 would be termed '10-fold cross-validation.'

Unfortunately, k-fold cross-validation may not be suitable for assessing imbalanced classifiers. This is because the data is divided into k-folds based on a uniform probability distribution.

While this approach may be effective for datasets with a balanced class distribution, it can falter when faced with severely skewed distributions. In such cases, one or more folds may contain minimal or no instances of the minority class. As a result, many model evaluations could be misleading, since the model could achieve high accuracy by simply predicting the majority class.

Balanced dataset steps. Machine learning algorithm

performance is often assessed using public datasets like LFWA (see Fig. 10), but this approach can be problematic for imbalanced data. For instance, consider the task of gender classification in face attributes. A typical face dataset might have a distribution of 98% male and 2% female samples. Simply guessing the majority class would result in a predictive accuracy of 98%. However, the application demands high accuracy for detecting the minority class (female) while allowing for some errors in the majority class (male) to achieve this precision. Relying solely on straightforward predictive accuracy is not suitable in such scenarios. This realization underscores the necessity of balancing the dataset to obtain more accurate and meaningful results.

In this study, we adopted the method proposed in study [25] to balance the dataset for each subnet within our proposed pipeline. We opted for this algorithm due to its approach of over-sampling the minority class by generating "synthetic" examples rather than simply duplicating existing ones. This method creates additional training data by applying specific operations to real data, such as selecting k nearest neighbors from the minority class. However, it should be noted that this approach generates synthetic examples in a more generalized manner, operating in "feature space" rather than directly in "data space". Conversely, the majority class is addressed by under-sampling, wherein samples are randomly removed until the minority class comprises a specified percentage of the majority class.

As motioned in the sections above, our model combined five subnets, each one has a specific subset of attributes. Therefore, we have been applied SMOTE algorithm for each part of subnets parts. More details have been shown in figures; Fig. 11, Fig. 12, Fig. 13, Fig. 14, Fig. 15, Fig.16, Fig. 17 and Fig. 18.

Fig. 11. Data distribution (LFWA dataset) before applied SMOTE algorithm to 16 face attributes according to WI-Net (Best viewed in color) (I).

Fig. 12. Data distribution (LFWA dataset) after applied SMOTE algorithm to 16 face attributes according to WI-Net (Best viewed in color) (II).

Fig. 13. Data distribution (LFWA dataset) before applied SMOTE algorithm to 8 face attributes according to FP-Net (Best viewed in color) (I).

Fig. 14. Data distribution (LFWA dataset) after applied SMOTE algorithm to 8 face attributes according to FP-Net (Best viewed in color) (II).

Fig. 15. Data distribution (LFWA dataset) before applied SMOTE algorithm to 7 face attributes according to LP-Net (Best viewed in color) (I).

Fig. 16. Data distribution (LFWA dataset) after applied SMOTE algorithm to 7 face attributes according to LP-Net (Best viewed in color) (II).

Fig. 17. Data distribution (LFWA dataset) before applied SMOTE algorithm to 6 face attributes according to UP-Net (Best viewed in color) (I).

Fig. 18. D Data distribution (LFWA dataset) after applied SMOTE algorithm to 6 face attributes according to UP-Net (Best viewed in color) (II).

For nose part of our model, we have approximation the same number of classes; 4302 for Pointy Nose compared with 4321 for Big Nose. In this case there is no need to applied SMOTE algorithm.

D. Network Parameters

In the previous subsections, we have been described evaluation metrics, data augmentation and data pre-processing steps and this subsection, we will give more details about some parameters of our method. Therefore, we have been used the grid search algorithm [27], implemented in the kears framework to determine the values of some parameters; optimizer, Mini-batch size and Initial learning rate. See Table III for more details about search space of those parameters.

TABLE III. DETAILS OF SEARCH SPACE FOR EACH PARAMETER IN GRID SEARCH ALGORITHM [27]. WE HAVE BEEN INSPIRED FROM WORK IN [28] TO CHOOSE THE INTERVAL OF VALUES SPECIFIED FOR MINI-BATCH SIZE

Parameters	Values
Optimizer ^a	SGD; RMSprop; Adam; AdamW; Adadelta; Adagrad; Adamax; Adafactor; Nadam and Ftrl.
Mini-batch size	16; 28; 32; 64; 128; 256
Initial learning rate	0.1; 0.01; 0.001

^a. All optimizer function names are reported from there implementation in Keras framework.

Thought a set test, we have concluded that the best values of the previous parameters are; SGD (the Stochastic Gradient Descent) as optimizer, mini-batch size equal to 28 and Initial learning rate equal to 0.001. All test has been made on FP-Net subnet for gender estimation attribute (#21) with a number of epochs equal to 100. In the next step, we have been increased the number of epochs from 0 to 600 in the training experiments, in order to set the epoch number which, get the better results in term of accuracy. This experiment shown that the achieves 100% and 0%, respectively, for Accuracy and Loss at the number of epoch equal to 500 (See Fig. 19 for more details). Therefore, we have been based on this conclusion to applied the parameters for all five subnets listed above (WI-Net, FP-net, UP-Net, LP-Net and NP-Net).

E. Experimental Results

This subsection summarizes the results that were obtained from the experiments for both datasets LFWA and IITM face emotion. The most methods in the literature use LFWA to make those evaluation. In addition, we have been choosing to use IITM face emotion, which has Asian people as subject, since the LFWA dataset has Asian people as minority class compared

with others ethnicity (White, Africans). Another reason to use IITM face emotion dataset is all images has been taken in constrained condition for head pose, emotions and light when LFWA is unconstrained dataset. In short, we have been used the LFWA dataset to shown the performance of our approach compared with state-of-the-art methods and we have been used IITM dataset to shown behavior of our method in constrained conditions on Asian people and to show the general ability of proposed model.

Through recent research, we have Gender and Smile are the most interested among all face attributes. To evaluate our proposed method on those two attributes, we have been used the FP-Net subnet to evaluate Gender estimation and LP-Net subnet to evaluate Smile estimation. The experimental set has been made on LFWA [7] and IITM face emotion [24] since those two datasets provide gender and smile information; therefore, LFWA dataset specified the smile by attribute number 32 (#32) and gender by attribute number 21 (#21) when the IITM face emotion dataset given that two information on image name (see [24] for attribute description).

The remaining subsections of this part are organized as follows. The results obtained on 40 face attributes compared with several state-of-the-art methods is described in subsection a). The subsection b) shown the performance of our model in Gender estimation. Finally, we have been shown the behaviors of our model on Smile estimation task in subsection c).

1) *40 face attribute estimations*: We have been training the five subnets on LFWA dataset trough 500 epochs after having applied pre-processing and data augmentation steps. All subnet parameters have been fixed like described in previous Network parameters subsection. However, the results of competing methods are reported from those originals paper whose respect the same protocol provided by dataset owners. Despite, in our method we have been applied SMOTE algorithm on dataset

before training process. The classification results of proposed method and the competing methods on LFWA dataset have been presented in Table IV.

Fig. 19. Training and validation Accuracy/Loss for FP-Net on LFWA dataset (a and b) (Best viewed in color).

TABLE IV. ATTRIBUTE ESTIMATION ACCURACIES (IN %) FOR THE 40 BINARY ATTRIBUTES ON THE LFWA DATABASE BY THE PROPOSED APPROACH AND STATE-OF-THE ART METHODS [5], [6], [10], [14], [16], [15], [29]. THE AVERAGE ACCURACIES OF [5], [6], [10], [14], [16], [15], [29], AND THE PROPOSED APPROACH ARE 86.0%, 83.8%, 81.0%, 86.3%, 86.1%, 73.9%, 84.7% AND 86.8% RESPECTIVELY. SEE TABLE I FOR MORE DESCRIPTION ABOUT ATTRIBUTES LABELS

2) *Gender estimation*: In this subsection, we have been shown the results of our proposed approach for gender estimation task. As mentioned in section above, we have been pre-processed each image by denoising and splitting to remove the noise and adjusted them to input blocks.

We have been compared our approach with FaceTracer [15], PANDA[10], LNet+ANets [6] and all models (R-CNN_Gender, Multitask_Face, HyperFace and HF-ResNet) proposed in [8]. The gender estimation performance of different methods is reported in Table V. On the LFWA dataset, our method outperforms all competing methods listed above. Unlike all these methods in our approach, we have been processed to balanced dataset before the training step.

The imbalanced distribution in datasets make behavior of each model change from dataset to another. In addition, we have been evaluated the generalization ability of our FP-Net approach with cross-database testing on the IITM face emotion and LFWA. See Table VI for more details.

3) *Smile estimation*: Smile detectors find applications across various sectors, including the media industry. Here, they play a crucial role in enabling companies to gauge public sentiment towards their products and services. For this reason, in this part of our paper, we have been interested to Smile

estimation task. However, we have been presented the Smile estimation performance on LFWA and IITM face emotion datasets since these datasets come with Smile information. We have been compared our LP-Net with MCFA [30], PANDA [10], FMTNet [21] and LNet+ANets [6]. The Smile estimation performance of different method is reported in Table VII. Furthermore, we have been evaluated the generalization ability of our LP-Net approach with cross-database testing on the IITM face emotion and LFWA. See Table VIII for more details.

TABLE V. PERFORMANCE COMPARISON (IN %) OF GENDER ON LFWA DATASET

Method	LFWA dataset
FaceTracer[15]	84.00
PANDA[10]	92.00
LNet+ANets[6]	94.00
R-CNN_Gender[8]	91.00
Multitask_Face[8]	93.00
HyperFace[8]	94.00
HF-ResNet[8]	94.00
Proposed FP-Net	95.00

LFWA	IIITM	54%	99%	48%	65%

V. DISCUSSION

In this section, summarized the discussion of the results achieved about 40 faces attributes, gender recognition, smile estimation and generalization ability of the proposed system. In the first subsection, we have been presented the effectiveness in the most face attributes (30/40) of the proposed approaches and some lower results (10/40). Additional results analysis about gender recognition has been shown in the second subsection. the third subsection contains behavior of our proposed approach in smile estimation task, and finally we a subsection on generalization ability of our system evaluated on cross-database testing.

A. 40 Face Attributes Estimation

The results on LFWA dataset by proposed approach and the state-of-the-art are reported in Table IV. The proposed approach outperforms [5], [6], [10], [14], [16], [15] and [29] for the most of the 40 attributes. Specifically, the proposed approach outperforms competing methods by 30 face attributes. The remaining 10 attributes belongs to WI-Net, FP-Net and LP-Net. Those attributes can be subdivided into three groups; {#14, #35, #36 and #38} from Whole Image group, {#19, #20, #27 and #40} from Face Part group and {#17, #37} from Lower Part group. For WI-Net, we have four attributes has lower results from 17 attributes according to this subnet. All those attributes have a number of attributes in correlation, less than 5 attributes (see Table II) and belongs to image segments which need

Meged-CNN structure like [14], very deep structure like in [29] or more the 4 attributes in correlation like the work in [16]. Further, the subnet FP-Net show 4 attributes with poor results from 8 attributes according to this subnet, while the competing methods in [16] and [6] show better results than our FP-Net. Despite, they use similar network structure to ours (AlexNet) but they use more attributes in correlation task (attributes inter-correlation). In addition, the attributes #17 from LP-Net subnet show similar results to [15] which use pixel of image combined with AdaBoost algorithm to achieve classification process but this approach show a limitation for profile face image even though, our subnet show lower results compared to [6], [5] and [29]. Since, the work in [5] use network structure similar to ours, and they add auxiliary block (coined AUX) which use fully connection approach between all attributes to handle attribute #17 estimation, when our LP-Net use just 3 attributes (see Table II for more details). In the same manner, the work in [6] use more than 3 attributes to make #17 estimation. However, the good results provided in [27] has been achieved by a deeper structure (similar to VGG) than ours. On the other hand, our proposed subnet shows better results about #17 than [10], [14] and [16] who's adopted AlexNet as backbone like ours, but LP-Net outperforms the estimation in task specification step (feature selection and AdaBoost classifier). Finally, for attribute #37 our LP-Net shows lower results compared to all competing methods listed in Table IV. Thus, the works [8], [12] and [13] use similar backbone model like ours when [3], [4] use a deeper structure than AlexNet when the number of attributes used in classification step for all those methods is bigger than 5 attributes (see Table II) used in our proposed method.

Through all previous analysis, we have been concluded for WI-Net and LP-Net necessity to increase a number of attributes used in classification process to a number bigger than 5 and we have been concluded about FP-Net necessity to change AlexNet model by another structure like VGG or ResNet.

B. Gender Recognition

We present the gender recognition performance on LFWA and IIITM Face Emotion datasets since these datasets come with gender information. Our approach shows better results compared with PANDA [10] (see Table V). Based on results reported from there paper, this approach shows good performance in gender estimation on LFWA (92%) even when images are tightly cropped and variation in pose is reduced, but our FP-Net reach 95% with a wide variation in facial pose (our approach gain more from parts-based assumptions in term of head pose challenge). In the same manner, our FP-Net model outperformed FacTracer [15] methods by 11% in term of improvement. The FaceTracer [15] approach spite the input face to 10 parts while our FP-Net split the face into 4 parts only which get further advantage in terms of pre-processing time and has limitation with non-frontal face. In addition, our FP-Net outperforms LNets+ANets[6] by 1% with 5 attributes groups for our and six groups for LNets+ANets (more advantage in terms of group number). However, our FP-Net use one Modified AlexNet structure when LNets+ANets use a cascade of two AlexNet model which make advantage, on parameter number, train/test time complexity and memory consumption. Although, HyperFace models proposed in [8] has the same backbone network like our FP-Net (Modified AlexNet) even the FP-Net

shows better results more than R-CNN_Gender and Multitask_Face. Respectively, by 4% and 2% in the term of improvement. R-CNN_Gender predicts gender task only when our FP-Net can estimate 8 more attributes in addition of gender task (multi labels estimation against one task estimation). Since, Multitask_Face predicts gender in multitask approach which make training process hard than ours (multi labels against multitask process in the training set). Furthermore, the HF-ResNet approach use ResNet-101 model as a backbone network combined with AlexNet model which make it a very deep structure compared with our FP-Net model and slower than our train/test set. However, our FP-Net approach improved HF-ResNet by 1% in the term of accuracy. On the whole, the proposed FP-Net model for joint estimation of gender attribute demonstrates their effectiveness compared with existing approaches at many specific levels like; parameters number, memory consumption, number of attributes subgroups, accuracy and time complexity.

C. Smile Detection

Our proposed LP-Net model outperformed the state-of-the-art methods (see Table VII) in Smile detection on LFWA dataset. All accuracies value presented in Table VII has been reported from their original papers. To illustrate, our LP-Net outperformed the work in [30] by 4% of accuracy and the cited work used a cascade of three VGG-16 models (SNet, MNet and LNet) which made the detection process more complex and harder to train. Even though, our LP-Net use just one Modified AlexNet with seven attributes in the output combined with Adaboost classifier which made it less complex in train and test sets. Further, FMTNet presented in [21] take 40 attributes and split them to many subgroups, while each attribute has weight depending on the number of groups and the number of attributes in each group. Which means this approach investigate 40 attributes to estimate smile attribute when our LP-Net use just 3 attributes selected by cited algorithm from 7 attributes in relation with lower part of face. Therefore, LP-Net proposed in this work use less attributes to show a attributes correlation and gained 3% in the term of accuracy compared with FMTNet. On the other hand, the work in [21] investigate three model use VGG-16 as backbone (FNet, MNet and TNet) when our LP-Net use just one AlexNet model, to handle the smile task. The proposed LP-Net shows improvement reach 1% and 3%, compared the results provide, respectively, by LNet+ANet and PANDA methods. In short, we find that LP-Net proposed in this work performs better for Smile detection task compared to competing methods. In the other hand, our approach shows a discriminating capability for multis and individual tasks.

D. Generalization Ability

We believe that the real scenario is different from the laboratory scenario which mean the generalization ability provided in [16] for the first time (for the best of our knowing) can give more information about our proposed approach. Hence, we evaluate the generalization ability of the proposed approach with cross-database testing on LFWA and IIITM Face emotion databases.

Specifically, cross-database testing of gender and smile estimation between LFWA and IIITM Face emotion databases is performed by training our approach on LFWA and testing it

on IIITM Face emotion, and vice versa. The estimation results with cross-database are shown in Table VI and Table VIII. The results provided by cross-database testing is lower than intra-database testing. Image conditions (constrained in IIITM Face emotion and unconstrained in LFWA) and the number of images (1,928 images in IIITM face emotion and 13,143 images in LFWA) are responsible for the drop in performance. This experiment suggests that varying image sources can introduce additional hurdles for accurately estimating facial attributes. Nevertheless, we maintain confidence that our proposed approach yields commendable results even within this demanding context.

VI. CONCLUSIONS

The paper proposes a method to decode face attributes using a multi-task, part-based approach and attribute relationships. In contrast of exciting works, it introduces two preprocessing steps: image denoising with the Non-Local Means algorithm and dataset balancing using the SOME algorithm. The feature selection has been done by splitting images into five parts (WI, FP, UP, LP, NP) and each one has been processed by a corresponding subnet (modified AlexNet as backbone). The correlation-heterogeneity relationship between attributes has been achieved by a novel feature selection Algorithm (proposed in this work) combined with AdaBoost algorithms.

To evaluated the proposed approach, we have been used LFWA and IIITM Face Emotion datasets. The first one has images in unconstrained conditions and large scale of illumination, head pose, ... when the second one has images with constrained conditions of head pose, illumination and expression. This strategy helps to studies the performance of proposed approach in different conditions and ethnicity.

Trought a set of experiments has been made in this work, our approach performs well the state-of-the-arts methods specifically, on gender and smile attributes. Nevertheless, the results presented in this work shown that our subnets; WI-Net, UP-Net, LP-Net and NP-Net outperforms the competing methods on specific attributes groups, according to those parts of face, when the subnet FP-Net shown some lower results for attributes {#19, #20, #27 and #40}. One possible solution to this issue could be replaced AlexNet with deeper structure similar to VGG or ResNet. While, the lower results present by this work for attributes number {#14, #35, #36 and #38} and {#17, #37} returned respectively, by WI-Net and LP-Net, could be handle by increasing a number of attributes used to shown the relationship in classification process.

Finally, we have been studied the generalization ability of the proposed approach under cross-database testing scenarios on LFWA an IIITM Face Emotion datasets. Through a results analysis, the cross-database testing highlights the importance of training database in real-world face attributes estimation systems.

For future work, we will try to use a deeper structure for attributes with lower results in FP-Net subnet and we will investigate more time in feature selection to get better results for attributes number {#14, #35, #36 and #38} and {#17, #37}. On the other hand, we will adapt the proposed approach to estimate

age task and face emotion. The age task will be studied in regression manner.

Evaluation of Eye Movement Features and Visual Fatigue in Virtual Reality Games

Yuwei Ji

Department of Basic Education, Zhengzhou Urban Construction Vocational College, Zhengzhou-451263, China

Abstract—VR games make people happy physically and mentally, but also lead to eye health problems. At present, the existing VR systems lack fatigue detection technology, which makes it difficult to help users use their eyes reasonably. In order to improve the user experience of VR gamers, this paper proposes a visual fatigue detection algorithm based on eye movement features, which uses the relationship between the lateral and longitudinal displacements of the human head and the displacement of the center point of the human eye to locate the position of the human eye. Moreover, in this paper, the human eye position tracking model is input into the three-frame difference algorithm to detect eye movement features. In addition, for tiny motion interference such as eyebrows, the image opening operation of eroding first and then expanding is used to remove it. Through experiments, it is found that the eye movement feature detection method adopted in this paper can greatly improve the detection speed with less accuracy loss, meet the sensitivity requirements of eye movement feature capture, improve the real-time performance of the system, and effectively improve the real-time analysis of player status. Therefore, integrating this algorithm into the virtual game system can help players adjust their own state, which has a positive effect on improving the game experience and reducing eye damage.

Keywords—Virtual reality; games; eye movement features; visual fatigue

I. INTRODUCTION

In three-dimensional game design, the application value of VR technology cannot be ignored. First of all, VR technology can provide an immersive gaming experience, which is one of its most significant advantages. Through technical means such as headsets and surround sound effects, VR technology can completely immerse players in a virtual environment, making them feel as if they are in the three-dimensional world of the game. This immersion greatly enhances the player's gaming experience, allowing them to get a more realistic feel for everything that's happening in the game. From a technical point of view, VR technology adjusts the game screen in real time by tracking the movement of the player's head, making the player's field of vision and observation angle in the game more natural. At the same time, surround sound technology can make players feel sounds from all directions, further enhancing the realism of the game.

Secondly, immersive experiences bring more possibilities to game design. In traditional game design, there is a certain sense of distance between players and the game world, and the application of VR technology can break this boundary and enable players to integrate more deeply into the game world. This provides a broader creative space for game designers, and

can design richer and more complex game scenes and plots, thus enhancing the attractiveness and interest of the game [1].

However, long-term use of VR (more than 30 minutes) may have a certain negative impact on the visual health of the whole body and eyes. The specific manifestations include dizziness, nausea and other symptoms. At the same time, users are accompanied by dry eyes, and even symptoms such as diplopia, tearing, eye pain, eye soreness, and inability to concentrate, as well as related symptoms such as visual asthenopia and video terminal syndrome. The illusion caused by the virtual environment can produce uncomfortable symptoms, such as eye fatigue, dizziness, and other visual fatigue symptoms [2].

There are depth cues in virtual environment scenes, which stimulate eye movements. There is a strong correlation between eye movements and asthenoptic fatigue. Many studies have shown that eye movement behavior can reflect people's thinking movement, and rich information can be obtained from eye tracking movement. Its core purpose is to obtain the gaze point trajectory of human eyes during observation. Combined with knowledge in various fields, we can conduct in-depth analysis of users' visual behavior. Eye trackers are instruments that carry eye tracking technology to track and analyze eye movements, and eye tracking is the core function of eye trackers. From a mental and physical perspective, eye movements are a fundamental reflection of the human state. Meanwhile, eye movements are arguably the most frequent of all human movements, and eye movements are essential to the work of the human visual system. In addition, multiple observations of the eyes are not smooth movements, but multiple eye movement patterns are performed concurrently [3].

Visual fatigue and visual discomfort can be used alternately, but there are still differences between them. Visual fatigue refers to the decline of human visual system performance, which can be measured objectively, and visual discomfort is the subjective response of the visual system. Some researches on eye movement behavior in virtual reality focus on comparing the States before and after use, and some researches also compare the eye movement differences under watching different video content. However, up to now, there has been no research on the differences of visual fatigue and eye movement in different interactive environments of VR. Eye movement behavior is closely related to visual fatigue and the physiological and pathological state of the eye. The changes of eye movement speed, fixation time and blink frequency determine fatigue and mental load.

In response to the design requirements of high speed, small size and non-contact of detection equipment, the face image is

preprocessed by image processing technology such as noise reduction; Then the YCbCr color space domain conversion algorithm is used to segment and locate the face and eye region; The blink frequency is counted by frame difference multiple moving object detection algorithm in the face region after positioning; By comparing the real-time detected blink frequency data with the given threshold, it can provide real-time fatigue data reference for VR game users, which is convenient for timely and effective control of game duration and timely and effective protection.

In order to improve the user experience of VR gamers, this paper proposes a visual fatigue detection algorithm based on eye movement features, which uses the relationship between the lateral and longitudinal displacements of the human head and the displacement of the center point of the human eye to locate the position of the human eye. Moreover, in this paper, the human eye position tracking model is input into the three-frame difference algorithm to detect eye movement features. In addition, for tiny motion interference such as eyebrows, the image opening operation of eroding first and then expanding is used to remove it.

II. RELATED WORK

1) *Research on fatigue*: A lot of research has been done on fatigue at home and abroad. In early foreign studies, fatigue was defined as the loss of energy resources after overwork. The resources here are reflected in two aspects. On the one hand, it represents the loss of internal motivation and action from the psychological aspect, and on the other hand, it represents the decrease of external work performance. The study in [4] hold that the decrease of efficiency caused by excessive physical or mental activities is a manifestation of fatigue. Researchers divided fatigue into psychological fatigue and physical fatigue, central fatigue and peripheral fatigue, cognitive fatigue and exercise fatigue, subjective fatigue and objective fatigue, overall fatigue and local fatigue from different dimensions, among which psychological fatigue and physical fatigue are the most widely studied. At present, the most widely studied is to divide fatigue into mental fatigue and physical fatigue. At the same time, it involves psychological state changes in multiple dimensions such as behavioral response, attention, emotion and motivation [5].

2) *Visual fatigue*: Visual fatigue is one of the types of fatigue. Studies have shown that the characteristics of visual display terminal (VDT) work are directly related to eye discomfort and psychological symptoms. Visual fatigue is defined as subjective symptom syndrome produced when working with eyes, while VDT visual fatigue is more due to eye discomfort and other comprehensive symptoms caused by eyes staring at video terminals for a long time, such as dry eyes, astringent eyes, tingling, eye fatigue, soreness, photophobia and tears, frequent eye movement behaviors, diplopia, blurred vision, heavy eyelids, etc. At the same time, it is also accompanied by headache, dizziness, loss of appetite, memory loss, neck, shoulder, waist, back, joint dysfunction, etc. [6]. Visual fatigue caused by electronic screen operation has

become one of the key research fields of human factors engineering since 1970s. The most common fatigue symptom in video display task is eye fatigue, which includes both physiological fatigue and psychological fatigue. The former is manifested as the general symptoms of eye fatigue and fatigue caused by excessive eye use with the extension of working hours, including symptoms that occur after excessive eye function is stressed. It is manifested by low function of central nervous system, a large decrease in flicker fusion frequency, long-term tension of ciliary muscle, significantly low function of eyeball accommodation system, eye fatigue, eye tingling, and temporary decrease of eyesight. The latter, like mental fatigue, is manifested as cognitive fatigue, such as difficulty in maintaining the initial state and continuing to complete the current task, decreased task performance, decreased attention, etc. [7].

3) *Eye movement behavior*: There are three main types of eye movement behaviors: Saccade, Fixation and SmoothPursuit. The saccades are rapid eye movements that align the fovea with the target. During the experiment, it is important to ensure that the subject does not have saccades while chasing the target smoothly. This eye movement is called catch-up saccades and is more common when catching up at high speeds. Fixation is to keep the foveal visual field on the target for a certain period of time to obtain sufficient visual image details. Smooth pursuit is a kind of fairly slow eye movement that minimizes the movement of retinal targets, and it keeps the eyes fixed on moving objects. The saccade eye movement differs from the smooth pursuit eye movement in that the initial acceleration and deceleration and peak velocity of the former are both higher [8]. A large number of related studies in physiology and psychology have confirmed that some behaviors of human eyes are related to the degree of visual fatigue. Therefore, when collecting eye movement data, it is collected by instruments, and the visual fatigue state of subjects is detected by analyzing the data of eye movement indexes. Through the collation of a large number of references, this paper mainly selects six eye movement parameters, namely, average eye movement duration, average fixation duration, number of eye movement behaviors, number of fixation points, average saccade amplitude and average pupil area, for analysis and research [9].

The average duration of eye movement behavior (unit: ms) refers to the duration of the average single eye movement behavior in the sample. The length of eye movement behavior can also reflect the current level of mental activity and drowsiness, which is closely related to fatigue. By watching different types of videos, study in [10] found that although there was no significant difference in the average duration of eye movement behavior on the whole, it showed an increasing trend with time. The study in [11] studied the continuous viewing of movies, and compared which display can induce visual fatigue more in two kinds of visual display terminals (linear polarization and circular polarization), and found that the average duration of eye movement behavior in the two display terminals increased significantly. The study in [12] explored the effects of different

polarized light displays on human visual comfort, and found that the average duration of eye movement behavior increased with the extension of viewing time of subjects who watched the video content displayed by linearly polarized light and the video content displayed by circularly polarized light liquid crystal.

The average fixation duration (unit: ms) refers to the average of the time allocated by subjects at each fixation point in an experimental process, usually in milliseconds. The length of fixation time can reflect the difficulty of information capture and processing, and can indirectly reflect whether the subjects are tired [13]. Generally speaking, the longer the average duration of the fixation point, the deeper the processing degree of the fixation point, and it also reflects the more concentrated the attention of the current subjects. Therefore, the quality of the subjects' fixation ability also reflects the depth of information processing degree and the concentration and distraction of attention to a certain extent. The study in [14] conducted a comparative study on mental fatigue between the elderly and young people, and found that the average fixation duration of both the elderly and young people increase with the development of fatigue, and the average fixation duration of the elderly is significantly higher than that of the young people. The study in [15] divided the subjects into fatigue group and non-fatigue group, and found that the average fixation duration in the fatigue group is significantly lower than that in the non-fatigue group. Relevant studies have proved that the average fixation duration can indirectly reflect the degree of fatigue of the subjects.

Number of eye movement behaviors (unit: units/min) refers to the number of times the upper and lower eyelids are closed per unit time. Number of eye movement behaviors involves the interaction of efferent nerves between the brain mechanisms responsible for controlling eyelid muscles and other muscle groups, and is closely related to mental activity and visual fatigue. A large number of studies have proved that eye movement behavior is related to visual fatigue, which can be used as an index to evaluate visual fatigue. Generally speaking, the number of eye movement behaviors will increase with visual fatigue. The study in [16] found that the number of eye movement behaviors increases significantly with time by watching different types of videos. The study in [17] studied the continuous viewing of movies, and compared which display can induce visual fatigue more in two kinds of visual display terminals (linear polarization and circular polarization). The results found that the number of eye movement behaviors in the two display terminals increases significantly with time. The study in [18] evaluated the visual fatigue caused by long-term viewing of visual display terminal (VDT) and reading hard-copy, and found that the number of eye movement behaviors under VDT increases significantly from the 2nd hour. The study in [19] studied fatigue driving and found that the number of eye movement behaviors increases with the increase of driving fatigue.

To sum up, visual fatigue includes two meanings: on the one hand, it is eye fatigue caused by some reason, and on the other hand, it refers to psychological fatigue caused by boredom of something and cognitive load.

III. VISUAL FATIGUE DETECTION BASED ON EYE MOVEMENT FEATURES

In terms of limitations, although a lot of research has been done on VR game fatigue, there are still some challenges and limitations. Firstly, the hardware limitation of VR technology is an important factor leading to fatigue. For example, the weight and volume of VR head display equipment are relatively large, and wearing it for a long time can easily lead to discomfort and fatigue. The resolution and scene rendering ability of the device also need to be improved to provide a clearer and more realistic visual experience. Secondly, the rendering amount of VR game images is much higher than that of general games, which requires higher computing power to support, which is a technical bottleneck in the actual development. In addition, the current research on how to effectively alleviate the fatigue of VR games lacks systematic solutions and guidelines.

To sum up, the research on VR game fatigue has made some progress, but it still needs more in-depth research and exploration in hardware technology, image rendering and mitigation strategies. Therefore, this paper attempts to summarize the anti-fatigue system suitable for VR games based on eye movement feature recognition, so as to reduce the impact of game fatigue on players' physical and mental health.

By analyzing the relationship between binocular center point displacement and face displacement, a dynamic video eye position tracking model is established, and then the eye movement behavior rate is detected by frame difference algorithm in the human eye area, and finally the game fatigue judgment is completed.

A. Eye Movement Behavior Detection Algorithm

In this project, the eye movement behavior detection algorithm based on eye features, the eye movement behavior detection algorithm based on background differential moving target detection algorithm and the eye movement behavior detection algorithm based on inter-frame differential moving target detection algorithm are analyzed and studied. The eye movement behavior detection algorithm is comprehensively evaluated from three aspects: effective detection rate, false detection rate and detection speed, and finally the eye movement behavior detection algorithm suitable for this project is selected.

1) *Haar-Adaboost human eye coarse positioning*: Haar-Adaboost algorithm combines Haar-like features with Adaboost cascade classifier. The core idea of the algorithm is to take the Haar-like sub-window as the input of the weak classifier, and use the window template to traverse each region of the image to calculate the features of the window. It then uses the trained Adaboost cascade classifier to screen the feature. If the feature passes each strong classifier screening in the cascade classifiers, the region is determined to be the human eye. The process of Haar-like sub-window traversing the image is shown in Fig. 1.

Fig. 1 shows a Haar-like linear feature template traversing from bottom to top and left to right in an image. Adaboost iterative algorithm is to train weak classifiers to form a strong classifier with better classification effect. Multiple strong classifiers are arranged from low to high according to their

complexity, and the detection results of each level can only be passed to the next level classifier after being screened, and the detection results can only be output after being screened by all

strong classifiers. The flow of human eye coarse positioning of Haar-Adaboost algorithm is shown in Fig. 2.

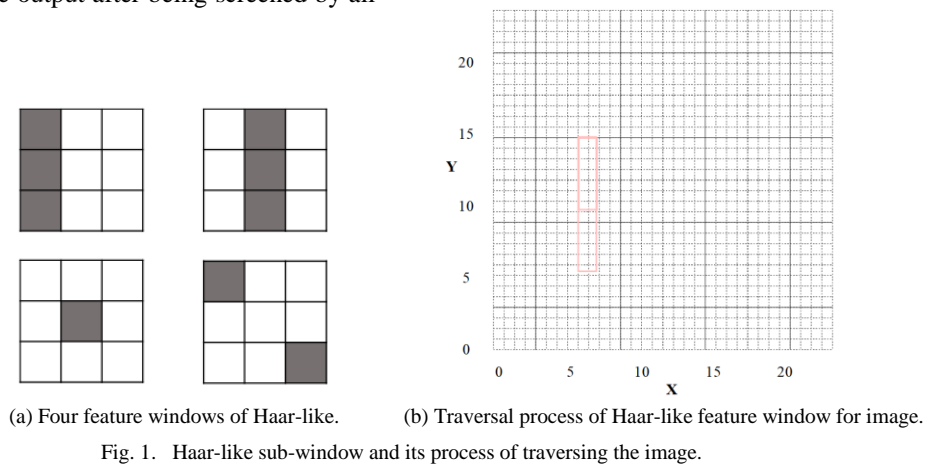

Fig. 2. Human eye coarse positioning process of Haar-Adaboost algorithm.

2) *ERT human eye fine positioning and eye movement behavior detection*: On the basis of coarse localization of human eye area, ERT algorithm is used to accurately segment human eye area and judge eye movement behavior. The ERT algorithm needs to establish a GBDT (Gradient Boosting Decision Tree), which is an object detection method based on the idea of face alignment. Human eye detection using face feature point matching is shown in Fig. 3 [20].

Fig. 3. Accurate positioning of human eye area based on face feature points.

The background difference algorithm can detect moving objects only by comparing the gray value of the current frame

image with the standard background gray value. The algorithm is simple and easy to implement, and it is widely used in the field of video surveillance.

The video frame image at time t is $F(x, y, t)$, the standard background image is $G(x, y, t)$, the binarized image is $B(x, y, t)$, the dynamic judgment threshold is T , and the binarized gray difference image is $D(x, y, t)$, which can be expressed as Eq. (1).

$$D(x, y, t) = \begin{cases} 1, & |F(x, y, t) - G(x, y, t)| > T \\ 0, & \text{Othes} \end{cases} \quad (1)$$

After the image is processed by Eq. (1), the part with gray value of 1 is the moving target, and the portion with a gray value of 0 is the background of the image. The limitation of background difference algorithm is that it needs to set the standard background in advance, and it requires high stability of the background. Because of the dynamic changes of the background, it is difficult to selectively reconstruct the background. In addition, when the image environment is shaken, the illumination changes suddenly, and the like, it is also

considered that a moving target appears after background difference.

Using inter-frame difference algorithm to detect moving objects in face area can achieve the purpose of detecting eye movement behavior. Similar to the principle of background difference algorithm, it assumes that the image function of the current video frame is $F(x, y)$, the image function of the first frame of the current image is $F_{k-\tau}(x, y)$, and the gray difference function $D_k(x, y)$ of the two images can be expressed by Eq. (2) [21]:

$$D_k(x, y) = |F(x, y) - F_{k-\tau}(x, y)| \quad (2)$$

The target region gray function in (2) is binarized, as shown in Eq. (3).

$$B_{D_k}(x, y) = \begin{cases} 1, D_k(x, y) > T \\ 0, Others \end{cases} \quad (3)$$

Three-frame difference method obtains the same part of two difference images by AND operation of two difference images, which avoids the image hole phenomenon of adjacent difference algorithm and enhances the robustness of the algorithm. When the three-frame difference method is used, Eq. (3) becomes Eq. (4).

$$\begin{cases} D_k(x, y) = |F_k(x, y) - F_{k-1}(x, y)| \\ D_{k-1}(x, y) = |F_{k-1}(x, y) - F_{k-2}(x, y)| \end{cases} \quad (4)$$

In Eq. (4), $D_k(x, y)$ is the expression of the difference between the k -th frame image and the $k-1$ -th frame image, and $D_{k-1}(x, y)$ is the expression of the difference between the k -th frame image and the $k-2$ -th frame image. By bringing Eq. (4) into Eq. (3), the binarization, Eq. (5) of the two difference images is obtained.

$$\begin{cases} B_{D_k}(x, y) = \begin{cases} 1, D_k(x, y) > T \\ 0, Others \end{cases} \\ B_{D_{k-1}}(x, y) = \begin{cases} 1, D_{k-1}(x, y) > T \\ 0, Others \end{cases} \end{cases} \quad (5)$$

In Eq. (5), T is the moving target judgment threshold. When $B_{D_k}(x, y)$ and $B_{D_{k-1}}(x, y)$ are equal to 1, it indicates that there are moving targets in two adjacent frames. Because the movement of the moving target is continuous and continuous, the calculation results of two consecutive differences will be 1. If the false detection is caused by noise such as holes, it will be eliminated by AND operation. The target object to be detected obtained by doing and operation in Eq. (5) is shown in Eq. (6).

$$A(x, y) = B_{D_k}(x, y) \& B_{D_{k-1}}(x, y) \quad (6)$$

In Eq. (6), $\&$ represents the AND operation, and $A(x, y)$ is the detection objective function. When the value of $A(x, y)$ is 1, it indicates that there is a moving target in the measured picture, otherwise it is stationary.

The frame difference method has a good effect in detecting eye movement behavior, but it can't judge the non-eye movement area. The three-frame difference method will still be affected by small moving objects such as hair and clothes pleats. Therefore, it is necessary to improve the three-frame difference method to improve the detection accuracy.

B. Three-Frame Difference Eye Movement Behavior Detection Algorithm

In this section, an eye movement behavior detection algorithm based on the combination of binocular position tracking in face region and three-frame difference method is proposed. The improved eye movement behavior detection algorithm is shown in Fig. 4.

Fig. 4. Flowchart of improved algorithm.

As shown in Fig. 4, the optimization of the three-frame difference method in this project mainly includes the following points.

1) *Definition of face area:* In the face detection algorithm, the coordinate vertices of the face area are successfully found and input into the three-frame difference algorithm, and only the areas within the coordinates are differentiated. The gray value of the non-face areas outside the coordinates is 0, so that the interference of moving targets outside the face area on eye movement behavior detection is eliminated, as shown in Fig. 5.

2) *Human eye position tracking:* Before obtaining the three-frame difference map, the human eye position tracking model is introduced to estimate the position of both eyes, and the difference operation is only carried out in the human eye area, and the rest areas are set to 0, so as to eliminate the

interference of other moving targets in the face area on eye movement behavior detection.

3) *Corrosion expansion*: The image obtained by further processing the corrosion expansion operation is used to remove sharp noise around the eyes and eliminate motion noise such as eyebrows that may affect the detection results.

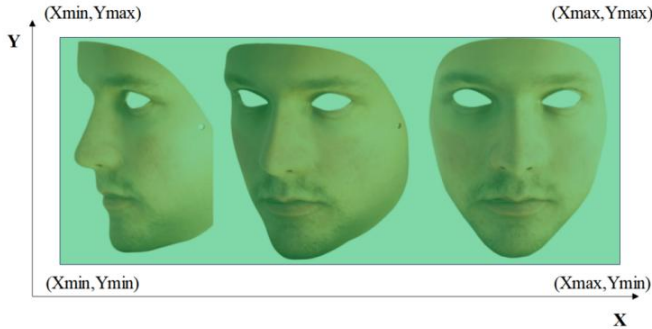

Fig. 5. Face area coordinate vertices.

All the gray values of pixels in areas other than the face are set to 0, and the coordinate level values (X_{min}, Y_{min}) , (X_{min}, Y_{max}) , (X_{max}, Y_{min}) , and (X_{max}, Y_{max}) selected by the face frame are found. When the adjacent difference operation is performed, only the difference operation is needed on the targets falling within the coordinate level value range, as shown in Eq. (7).

$$\bar{F}_k(x, y) = \begin{cases} F_k(x, y) \& M_k(X_i, Y_i), \text{Human face area} \\ 0, \text{Others} \end{cases} \quad (7)$$

In Eq. (7), $\bar{F}_k(x, y)$ represents the first image used as the adjacent difference operation, $M_k(X_i, Y_i)$ represents the detected face region function, $F_k(x, y)$ represents the first frame image, $\&$ represents an AND operation, which eliminates other regions other than the face by the AND operation of the image to be detected with the face position, and X_i and Y_i represents the face region coordinate level value:

$$\begin{cases} X_i = X_{min}, X_{max} \\ Y_i = Y_{min}, Y_{max} \end{cases} \quad (8)$$

After introducing the face region coordinate level values, the following form is obtained.

$$\begin{cases} D_k(x, y) = |\bar{F}_k(x, y) - \bar{F}_{k-1}(x, y)| \\ D_{k-1}(x, y) = |\bar{F}_{k-1}(x, y) - \bar{F}_{k-2}(x, y)| \end{cases} \quad (9)$$

After the operation of Eq. (8) and Eq. (9), the difference operation of two adjacent frames is only performed in a specific area containing the face, which can avoid bringing moving targets other than the face into the three-frame difference algorithm, and eliminate the interference of moving targets other than the face to eye movement behavior detection.

A human eye position estimation algorithm under head movement is proposed. The algorithm ideas are divided into the following points.

1) A head surveillance video of a player playing a game is selected, and the video is decomposed into 100 frames of images.

2) The improved YCbCr algorithm is used to extract the player's face image, and the lateral displacement Δx_k^h and Δy_k^h of the player's head in two consecutive frames is calculated by combining the adjacent frame difference method, and a total of 99 groups of displacement data are extracted, as shown in Eq. (10).

$$\begin{cases} \Delta x_k^h = |x_k^h - x_{k-1}^h| \\ \Delta y_k^h = |y_k^h - y_{k-1}^h| \end{cases} \quad (10)$$

3) The minimum area of the human eye position in each frame image is manually framed, the center position of the box is found, the displacement of the center position of the box is used to represent the displacement of both eyes, and the sum of the transverse and longitudinal displacement differences of the center position of the box is calculated by using the method of step 2, as shown in Eq. (11).

$$\begin{cases} \Delta x_k^e = |x_k^e - x_{k-1}^e| \\ \Delta y_k^e = |y_k^e - y_{k-1}^e| \end{cases} \quad (11)$$

4) Two groups of data of transverse displacement of human head and transverse displacement of binocular center point, longitudinal displacement of human head and longitudinal displacement of binocular center point are extracted respectively, and the functional relationship fitting is carried out to find the relationship expression of the two groups of data. The calculation of the horizontal and longitudinal displacement of the face and the horizontal and longitudinal displacement of the center of the human eye in two consecutive images is shown in Fig. 6.

Fig. 6. Head displacement and binocular center point displacement.

The 99 groups data of Δx_k^h , Δx_k^e , Δy_k^h and Δy_k^e are counted and data relationship fitting is performed, and the results are shown in Fig. 7. Fig. 7 (a) is Relationship between the lateral displacement of the center point of both eyes and the lateral displacement of the head, Fig. 7 (b) is Relationship between longitudinal displacement of center point of binocular eyes and longitudinal displacement of head.

(a) Relationship between the lateral displacement of the center point of both eyes and the lateral displacement of the head.

(b) Relationship between longitudinal displacement of center point of binocular eyes and longitudinal displacement of head

Fig. 7. Relationship between human eye center displacement and head displacement.

As can be seen from Fig. 6, the distribution of the two sets of data shows a strong linear relationship, and the relationship between Δx_k^h and Δx_k^e and Δy_k^h and Δy_k^e is shown in Eq. (12) after data fitting.

$$\begin{cases} \Delta x^e = 1.22\Delta x^h - 1.33 \\ \Delta y^e = 0.94\Delta x^h + 0.15 \end{cases} \quad (12)$$

In Eq. (12), Δx^e represents the lateral displacement of the eye to be measured, Δy^e represents the longitudinal displacement of the eye to be measured, Δx^h represents the lateral displacement of the head of two adjacent images calculated by the adjacent frame difference method, Δy^h represents the longitudinal displacement of the head of two adjacent images calculated by the adjacent frame difference

method. Through Eq. (12), the detection range is further compressed to the human eye area, the motion noise in the skin color area is filtered, and the detection accuracy is improved.

IV. SYSTEM CONSTRUCTION AND EXPERIMENT

A. System Construction

Based on the MCIA architecture designed in this paper, the sharing framework of eye tracking data is shown in Fig. 8.

In this paper, the eye tracking and gesture data of users in the scene are captured. After that, this paper builds a collaborative scene to transmit and visualize the data of both users in the scene, thus realizing the sharing of users' eye movements and gestures in VR scenes and providing data support for visual fatigue analysis in VR games.

Fig. 8. Eye tracking data sharing framework diagram.

In order to verify whether the algorithm model designed in this paper is suitable for visual fatigue analysis in VR games, and to verify the influence of the best eye-hand visualization mode on the communication degree of both parties, this paper designs a VR game visual fatigue analysis system as shown in Fig. 9. The system is mainly divided into two modules: eye-hand data processing module and virtual scene interaction module. The eye-hand data processing module mainly provides data support for the virtual scene interaction module. The virtual scene interaction module will visually display user data and give users visual feedback. After receiving the visual feedback, the user's behavior is corrected again, so that the ability of collaborative interaction between the two sides is trained through the real-time interaction and real-time feedback of the system.

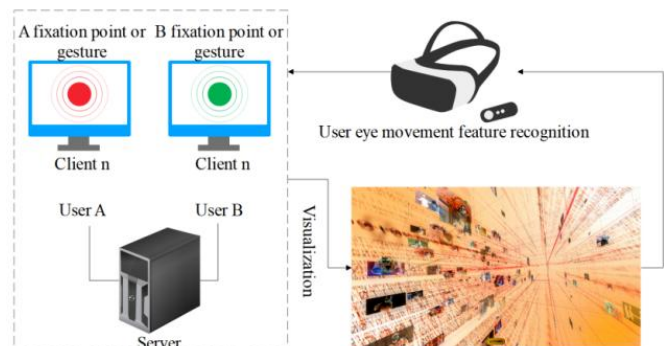

Fig. 9. System structure.

The data set in this article is a self-built data set, which is tested by 40 volunteers. These 40 volunteers are all VR game enthusiasts, so they meet the experimental verification needs of visual fatigue in this article. This paper conducts experiments through popular games, and selects two popular plot games to conduct experiments.

B. Results

In this project, the head images of 40 volunteers in VR game state are taken, and the video is decomposed into 10,000 frames. The number of eye movement behaviors is counted by using the ERT algorithm based on Haar-Adaboost feature, the unimproved three-frame difference method and the improved

three-frame difference method based on binocular position tracking in face area. The results are shown in Table I and Fig. 10 and Fig. 11.

Since this project judges whether there is visual fatigue based on the eye movement behavior rate of VR games, it is particularly important to obtain the frequency data of eye movement behavior under normal circumstances. Through the VR game test of the respondents in this paper, the frequency of eye movement behavior is artificially counted to explore the relationship between the frequency of eye movement behavior and fatigue. The results are shown in Table II.

TABLE I. COMPARISON OF STATISTICAL EFFECTS OF DIFFERENT ALGORITHMS ON EYE MOVEMENT BEHAVIOR

Algorithms	Game 1			Game 2		
	Detection rate (%)	False detection rate (%)		Detection rate (%)	False detection rate (%)	
Human eye feature ERT algorithm	94.45	4.26	Human eye feature ERT algorithm	94.45	4.26	Human eye feature ERT algorithm

Fig. 10. Comparison of detection effects of different algorithms on eye movement behavior (Game 1).

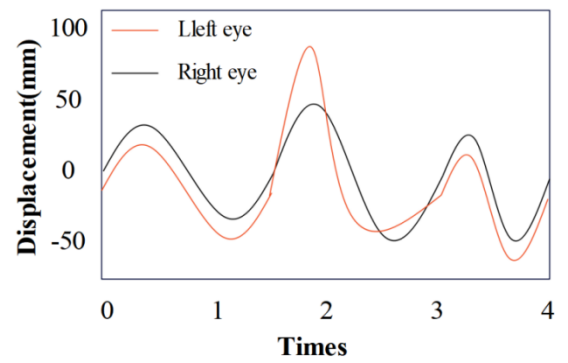

Fig. 11. Comparison of detection effects of different algorithms on eye movement behavior (Game 2).

In order to verify the influence of players' body movements on the detection results of eye movement features in VR games, this paper takes racing games as an example to analyze, and designs the tilt experiment of VR racing games passing through speed bumps. When the vehicle speed is 10 km/h, the tires on one side of the car body pass through the speed bump, and the tester's head also shakes violently. The experimental results obtained by processing are shown in Fig. 12. Fig. 12 (a) shows the moving directions of the right and left eyes in the X axis, Fig. 12 (b) shows the moving directions of the right and left eyes in the Y axis, and Fig. 12 (c) shows the moving directions of the right and left eyes in the Z axis.

In the Y direction, the black line and the red line obviously cross, indicating that the movement states of the left eye and the right eye are different at this time. Furthermore, the movements of the right and left eyes are also different in the X and Z directions. The root cause of these differences is that the right and left eyes move in opposite directions on the same axis (namely, X, Y, and Z axes). For example, the difference between the right and left eye on the Y axis indicates that the left eye moves down and the right eye moves up, or the left eye moves up and the right eye moves down. Therefore, by detecting the motion states of the right eye and the left eye, it is possible to determine whether there is a lateral tilting motion of the human body.

In order to further verify the accuracy of this model in VR game fatigue detection, this model is compared with study [4] (visual tracking), study [10] (EEG), study [16] (brain computer interface), and the accuracy of the above methods in VR game fatigue detection is verified through comparative tests, A total of six groups of tests were conducted, and the comparison results in Table III are obtained.

6	70.80	75.16	80.67	91.83

C. Analysis and Discussion

For humans, the position of the human eye on the head is relatively fixed, and the area other than the head needs to be removed. Therefore, the area of the human eye can be located only by estimating the position of the human eye on the head. Based on the fact that the human eye is fixed at the position of

the face, when the player's head remains stationary, it is enough to detect moving targets in more than two-thirds of the skin color area of the face. However, in VR ordered scenes, the player's head is often in a constant state. In a state of shaking, finding the approximate position of the human eye when the head is shaking is the difficulty of algorithm improvement. Through observation, it can be found that when the player's head shakes, the movement trajectory of the center point of both eyes and the movement trajectory of the head show a certain regularity, and the relationship between the movement trajectory of the center point of both eyes and the displacement of the head can be located for the human eye only by finding the relationship between the movement trajectory of the center point of both eyes and the movement trajectory of the head.

The eye movement behavior detection algorithm based on human eye features needs to locate the human eye first, and then judge whether there is eye movement behavior according to the coordinate changes of human eye feature points. In the process of cascade classifier training and human eye feature matching, a large number of image samples need to be trained, and to traverse the whole detected image, the algorithm complexity is high, and it is extremely difficult to implement in FPGA development board. After observing the player's face in the game state, it is found that in the normal game state, the player's face is basically stationary, and only the eyes and mouth will appear tiny movements. Therefore, the detection of eye movement behavior can be completed only by detecting whether there is moving target in the face range, and no longer need to waste a lot of computing power for data sample training and feature point acquisition. At present, most algorithms have realized the location of face area. Therefore, the background difference algorithm is considered to detect the moving target of human face and then judge whether there is eye movement behavior.

It can be seen from Table I and Fig. 10 and Fig. 11 that the ERT algorithm based on Haar-Adaboost human eye features has the highest detection rate and the lowest false detection rate for human eye movement behavior, but the processing speed of the algorithm is the slowest among the three algorithms, and the algorithm is complex, which is difficult to implement in FPGA development board. The traditional three-frame difference algorithm has the fastest detection speed, but its detection is the lowest among the three algorithms, and the false detection rate reaches about 20%. The detection rate of eye movement behavior of the improved three-frame difference algorithm is about 91%, the average detection rate is nearly 7% higher than that of the traditional three-frame difference method, and the average false detection rate is 56% lower than that of the traditional three-frame difference method. Because the algorithm introduces the human eye position estimation model, the processing speed is lower than that of the traditional three-frame difference method, but the processing frame rate still reaches 42 fps, which meets the performance requirements of visual fatigue detection of VR games.

It is pointed out that under normal circumstances, the frequency of players' eye movement behavior is between 12-17, and with the increase of game duration and fatigue, the highest rate of eye movement behavior reaches 40 times per minute. As can be seen from Table II, under normal conditions, the

frequency of normal people's eye movement behavior is mainly distributed between 11 and 19. Considering that VR gamers are more concentrated in the game situation, and the rate of eye movement behavior is relatively low, this project will set the threshold of vision through attention to 11-19. Combined with the actual experimental data, it is found that setting the threshold of fatigue state to 11-19 times per minute has the greatest correlation with the fatigue state of VR gamers. When the eye movement behavior fatigue is 5 to 10 times per minute or more than 18 times per minute, it is determined that the VR game player has abnormal eye movement behavior phenomenon and visual fatigue.

It can be seen from Fig. 12 that the experimental results in this paper are consistent with the actual situation, which further verifies that the proposed stereo vision measurement method can be used for tracking measurement of eye movement and verifies the robustness of the algorithm under real conditions.

In Table III, visual tracking has the lowest accuracy, and the highest accuracy is only 72.64%. The recognition results of EEG and brain computer interface are similar, and the highest recognition accuracy can reach 82%. The accuracy of this research model in VR game fatigue detection can reach more than 88%, and the highest can reach 91.83%.

Through comparative analysis, it is verified that this research model has excellent performance in VR game fatigue detection

Taken together, the eye movement feature method proposed in this paper has a good effect in visual fatigue monitoring of VR games and can effectively improve the real-time analysis of player status. Therefore, integrating this algorithm into the virtual game system can help players adjust their own state, which has a positive effect on improving the game experience and reducing eye damage.

There are significant differences in the fatigue state of different individuals while playing games.

This difference is mainly reflected in individuals' reactions to the side effects of VR games. For example, some people may experience severe dizziness, nausea, eye fatigue, and overall fatigue after playing high-intensity VR games, while others may have mild or almost no symptoms. This difference is influenced by various factors, including individual sensory adaptation, age, gaming experience, and duration of continuous use of VR devices.

Specifically, an individual's sensory adaptation plays a crucial role in understanding the severity of VR vertigo. Some people are more likely to experience subjective visual vertical line changes after exposure to VR, especially under high intensity, which may be related to their milder VR dizziness symptoms. On the contrary, those who suffer from the most severe VR vertigo are unlikely to change the way they perceive vertical lines.

In addition, the study also found that women are more likely to experience screen sickness when using VR than men, which may be consistent with statistical data showing that women are also more prone to motion and screen sickness in other environments. This gender difference is particularly important in the widespread application of VR technology, as it may affect

the acceptance and user experience of VR technology among users of different genders.

In addition to gender and sensory adaptation, an individual's gaming experience can also affect their fatigue state. Novice players may feel more exhausted and uncomfortable due to unfamiliarity with the VR environment, while experienced players may be better able to adapt and reduce fatigue. Therefore, for different individuals, the fatigue state while playing games is a complex and variable problem, influenced by multiple factors.

The system has a good statistical effect on capturing eye movement behavior and eye movement behavior rate. However, although there is a great correlation between eye movement behavior rate and fatigue degree, it is difficult to accurately judge the mental state of VR game players only through this single index. In addition, due to factors such as living habits, there are differences in the frequency of eye movement behavior among individuals. Therefore, we should further eliminate individual differences through experiments, and make a comprehensive evaluation of fatigue state in combination with factors such as head posture and mouth characteristics.

V. CONCLUSION

In order to improve users' immersion and experience in VR game environment, this paper proposes a visual skin fatigue recognition algorithm based on eye movement tracking, which uses the relationship between the lateral displacement and longitudinal displacement of the human head and the displacement of the center point of the human eye to locate the position of the human eye, and inputs the human eye position tracking model into the three-frame difference algorithm to detect eye movement behavior. In addition, for tiny motion interference such as eyebrows, this paper adopts the image open operation of eroding first and then expanding to remove it. The eye movement behavior detection method adopted in this paper greatly improves the detection speed, meets the sensitivity requirements of eye movement behavior capture, and improves the real-time performance of the system with less accuracy loss. Moreover, the correlation between eye movement behavior frequency and fatigue is based on relevant reference and actual experiments, and the data are reliable.

The system has a good statistical effect on capturing eye movement behavior and eye movement behavior rate. However, although there is a great correlation between eye movement behavior rate and fatigue degree, it is difficult to accurately judge the mental state of VR game players only through this single index. In addition, due to factors such as living habits, there are differences in the frequency of eye movement behavior among individuals. Therefore, we should further eliminate individual differences through experiments, and make a comprehensive evaluation of fatigue state in combination with factors such as head posture and mouth characteristics.

High-Accuracy Vehicle Detection in Different Traffic Densities Using Improved Gaussian Mixture Model with Cuckoo Search Optimization

Nor Afiqah Mohd Aris, Siti Suhana Jamaian

Department of Mathematics and Statistics-Faculty of Applied Sciences and Technology,
Universiti Tun Hussein Onn Malaysia, Pagoh Education Hub, Pagoh, 84600, Malaysia

Abstract—Background subtraction plays a critical role in computer vision, particularly in vehicle detection and tracking. Traditional Gaussian Mixture Models (GMM) face limitations in dynamic traffic scenarios, leading to inaccuracies. This study proposes an Improved GMM with adaptive time-varying learning rates, exponential decay, and outlier processing to enhance performance across light, moderate, and heavy traffic densities. The model's parameters are automatically optimized using the Cuckoo Search algorithm, improving adaptability to varying environmental conditions. Validated on the ChangeDetection.net 2014 dataset, the Improved GMM achieves superior precision, recall, and F-measure compared to existing methods. Its consistent performance across diverse traffic scenarios highlights its effectiveness for real-time traffic flow analysis and vehicle detection applications.

Keywords—Gaussian mixture model; vehicle detection; adaptive time-varying learning rate; exponential decay; outlier processing; cuckoo search optimization

I. INTRODUCTION

In recent years, the significance of vehicle detection and tracking systems has increased, driven by the growing demand for efficient and intelligent transportation systems. These systems play a pivotal role in diverse applications such as traffic management, accident prevention, and autonomous vehicle navigation [1-5]. To meet these demands, accurate and dependable Background Subtraction (BS) methods are essential in handling the complexities posed by dynamic and different traffic scenarios. Researchers have proposed many methods to study vehicle detection, such as traditional computer vision, machine learning, deep learning, motion-based, radar-based, and fusion techniques. This research specifically focuses on traditional computer vision methods: background subtraction in terms of mathematical contributions.

The BS method is a technique used for object detection. It involves segmenting the foreground from the background scene by generating a binary mask that identifies moving objects. The core principle of the BS method is to compute the difference between the current frame and a reference frame (background image). Thresholding techniques are then applied to classify the segmented pixels as either foreground or background. This process effectively isolates moving objects from the stationary background.

BS is a pivotal component in detection, tracking, and scene understanding, has been extensively addressed through GMM. GMM, known for their efficacy, are widely utilized to model complex and multi-modal background scenes by capturing statistical distributions of pixel intensities over time [6-8]. However, the application of traditional GMMs encounters notable challenges in the domain of vehicle detection, particularly when faced with different traffic densities. These challenges stem from the inherent limitations of constant learning rates in traditional GMMs, which are unable to adjust dynamically to the varying characteristics of the data. Traffic density and vehicle movement patterns can vary significantly over time and across environments. In such scenarios, a fixed learning rate often proves suboptimal, leading to issues such as slow convergence or convergence to suboptimal solutions, thereby impacting detection accuracy.

Moreover, traditional GMMs treat all observations equally, including outliers, which can distort the underlying data distribution and reduce the precision of the segmentation. They also assume that pixels do not closely match the mean belonging to the same statistical cluster, which may not be accurate in highly dynamic environments. These shortcomings hinder the ability of traditional models to adapt effectively to rapid changes in traffic conditions, such as those encountered in heavy or fluctuating traffic densities.

To address these limitations, this study proposes an Improved Gaussian Mixture Model (Improved GMM) that builds upon the strengths of traditional GMMs while introducing key enhancements. The Improved GMM incorporates an adaptive time-varying learning rate, which allows the model to dynamically adjust its parameters based on the characteristics of the current data. This adaptability improves performance across different traffic densities by better accommodating environmental changes.

Additionally, the model introduces exponential decay, which emphasizes pixels closer to the mean, enhancing the model's ability to distinguish between objects and background elements with higher precision. Outlier processing is also incorporated to control the influence of new covariance update observations, ensuring robustness against noisy data and outliers. These modifications collectively enable the Improved GMM to handle the complexities of vehicle detection under varying traffic densities.

Finally, to further enhance the robustness and adaptability of the Improved GMM, the Cuckoo Search (CS) optimization technique is employed for automatic parameter tuning. Inspired by the breeding behavior of cuckoos, this metaheuristic algorithm intelligently selects optimal values for critical parameters, such as the number of Gaussian components and learning rates, by exploring the parameter space efficiently. Unlike manual tuning, CS optimization dynamically adapts to the complexity of different traffic scenes, ensuring that the Improved GMM consistently delivers high detection accuracy across diverse environmental conditions with minimal human intervention.

Traffic density affects the dynamics of the background scene. In light traffic conditions, background updates may occur less frequently as there are fewer changes to the background. In contrast, the background may change rapidly in heavy traffic conditions due to the movement of multiple vehicles. Understanding and adapting to these variations in background dynamics is essential for accurate background subtraction [9-10].

The focus extends beyond the general challenges of vehicle detection to performance under different traffic densities—light, moderate, and heavy traffic conditions. The classification can be defined by the number of vehicles per square foot. Light traffic scenarios may involve less than three vehicles distributed per 500 square feet; moderate traffic represents a balance of vehicles, which is less than five vehicles distributed per 500 square feet, while heavy traffic introduces challenges, such as more than six vehicles distributed per 500 square feet. These variations necessitate developing an adaptive method to effectively address these issues while maintaining high detection accuracy and computational efficiency.

The structure of this paper is organized as follows: Section II reviews related works, providing an overview of existing approaches and background subtraction enhancements. Section III comprehensively discusses GMM and its applications in background subtraction. Section IV details the proposed Improved GMM, outlining modifications and introducing key elements. Section V describes the experimental setup and datasets utilized for evaluation, while results and discussion is given in Section VI and finally, the paper is concluded in Section VII.

II. RELATED WORKS

In the realm of computer vision, the study of background subtraction has been both significant and extensively explored. This led to the development and presentation of numerous methods and techniques to overcome diverse challenges, particularly in the context of detecting vehicles within dynamic traffic scenarios. The GMM has been widely adopted for background subtraction in computer vision applications, particularly in the vehicle detection field [7]. Initially, Friedman and Russel introduced the GMMs for background subtraction [11], while Stauffer and Grimson subsequently developed effective modified equations [6]. Numerous researchers also proposed additional modifications and improvements on the original model to enhance its performance in various traffic scenarios. Hence, this section

reviews several key developments and recent field advancements, focusing on an overview of the existing GMM methods and their improvements in background subtraction. Stauffer and Grimson denoted the GMM as a background subtraction method, which gained significant popularity due to its ability to model complex and multi-modal background scenes [6]. The study successfully achieved the objectives by capturing the statistical distribution of pixel intensities over time. Consequently, numerous researchers proposed improvements and modifications to the traditional GMM.

Zivkovic developed an adaptive GMM with a configurable number of Gaussian components, producing improved model adaptations to changing conditions [7]. Meanwhile, Zuo et al. designed an enhanced method for noise interruption for the traditional GMM [12]. The study incorporated several techniques to improve performance, including image block averaging, wavelet semi-thresholding, and adaptive background updating. Thus, the method effectively eliminated noise issues and enhanced the detection performance of the moving targets. The study also utilized an adaptive background update during the background updating phase, resulting in more accurate detection results. Another study by Lin and Chen discovered a novel method for recognizing moving objects that integrated GMM with visual saliency maps [13]. The approach effectively overcame the challenges caused by shadow situations while producing stable detection results, which transformed each image frame to the L^* , a^* , and b^* colour spaces. A Gaussian filter was then utilized to smooth the L^* , a^* , and b^* channels, eliminating small texture features and noise. The saliency maps were estimated for each channel and linearly merged to generate a comprehensive saliency map, which was combined with the foregrounds to obtain the moving objects.

Meanwhile, Zivkovic and Heijden present two efficient adaptive density estimation methods for background subtraction in video surveillance systems. The first method is based on a GMM and uses recursive equations to update model parameters and select appropriate components for each pixel. The second method is a nonparametric kernel-based approach that adapts to changes in the scene by updating the training data set. The performance of both methods is evaluated and compared to other algorithms. The results show that the nonparametric method outperforms the GMM approach in terms of accuracy but at the cost of increased processing time. This research provides valuable insights into the challenges of background subtraction and offers practical solutions for real-world applications [14]. A study by Varadarajan et al. proposes a new approach to modeling and subtracting backgrounds effectively in scenes with complex dynamic textures. The proposed method considers the spatial relationship between pixels, modeling regions as mixture distributions rather than individual pixels. In this research, the researchers derive novel online update equations using expectation maximization (EM) for modeling scenes containing dynamic textures. The effectiveness of the proposed algorithm is experimentally verified on various video sequences and compared with other well-known background subtraction algorithms. The results show that the proposed algorithm performs better than most algorithms and produces comparable results to ViBe, one of

the best background subtraction algorithms currently in the literature [15].

Another study by Cioppa et al. introduces a novel algorithm called Real-Time Semantic Background Subtraction (RT-SBS), which combines real-time background subtraction with high-quality semantic information for improved performance. The algorithm addresses the limitations of traditional background subtraction methods by leveraging semantic information provided at a slower pace and for some pixels. RT-SBS reuses previous semantic information by integrating a change detection algorithm during the decision process, ensuring real-time applicability while maintaining performance comparable to SBS. This work advances real-time background subtraction algorithms, particularly in scenarios with dynamic backgrounds, illumination changes, and moving objects [16].

Işık et al. proposed a novel method for foreground or background extraction in videos, specifically designed to address challenges posed by dynamic backgrounds. The Common Vector Approach for Background Subtraction (CVABS) leverages the Common Vector Approach (CVA) obtained through Gram-Schmidt Orthogonalization to achieve accurate background modeling. By treating background modeling as a spatiotemporal classification problem, the algorithm computes the common vector of frames to acquire the background model, enabling effective foreground object detection. The method incorporates a self-learning feedback mechanism to mitigate the impact of dynamic scenes and illumination changes on foreground detection accuracy. Experimental evaluations on diverse, dynamic backgrounds demonstrate the effectiveness of CVABS, positioning it as a competitive solution in the field of moving object segmentation [17].

In recent years, researchers also emphasized optimizing the GMM framework for specific applications, such as vehicle detection in traffic scenarios. A study by Zhang et al. described GMM with Confidence Measurement (GMMCM) as a potential solution [18]. The study addressed the susceptibility of background subtraction models towards contamination by slowly moving or temporarily stopping vehicles. Furthermore, the GMMCM incorporated a Confidence Measurement (CM) technique, assigning trust values to each pixel in the background model. This method quantified the current reliability of background pixels, and the design was developed to balance the dynamic changes in brightness and background (resolving contamination challenges) in complex urban traffic scenes. Consequently, this method was successful through a self-adaptive learning rate, which ensured the background model remained accurate. Another study by Lima et al. included a method for estimating the region-specific thresholds using a feedback step [19]. The approach employed spatial analysis to select an appropriate threshold for each region, which was utilized for pixel classification. A filtering technique was applied to the segmentation before the threshold estimate to address classification errors. This filtering process eliminated disturbances and consolidated the entire area into a cohesive unit. During the feedback phase, segmentation corrections estimated the thresholds for subsequent iterations. Notably, the filtering stage focused on correcting foreground errors, significantly enhancing the vehicle areas. This

recommended strategy facilitated the segmentation of previously segmented regions and resembled a first-order Markov chain estimate of the threshold.

In a study by Agrawal and Natu, a novel approach was developed by combining GMM with blob analysis, including labelling and morphological operations, to enhance the accuracy of foreground detection [20]. The model computed the difference between the reference frame BMG (x, y) and the current frame while applying a threshold to isolate the region of interest. In constructing the foreground model, a threshold value was selected for each pixel, which was determined using the standard deviation. A study by Luo et al. summarised a motion detection method considering spatial variation in image thresholds [21]. The approach required calculating the projected motion size under different image regions, established using a mapping correlation between the geometric motion features and the appropriate enclosing rectangle (BLOB) level in the spatial domain. This discovery enabled an adaptive threshold for each motion, effectively removing unwanted noise during motion detection.

Chen and Ellis employed a multi-dimensional Gaussian Kernel Density Transform (MDGKT) pre-processor to reduce noise in the spectral, temporal, and spatial domains [22]. This pre-processor applied spatial and temporal smoothing to each spectral component using a multivariate kernel, regarded as the product of two radially symmetric kernels. The MDGKT was a crucial component in improving the reliability of the GMM. Thus, the time interval and resolution of the GMM were changed by modifying the size of the kernel through a pair of bandwidth parameters. Kalti and Mahjoub designed a unique approach that incorporated a fuzzy distance into the Expectation-Maximisation (EM) and Adaptive Distance-based Fuzzy-C-Means (ADFCM) algorithms [23]. The pixel characterization in the study was based on two factors: the inherent attributes of the pixel and the characteristics of its surrounding neighbourhood. The classification was then measured using an adaptive distance that preferred one of the attributes concerning the pixel spatial location within the image. Another study by Wei and Zheng studied a method that calculated the L2 norm between the GMMs to measure the similarity corresponding to two pixels [24]. The study recorded the grayscale information of the pixel and the feature abundance in the local image region. Compared to individual pixels based on their differences, higher accurate pixel intensity measurements and information variation in the surrounding region were obtained. This similarity-based approach enhanced the performance of image-denoising models and preserved the detailed information in the image. Likewise, Chen and Ellis discussed an innovative approach that addressed the global illumination change concern in background model adaptation [22]. The study applied a revised adaptive strategy within the iterative learning process of the Zivkovic-Heijden GMM (ZHGM). This method was implemented by integrating a modified adaptive schedule into an existing filtering system, yielding superior performance than previous approaches (particularly in scenarios involving sudden illumination changes).

Martins et al. designed a novel classification mechanism that combined colour space discrimination, hysteresis, and

dynamic learning rate to address sudden illumination changes in the background model [25]. Each channel element (L*, a*, and b*) was analyzed individually, and the decisions obtained from each channel were merged using the AND rule, producing superior results than majority voting. This approach ensured a faster model and slower adaptations in dynamic and static regions. A higher learning rate (α_{UBG}) was applied if the pixel classification transitioned from foreground to background. Therefore, this mechanism promoted rapid adaptation when the background reappeared, effectively preventing the phantom image from emergence.

Regarding mathematical contributions, Su introduced a GMM with a data model optimization approach to address the adapting challenge of light transitions [26]. The initial step in the process included gradient picture calculation of the video stream using the Scar Operator. Subsequently, the RGB values and gradients were integrated, and noisy movement areas were eliminated using various techniques (combining the remaining sites). The two model outputs were compared to determine the final makeup area in mitigating incorrect diagnosis risk. Thus, the results demonstrated that the approach enhanced the detection process accuracy by minimizing the erroneously detected area occurrences caused by sudden illumination changes.

The advancements in GMM-based background subtraction have significantly addressed noise, dynamic textures, and illumination changes. Approaches such as RT-SBS, CVABS, and adaptive density estimation have demonstrated success in handling specific scenarios, including dynamic backgrounds and complex traffic environments. However, these methods often rely on manually tuned or fixed parameters, hindering their adaptability to fluctuating traffic densities and varying environmental conditions. This study bridges these gaps by proposing an Improved GMM that incorporates adaptive time-varying learning rates, exponential decay, and robust outlier processing, supported by CS Optimization for automatic parameter tuning. This ensures consistent and robust performance across light, moderate, and heavy traffic scenarios, contributing to the development of efficient vehicle detection systems.

III. GAUSSIAN MIXTURE MODEL IN VEHICLE DETECTION

GMM is a Mixture of Gaussians (MoG), a prominent strategy for background subtraction methods in computer vision applications. A study by Stauffer et al. discovered this strategy based on a parametric model in handling multiple modes within the pixel values [6]. The study implied that the background and foreground distributions for the GMM were Gaussian, in which the background area was more visible and exhibited smaller variances than the foreground. This assumption enabled the GMM to effectively manage slow-lighting changes and -moving objects, periodic motion, long-term scene changes, and camera noise. Conversely, the GMM was only used for its computational efficiency and excellent performance in numerous applications, as the previous assumption was not always true.

The GMM aims to construct a background model for each pixel to the time-domain distribution of pixel values in a video sequence. This model represents the weighted sum of a finite

number of Gaussian functions, which describes the multi-peak state of pixels while being suitable for complex background models (light gradients and swaying trees). In the GMM, Gaussian components with large weights represent the background, while those with small weights represent the foreground. Generally, a new pixel is part of the background if it correspondingly matches the Gaussian model. Otherwise, the pixel is treated as a foreground pixel if it does not match a Gaussian model (or match a Gaussian model with only a small weight). The efficacy of GMM has prompted various improvements and extensions in the field, which has become a widespread practice for background extraction in computer vision applications [7, 10, 26, 27, 28]. Hence, the application of GMM in vehicle detection can be expressed as in Eq. (1), where the weighted sum of K Gaussian distributions times the Gaussian component.

$$f(x_t) = \sum_{k=1}^K \Pi_{k,t} \cdot \Phi(x_t, \mu_{k,t}, \sigma_{k,t}) \quad (1)$$

where x_t is the pixel value; $\Phi(x_t, \mu_{k,t}, \sigma_{k,t})$ is the Gaussian component density with mean $\mu_{k,t}$ with covariance matrix $\sigma_{k,t}$; $\Pi_{k,t}$ is the weight associated with the k^{th} Gaussian component. Subsequently, $\Phi(x_t, \mu_{k,t}, \sigma_{k,t})$ is formulated as:

$$\Phi(x_t, \mu_{k,t}, \sigma_{k,t}) = \frac{1}{(2\pi)^{\frac{n}{2}} |\sigma_{k,t}|^{\frac{1}{2}}} e^{-\frac{1}{2}(x_t - \mu_{k,t})^T \Sigma_{k,t}^{-1} (x_t - \mu_{k,t})} \quad (2)$$

where n is the dimension of the pixel intensity. The covariance matrix is also assumed as $\sigma_{k,t} = \sigma_{k,t}^2 I$. Each new pixel value, x_t is compared with each of the existing K Gaussian distributions. A pixel is considered to match a Gaussian distribution if its value falls within a range of 2.5 standard deviations from the mean of that distribution where the matching condition is $|x_t - \mu_{k,t-1}| \leq 2.5\sigma_{k,t-1}$. The classification process involves categorizing a pixel as background if it matches with the Gaussian distribution identified as background, and as foreground if it matches with the Gaussian distribution identified as foreground. In cases where the pixel does not match with any of the K Gaussians, it is classified as foreground. This process results in the creation of a binary mask. A new Gaussian distribution is added if $k < K$, while the Gaussian distribution is replaced with the lowest priority $k = K$ ($\sigma_{k,t}^2 = \Pi_{k,t} / \sigma_{k,t}$) if $k = K$. The weights of every Gaussian distribution must be updated for the next foreground detection,

$$\Pi_{k,t} = (1 - \alpha)\Pi_{k,t-1} + \alpha\psi_{k,t} \quad (3)$$

where ψ is the indicator function and α is the constant learning rate. The mean and variance that do not find a match remain unchanged. However, for the component that does match, its mean and variance are updated according to the following criteria:

$$\mu_{k,t} = (1 - \beta)\mu_{k,t-1} + \beta x_t \quad (4)$$

$$\sigma_{k,t}^2 = (1 - \beta)\sigma_{k,t-1}^2 + \beta(x_t - \mu_{k,t})(x_t - \mu_{k,t})^T \quad (5)$$

where $\beta = \alpha \cdot \Phi(x_t, \mu_{k,t}, \sigma_{k,t})$. If the k^{th} Gaussian distribution matches x_t , then $\psi = 1$. Otherwise, $\psi = 0$ if the k^{th} Gaussian distribution does not match with x_t . The Gaussian distribution weights are then normalized after being modified. The K Gaussian distribution for each pixel is described after the modification process as:

$$B = \operatorname{argmin} \left(\sum_{k=1}^b \Pi_k > th \right) \quad (6)$$

where th is the threshold. Based on the ratio (Π/σ) , these distributions are listed by priority order, beginning with the B Gaussian distribution. Subsequently, a continuous comparison of the x_t and B Gaussian distribution is performed. The pixel is considered a background point if the x_t distribution matches any preceding B Gaussian distribution points. Alternatively, the pixel is regarded as a foreground point if it does not match, and the moving object detection is considered complete.

IV. PROPOSED IMPROVED GMM

The proposed Improved GMM model is fixed as in Eq. (1) and the Gaussian component in Eq. (2), but there are some modifications in Eq. (3) to Eq. (5), which are the updating parameters of the Gaussian component. This section presents the GMM modifications for achieving high accuracy in vehicle detection across various traffic densities, which addresses the traditional GMM limitations by introducing an adaptive time-varying learning rate, exponential decay, and outlier processing. Traditional GMMs have limitations, such as fixed learning rates, sensitivity to outliers, and difficulties in distinguishing between closely spaced objects. Therefore, these enhancements allowed the Improved GMM to effectively capture the dynamic nature of traffic density variations and improve detection accuracy. The suggested Improved GMM was founded on the improvements to the mean, covariance, and weight equations presented by Stauffer and Grimson [6]. The upgrades are as follows:

$$\mu_{k,t} = (1 - \beta(t))\mu_{k,t-1} + \beta(t)x_t \cdot e^{-\lambda d_t} \quad (7)$$

$$\sigma_{k,t}^2 = (1 - \beta(t))\sigma_{k,t-1}^2 + \beta(t)(1 - \gamma)(1 - e^{-2\lambda d_t})(x_t - \mu_{k,t})(x_t - \mu_{k,t})^T \quad (8)$$

$$\Pi_{k,t} = (1 - \alpha)\Pi_{k,t-1} + \alpha e^{-\lambda d_t} \quad (9)$$

where $\beta(t) = c/(c + t)$.

A. Adaptive Time-Varying Learning Rate

Traditional GMMs use a constant learning rate, which struggles to adapt to changing traffic densities. For example, in heavy traffic, where vehicles move closely together, or in light traffic, where vehicles are sparse, a fixed learning rate may result in slow adaptation or inaccurate background modeling. An adaptive time-varying learning rate controls the weights assigned to the newly arriving data samples [30]. This suggestion enables the algorithm to quickly adapt to traffic flow changes and detect vehicles more accurately by considering the distance between the pixel and the current means. This modification is mathematically represented by Theorem 1.

Theorem 1. The $\beta(t)$ is derived using the Robbins-Monro stochastic approximation method, which involves solving the recursive equation as:

$$\beta(t) = c/(c + t) \quad (10)$$

where c is a constant that controls the learning rate.

Proof. The Robbins-Monro stochastic approximation method is an iterative algorithm to solve root-finding issues for non-linear equations in form $f(x) = 0$, which is based on stochastic gradient descent [31, 32, 33]. The Robbins-Monro conditions are satisfied to demonstrate the validity of the update rule in Eq. (10). This validity ensures the convergence of the stochastic approximation method, which two main criteria of the Robbins-Monro conditions are as follows:

Condition 1: The sum of the learning rates $[\sum_t \beta(t)]$ should diverge and $\sum_t \beta(t) = \infty$. By evaluating the summation, a telescoping series is expressed as:

$$\sum_t \beta(t) = \frac{c}{c+1} + \frac{c}{c+2} + \frac{c}{c+3} + \dots + \frac{c}{c+t} \quad (11)$$

When the terms are rearranged, they can be written as:

$$\sum_t \beta(t) = c \left[\frac{1}{c+1} + \frac{1}{c+2} + \frac{1}{c+3} + \dots + \frac{1}{c+t} \right] \quad (12)$$

Since Eq. (12) diverges, it can reach infinity as t approaches infinity. Therefore, $\sum_t \beta(t)$ also diverges, satisfying Condition 1.

Condition 2: The $\sum_t \beta^2(t)$ should converge and $\sum_t \beta^2(t) < \infty$. By expanding and simplifying the expression, an equation is formulated as:

$$\sum_t \beta^2(t) = \frac{c^2}{(c+1)^2} + \frac{c^2}{(c+2)^2} + \frac{c^2}{(c+3)^2} + \dots + \frac{c^2}{(c+t)^2} \quad (13)$$

As in Eq. (13) converges, a finite sum is demonstrated as t approaches infinity. Hence, $\sum_t \beta^2(t)$ also converges, satisfying Condition 2. When both conditions are satisfied, the updated rule in (10) is proven valid within the context of the Robbins-Monro stochastic approximation method [34]. This updated rule ensures the learning algorithm convergence as the iteration or t approaches infinity. This strategy provides more weight to the newer data pixels while maintaining a certain importance level for the past data pixels. The constant (c) in the Robbins-Monro stochastic approximation method controls the learning rate and should be chosen based on the data characteristics and the specific application [35].

The c parameter value is selected based on a priori data knowledge, such as possible value ranges for the model parameters and the data distribution. Notably, the c value affects the performance of the algorithm, which selecting the incorrect value leads to slow convergence or instability. The value of the iteration or t is typically set to increment by one with each iteration. The t value is also interpreted as the number of algorithm iterations or observations analyzed, which the t initial value and the growth rate impact the convergence speed and algorithm stability. If the t initial value is too small, the step size can be excessively large, causing instability and

overestimating the optimal solution. Similarly, if the t initial value is too high, the step size can be extremely small, leading to slow convergence and the possibility of becoming trapped with a suboptimal solution. The t growth rate also affects the convergence speed and algorithm stability. A rapid increase in t promotes faster convergence, which leads to instability and overestimation. Alternatively, a slower growth in t produce stable behaviour, which leads to slow convergence.

B. Exponential Decay

Exponential decay improves the model's ability to handle dynamic objects and lighting changes by giving more weight to recent pixels closer to the mean. For example, when vehicles move closer to the camera, their pixels influence foreground detection more significantly. The parameter λ adjusts the contributions of each current pixel (mean, covariance, and weight parameters) to the Improved GMM. When this adjustment is incorporated, the vehicle detection precision increases to the distance between the current pixel and the current mean. The $\mu_{k,t-1}$ is the previous mean, x_t is the current pixel, and d_t is the Euclidean distance between x_t and the previous mean $\mu_{k,t-1}$. Furthermore, the introduction of the exponential decay factor ($e^{-\lambda d_t}$) from Eq. (7) to Eq. (9) ensures that the contribution of each pixel decreases as its distance from the current mean increases [36]. This characteristic is consistent with the notion that pixels closer to the mean influence the parameter changes more than those further away [37]. The additional term $(1 - e^{-2\lambda d_t})$ adjusts the contribution of each pixel to the covariance parameter based on its distance from the current mean. From Eq. (7) to Eq. (9), $\Pi_{k,t-1}$ represents the previous weight, and $e^{-\lambda d_t}$ modifies the contribution of each data point to the weight parameter with respect to its distance from the current mean. This modification assures that the contribution of each data point to the weight reduces as its distance from the current mean increases [38]. The updated parameter equation is explained in the Theorem 2:

Theorem 2. Consider $e^{-\lambda d_t}$ to be the exponential decay factor introduced from the Improved GMM ((7) to (9)) for vehicle detection in real-time traffic flow analysis. Based on the distance from the current mean, this exponential decay factor modifies the contribution of each current pixel to the mean, covariance, and weight parameters. Therefore, the equations are:

$$\mu_{k,t} = (1 - \beta)\mu_{k,t-1} + \beta x_t \cdot e^{-\lambda d_t} \quad (14)$$

$$\sigma_{k,t}^2 = (1 - \beta)\sigma_{k,t-1}^2 + \beta(1 - e^{-2\lambda d_t})(x_t - \mu_{k,t})(x_t - \mu_{k,t})^T \quad (15)$$

$$\Pi_{k,t} = (1 - \alpha)\Pi_{k,t-1} + \alpha e^{-\lambda d_t} \quad (16)$$

Proof. Consider two pixels (x_{t1} and x_{t2}), where d_{t1} is the distance between x_{t1} and the mean. In addition, d_{t2} is the distance between x_{t2} and the mean. Assume $d_{t1} < d_{t2}$. Hence, x_{t2} and d_{t2} are substituted into Equation 14 produces a new equation:

$$\mu_{k,t} = (1 - \beta)\mu_{k,t-1} + \beta x_{t2} \cdot e^{-\lambda d_{t2}} \quad (17)$$

Since $d_{t1} < d_{t2}$, the $e^{-\lambda d_{t1}}$ is greater than $e^{-\lambda d_{t2}}$. The x_{t1} contribution to the mean parameter is higher than x_{t2} . Similar

reason is extended to Eq. (15) and Eq. (16) to demonstrate that $e^{-\lambda d_{t1}}$ influences the covariance and weight parameters (in a manner that decreases the pixel contribution as its distance from the mean rises) [39].

The contribution of each pixel to the mean parameter decreases as the pixel moves away from the current mean. This outcome prevents outliers or noisy data points from significantly affecting the estimated mean [40]. If a pixel is far from the current mean, it may not accurately represent the underlying distribution, so its contribution to the mean should be downweighed. In vehicle detection, a pixel corresponds to a vehicle far from the current mean is an outlier or an erroneous detection caused by noise in the sensor data. When downweighing the contribution of each pixel to the mean, the algorithm is more robust to such outliers and minimizes the likelihood of false positives or misclassifications. Therefore, adjusting the contribution of each data point to the mean parameter based on its distance from the current mean improves the accuracy and robustness of the GMM algorithm for vehicle detection in real-time traffic flow analysis.

C. Outlier Processing

Traditional GMMs treat all data points equally, including outliers, which can distort the background model. For instance, sudden reflections, shadows, or noisy pixels may lead to false detections. To address this, a robustness parameter (γ) is added to control how much the model updates with new data [41]. This modification permits the influence control of new observations on covariance matrix updates [42]. The γ in the covariance updated equation of the GMM improves the robustness of the model against outliers and noisy data. This new equation is expressed as:

$$\sigma_{k,t}^2 = (1 - \beta)\sigma_{k,t-1}^2 + \beta(1 - \gamma)(x_t - \mu_{k,t})(x_t - \mu_{k,t})^T \quad (18)$$

The updated equation treats all observations in traditional GMM, including the outliers. Hence, the covariance matrix adapts to the outliers and incorporates their influence, potentially leading to distorted estimates of the underlying data distribution. On the contrary, the Improved GMM presented with γ allows the influence control of the new covariance update observations. When adjusting γ value, the weight provided to outlier-like observations is reduced, effectively downplaying their impact on the covariance estimation. When γ is closer to 1, the impact of new observations is reduced, making the model more robust to outliers. Robust estimators mitigate the influence of outliers or departures from model assumptions, providing more reliable parameter estimates [43].

The model responsivity is controlled by incorporating γ into the covariance update equation. This control mechanism balances integrating new information and protecting against outliers. When γ is adjusted, the weight given to outlier-like observations is reduced, allowing the model to focus more on reliable and representative data points [44]. Extensive experiments on real-world datasets were investigated in this study to assess the effectiveness of the proposed modification. The performance of the traditional GMM formulation was then compared with the modified version, incorporating an adaptive

time-varying learning rate, exponential decay, and outlier process.

V. COMPUTATIONAL SETUP

A. Algorithm

The discussion above outlines the computational algorithm for Improved GMM by introducing an adaptive time-varying learning rate, exponential decay, and outlier processing. The steps are similar to traditional GMM, except for steps (4) and steps (5), where there are modifications to the updating parameters means, variance, and weight. The algorithm can be summarized as:

Algorithm 1: Improved GMM

Initialize $K, k, \alpha, \lambda, \gamma, d$ and c

- Step 1 Obtain the current pixel value x_t from video frames.
 - Step 2 Compare the current pixel value with k existing Gaussian distributions, with a matching condition $|x_t - \mu_{k,t-1}| \leq 2.5\sigma_{k,t-1}$. A match is identified if the pixel value falls within 2.5 standard deviations of the distribution.
 - Step 3 If the matching condition is satisfied, classify the pixel values as background. Otherwise, consider the pixel value part of the foreground. If $k < K$, add a new Gaussian distribution; otherwise, replace the Gaussian distribution with the lowest priority $k = K$.
 - Step 4 Update expressions in (7) and (8) if mean and standard deviation do not match.
 - Step 5 After match inspection, update (9) and normalize it after modification.
 - Step 6 List distributions by priority order based on the ratio Π/σ , starting with the B Gaussian distribution.
 - Step 7 Conduct a continuous comparison of x_t and (6). Classify the pixel as a background point if it matches any preceding B Gaussian distribution points; otherwise, consider it a foreground point, indicating the completion of moving object detection.
-

B. Dataset

The Improved GMM was implemented using Python, leveraging libraries such as NumPy for numerical computations, OpenCV for video processing and background subtraction, Scikit-learn for Gaussian Mixture Model operations, and Matplotlib for result visualization. Jupyter Notebook served as the primary development environment, enabling interactive code execution and analysis. The experiments were conducted on a standard laptop equipped with an Intel Core i5 processor (2.50 GHz), 8 GB RAM, and Windows 11 (64-bit). The system achieved a processing speed of approximately 0.75 seconds per frame.

The evaluation of the Improved GMM was conducted using the CDNet 2014 dataset, a benchmark dataset widely used for background subtraction methods. This dataset includes videos representing various traffic densities, categorized as light traffic (less than three vehicles per 500 square feet), moderate traffic (three to five vehicles per 500 square feet), and heavy traffic (more than five vehicles per 500 square feet).

To prepare the dataset for analysis, each video was divided into individual frames for frame-by-frame processing. The

frames were resized to a consistent resolution of 640×480 pixels to ensure efficient processing. Ground truth masks provided in the dataset were used for validation by comparing them against binary masks generated by the Improved GMM. The implementation of the Improved GMM algorithm followed the modifications outlined in Section III. Key parameters were initialized. The CS algorithm was employed to automatically tune these parameters, ensuring optimal performance for various traffic conditions. During frame processing, the GMM dynamically updated its parameters using adaptive learning rates and exponential decay to refine the model, while outlier processing mitigated noise and sudden changes. Finally, the binary masks were refined through morphological operations, such as dilation and erosion, to eliminate noise and enhance detection accuracy. The experiment involved the Improved GMM method and was compared with masks generated using the traditional GMM [6], Effective Adaptive GMM (EGMM) [14], Region-based Mixture of Gaussians (RMoG) [15], Boosted GMM (BMOG) [25], Competitive Learning for Varying Input Distributions (CL-VID) [45], Real-Time Sematic Background Subtraction Version 2 (RT-SBS-V2) [16] and Common Vector Approach Background Subtraction (CVABS) [17].

C. Cuckoo Search Optimization

The CS optimization algorithm was employed to automatically tune the key parameters of the Improved GMM, including $c, K, \alpha, \lambda, \gamma$, and threshold (th). This algorithm, inspired by the breeding behavior of cuckoos, efficiently explores the parameter space using a balance between local and global search mechanisms. To determine the appropriate parameter ranges, prior literature and empirical experimentation were consulted. Table I provides the initial ranges for each parameter:

TABLE I. RANGE PARAMETERS OF OPTIMIZED PARAMETERS

Parameters	Range
c	$0.01 \leq c \leq 0.1$
K	$2.0 \leq K \leq 5.0$
α	$5.0 \leq \alpha \leq 50.0$
λ	$0.01 \leq \lambda \leq 1.0$
γ	$0.1 \leq \gamma \leq 1.0$
th	$3.0 \leq th \leq 7.0$

The CS algorithm began by initializing a population of candidate solutions, each representing a unique set of parameter values within the predefined ranges. These candidates were evaluated using a fitness function designed to maximize the accuracy of the Improved GMM's background subtraction. The fitness function compared the binary masks generated by the model with the ground truth annotations, considering metrics such as precision, recall, and F-measure. During each iteration, the algorithm updated the candidate solutions by simulating the levy flights of cuckoos, which allow for both local fine-tuning and global exploration of the parameter space. Poor-performing solutions were replaced by better-performing ones, ensuring that the algorithm converged towards an optimal set of parameter values.

Default settings for CS algorithm hyperparameters were replaced with experimental investigations to determine the most effective parameter combinations for the Improved GMM. Specifically, the number of Gaussian components (N) and the probability of adaptation (Pa) were key factors in optimizing the background modeling process.

The number of Gaussian components (N) represents the number of distributions used to model each pixel's background, which is crucial in capturing the complexity of background variations. A higher N allows for more sophisticated background modeling, enabling the algorithm to better handle complex scenes with multiple background states such as changing lighting conditions, moving shadows, or repetitive background patterns. The probability of adaptation (Pa) controls the rate at which the model updates its background distributions. By experimenting with different values of N and Pa, we aim to find the optimal configuration that provides the most accurate and robust background subtraction across various traffic scenarios. Table II and Table III illustrate the experimental results for different values of N and Pa.

TABLE II. EXPERIMENTAL RESULTS FOR DIFFERENT VALUES OF N USING PA=0.25 OVER CDNET2014 DATASET

#1517				

TABLE III. EXPERIMENTAL RESULTS FOR DIFFERENT VALUES OF PA USING N=30 OVER CDNET2014 DATASET

Frame	Input	Pa=0.25	Pa=0.5	Pa=0.75
#0672				
#0808				
#1328				
#1517				

Table II presents the experimental results for different values of N (number of Gaussian components in the GMM) while keeping the probability parameter Pa = 0.25 constant. It showcases how varying the number of Gaussian components

affects the background subtraction performance across multiple frames. Increasing N typically balances model complexity and overfitting, influencing detection accuracy. Table III evaluates the impact of varying probability thresholds for background classification using a fixed N=30. The results demonstrate how different threshold values influence the system's sensitivity to classify pixels as foreground or background, emphasizing the importance of parameter tuning for effective detection in varying conditions.

The combined insights from these tables underscore the sensitivity of the GMM model to these parameters and highlight the necessity for optimization methods, such as CS Optimization, to automatically determine the best parameter values for achieving optimal detection performance. Through the CS optimization method, the algorithm converged on an optimal set of parameters, as shown in Table IV:

TABLE IV. OPTIMIZED PARAMETER OF IMPROVED GMM AUTOMATIC TUNING BY CS OPTIMIZATION METHOD

c	K	α	λ	γ	th
0.1	2.0	9.1	1.0	0.6	3.2

The effectiveness of the automatic parameter tuning was compared against empirical tuning, as demonstrated in Table V. The automatic tuning approach demonstrates improved adaptability, producing masks closer to the ground truth across different frames. The empirical tuning approach may suffer from inconsistency due to the lack of parameter optimization for specific scenarios. The visual comparison indicates that automatic tuning effectively reduces background noise and captures more accurate object contours, particularly in challenging scenarios.

TABLE V. COMPARISON OF FOREGROUND MASKS OF AUTOMATIC TUNING PARAMETER OF IMPROVED GMM AND EMPIRICAL TUNING PARAMETER OF IMPROVED GMM

Frame	Input	Ground Truth	Automatic Tuning	Empirical Tuning
#0672				
#0808				
#1328				
#1517				

Table VI evaluates the average performance metrics of the Improved GMM with automatic tuning (optimized parameters) and empirical tuning (manually set parameters). The values demonstrate that the automatic tuning of parameters using CS optimization substantially outperforms empirical tuning. The improved precision reduced false positives, and higher overall accuracy highlight the importance of optimization in achieving robust and reliable vehicle detection.

TABLE VI. AVERAGE PERFORMANCE PARAMETER EVALUATION OF AUTOMATIC TUNING IMPROVED GMM AND EMPIRICAL TUNING IMPROVED GMM

Tuning	RC	PR	FM	FPR	FNR	WC	AC
Automatic	0.533	0.634	0.579	0.033	0.467	0.077	92.3%
Empirical	0.480	0.292	0.422	0.232	0.160	0.225	77.5%

Fig. 1 provides a visual comparison of the accuracy values between automatic and empirical tuning methods. The accuracy achieved with automatic tuning is 92.3%, as observed in Table VI. This high value underscores the effectiveness of automatic tuning in optimizing the Improved GMM parameters for robust and consistent detection across frames. Empirical tuning achieves an accuracy of 77.52%, significantly lower than automatic tuning. The drop in performance highlights the limitations of manually setting parameters, which are less adaptable to variations in input conditions such as different lighting, occlusions, or traffic densities. The results validate the incorporation of CS optimization as a robust method for parameter optimization in vehicle detection tasks.

Fig. 1. The core principle of the BS method (a) input image (b) reference image (c) foreground or background.

D. Evaluation Metrics

The poor performance of methods that use GMM for background subtraction is mostly caused by assumptions about the parameters, where different issues produce varying effects on methods performance. Additionally, performance evaluation metrics showcase the advantages of background subtraction methods in vehicle detection accuracy. The pixel features from vehicle detection results were divided into two groups (foreground considered positive and background considered negative) to evaluate the detection accuracy objectively [18].

Pixel-based performance evaluation metrics were widely employed to assess the accuracy of image segmentation algorithms. These metrics compared the pixel-wise segmentation results obtained by the algorithm to the ground truth (GT) annotations. Once the GT was determined, several generally accepted methods were compared to a proposed binary foreground map. In this evaluation, four types of pixels are utilized as follows:

- True positive (TP)
- False positive (FP)

- False negative (FN)
- True negative (TN)

The TP represents pixels correctly classified as positive by the segmentation algorithm and positive in the GT annotation. Meanwhile, FP represents pixels classified as positive by the segmentation algorithm but are negative in the GT annotation. The FN represents negative pixels in the segmentation algorithm but positive in the GT annotation. Subsequently, TN represents pixels correctly classified as negative by the segmentation algorithm and negative in the GT annotation [46].

Based on these four types of pixels, several metrics were computed to evaluate the performance of the segmentation algorithm, including recall (RC), precision (PR), F-measure (FM), FP rate (FPR), FN rate (FNR), and accuracy (AC). The RC is a metric used to evaluate the ability of an algorithm to correctly identify positive pixels, which is calculated as the ratio of TP pixels to the total number of ground TP pixels (also known as a TP rate). The TP rate measures the fraction of foreground pixels accurately identified out of the total number of foreground pixels, which the algorithm has categorized as [47]:

$$RC = TP / (FN + TP) \quad (19)$$

Since PR is the fraction of TP pixels over the number of positive pixels classified by the segmentation algorithm, the proportion of positive predictions that are TPs is measured given by:

$$PR = TP / (TP + FP) \quad (20)$$

The FM, or F1 score, is the harmonic mean of PR and RC. Therefore, FM provides a single metric to evaluate the overall performance of the algorithm as follows:

$$FM = (2 \times RC \times PR) / (RC + PR) \quad (21)$$

The FPR is the fraction of FP pixels over the total GT negative pixels. Hence, the proportion of negative predictions that are FPs is expressed as:

$$FPR = FP / (FP + TN) \quad (22)$$

In FNR, the fraction of FN pixels over the total number of GT positive pixels is obtained. Therefore, the proportion of positive pixels that are missed by the algorithm is described by:

$$FNR = FN / (FN + TP) \quad (23)$$

The AC is the fraction of correctly classified pixels over the total number of pixels and measures the overall correctness of the segmentation of the algorithm is represented by:

$$AC = (TP + TN) / (TP + FP + FN + TN) \quad (24)$$

Finally, wrong classification (WC) is the fraction of wrongly classified pixels over the total number of pixels. The WC also measures the overall error rate of the segmentation of the algorithm is expressed by:

$$WC = (FP + FN) / (TP + FP + FN + TN) \quad (25)$$

These seven indicators explain and evaluate the performance of the proposed model. Generally, these metrics provide a quantitative evaluation of the performance of the segmentation algorithm while aiding in identifying areas where the algorithm requires improvement [48].

VI. RESULT AND DISCUSSION

To validate the effectiveness of the proposed Improved Gaussian Mixture Model (GMM) [29], extensive experiments were conducted using over 1700 frames of moving vehicles on the road. Table VII compares the Improved GMM method with several state-of-the-art background subtraction and vehicle detection methods. The table includes the evaluation metrics used in this study and the results obtained for each method under different traffic densities.

TABLE VII. SUMMARY OF GMM, EGMM, RMOG, BMOG, CL-VID, RT-SBS-V2, CVABS AND IMPROVED GMM AVERAGE METRICS

Method	RC	PR	FM	FPR	FNR	AC	WC
GMM [6]	0.972	0.806	0.891	0.026	0.002	0.970	0.024
EGMM [14]	0.970	0.783	0.876	0.029	0.004	0.970	0.027
RmoG [15]	0.970	0.662	0.795	0.047	0.005	0.957	0.043
BMOG [25]	0.949	0.814	0.906	0.026	0.002	0.974	0.023
CL-VID [45]	0.967	0.849	0.922	0.019	0.013	0.975	0.018
RT-SBS-V2 [16]	0.973	0.790	0.881	0.031	0.004	0.969	0.028
CVABS [17]	0.916	0.849	0.886	0.020	0.084	0.972	0.028
Improved GMM	0.959	0.835	0.890	0.026	0.041	0.973	0.027

A high RC value was desirable to minimize FNs. The FNs occurred when actual positive instances were incorrectly classified as negative, presenting missed detections or opportunities. Thus, a high RC indicated that the model effectively captured the majority of positive instances and was less likely to overlook essential or critical cases [48]. The RC value of the Improved GMM outperformed a few methods with a value of 0.9586. This improvement is particularly impactful in scenarios with heavy traffic densities, where high vehicle overlap increases the likelihood of misclassification in traditional methods. The adaptability of the Improved GMM allows it to differentiate subtle variations in pixel distributions, reducing false negatives in densely packed vehicle scenarios, such as urban intersections or peak highway traffic conditions.

Alternatively, a high PR value suggested that the methods produced a lower FP rate, which could accurately identify positive pixels with a lower tendency to incorrectly classify background pixels as foreground. In other words, a high PR denoted that the methods of a pixel as foreground was more likely to be accurate. The PR value for the Improved GMM was 0.8353, which only slightly differed from the highest values from CL-VID and CVABS. This demonstrates the Improved GMM's effectiveness in reducing false positives, particularly in moderate traffic conditions where objects such as pedestrians, shadows, or reflections might otherwise be misclassified. By maintaining a robust precision level, the Improved GMM ensures reliable vehicle detection, crucial for real-world applications like urban traffic monitoring or congestion management.

The FM is a widely used metric that combines PR and RC to evaluate the overall performance of a method. A higher FM indicated that the methods significantly balanced PR and RC, effectively identifying positive pixels while minimizing FPs. Therefore, a higher FM value suggested better performance. Meanwhile, the FM value for the Improved GMM was among the highest among the other state-of-the-art methods. This positions the Improved GMM as a balanced performer, particularly in traffic scenarios with moderate density, where both precision and recall are crucial for maintaining detection reliability. Compared to CL-VID and BMOG, which excel in heavy and light traffic respectively, the Improved GMM demonstrates consistent and reliable performance across varied traffic densities, making it a versatile choice for real-world applications. The optimal FM value depended on the specific application and the desired trade-off between PR and RC [48].

A low FNR was considered desirable in most situations in which the system accurately identified positive instances and minimized missed detections or incorrect negative predictions. For example, the Improved GMM achieved a lower FNR compared to traditional GMM (0.041 vs. 0.084), highlighting its superior ability to identify true positives effectively. This improvement is particularly beneficial in high-density traffic scenarios, where the risk of missed vehicle detections is higher due to occlusions. Like FPR, the desired FNR depended on the specific context and application [49]. In some cases, a trade-off could occur between the FNR and other factors, including FPR or the overall system cost. The appropriate balance could vary depending on the situation's specific goals, constraints, and acceptable risks. Nonetheless, a low FNR was generally preferable to ensure the highest AC and detection performance [49].

The AC metric measures the percentage of correctly classified pixels in the foreground mask. A high AC suggested that the methods successfully classified a larger proportion of positive and negative pixels relative to the total number of pixels. This value accurately reflected the ability of the methods to distinguish between foreground and background regions. Lastly, WC referred to incidents in which a classification or prediction system improperly categorized them. For instance, in a real-world traffic monitoring system deployed at a busy urban intersection, high WC rates could lead to incorrect vehicle counts or misclassifications, potentially compromising traffic flow optimization or accident detection. The Improved GMM's ability to minimize WC ensures more accurate vehicle detection and tracking, leading to improved reliability in such critical applications. Depending on the applications, high WC rates could produce errors, misinterpretations, and negative consequences [48].

Fig. 2 illustrates the comparative recall performance of eight computational methods across three different traffic densities: light, moderate, and heavy. Recall is a metric that measures the percentage of true positive detections from all the actual positive instances in the video. Recall measures the percentage of true positive detections from all actual positive instances in the video. The graph reveals that some methods, such as CL-VID and RT-SBS-V2, maintain consistently high recall in specific conditions, while others show greater variability. For instance, GMM demonstrates a slight edge in

heavy traffic scenarios, likely due to its strong adaptability to high-density environments. Meanwhile, RT-SBS-V2 excels in light conditions, benefiting from its sensitivity to minimal background dynamics. Conversely, the CVABS method demonstrates a notable decline in recall under moderate traffic conditions compared to its performance in light and heavy conditions. This inconsistency may indicate specific weaknesses, such as sensitivity to moderately complex environments with fluctuating vehicle densities or partial occlusions. By analyzing the recall trends across traffic densities, Fig. 2 highlights the strengths and areas for improvement in the Improved GMM, emphasizing its potential as a balanced performer for diverse real-world applications.

Fig. 2. The comparison of recall results of our proposed method and the other methods.

The PR values are a key performance indicator, particularly in fields with high costs of false positives. Fig. 3 shows that the method labelled CL-VID shows the highest PR value in the heavy category, underscoring its exceptional accuracy under challenging conditions where vehicle overlap, and background complexity are prominent. This suggests that CL-VID is particularly adept at minimizing false positives when the scene dynamics are most intricate. In contrast, RMoG exhibits lower PR values, especially in the moderate traffic category. This performance discrepancy could be attributed to its limitations in handling medium-complexity scenarios, such as moderate occlusions or partially visible vehicles. The proposed Improved GMM achieves consistently high precision across all traffic densities, highlighting its robustness and versatility. While it does not outperform CL-VID in the heavy category, its balanced performance across light, moderate, and heavy traffic conditions signifies its reliability as a general-purpose solution for diverse environments. This generalist approach ensures that the Improved GMM maintains low false-positive rates regardless of traffic complexity, making it a dependable choice for real-world applications.

BMOG and CVABS methods show competitive PR values, particularly in moderate and heavy traffic scenarios. Their ability to sustain high precision in demanding conditions emphasizes their effectiveness in environments with increased vehicle density and dynamic lighting changes. A noteworthy observation is that PR values exhibit less variation across methods compared to RC. This stability indicates that these methods generally maintain a consistent ability to identify true positives. However, differences in precision suggest that their

effectiveness in rejecting false positives varies, which is critical in applications requiring high reliability and minimal false alarms.

Fig. 3. The comparison of precision results of our proposed method and the other methods.

Fig. 4 illustrates the FM results of eight different background subtraction methods: GMM, EGMM, RMoG, BMOG, CL-VID, RT-SBS-V2, CVABS, and the proposed method. As a harmonic mean of precision and recall, FM provides a comprehensive measure of segmentation accuracy, making it a crucial metric for evaluating the effectiveness of these methods. The graph highlights the superior performance of CL-VID in scenarios with moderate and heavy background motion, showcasing its robustness and adaptability in handling complex conditions such as dynamic lighting and high traffic density. This positions CL-VID as a strong candidate for scenarios requiring high reliability in challenging environments. In simpler conditions, the BMOG method achieves the highest FM in the light traffic category. This indicates its ability to excel in straightforward segmentation tasks where background dynamics are less pronounced, making it suitable for environments with minimal motion complexity.

The Improved GMM demonstrates consistent performance across all traffic categories. While it does not achieve the top FM score in any specific category, its stability across light, moderate, and heavy conditions highlights its versatility and reliability as a general-purpose solution. This balanced performance makes the Improved GMM particularly suitable for applications requiring robust results across diverse operational scenarios. In contrast, RMoG exhibits lower FM values across all categories, signalling potential limitations in adapting to varying background complexities. This underperformance may stem from its inability to handle dynamic textures or abrupt changes effectively. A general trend observed from the results is that most methods perform better in light and moderate categories, with a slight decline in heavy traffic conditions. This trend underscores the increasing challenge posed by higher background complexity and overlapping objects in heavy traffic scenarios, which can impact segmentation accuracy.

The stable performance of the Improved GMM across different conditions underscores its potential for applications requiring consistent and reliable segmentation, such as real-time traffic monitoring and video analytics. While other

methods, such as CL-VID and BMOG, excel in specific conditions, the Improved GMM offers a balanced approach, ensuring dependable performance irrespective of environmental variability.

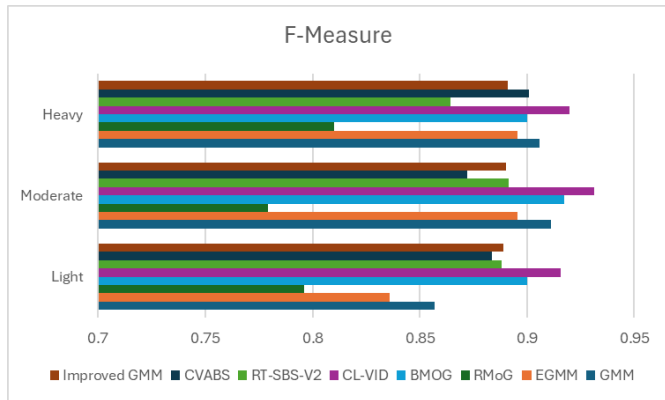

Fig. 4. The comparison of F-measure results of our proposed method and the other methods.

Fig. 5 illustrates the AC results of various background subtraction methods under different traffic conditions. The data reveals that all methods achieve high accuracy, with most exceeding 0.95, reflecting their overall effectiveness in segmentation tasks. However, noticeable differences emerge when comparing performances across specific traffic conditions. BMOG and CL-VID stand out with superior accuracy in light and moderate conditions, respectively, demonstrating their specialised efficiency in less complex environments. Their performances converge under heavy traffic conditions, suggesting that their methodologies are similarly adept at handling challenging scenarios with high background complexity and vehicle overlap. The proposed Improved GMM maintains consistently high accuracy across all traffic densities, highlighting its robustness and adaptability. This consistency suggests that the Improved GMM effectively balances precision and recall, making it well-suited for diverse operational contexts, including scenarios with fluctuating background dynamics. While the RMoG method achieves relatively high accuracy, its lower performance in moderate and heavy conditions indicates potential limitations in handling dynamic or complex backgrounds. This shortfall could be attributed to its reduced ability to effectively manage abrupt changes or intricate textures.

The subtle variations in accuracy among these methods carry significant implications for practical applications where precision is critical. For example, in high-security environments or scenarios requiring detailed video analysis, even small accuracy differences can influence the choice of method. The slight decline in accuracy under heavy traffic conditions observed for most methods emphasizes the need for enhanced robustness against complex backgrounds, direction future research should explore. The consistent performance of the proposed Improved GMM suggests a well-balanced integration of techniques tailored to address varying complexities. This adaptability makes it a compelling option for researchers aiming to develop versatile background subtraction methods that perform reliably across diverse conditions.

Table VIII compares foreground masks obtained using eight different methods. The table shows each method's original frame (input), ground truth (GT), and segmentation masks. The frames displayed are from three different traffic densities:

- 1) Frame 1213: Heavy traffic scenario
- 2) Frame 1480: Moderate traffic scenario
- 3) Frame 795: Light traffic scenario

The first column displays the original input frames, representing the raw video data captured by the camera. The second column shows the GT, which consists of manually annotated masks indicating the precise locations of vehicles in the respective frames. The subsequent columns (third to tenth) present segmentation masks produced by the different methods, allowing a direct comparison against the GT and input frames.

Fig. 5. The comparison of accuracy results of our proposed method and the other methods.

As illustrated in Table VIII, the Improved GMM demonstrates satisfactory detection performance across all traffic densities. For example, in the heavy traffic scenario, the Improved GMM effectively captures vehicle locations and shapes with notable accuracy, achieving a balance between minimizing false positives and negatives. While the Improved GMM exhibits competitive performance, the results also reveal the distinct strengths and weaknesses of other methods. For instance, CL-VID and BMOG show strong performance in scenarios with moderate traffic, excelling in precision and segmentation clarity. Meanwhile, EGMM and CVABS perform well in light traffic scenarios, accurately identifying individual vehicles with minimal background noise.

False positives and false negatives are present to varying degrees across all methods, including the Improved GMM. This indicates the inherent challenges of background subtraction in dynamic traffic environments, such as occlusions, varying lighting conditions, and overlapping vehicles. The Improved GMM method aims to strike a balance between computational efficiency and segmentation accuracy, making it a viable option for real-time applications where processing time is a critical constraint. However, the increased complexity introduced by the Improved GMM, particularly due to features like adaptive learning rates and exponential decay, warrants further investigation to fully assess its scalability and efficiency under diverse operational scenarios.

VII. CONCLUSION AND FUTURE WORK

This study proposed an Improved GMM for high-accuracy vehicle detection across varying traffic densities. By incorporating an adaptive time-varying learning rate, exponential decay, and outlier processing, the model effectively addressed limitations in traditional GMM methods, such as fixed learning rates and sensitivity to outliers. The use of CS Optimization for automatic parameter tuning further enhanced the robustness and adaptability of the model. Experimental results demonstrated that the proposed method consistently achieved superior performance metrics, including accuracy, precision, recall, and F-measure, across light, moderate, and heavy traffic scenarios.

Despite these promising results, several limitations warrant consideration. First, the computational complexity of the proposed model may present challenges for deployment on low-resource systems. Second, the model's reliance on hand-crafted features might limit its adaptability to rapidly evolving traffic scenarios. Future work should explore integrating deep learning techniques to complement the Improved GMM for enhanced robustness and scalability. Additionally, incorporating real-time optimization and reducing

computational overhead will be critical for broader adoption in resource-constrained environments.

In conclusion, the proposed method offers a significant step toward reliable and efficient vehicle detection in diverse traffic scenarios, paving the way for further advancements in intelligent transportation systems.

ACKNOWLEDGMENT

The authors are grateful to the anonymous reviewers and editors for their valuable suggestions and comments. This research was supported by the Ministry of Higher Education (MOHE) through Fundamental Research Grant Scheme (FRGS/1/2021/STG06/UTHM/02/1).

Abstract—Data security in cloud storage is a pressing concern as organizations increasingly rely on cloud computing services. Transitioning to cloud-based solutions underscores the need to safeguard sensitive information against data breaches and unauthorized access. Traditional cryptography algorithms are vulnerable to brute-force attacks and mathematical breakthroughs, necessitating large key sizes for security. Moreover, they lack resilience against emerging quantum computing threats, posing a significant risk to encryption. To tackle these issues, this study presents a novel lightweight cryptography algorithm named as PSR which is aimed at encryption so as to improve data security before storage in cloud systems. The proposed system converts 128 bit plaintext to cipher by employing techniques such as substitution, ASCII and hexadecimal conversions, block-wise transformations including Rail Fence, Grey Code, and XOR operations with random prime numbers. Notably, the proposed algorithm demonstrates superior performance with minimal runtime and memory usage, satisfying the avalanche effect criterion with a noteworthy efficacy in all executions and resistant to brute force attack.

Keywords—Cryptography; cloud security; PSR; encryption; decryption; avalanche effect

I. INTRODUCTION

Cloud computing plays a vital role in modern businesses by offering flexible and scalable solutions for storing and accessing data, facilitating innovation, and enhancing collaboration while reducing infrastructure costs and improving efficiency [1]. Ensuring data security in cloud computing is paramount, safeguarding sensitive information from unauthorized access and cyber threats. It fosters trust among users, promotes compliance with data privacy regulations, and mitigates the risks associated with data breaches. Robust security measures uphold the integrity and confidentiality of data, bolstering the reliability and credibility of cloud-based systems [2]. Traditional cryptography and lightweight cryptography represent two distinct approaches to securing data, each tailored to different needs and constraints. Traditional cryptography typically involves complex algorithms and protocols designed to provide high levels of security but may require significant computational resources and power consumption, making them less suitable for resource-constrained environments [3]. On the other hand, Lightweight cryptography is essential in cloud computing to

optimize performance and resource usage, ensuring efficient data processing and secure communication across distributed networks while minimizing computational overhead [4]. In cloud computing, although current lightweight cryptographic algorithms provide efficiency, the ongoing development of new ones is crucial. Continuous development of new lightweight cryptographic algorithms in cloud computing ensures staying proactive against emerging threats and optimizing performance as environments evolve, supporting stronger, more resilient systems [5].

Encrypting data before storing it in the cloud enhances security by ensuring that only authorized parties with the decryption key can access the data, thus protecting against unauthorized access and data breaches. Additionally, encryption helps organizations meet regulatory compliance requirements and safeguards data integrity during transmission and storage [6]. In this research, the authors made progress in developing a novel cryptographic algorithm named as PSR, with the objective of encrypting data prior to its storage in cloud systems.

The subsequent sections of this paper are structured as follows: Section II outlines fundamental security requirements in cloud computing and explore research on lightweight cryptographic systems. Section III provides a brief overview of the proposed algorithm. Section IV presents the performance and security analysis of the proposed algorithm. Lastly, Section V offers conclusions and outlines future prospects.

II. RELATED WORK

This section includes essential security needs in cloud computing along with research on lightweight cryptographic systems.

A. Security Requirements of Cloud Computing

Key security requirements in cloud computing, as outlined by NIST [7], include confidentiality, availability, integrity, authorization, authentication, accountability, and privacy.

Confidentiality involves restricting access to customer information to authorized individuals. Integrity ensures that information remains unaltered during processing or transmission, and that only authorized individuals can modify or delete it. Authentication verifies the identity of users accessing

*Corresponding Author.

data, typically through account security measures. Availability ensures that customer data and services are consistently accessible. Authorization controls access to data, allowing only authorized individuals to retrieve it [8-9].

B. Cloud Computing Security

Recent studies explore cloud computing security, focusing on cryptography. They analyze encryption algorithms like AES, IDEA, and DES, comparing symmetric and asymmetric methods. Parameters such as Block Size, Key Length, and Execution Time are evaluated for efficiency, especially in the cloud environment [10]. [11] conducted a study on major cloud service providers like Google (Google Drive) and Microsoft (Azure and OneDrive). They examined cryptographic algorithms commonly utilized in cloud computing, including modern cryptography, searchable encryption, homomorphic encryption, and attribute-based encryption (e.g., DES, 3DES, AES, RC6, and BLOWFISH). By combining multiple cryptographic techniques, they introduced a hybrid encryption approach to enhance cloud data security. Additionally, [12] compared IDAs, SHA-512, 3DES, and AES-256, focusing on on-premise data encryption and decryption.

C. Study of Lightweight Cryptography Systems

M. Usman *et al.*, [13] examined the Stable IoT (SIT) lightweight encryption algorithm, which utilizes a 64-bit block cipher and mandates data encryption with a 64-bit address. This approach incorporates elements of both the Feistel structure and a uniform substitution-permutation network. In study [14], a novel symmetric stream cipher, Ultramodern Encryption Standard (UES), is introduced for secure data transmission, utilizing prolific series numbers for key generation and binary/gray code operations for encryption and decryption. Sriram C P *et al.* introduced the Modular Encryption Algorithm (MEA) [15], a novel symmetric block cipher utilizing a trimodular matrix for key generation and employing matrix operations, permutations, and substitutions for encryption and decryption processes. Authors in study [16] present a new symmetric stream cipher called the "Random Prime Key (RPK)" Algorithm, with an evaluation of its resilience against differential cryptanalysis and other pertinent factors, aiming for equilibrium between simplicity and security. In study [17], the "RECTANGLE" cryptosystem is outlined, designed for a 64-bit block size with key lengths of either 80 or 128 bits, and it executes 25 rounds. In study [18], the paper discusses a lightweight encryption algorithm for IoT devices, featuring a 64-bit block cipher and an 80-bit key for data encryption. In study [19], a lightweight cryptosystem features a 64-bit block size and 128-bit key, executed over 32 rounds with XOR operations and rotations. Its goal is hardware deployment in ubiquitous devices like wireless sensors and RFID tags, aiming for AES-level chip size but with faster performance.

III. THE PROPOSED ALGORITHM

To enhance data security within cloud computing, the authors introduced a new lightweight cryptography algorithm named as PSR, aimed at encrypting data prior to storage in cloud systems. PSR encrypts 128-bit binary blocks using a 128-bit key through 10 encryption rounds, relying on mathematical functions for diffusion and confusion in each round. The system

employs techniques like substitution, ASCII and hexadecimal conversions, block-wise transformations including Rail Fence and Grey Code, and XOR operations with random prime numbers. Additionally, it assesses the avalanche effect by comparing differing bits between the original plaintext and resulting cipher text.

A. Encryption Process

To safeguard sensitive data, the proposed algorithm PSR employs an encryption process that involves a sequence of cryptographic techniques. This process converts plain text into cipher-text while ensuring confidentiality and integrity. Here's a summary of the steps involved in one round of encryption process:

Input: Plain text message

Substitution Box Transformation:

```
Define substitution_box mapping characters to substitutes
substituted_text = ""
for each character in input_text:
    substitute = substitution_box[character]
    append substitute to substituted_text
```

ASCII Conversion:

```
ascii_values = []
for each character in substituted_text:
    ascii_value = convert character to ASCII value
    append ascii_value to ascii_values
```

Hexadecimal Conversion:

```
hexadecimal_values = []
for each ascii_value in ascii_values:
    hexadecimal_value = convert ascii_value to hexadecimal
    append hexadecimal_value to hexadecimal_values
```

Hexadecimal to Binary Conversion:

```
binary_values = []
for each hexadecimal_value in hexadecimal_values:
    binary_value = convert hexadecimal_value to 8-bit binary
    append binary_value to binary_values
```

Block-wise Transformation:

```
cipher_text = ""
for each block in binary_values:
    rail_fence_1 = ""
    rail_fence_2 = ""
    for each bit in block:
        if position_of_bit is even:
            append bit to rail_fence_1
        else:
            append bit to rail_fence_2
    grey_code = generate_grey_code(block)
    left_shifted = left_shift(grey_code, 2)
    not_operation_result = apply_not_operation(left_shifted)
    new_substitution_box_result =
    apply_new_substitution_box(not_operation_result)
    prime_number = generate_random_prime(min,max)
    prime_binary = convert prime_number to binary
    xor_result = perform_xor(new_substitution_box_result,
    prime_binary)
    hexadecimal_result = convert xor_result to hexadecimal
    ascii_result = convert hexadecimal_result to ASCII
    character_result = convert ascii_result to character
    append character_result to cipher_text
```

Output: cipher_text

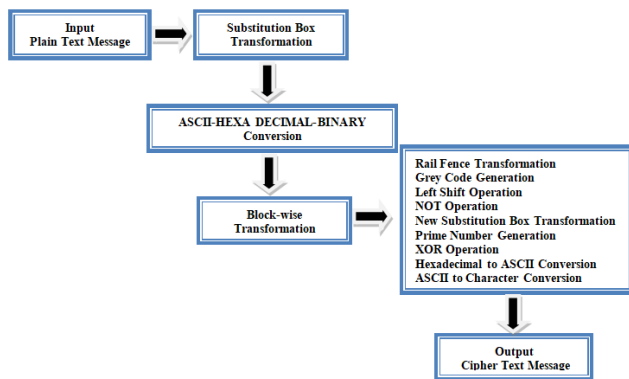

Fig. 1. PSR-Encryption process-flowchart.

The encryption process outlined in Fig. 1 begins by substituting characters in the plain text with predefined substitutes using a Substitution Box Transformation. ASCII Conversion converts substituted characters into ASCII values, followed by Hexadecimal Conversion for easier handling. Hexadecimal to Binary Conversion prepares data for block-wise transformation, where Rail Fence, Grey Code, Left Shift, and NOT operations are applied successively. Subsequent steps include a new Substitution Box Transformation, XOR operation with a key i.e., random prime number, and conversion back to cipher-text.

B. Key Exchange

The random prime keys used during the encryption process need to be exchanged with receiver so as to make use of them in decryption process. For safer exchange of keys between server and client, hybrid model that combines Diffie-Hellman (DH) and New-Hope (NH) is adopted [20].

C. Decryption Process

The decryption process that takes the cipher text as input and reverses the transformation steps to obtain the original plaintext message.

Input: Cipher text message

Character to ASCII Conversion:

```
ascii_values = []
for each character in cipher_text:
    ascii_value = convert character to ASCII value
    append ascii_value to ascii_values
```

Binary to Hexadecimal Conversion:

```
hexadecimal_values = []
for each 8-bit binary_value in ascii_values:
    hexadecimal_value = convert binary_value to hexadecimal
    append hexadecimal_value to hexadecimal_values
```

Block-wise Transformation:

```
original_binary_values = []
for each hexadecimal_value in hexadecimal_values:
    binary_value = convert hexadecimal_value to binary
    append binary_value to original_binary_values
```

Rail Fence and Grey Code Reconstruction:

```
reconstructed_binary_values = []
for each block in original_binary_values:
    not_operation_result = apply_not_operation(block)
    new_substitution_box_result =
```

```
reverse_apply_new_substitution_box(not_operation_result)
xor_result = perform_xor(new_substitution_box_result,
prime_binary)
reconstructed_binary_values.append(xor_result)
```

Binary to ASCII Conversion:

```
decrypted_ascii_values = []
for each binary_value in reconstructed_binary_values:
    decrypted_ascii_value = convert binary_value to ASCII
    append decrypted_ascii_value to decrypted_ascii_values
```

ASCII to Character Conversion:

```
original_text = ""
for each ascii_value in decrypted_ascii_values:
    character_result = convert ascii_value to character
    append character_result to original_text
```

Output: original_text

IV. RESULTS AND DISCUSSION

To validate the proposed algorithm, comparative analysis and a series of security experiments were conducted to gauge the effectiveness of the coding scheme, focusing on evaluation metrics including processing time, confusion and diffusion, avalanche effect.

A. Comparative Analysis of Proposed Encryption Algorithm

A comparison between the proposed method and current encryption techniques mentioned in Table I which reveals notable differences. While existing methods like DES, AES, Blowfish, and LED utilize various structures and operations, the proposed technique introduces a distinct approach. Unlike DES's limited block and key sizes or AES's variable configurations, the proposed technique offers a fixed 128-bit block and key size. Notably, PSR introduces unique mathematical operations like Rail-fence and Grey code conversions, enhancing its security. With a focus on security, PSR demonstrates a highly secure approach, surpassing the proven inadequacies of DES while matching or exceeding the security levels of AES, Blowfish, and LED as shown in Table I.

B. Processing Time

In cryptography, "processing time" is crucial, determining how long it takes to perform cryptographic tasks, impacting the speed of secure communication. Less processing time in cryptography algorithms is important for ensuring efficient and timely secure communication. The data presented in Table II represents the average encryption time obtained from five consecutive experimental runs. Fig. 2 illustrates that the proposed PSR algorithm consistently outperforms or matches the processing times of established algorithms like DES, AES, Blowfish, and LED across different file sizes. This underscores the superior efficiency and competitive advantage of the PSR algorithm in cryptographic operations.

C. Security Analysis

The proposed algorithm enhances the security of data before it gets stored onto the cloud by bolstering confidentiality and integrity while ensuring accessibility when needed. In terms of security, the PSR cryptographic algorithm can withstand well-known threats like weak key attacks, symmetric properties, related-key attacks, and differential and linear cryptanalysis [25, 26].

Algorithm	DES[21]	AES[22]	Blowfish[23]	LED[24]	Proposed Algorithm-PSR
File Size (KB)	Processing time (seconds)				
28	0.0011	0.0014	0.0012	0.019	0.013
29	0.017	0.016	0.015	0.029	0.0152
210	0.028	0.029	0.031	0.0548	0.0352
213	0.29	0.29	0.24	0.62	0.45
214	0.945	0.805	1.06	1.45	0.789
215	1.91	1.74	2.01	2.53	1.65

Algorithm Processing Time Comparison

Fig. 2. Processing times of proposed algorithmm PSR cryptography algorithm and existing techniques.

$$\text{Percentage of Avalanche Effect} = \left(\frac{\text{Number of bits flipped in the cipher text}}{\text{Number of bits present in the cipher text}} \right) \times 100$$

D. Impact of Avalanche Effect-SPAC and SKAC

The algorithm must adhere to the Strict Plaintext Avalanche Criterion (SPAC), which implies that even a minor alteration in

the plaintext, while keeping the key constant, should lead to substantial changes in the resulting cipher text. Similarly, it should also meet the Strict Key Avalanche Criterion (SKAC), meaning that with the plaintext fixed, any slight modification in the key should produce significant variations in the generated cipher text [27]. The effectiveness of the PSR cryptography algorithm's security was assessed using SPAC and SKAC. Table III presents the outcomes of this assessment for a fixed plaintext ("Cryptography") across varying keys.

TABLE III. (A) SKAC ANALYSIS OF PSR CRYPTOGRAPHY ALGORITHM

Fixed Plaintext			
Test case	Cipher-text (128 bits)	Number of Bits Changed	Avalanche effect (%)
1	ùÂ¿ØbQDp"Š /	69	53.9
2	°s4ÂROpiÆøe	74	57.59
3	ï"WhÚ Fp*1	71	55.41
4	7hÂB¿ændD¿	78	60.62
5	bEÖÜ»Db@y	80	62.64
6	â2Û>¿-D2"èe	86	67.56
7	Ed¿Ø€ ðÖ,â>P³	109	85.83
8	³^ØÊµØÆhê	64	50.09
9	OðE\öC^ì •	92	72.54
10	7°©&:Â[ï"@@³	99	77.91
Average SKAC			64.40

(B): SPAC ANALYSIS OF PSR CRYPTOGRAPHY ALGORITHM

Fixed key			
Plaintext	Cipher-text (128 bits)	Number of Bits Changed	Avalanche effect (%)
Algorithm	Dâ_@p!¼Ö@s	70	51.66
Percentage	&@Â½/Âê	71	52.58
Avalanche	n*êEØð(77	57.22
Cloud Security	=oX÷Ë#Âèo©&,	92	69.10
Computing	QòkâbT¥	86	64.44
Brute Force Attack	lÂ[J,eZÖ*=&]pÂh´=2	83	62.08
Diffusion	gh ÂtÖjþ	79	58.98
Confidentiality	âê8Â • ø&¶,b7Äv¿	92	68.99
Integrity	!V@è#ð >5	95	71.66
Light weight	@9*#pÖÇ8v	86	64.56
Average SPAC			62.12

The results from the Tables III (A) and III (B) reveal that the percentages for SKAC (Strict Key Avalanche Criterion) and SPAC (Strict Plaintext Avalanche Criterion) are 64.40% and 62.12%, respectively. These thresholds demonstrate the algorithm's effectiveness in achieving a notable avalanche effect, which is critical for ensuring strong diffusion and enhanced security. Among the various test cases evaluated, the PSR

algorithm stands out for delivering the highest avalanche percentages, showcasing its superior performance. This makes it particularly well-suited for encrypting the texts before storing them onto cloud systems, where data confidentiality, integrity, and resilience against brute force attacks are well maintained. With its ability to ensure high levels of diffusion, the PSR algorithm is an excellent choice for protecting sensitive data with respect to cloud-based environments.

E. Confusion and Diffusion

Confusion and diffusion, concepts initially explored by Shannon [28], are fundamental to encryption, aiming to complicate the relationship between encrypted text and keys. Proposed encryption technique employs operations such as substitution, ASCII and hexadecimal conversions, block-wise transformations including Rail Fence and Grey Code, and XOR operations with random prime numbers. Altering a single letter in the original text impacts numerous sections of the encrypted text, while each encryption of identical text generates a varied outcome, enhancing both complexity and security. Consequently, our approach seamlessly integrates the fundamental concepts of confusion and diffusion.

F. Resistant to Brute Force Attack

A brute force attack exhaustively tests all potential combinations to compromise encryption keys. The PSR cryptography algorithm employs a 128-bit binary key, leading to 2¹²⁸ possible key combinations, guaranteeing unique keys for each encryption process.

V. CONCLUSION AND FUTURE SCOPE

Ensuring data security prior to its storage in the cloud has become increasingly crucial. Despite the existence of numerous cryptography algorithms aimed at bolstering data protection, there remains a significant demand for innovative approaches. This paper presents a novel cryptography algorithm, denoted as PSR, which operates on 128-bit plaintext using a 128-bit key to produce 128-bit cipher text. It draws inspiration from the architectural models of Fiestal and SP. The encryption method under consideration utilizes various operations, including substitution, ASCII and hexadecimal conversions, block-level transformations such as Rail Fence and Grey Code, as well as XOR operations involving random prime numbers. Despite boundaries like fixed key length and computational overhead, the PSR algorithm ensures high security with innovative techniques such as prime-based XOR, Rail Fence, and Grey Code. The experimental findings presented in Table I clearly indicate that the PSR algorithm, as proposed, offers a high level of security. Furthermore, Table II illustrates shorter processing times compared to current algorithms, affirming its applicability even in resource-limited environments. Table III data shows PSR cryptography excels in SKAC and SPAC, averaging 64.40% and 62.12%. The PSR algorithm's responsiveness to input variations increases output randomness, a desirable trait in cryptographic algorithms, thwarting attackers' predictions. Future work can focus on benchmarking PSR in real-world scenarios to evaluate its scalability and seamless integration with diverse cloud systems.

AUTHORS' PROFILE

Dr. P. Sri Ram Chandra serves Shri Vishnu Engineering College for Women, bringing a wealth of academic and professional experience. He holds a B.Tech from Andhra University and both an M.Tech and a Ph.D. from GITAM University. Dr. PSR has made significant contributions to his field, including the publication and review of books. He has also delivered guest lectures under the AICTE-STTP program and evaluated doctoral theses. Dr. PSR has an extensive record in academic service, having reviewed numerous research articles. His teaching career spans over a decade, during which he achieved numerous technical and research certifications. In addition to his academic achievements, Dr. PSR has published many patents and research publications. His research interests include, cryptography and information security, Theory of Computations. Detailed Profile: <https://sites.google.com/view/dr-psr>

Dr. Syamala Rao P. secured his Ph.D degree from Acharya Nagarjuna University. He is a topper in academics and secured gold medal in his M.Tech. He has 20+ years of experience in Academics and he is currently working as an Associate Professor in Information Technology department of S.R.K.R Engineering College, Bhimavaram. His research areas are cryptography, Machine Learning, Artificial Intelligence and Mining.

Dr. NARESH K is an Assistant Professor in the Department of CSE at TKR College of Engineering and Technology, Autonomous, Hyderabad. He received his Ph.D. in Computer Science & Engineering from the NIILM UNIVERSITY, Haryana in 2023. M.Tech in Software Engineering, Jagruthi institute of Engineering and Technology, JNTU HYDERABAD in 2012. His research interests in cryptography, Machine Learning, Deep Learning and Computer Networks.

Dr. M. RaviSankar, working as an Associate Professor in Department of Computer Science and Engineering, K.L. deemed to be University, Guntur dist., Andhra Pradesh, India. He has 24 years of teaching experience. Dr. Ravi has received Excellence in Research Award and Best Senior Faculty Award. He has Published 5 Patents and he has published more than 20 articles in Scopus, SCI, WOS and International Journal., His areas of specializations are cryptography, Data Mining and Artificial Intelligence.

Optimizing Feature Selection in Intrusion Detection Systems Using a Genetic Algorithm with Stochastic Universal Sampling

Abstract—The current study presents a hybrid framework integrating the Genetic optimization algorithm with Stochastic Universal Sampling (GA-SUS) for feature selection and Deep Q-Networks (DQN) for fine-tuning an ensemble of classifiers to enhance network intrusion detection. The proposed method enhances genetic algorithms with stochastic universal sampling (GA-SUS) combined with recursive feature elimination (RFE). An ensemble of machine learning methods which includes gradient boosting and XG boost as base learners and subsequently logistic regression as meta learner is developed. A deep Q-networks (DQN) is used to optimize the base algorithms XG boost and gradient boost. The suggested method attains an accuracy of 97.60% on the popular NSL-KDD dataset and proficiently detects several attack types, such as probe attacks and Denial of Service (DoS), while tackling the issue of class imbalance. The multi-objective optimization approach is evident in anomaly detection and enhances model generalization by diminishing susceptibility to fluctuations in training data. Nonetheless, the model's efficacy regarding infrequent attack types, such as User to Root (U2R), remains inadequate due to their sparse representation in the dataset.

Keywords—GA-SUS; anomaly detection; IDS; RFE; DQN

I. INTRODUCTION

An Intrusion Detection System (IDS) is a cybersecurity tool with the primary goal of monitoring and analysing network traffic or system activity for possible malicious behaviour and unauthorized access. IDS can identify attempts that can lead to potential intrusions, that is, whether it be network attacks, unauthorized access to systems, or any other abnormal statistics to detect that we are dealing with malware or other cyber threats [1]. IDS can identify attempts that can lead to potential intrusions, that is, whether it be network attacks, unauthorized access to systems, or any other abnormal statistics to detect that we are dealing with malware or other cyber threats [2]. Anomaly-based detection and signature-based detection are two methodologies employed by Intrusion Detection Systems to identify suspicious activities.

Integrating IDS with machine learning has remarkably improved the potency of IDS to locate cyber threads accurately [3]. However, these are insufficient to address the complex dynamic threats posed by cyber threats [4]. Machine learning mitigates these constraints by allowing Intrusion Detection Systems to learn from data, adapt to emerging threats, and

enhance detection precision over time. Machine learning improves intrusion detection systems by discerning the most pertinent features for spotting intrusions. Emerging issues are seen in the increased incidence of assaults and the advancements in technologies noticed in contemporary IDS systems. Additional recommendations may be required for machine learning approaches while processing extensive data and transitioning throughout networking environments [5]. Consequently, there is a growing apprehension regarding the development of a way to extract superior high-order features when the objective is situated amongst a sea of nonstationary traffic. This necessitates the improvement of the generality and efficiency of the IDS to bolster the network's defences against novel and unidentified attacks [6].

Feature selection (dimensionality reduction) is an essential step in machine learning which entails choosing the most pertinent and informative characteristics from a dataset to enhance model performance. Feature selection minimizes model complexity, boosts generalizability, and frequently improves both accuracy and interpretability of predictions by retaining only the important features [7]. Feature selection Improves predictive accuracy by concentrating on the most pertinent features. Feature selection diminishes the likelihood of overfitting by removing noise and redundant information. It also simplifies the model, resulting in faster training and inference. In addition to that, it will minimize the storage and memory requirements while minimizes the computational complexity. Fig. 1 showcases the importance of feature selection. There exist three kinds of feature selection strategies namely, wrapper models [9], filter methods [8] and embedded methods [10]. Filter-based approaches evaluate feature significance according to the statistical characteristics of the data. They are not related to any specific machine learning algorithm. Parallely, wrapper methods use a specific learning algorithm to evaluate the performance of feature subsets [11]. Embedded approaches conduct feature selection during the model training phase. In this study we approach the feature selection mechanism with the aid of a wrapper method. Genetic Algorithms (GA) [12] are an optimization method derived on the concepts of genetics and natural selection. The genetic algorithms can effectively navigate extensive feature spaces and discern optimal or near-optimal feature subsets, rendering them particularly appropriate for high-dimensional datasets. The GA optimization is used for selecting most relevant features in this work.

To this end, it helps the model reduce overfitting, and thereby the model performs well when tested on unseen data. However, feature selection proved to be helpful in eliminating noisy components, resulting in an improvement in the quality of the provided dataset. In other words, when feature selection is performed properly, one is left with models that are accurate, efficient, and understandable - all qualities that are critical in the quest for insights and trustworthy predictions.

Feature selection is the core of any IDS in which the discovery of discrete features that characterize communications taking place in a network and the capability to discern between anomalous and normal is achieved. Feature selection is essential in the creation of efficient IDS by pinpointing the most pertinent aspects from network traffic data. Because of the complexity and high dimensionality of standard IDS datasets as NSL-KDD, UNSW-NB15 and CICIDS, feature selection enhances analysis by increasing detection accuracy and processing efficiency. By concentrating on the most informative attributes, the IDS can efficiently discern between regular and malicious actions. Minimizing the number of features decreases the computational load, resulting in expedited model training and real-time detection.

The ultimate aim of the current research is to propose and enhance a new approach to enhancing an NDIS by a more refined feature selection and optimization process. The primary contributions of the study are listed below.

- Enhancement of genetic algorithms with stochastic universal sampling (GA-SUS) combined with recursive feature elimination (RFE).
- An ensemble of machine learning methods which includes gradient boosting and XG boost as base learners and logistic regression as meta learner is developed.
- A deep Q-networks (DQN) is used to optimize the base learners XG boost and gradient boost.

The remainder of this paper is structured as below: Section II gives the literature review; Section III proposes the methodology; Section IV gives results and discussion and finally Section V concludes the study.

II. LITERATURE REVIEW

A research by Bakir et al. in study [13] explored innovative ways to enhance IDS using ML, specifically focusing on IoT networks. Using a genetic algorithm for tuning of hyperparameter along with a new hybrid feature selection, the authors propose a substantial increase of IDS effectiveness with the means of security threat identification. The authors combined several approaches looking for the most representative feature subset for detection through a hybrid feature selection methodology. Among others, Mutual Information-based Feature Selection (MIFS) is one among the several ways in which feature selection is performed by MIFS by selecting features from the original set according to their mutual information with the target value while reducing redundancy. Five (Decision Tree, XGBoost, Bagging, Extra Tree, Random Forest) ML algorithms were trained with their existing hyperparameters. The XGBoost classifier elevated the

performance, reaching 99.98% F1 score and 99.98% detection accuracy. The Extra Tree algorithm had a good performance as well, detecting with an accuracy of 99.96%.

A study by Cheng et al. in study [14] developed a pioneering approach known as Detection-Rate-Emphasized Multi-objective Evolutionary Feature Selection (DR-MOFS). The selected features are important for reducing the complex data sets for better efficiency and accuracy of IDS, according to the study. The goal is to decrease the features considered, thereby simplifying the framework and increasing performance. The second main aim of the study highlights optimizing the detection rate, which must be achieved as it minimizes the number of missed attacks. Also it overcomes the limitations of the previous Feature selection approaches based on feature subset size and classification accuracy which often led to low detection rate. Experiments were conducted on well-known network intrusion detection datasets, including UNSW-NB15 and NSL-KDD, in order to validate the suggested method. The results show that DR-MOFS is better than previous methods in most of the measures of less features selected, more accuracy, and more detection rate.

A research work by Ren et al. in study [15] generated a model MAFSIDS that aims to reduce the complexity of the feature selection process by eliminating close to 80% of repeating features in comparison to the base feature set. The MAFSIDS adopts a multi-agent framework in which a large number of feature agents compete with each other. The model provides adaptability to the evolving nature of network attacks (i.e. network IDS becomes more effective against new attacks). MAFSIDS improves the typical feature selection search strategy by formulating the feature selection problem as the target of MAFSIDS implemented in a multi-agent reinforcement learning framework in which the number of features selections in a general case is an exponential 2^N which it can specify those features which make up unit subsets. Here, you will find our model implementation which consists of Deep Q-Learning (a form of deep reinforcement learning). This approach allows the model to learn optimal policies for attacking the environment, through the interactions and feedback given based on the actions taken. GCNs are used to obtain deep features by MAFSIDS. As a result, this approach can significantly improve the feature selection process by allowing the model to better capture complex relationship in the data. While MAFSIDS model did very well with 96.8% accuracy rate on the dataset.

Another work by Ren et al. For example, [16] uses RFE and DT classifiers to remove 80% of all features and finds the most useful subset of features to identify all network attacks, especially unknown attacks. This article is referring on RFE which is used to assign importance the attributes in the ordinal manner of their significance related to target variable (i.e. intrusion detection in the network). Typically, the algorithm removes the least relevant features iteratively from the data. The model is refitted to the features after each iteration. The data is re-coded by way of Mini-Batch processing making the data-set relevant to the DRL model which is helpful in deriving more profound associations between features so it enhances accuracy and efficiency. Using the CSE-CIC-IDS2018 dataset for testing, the model achieved an F1-score of 94.9% and

accuracy of 96.2%. This shows that it is pretty effective at detecting network intrusions.

A study by Thajeel et al. in study [17] proposed DQN-MAFS implements a dynamic feature selection framework that continuously assesses the relevance of features in real-time and updates them accordingly. It is very important for capturing the changes in the data and eliminating irrelevant features for detection. Each feature is treated as an individual agent within the Multi-Agent System framework. Each agent acts to include/exclude a feature with some determination. Its architecture is based on reinforcement learning, which uses a deep Q-learning approach to facilitate online updates. As new labeled data becomes available, agents are rewarded to understand how much to rely on their own features and update their selection accordingly. FARD-DFS is a reward allocation sub-model within the DQN-MAFS framework.

A research work by Kavitha et al. in study [18] introduces a Deep Learning Model and Filter-based Ensemble Feature Selection for Intrusion Detection in Cloud Computing Environment. This research utilizes two publicly available datasets, NSL-KDD and KDDCup-99, for gathering the intrusion data. In the FEFS, three kinds of feature extraction process are involved, which are filter, wrapper and embedded algorithms, and it is obtained from this process that those features are extracted which will help the DLM in the training process. DLM combines RNN with a process known as Tuning Dynamic Optimization (TDO) for its optimization of weighting parameters. The proposed technique acquired a sensitivity of 0.90% and a recall of 0.93%. In relativity, the conventional methods achieved lower recall rates of 0.83% (DNN), 0.88% (RNN), 0.91% (RNN-GA) for recall, and 0.81% (DNN), 0.85% (RNN) for sensitivity.

A study by Mananayaka and Chung in study [19] proposed an innovative methodology for Network Intrusion Detection Systems (NIDS) that integrates Two-Phased Hybrid Ensemble Machine Learning with Automated Feature Selection, employing various ML classifiers to proficiently identify and shortlist the most pertinent attributes for identifying both familiar and unfamiliar attacks, thereby tackling the challenges associated with high-dimensional network data. The framework utilizes an automated feature selection engine that discerns the most pertinent elements from high-dimensional network data. Utilizing four distinct machine learning classifiers, the system may concentrate on the most pertinent information for attack detection, hence improving the accuracy and efficiency of the detection process. The suggested framework exhibited a high detection rate (0.9431) and an exceedingly low false alarm rate (0.0005) in evaluations performed on both wired and wireless networks.

A study by Yin et al. in study [20] aimed to improve the multi-classification efficiency of IDS by the judicious pertinent features selection and the reduction of feature space dimensionality. The IGRF-RFE method integrates wrapper and filter techniques to improve feature importance selection. The initial phase employs Random Forest (RF) and Information Gain (IG) to eliminate less significant features, while the subsequent phase utilizes RFE to further optimize the attribute subset by discarding features which detrimentally affect model

performance. This hybrid methodology seeks to improve the precision of the MLP-based detection of intrusion model utilizing the dataset of UNSW-NB15 through the selection of a more pertinent feature collection. The feature selection procedure decreased the number of features from 42 to 23, hence eliminating redundant and less pertinent characteristics. The MLP model's accuracy increased to 84.24% from 82.25% following the use of the "IGRF-RFE" approach. The weighted F1 score improved to 82.85%, indicating enhanced overall model performance for precision and recall.

The primary goal of the research by Saheed et al. in study [21] is to precisely detect fraudulent activity in computer networks by employing an advanced bat optimization technique in conjunction with the distinctive characteristics of the number system (residue). The work seeks to successfully diminish the complexity of the feature space by integrating the residue number system with the bat algorithm, while preserving or enhancing detection accuracy. The Bat algorithm is efficient for feature selection, although it may exhibit prolonged training and testing durations. The integration of RNS mitigates this constraint by enhancing processing speed. The study additionally utilizes PCA for feature extraction, which further enhances the chosen features. PCA facilitates the transformation of selected features into a lower-dimensional space while maximizing variance retention. The PCA + NB + Bat-RNS algorithm attained an accuracy of 97.82%. The Bat-RNS+PCA+KNN model exhibited an enhanced detection accuracy of 99.15%. The integration of the Bat method with RNS and PCA markedly improves the efficiency of the KNN classifier in intrusion detection.

A study by Francis and Sheeja in study [22] created an Intrusion Detection Model utilizing Bagging and Deep Reinforcement Learning (DRL). The model derives features from pre-processed data via the Enhanced Principal Component Optimization approach in conjunction with the Self-Optimizing Seagull Algorithm. This strategy aids in identifying pertinent features that can improve the model's efficacy. The chosen features are utilized to train the Bagging-DRL Intrusion Detection model, which integrates Convolutional Neural Networks, Multi-Layer Perceptron, Optimized Recurrent Neural Networks. The model is refined utilizing the Self-Improved Seagull Optimization Algorithm to augment detection precision. The model acquired an accuracy of 98.3% on the current dataset and 96% on the CSE-CIC-IDS2018 dataset. The framework demonstrated exceptional specificity rates of 99% for the NSL-KDD dataset and 97.6% for the CSE-CIC-IDS2018 dataset, highlighting its proficiency in accurately identifying non-intrusive cases. The sensitivity rates were robust, registering at 95% for the dataset of NSL-KDD and 98.3% for the CSE-CIC-IDS2018 dataset, indicating the model's efficacy in accurately detecting genuine intrusions.

A research paper by Rabash et al. in study [23] aims to selectively and adaptively identify pertinent characteristics in response to data alterations, tackling the issues presented by feature drift and concept drift in Intrusion Detection Systems. The suggested method employs a multi-objective optimization strategy to equilibrate several criteria, including feature relevance and feature reduction, so assuring that the chosen features enhance the classification model's performance

effectively. The research aims to increase the efficacy and precision of the IDS by the implementation of an “Enhanced Dynamic Filter-Based Feature Selection” (EDFBFS) architecture. The method utilizes a dual-mode strategy to produce optimal dynamic feature selection outcomes. The best feature set length is dictated by either the median or mean of the identified solutions in the Pareto, facilitating improved adaptation to varying circumstances. The method functions via iterative cycles encompassing initialization, crossover, and mutation processes. Throughout these cycles, objective functions are assessed according to feature relevance and feature reduction, directing the selection process. The E-DFBFS architecture proficiently tackles the issues of concept drift, facilitating enhanced adaptability in dynamic settings. Table I summarizes the contribution of previous researchers.

TABLE I. BACKGROUND WORK ANALYSIS

Study	Dataset(s)	Feature Selection Technique	Models
[13]	CICIDS2017	Mutual Information-based Feature Selection using genetic algorithm	Bagging, Random Forest XGBoost, Extra Tree and Decision Tree
[14]	NSL-KDD, UNSW-NB15	Multi-objective evolutionary algorithm	CART Decision tree, Logistic Regression, Random Forest
[15]	CSE-CIC-IDS2018, NSL-KDD	multi-agent feature selection	GCN

[17]	Four benchmark XSS datasets, which are, D3-30, D1-66, D4-30 and D2-167. T	Multi-agent feature selection and Deep Q-network	Multiple classifiers
[18]	KDDCup-99, NSL-KDD	Filter, wrapper, and embedded algorithms are classified as filter-based ensemble feature selection.	DLM is the short of RNN along with TDO
[19]	Aegean Wi-Fi Intrusion Detection Dataset	Automatic feature selection include (AFS-SVM, AFS-RF, AFS-ANN, and AFS-DT)	Two-phased Hybrid Ensemble learning
[20]	UNSW-NB15	Information gain and random forest with recursive feature elimination (RFE)	MLP
[21]	NSLKDD network data.	Bat algorithm with Residue Number System	NB, KNN
[22]	NSL-KDD and CSE-CIC-IDS2018 databases	Seagull algorithm for the enhancement of Enriched Principal Component Optimization	DRL uses MLP, CNN, while O-RNN interacts optimally with the surroundings or environment.

III. METHODOLOGY

The primary goal of this work is to develop a hybrid, ML model for network intrusion detection, in terms of feature selection, dimensionality reduction, and ensemble machine learning. The ameliorative model includes genetic algorithm

(GA), recursive feature elimination (RFE), kernel linear discriminant analysis (KL), principal component analysis (PCA), deep Q-network (DQN optimization steps) and stacked ensemble learning about it. The subsequent sections define and explain each phase of the identified methodology sequentially starting from the data pre-processing phase right up to the phase dealing with the evaluation of the final model. In this part of the research, we present the architecture of the proposed model in Fig. 1.

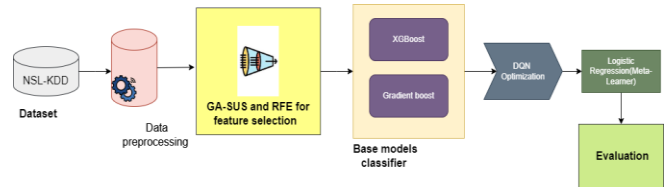

Fig. 1. Schematic architecture diagram of proposed system.

A. Preprocessing

The dataset used in this work has undergone a series of preprocessing methods to make it fit for the subsequent analysis. Firstly, the raw data is converted into a feature matrix with a corresponding vector label. The feature matrix contains a set of relative parameters that describe the network traffic, such as protocol type, packet size, and connection duration. The label vector comprises binary indicators that classify traffic into normal or incursion categories, facilitating supervised learning for ID.

To enhance the reliability and generalizability of the framework, the dataset was partitioned into testing and training subsets, a standard procedure for assessing model performance. The data division generally adheres to an 80:20 ratio, with 80% of the dataset designated for framework training and the residual 20% assigned for evaluating its predicted accuracy.

Prior to model training and feature selection, the data underwent supplementary preprocessing processes, encompassing demeaning and normalization of the features. Demeaning entails centering feature values around zero by subtracting the mean of each feature, whereas standardization adjusts the characteristics to achieve a standard deviation of one. These actions are essential for machine learning models, particularly when features display varying ranges or units of measurement. Standardization guarantees that all features contribute uniformly to the model, preventing those with more volatility or bigger magnitudes from overshadowing the learning process. This phase is crucial for models like as ensemble approaches and Support Vector Machines, which are sensitive to the relative scales of input features.

Standardizing the dataset before feature selection ensured a balanced representation of all features, enabling the feature selection method to discover the most pertinent qualities without bias. This thorough methodology strengthens the model's resilience, enabling it to more effectively identify trends in both legitimate and malicious network data.

B. Feature Selection using Genetic Algorithm (GA)

The process of feature selection involves reducing the number of attributes and identifying a subset of the original features. This technique is commonly utilised in data

preparation to uncover significant aspects that are often not known in advance and to eliminate superfluous or redundant features that have little bearing on classification tasks. In machine learning workflows, feature selection plays a pivotal role, particularly in enhancing the performance evaluation of classification models. The fundamental aim is to pinpoint the most crucial and informative features within the dataset, thereby improving accuracy.

Holland's genetic algorithm (GA) represents a computational optimisation methodology rooted in evolutionary biology principles. This technique operates in binary search spaces, managing a population of potential solutions. Each solution is encoded as a chromosome, comprising a finite sequence of binary digits. A fitness function assesses the viability of these solutions, with survival probability directly correlating to chromosomal fitness. The GA process commences with a randomly generated initial population, which then undergoes three primary mechanisms: selection, crossover, and mutation. The selection process identifies superior individuals for immediate progression to the next generation. Crossover involves the random exchange of chromosomal segments between two parent solutions to create offspring. Mutation introduces random alterations within individual chromosomes, contributing to genetic diversity.

This study employs Genetic Algorithms to remove inconsequential features. To achieve this objective, we designated chromosomes as a mask for attributes. For fitness evaluation, each individual in the population was assessed based on its ability to train a Random Forest classifier. If an individual selects at least one feature, the classifier is trained using these features, and its accuracy in the validation set determines the fitness score of the individual. If no features were selected, the fitness score was set to zero.

Selection was performed using stochastic universal sampling. First, the total fitness of the population was computed. The step size is then determined based on the total fitness and population size. Parents are chosen using a random start and pointers for a given size; the size is divided within the step size with the probability of high fitness being selected higher. Cross-over occurs whereby two selected parents are combined to form the offspring. A link was selected randomly and the child received some specific trait from both parents, or the first part was of one parent and the rest of the part was of other parent. Mutation is used in generating new offsprings by randomly setting bits to 0 or 1 adding new genetic feature to the population. A new population of the same size replaces the old one and this process a predefined number of generations or when some stopping criteria is fulfilled. Lastly the best from the final generation was chosen because it had the best fitness score out of all the individuals. This individual pertains to the best subset of features that are being searched sequentially by a genetic algorithm. The algorithm of GA along with mathematical formulae is given in Algorithm 1.

Algorithm 1: Genetic Algorithm for Feature Selection

Initialization:

Initialize the population $P = \{p_i \mid i = 1, 2, \dots, P\}$, where $p_i \in \{0, 1\}^N$ is a binary array representing a subset of features.

Fitness Evaluation:

For each individual $p_i \in P$, compute the fitness:

Let $F(p_i)$ be the set of selected features:

$$F(p_i) = \{j \mid p_i[j] = 1, j = 1, 2, \dots, N\} \quad (1)$$

If $F(p_i) \neq \emptyset$:

Then use the features of the dataset to train a random forest classifier

The accuracy $acc(p_i)$ of the classifier is calculated.

Otherwise, $acc(p_i) = 0$

Selection (Stochastic Universal Sampling):

Calculate the total fitness:

$$total_fitness = \sum_{i=1}^P acc(p_i) \quad (2)$$

Determine the step size:

$$step_size = \frac{total_fitness}{\frac{P}{2}} \quad (3)$$

Select parents:

Start point:

$$start_point = uniform(0, step_size) \quad (4)$$

Pointers: pointers = {start_point + k * step_size | k = 0, 1, ..., [P/2] - 1}

The indices based on cumulative fitness are selected.

Crossover:

For each pair of parents, p_i , and p_j :

Random crossover point $c = random(0, N - 1)$

Generate child:

$$c_k = (p_i[:c] \oplus p_j[:c]) \quad (5)$$

c_k inherits the first c bits from p_i and the remaining bits from p_j

Mutation:

For each child c_k :

For each bit $c_k[j]$:

$c_k[j] = 1 - c_k[j]$ with probability μ

New Generation:

The old population was replaced with the new generation of children.

This process continues for G generations or till we meet a certain criterion is met

Output:

Identify the best individual p^* from the final generation:

$$p^* = acc(p_i) \quad (6)$$

C. Recursive Feature Elimination (RFE)

RFE is a wrapper technique for feature removal. It removes repetitive and ineffective features that minimally affect the training error, while preserving strong and independent features to enhance the framework's generalization activity. It utilizes an sequential approach for feature importance, that is a variant of "backward feature elimination". This technique first develops the model utilizing the entire set of features and then prioritizes the features according to their importance. It subsequently removes the least significant feature, reconstructs the model, and recalculates the feature importance.

Following the feature subset derived by Genetic Algorithm (GA) optimization, Recursive Feature Elimination (RFE) was used to further enhance the selection process and ascertain a more ideal collection of features. RFE functions by iteratively removing the least important features based on the amount of

contribution they make towards the improvement of the model until we arrive at the number of features we need. Feature selection is addressed by using Random Forest algorithm as a model to predict the importance of the features. Subsequent process included turning off one feature after another from the bottom, beginning from the least contributing feature and retraining of the model. This process is continued until arrive at K best features only. These features were used in the subsequent features reduction. The following sections feature reduction and estimation steps.

D. Dimensionality Reduction

To address the curse of dimensionality and further reduce the feature space, two dimensionality reduction techniques are employed: Two methods identified are Principal Component Analysis (PCA) and Kernel Linear Discriminant Analysis (KLDA).

KLDA was used to transform the data onto a shorter feature dimension and also minimizing the interclass distance (normal – intrusion). Based on a kernel function, KLDA can model the nonlinear relationship of features, and then establish a better feature space.

$$Z_{KLDA} = W_{KLDA}^T X_{top} \quad (7)$$

where W_{KLDA} is the projection matrix obtained by maximizing the Fisher criterion.

After that, the features will be transformed by using the PCA in order to select only p principal components for comparison with the KLDA model. PCA removes projection directions determined to present high variability of the data and as such, most of the noise and redundant features.

$$Z_{PCA} = W_{PCA}^T Z_{KLDA} \quad (8)$$

Where W_{PCA} consists of eigenvectors corresponding to largest eigenvalues of the covariance matrix of Z_{KLDA} .

The final reduced dataset is denoted as Z_{final} .

E. Model Training and Stacked Ensemble Learning

1) *Base learners*: In order to construct a robust Intrusion Detection System (IDS), multiple base models were trained in the present study using a dataset that had been transformed into a lesser-dimensional vector space through the application of “Principal Component Analysis” (PCA). PCA, a prominent dimensionality reduction method, was utilized to identify the most critical characteristics while preserving the majority of the dataset's variation. XGBoost and Gradient Boosting Classifier were used as the main base models of the ensemble.

XGBoost is selected for handling large datasets and intricate pattern detection because of the gradient boosting framework upon which it is built. Additionally, GBC extends XGBoost, which iteratively provides better approximations to the model with fewer errors. These models complement each other to a great extent in the sense that they provide the benefit of handling numerous aspects of data complexity and drive up the predictive capability.

2) *Meta classifier*: A powerful binary classifier logistic regression takes the role of a meta-classifier. It is primarily deployed to merge the outcomes of the base, from which a final classification is generated. Logistic regression was again chosen because it is good at weighting the results of other models, and it calculates the best weights for each base model depending on the accuracy of the latter. The goal of this strategic integration is to increase the ability of the model to distinguish normal behaviour from non-normal or abusive behaviour.

3) Deep Q-Network (DQN) optimization

a) *Q-Learning setup*: Realising that the ensemble model could be enhanced, for hyperparameter tuning, we use a deep Q-network (DQN). Reinforcement learning is used in the form of a DQN, which helps in selecting the optimally-suited numerical for the hyperparameters for the best results. In this regime, the DQN influences the model in terms of the hyperparameters, and the response is a set of rewards derived from the model's evaluation results.

b) *Training*: When acquiring DQN, Q-values are updated when the amount of hyperparameters defined rises. The objective is to improve the reward function, which in the present case is the enhancement of the performance of the ensemble model. The same approach that is, following the above outlined feature selection scheme, benefits the DQN in a way that it is able to bring about ‘fine tuning’ of the hyperparameters to a level where classification differences of network activities are enhanced.

F. Proposed Model Algorithm

The combination of shortlisted features, the set of the training parameters, and performance metrics in a final model is preserved for future use. The documentation of the results comprises an evaluation of the proposed hybrid architecture for network intrusion identification. In this detailed record, the actual and the predicted markings are mentioned, which define how accuracy the model is beneficial for classifying the network threats; hence, comprehend how independent utilization of methodologies can be beneficial. The algorithm of the proposed model is given in Algorithm 2.

Algorithm 2: Proposed Machine Learning Framework for Network Intrusion Detection

Initialization

- $X, y \leftarrow$ Load data
- Hyperparameters \leftarrow Set parameters for GA, RFE, KLDA, PCA, DQN, and Stacking models

Feature Selection using Genetic Algorithm (GA)

- Initialize Population:
 - Population \leftarrow Random Initialization of N chromosomes
 - Evaluate Fitness:
 - For each chromosome $c_i \in$ Population:
 - Features \leftarrow Selected by c_i
 - Model \leftarrow Train RandomForest on Features
 - Fitness(c_i) \leftarrow Evaluate model accuracy
-

- Selection:
 - Selected Chromosomes ← Stochastic Universal Sampling (SUS) based on Fitness
- Crossover:
 - Offspring ← Apply Crossover on Selected Chromosomes
- Mutation:
 - Mutated Offspring ← Apply Mutation with rate pm
- Update Population:
 - Population ← Mutated Offspring
- Repeat:
 - Repeat steps for G generations or until convergence.
- Final Selection:
 - c_{best} ← Chromosome with highest Fitness

Recursive Feature Elimination (RFE)

- Feature Ranking:
 - Ranked Features ← RFE with RandomForest on Features selected by c_{best}
- Feature Selection:
 - Top Features ← Select k best features

Dimensionality Reduction

- Apply KLDA:
 - Z_{KLDA} ← KLDA on Top Features
- Apply PCA:
 - Z_{PCA} ← PCA on Z_{KLDA} reducing to p components

Model Training using Stacked Ensemble Learning

- Base Models:
 - Base Models ← Train models (XGBoost, GBC) on Z_{PCA}
- Meta-Classifer:
 - Meta-Model ← Train Logistic Regression on predictions of Base Models

Deep Q-Network (DQN) Optimization

- Q-Learning Setup:
 - States, Actions, Rewards, Q (s,a) ← Define for DQN
- Training:
 - $Q(s,a)$ ← Train DQN to optimize hyperparameters or thresholds Q (s,a)

Model Evaluation

- Prediction:
 - \hat{y} ← Predict using Meta-Model on test data
- Evaluation Metrics:
 - Recall, F1-Score, Accuracy, Precision, Confusion Matrix ← Evaluate on \hat{y}

Output Results

- Save (Features, Model Parameters, Metrics)
- Visualize Performance

IV. RESULTS

This section presents the results of the current study. Basis on the results attained, it is deduced that the intelligent hybrid model of GA-SUS feature selection and stacking ensemble

learning model with deep Q-learning neural network, which is proposed in the current research, is critical for using in network intrusion detection. NSL-KDD was used to benchmark the model with tests conducted to determine success rates, Precision, F1-score, recall, accuracy in differentiating between normal traffic, and anomalous traffic.

A. Dataset

The current dataset, NSL-KDD Dataset [24] is an improved and augmented version of the old KDD Cup 99 dataset, and is more suitable for IDS assessment. This approach eliminates certain inaccuracies in the initial data, for example, the presence of multiple records, which can introduce certain biases in the evaluation of an IDS. NSL-KDD consists of several types of records and probes: normal, DoS, R2L, U2R, and probes in the network traffic records. It is widely used to compare IDS effectiveness because it provides a reasonable distribution that is close to the real traffic distribution [16].

Fig. 2. Class distribution.

Fig. 2 illustrates the proportion of class labels within the dataset with the class label that appears most frequently. Such distribution forms can be skewed where some classes like ‘DoS’ and ‘normal’ are more frequent than classes like ‘U2R.’ Such distribution is important for model training and testing.

B. Evaluation Criteria

The assessment of the suggested model was performed using the following features: accuracy, confusion matrix, recall rate, precision rate, and F1 score. Accuracy gives a general measure of the developed model and checks correctness of the developed model. Precision, and recall measure to some extent how many of the positive instances are correctly classified and how few misclassifications in the form of false positives or false negatives are there. The F1 score is a metric that is in-between recall and precision. The confusion matrix allows estimating all the true, false, negations and positives that can be retrieved from the assessed model. It is the basis for calculating the said metrics. The formulae for the above metrics are given below.

$$Accuracy = \frac{TP1 + TN1}{TP1 + FP1 + TN1 + FN1}$$

$$Recall = \frac{TP1}{TP1 + FN1}$$

$$Precision = \frac{TP1}{TP1 + FP1}$$

$$F1 - Score = \frac{2}{\frac{1}{Precision} + \frac{1}{Recall}}$$

Where FN is false negative, FP is false positive, TP is true positive, TN is true negative. These outcomes are shown in various kinds of diagrams and graphs for the objective of understanding and evaluating the performances of the models.

C. Classification Performance

In Table II, the classification report of a model with GA-SUS feature selection is illustrated. The model achieves an appreciable degree of accuracy: the overall accuracy is 0.9761. Outstanding performance for “DoS” (Denial of Service) category, shown that the model made a highly accurate detection of such kind of attacks. The “Probe” category is another category that gives a good result, but ‘DoS’ performance is slightly higher with good identification rate. Needless to say, weaker performance can be observed in the “R2L” category that has lower effectiveness for this kind of recognition. The “U2R” category can be said as very poor with all the parameters being nearly low. Since the presence of this category is negligible in the dataset, the detection capability shows a very poor result. As for the last “normal” group, the model correctly correlates their network activity with high performance indicators. In conclusion, the macro levels of performance at each class are low to moderate but at the same time the weighted levels indicate high competency of the model at identifying certain classes that are more dominant. Figure 3 provides confusion matrix of the model that used GA-SUS feature selection algorithm.

TABLE II. CLASSIFICATION REPORT OF MODEL USING GA-SUS FEATURE SELECTION

	precision	f1-score	recall	support
Probe	0.96	0.95	0.95	2749
DoS	0.99	0.99	0.99	10688
U2R	0.00	0.00	0.00	25
R2L	0.85	0.79	0.74	792
normal	0.98	0.98	0.98	15450
weighted average	0.97	0.98	0.98	29704
macro average	0.76	0.74	0.73	29704

Fig. 3. Confusion Matrix of model using GA-SUS feature selection.

The suggested GA-SUS feature selection technique was contrasted with differential evolution-based algorithms that have the maturity extension feature selection proposed in [22]. When comparing the proposed GA-SUS with RFE ensemble learning approach to DE-ME, differences in performance and technique are evident.

Classification Report of model using DE-ME Feature Selection is shown in Table III. Classification report shows overall high performance of the model in using feature selection from DE-ME is 94.43%. Once more, the accuracy of the model is extremely high when it comes to the detection of “DoS” and “normal” classes due to high coefficients of F1-score, recall, and precision, which equals to 0.90 and above. The macro average F1-score is calculated to be 0.72 and clearly shows the variation in the performance of the model across the classes Hence the weighted average F1-score of 0.94 reveals the complete performance of the framework; however, it somewhat biases towards the majority classes “DoS and “normal”. But this means that the model is more accurate when it comes to frequent attacks but not as effective when it comes to rare attacks.

TABLE III. CLASSIFICATION REPORT OF MODEL USING DE-ME FEATURE SELECTION

	Recall	Precision	F1-score	Support
U2R	0.00	0.00	0.00	25
DoS	1.00	0.90	0.94	10688
R2L	0.83	0.91	0.87	792
Probe	0.68	0.96	0.80	2749
normal	0.96	0.98	0.97	15450
macro avg	0.70	0.75	0.72	29704
weighted avg	0.94	0.95	0.94	29704

(a). The Accuracy and loss of models using GA-SUS feature selection.

(b). The Accuracy and loss of models using DE-ME feature selection.

Fig. 4. Accuracy and loss plot.

Fig. 4 (a) and Fig. 4 (b) illustrates Accuracy and loss plot for GA-SUS and DE-ME feature selection respectively. The accuracy and loss plots compare model performance using two

feature selection methods: DE-ME and GA-SUS. For both methods, the accuracy plot shows how well the models correctly classify data over training epochs, while the loss plot tracks the error reduction. Typically, a rising accuracy and a decreasing loss indicate good model training. Comparing the two, GA-SUS likely shows better stability with smoother curves and higher final accuracy, while DE-ME may have more fluctuations, suggesting GA-SUS's feature selection yields a more consistent and accurate model. The plots help visualize the effectiveness of each feature selection approach.

Fig. 5. Comparative performance analysis.

Fig. 5 presents the comparative performances classification algorithms. It visually compares the corresponding performance indices of two different models or features selection algorithms. This is likely to report, on the same screen, metrics such as Recall, Precision, F1-score, and even accuracy for each class, enabling a calibration. This comparison illustrates how various solutions affect the framework's ability in screening different kinds of attacks and normal traffic. In the current case and by the overlap of figure we are able to easily compare which of the GA-SUS feature selection method performs better in general and which one has a problem with certain classes. It offers information about the best and inferior aspects that can be used to strengthen the model.

D. Discussion

This study proposes a novel technique of GA-SUS with RFE for selecting the features for an IDS employing three benchmark datasets. In comparison with the existing approach, the current approach yielded results listed in Table IV.

Various studies on IDS datasets have applied different feature selection and machine learning algorithms. Our proposed model yielded decent results compared with those of other feature selection approaches in the literature.

TABLE IV. COMPARISON OF GA-SUS WITH RFE IN EXISTING STUDIES

Study	Feature Selection algorithm	Model	Accuracy achieved (%)
[25]	BukaGini(gini Importance)	Random forest classifier	99
[26]	Feature importance (RF)	RF	-
[27]	Condensed nearest neighbors (CNN)	CNN	95.54
		Radial basis function (RBF)	94.28
[20]	IGRF-RFE	MLP	-
[28]	GA in Map-Reduce	LR, SVM, RT, NB, ANN	90.45%
Proposed model	GA-SUS with RFE	Ensemble learning -DQN	97.61%

BukaGini, with a Random Forest classifier, obtained a high accuracy of about 99%. Other methods, such as Radial Basis Function (RBF) and convolutional neural network (CNN), yielded accuracies of 95.54% and 94.28%, respectively. The GA in the MapReduce approach combined with LR, RT, ANN, SVM and NB achieved 90.45% accuracy. Our model, utilising GA-SUS with Recursive Feature Elimination (RFE) and ensemble learning optimised by DQN, achieved a notable accuracy of 97.61%, displaying its robustness in intrusion detection.

Although the proposed model offers good results, certain limitations still exist. There appears to be no perfect dataset for studying invertible graphs; however, the current work employed the dataset called NSL-KDD, which has been used in most previous studies but may not portray real-life network traffic and emerging threats. Furthermore, the optimisation process used in DQN is quite efficient, but at the same time, it is costly and time consuming; hence, its applicability to large datasets or real-time data may be problematic. This study also presupposes that the selected features remain the best under various network conditions, which may not be true. Future work could consider extending the work to other types of datasets with larger and diverse groups of users, and also compare the model performance in real-time activities in dynamic network topologies.

V. CONCLUSION

The findings from this study highlight the feasibility of the proposed hybrid model of GA-SUS with RFE for feature selection and DQN for fine-tuning an ensemble learning model of classifiers for network intrusion detection. It reaches an accuracy of 97.60% on the NSL-KDD dataset and is capable of detecting different kinds of attacks, such as revival of DoS and probe attacks, as it solves the problem of class imbalance. The proposed multi-objective optimization harnessing stochastic universal sampling with a Genetic Algorithm for selection and Deep Q-Networks thus contributes to the design of new approaches for improving the generalization of the model by reducing its sensitivity to changes in the training data. As a result, the development of the study has limitations evident as follows; this kind of attack is very rare, but because it is present in the dataset very few times, the performance for such types like U2R remains below par. Future work may investigate better detection rates for these minority classes by investigating better data augmentation techniques or by using enriched deep neural networks. Furthermore, the model could be tested on other datasets as well as real-time environments, and such aspects could also be further explored. Extending this approach to address dynamic cyber threats or using it for more general and larger sets would further improve the approach to help with network security use cases.

Optimizing Route Planning for Autonomous Electric Vehicles Using the D-Star Lite Algorithm

Bhakti Yudho Suprpto, Suci Dwijayanti, Desi Windisari, Gatot Aria Pratama

Department of Electrical Engineering, Universitas Sriwijaya, Inderalaya, South of Sumatera, Indonesia

Abstract—Every vehicle, including autonomous vehicles, requires a route to navigate its journey. Route planning is a critical aspect of autonomous vehicle operations, as these vehicles rely on guided paths or sequential steps to move effectively. Ensuring that the route is optimal is a key consideration. This study tests the D-Star Lite algorithm to determine the most efficient route. In simulation tests, the D-Star Lite algorithm was compared with the A-Star algorithm. The results showed that D-Star Lite outperformed A-Star, achieving an average distance reduction of 124 meters. Real-time testing involved finding a route from node 36 to node 0, resulting in a total distance of 803 meters. Additional tests focused on route replanning in real-time scenarios. For instance, the initial route passing through nodes 36 → 37 → 38 → 39 → 40 → 41 → 42 → 43 → 44 → 45 → 0 was adjusted to an alternative route: 36 → 37 → 38 → 46 → 26 → 11 → 2 → 4 → 1 → 0. Based on the results, the D-Star Lite algorithm proves effective in identifying the best route for autonomous electric vehicles while also enabling real-time route replanning.

Keywords—Autonomous vehicle; D-Star Lite; path planning; realtime; replanning route; optimal route

I. INTRODUCTION

Recent advancements in computing and communication technologies have significantly contributed to the development of autonomous vehicles. The emergence and evolution of these vehicles are the results of research in fields such as wireless communication technology, navigation, sensor technology, ad hoc networking, data acquisition and distribution, and data analysis [1] [2]. In addition to their ability to navigate autonomously to destinations, other critical factors must be considered in autonomous vehicles, such as the time required to reach the destination [3]. To plan movements efficiently, it is equally important to consider the routes the vehicle will follow [4].

Route planning is a critical aspect of robotics. Autonomous robots and vehicles require guidance paths or next steps to navigate effectively [5]. Defining a destination coordinate as a target ensures that the robot or autonomous vehicle can reach that destination via a predetermined route. This route must be the fastest to optimize efficiency and effectiveness while avoiding unnecessary steps [6]. This aspect is crucial to ensuring the efficiency and accuracy of the vehicle's movement [7]. Therefore, using a path planning method that works in dynamic environments is essential to handle obstacles that may change or be unpredictable [8]. Several methods can be used to determine the route, such as the Dijkstra algorithm, A-star, and D-Star Lite [9].

In research on the Dijkstra algorithm, it is explained that this algorithm is used for route planning in smart cars by implementing both the Dijkstra algorithm and the dynamic window approach [10]. This method was successfully applied to a self-developed smart car to avoid obstacles and reach a predetermined position. The study involved both simulation experiments and real-world testing, demonstrating the effectiveness and reliability of the Dijkstra algorithm and the implemented system.

In research on the A-star (A*) algorithm, improvements were made to the A-star-based path planning algorithm implemented in autonomous vehicles [11]. These improvements cover various aspects, such as the use of evaluation standards to measure performance, incorporating human guidance or global path planning to develop heuristic functions, leveraging key points around obstacles for more effective avoidance, and applying the variable-step-based A-star algorithm to reduce computation time [11].

However, both of these algorithms have their drawbacks. The Dijkstra algorithm is categorized as a greedy algorithm that can optimally find the shortest path solution [12]–[14], but it requires a longer search time. On the other hand, the A-star algorithm is a best-first search algorithm that can find the shortest path more quickly but does not always produce an optimal solution [15]. Nevertheless, A-star has an advantage over Dijkstra in its calculations. The A-star algorithm utilizes a heuristic distance [16] added to the straight-line path, resulting in a more efficient route. A-star is well-suited for situations where it is important to find a path quickly and efficiently in various environments [17]. Both the Dijkstra and A-star algorithms are only effective in solving the path search process in static environments (where conditions do not change) [18]. However, for an autonomous vehicle to adapt to unknown and potentially changing road conditions, a path planning algorithm that can be implemented in dynamic (changing) environments is needed. Therefore, the D-Star Lite algorithm will be developed.

The D-star Lite algorithm can address the efficiency issues of other algorithms when used in dynamic environments [18]. In previous research [10] and [11], path planning algorithms have been implemented using autonomous vehicles, some of which involved simulations. However, none of the studies using Dijkstra or A-star algorithms have been able to perform real-time replanning when obstacles change. In the study [19] that discusses the D-star Lite algorithm, the goal was to design a modified D-star Lite algorithm for global path planning in UAV-based (unmanned aerial vehicle) and mobile robots in large-scale disaster areas. This algorithm aims to address the

challenges of dynamic environments that are only partially known by providing shorter paths and faster execution times, ultimately improving the performance and efficiency of rescue robots in such situations. Although in study [19] explores the use of the D-Star Lite algorithm for path planning in dynamic environments with UAVs and mobile robots, no study has implemented the D-star Lite algorithm for path planning in autonomous vehicles. Therefore, this study uses the D-Star Lite algorithm to determine the fastest route for autonomous electric vehicles.

The contributions of this study are as follows: implementing the D-Star Lite algorithm to determine the fastest route for the autonomous vehicle, with real-time testing performed using a path on the Universitas Sriwijaya campus, which represents road conditions in Indonesia. Additionally, the study compares the D-Star Lite algorithm with other well-known path planning algorithms.

The paper is organized as follows: Section II explains path planning, the method is presented in Section III, Section IV discusses the results and findings, and finally, the paper is concluded in Section V.

II. PATH PLANNING

Path planning is a technique used to determine the best route for an autonomous electric vehicle to move from its current position to the desired destination while avoiding obstacles along the way [9]. Based on the environment in which it is applied, path planning can be performed in either static or dynamic environments.

In a static environment, obstacles have fixed positions and do not change location. In contrast, in a dynamic environment, obstacles may be partially known or entirely unknown, and their positions can change over time.

There are two types of path planning: global and local path planning.

1) *Global path planning*: Global path planning involves determining the route from the starting point to the destination within a larger environment. This requires extensive mapping and information about the robot's initial position and target destination. The focus is on finding the optimal route to reach the goal without considering the detailed surroundings near the robot. The global path planning process typically takes more time, as it involves analyzing the entire environment to identify the best route over a larger distance.

2) *Local path planning*: Local path planning focuses on determining the route around the robot's current position. Its primary objective is to avoid nearby obstacles and ensure the robot reaches its destination safely and efficiently. Local path planning is faster to execute because it focuses on a smaller area surrounding the robot.

Both approaches are essential for enabling autonomous vehicles to navigate complex environments effectively, combining broad-route optimization with immediate obstacle avoidance to ensure safety and efficiency.

B. Lifelong Planning A-star Algorithm (LPA*)

The Lifelong Planning A-Star (LPA*) algorithm is an enhancement of the A-Star algorithm. LPA* is an incremental version of A-Star, enabling it to adapt to changing environments by utilizing two key values: $g(s)$, which represents the cost accumulated so far to move from the current node to the start node (the formula for calculating $g(s)$ is provided in Eq. (1) [20]) and $rhs(s)$, which represents the best-known cost to reach a node from the start node (its formula is provided in Eq. (2) [20]).

By leveraging these two values, the LPA* algorithm efficiently recalculates paths as the environment changes, making it well-suited for dynamic scenarios.

$$g(s) = g(s') + d(s', s) \quad (1)$$

$$rhs(s) = \min_{s' \in neighbor(s)} (g(s') + d(s', s)) \quad (2)$$

where $g(s)$ is the cost to move from the start node to the current node, s is current node, s' is the predecessor node, and $d(s, s')$ is the cost of moving from the predecessor node to the current node.

If $g(s) = rhs(s)$, the node can be considered consistent. However, if the calculated node is inconsistent, it indicates a possible error in the calculation process.

In the LPA* algorithm, a priority queue is used to store nodes that are known and need to be evaluated or updated. Each node in the priority queue is assigned a key value, which determines the priority of the node. Nodes with the smallest key value are evaluated and updated first.

The function used to determine the key value of each node is provided in Eq. (3). This mechanism ensures that the algorithm efficiently processes nodes in the correct order, maintaining accuracy and minimizing computational overhead.

$$k(s) = \min(g(s), rhs(s)) + h(s) \quad (3)$$

where s is current node, $g(s)$ is g -value of the current node, $rhs(s)$ is rhs -value of current node and $h(s)$ is heuristic value of the current node.

C. D-star Lite (D* Lite) algorithm

The D-Star Lite algorithm, first developed by Sven Koenig and Maxim Likhachev in 2002, is a path planning algorithm capable of optimally finding a route between a start point and a goal point in environments that are known, partially known, or dynamic.

This algorithm operates on a data structure consisting of interconnected nodes. A node leading to the current position is called a predecessor node, while a node that will be traversed next is referred to as a successor node.

D-Star Lite is based on the Lifelong Planning A-Star (LPA*) algorithm, an incremental version of A-Star that adapts to changes in the map graph. However, unlike traditional approaches, D-Star Lite performs route planning starting from the goal node (finish) and works toward the start node. In this context, the $g(s)$ value represents the estimated cost from the current node to the goal node.

This reverse planning approach allows D-Star Lite to efficiently handle replanning when changes occur in the environment. The algorithm achieves this by maintaining an estimated cost for each traversed node, representing the distance to the goal node. This capability makes D-Star Lite particularly well-suited for dynamic and unpredictable environments.

D* Lite uses distance as a fundamental component because it is a path planning algorithm designed to find the shortest or least costly path between a start point and a goal. Here's why distance plays such a central role [7] [21] [22] [23]:

1) *Core purposes path planning:* The primary objective of D* Lite is to navigate an autonomous vehicle efficiently from a start point to a goal while avoiding obstacles. Distance or cost is the metric used to evaluate the optimality of the path. This ensures that the agent follows the shortest or least costly route, saving time, energy, or other resources.

2) *Adaptation to dynamic information:* In dynamic and partially known environments, the map can change due to new obstacles or updated information. D* Lite re-evaluates the distance (or cost) between nodes when changes occur, allowing the algorithm to efficiently update the path without recalculating everything from scratch. This incremental approach relies on comparing distances to ensure the agent can still reach the goal optimally.

3) *Grid representation and node expansion:* D* Lite often uses a grid or graph-based representation of the environment where nodes represent possible positions, and edges represent paths between these positions. The algorithm assigns a cost to each edge, typically based on physical distance or other factors like terrain difficulty. Calculating the shortest path through these nodes inherently involves summing distances or costs.

4) *Real-world relevance:* Distance is a straightforward and intuitive metric that directly translates to practical scenarios. Whether it's minimizing travel time, energy consumption, or fuel usage, distance serves as a universal measure of efficiency. For example, in rescue operations, D* Lite's reliance on distance ensures that the robot can reach victims or resources quickly.

D. Euclidean Distance

The Euclidean distance is a technique used to measure the distance between two points by considering the straight-line distance between them, not the angles. In Euclidean distance measurement, the calculation is conducted within a single plane and involves applying the Pythagorean theorem.

This method is commonly used to compute the distance between nodes and to determine heuristic values in the D-Star Lite algorithm. It achieves this by utilizing longitude and latitude values obtained from GPS sensors.

The formula for Euclidean distance is provided in the equation below, offering a straightforward way to calculate the straight-line distance between two points in a given space.

$$h = \sqrt{(x_{destination} - x_{start})^2 + (y_{destination} - y_{start})^2} \quad (4)$$

With x is the heuristic distance value, $x_{destination}$ is the longitude value of the target position, x_{start} is the longitude value of the starting position, $y_{destination}$ is the latitude value of the target position, and y_{start} is the latitude value of the starting position.

Eq. (4) above can be used to calculate the distance between two coordinate points, which will be applied in the D-star Lite algorithm. To obtain the distance in kilometers, Eq. (4) must be multiplied by the Earth's degree value, approximately 111.319888.

III. METHOD

A. Design System

In this study, the system design is presented in the form of a flowchart, as shown in Fig. 1 below. The flowchart illustrates the stages involved in determining the optimal route for an autonomous electric vehicle, as well as the steps taken to replan the route if obstacles are encountered.

In Fig. 1, the process begins with reading GPS data via ROS, followed by inputting the target node. The D-Star Lite algorithm determines the optimal route by identifying the direction of the next node based on the previous heading. The autonomous vehicle then starts moving toward the next node.

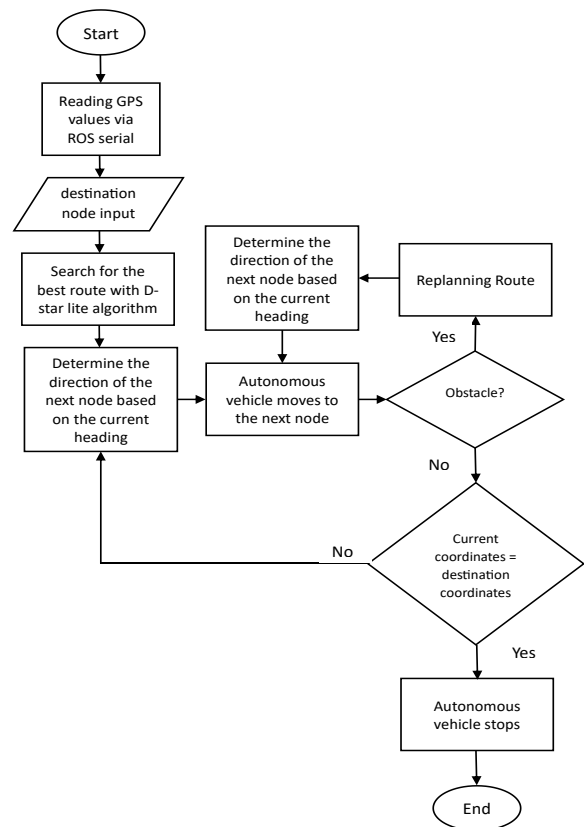

Fig. 1. Flowchart of path planning system design.

If obstacles are encountered along the route, the D-Star Lite algorithm will replan and determine a new direction for the next node. The autonomous vehicle will continue its movement. If no obstacles appear along the path, the system will check the vehicle's current position. If the current coordinates match the target coordinates, the autonomous vehicle will stop, indicating that it has reached the desired destination. The route search process using the D-Star Lite algorithm must be able to replan if obstacles are detected while the autonomous vehicle is moving toward the target point. The flow diagram for the designed software can be seen in Fig. 2.

In Fig. 2, it can be seen that the algorithm initially reads the coordinate values from the GPS system, which are transmitted via ROS serial communication. After obtaining the initial coordinates, the current coordinates are determined. The next step is to define the destination or target node. The D-Star Lite algorithm calculates the global path from the current node to the target node. The target node result is then sent to the controller via ROS serial communication.

The camera sensor provides image data that is sent to a computer for identification processing, which then sends input to the controller. If the camera detects an obstacle, the D-Star Lite algorithm adjusts the route and performs replanning, which is transmitted via ROS serial communication. However, if no obstacle is detected, the movement continues until the target node is reached.

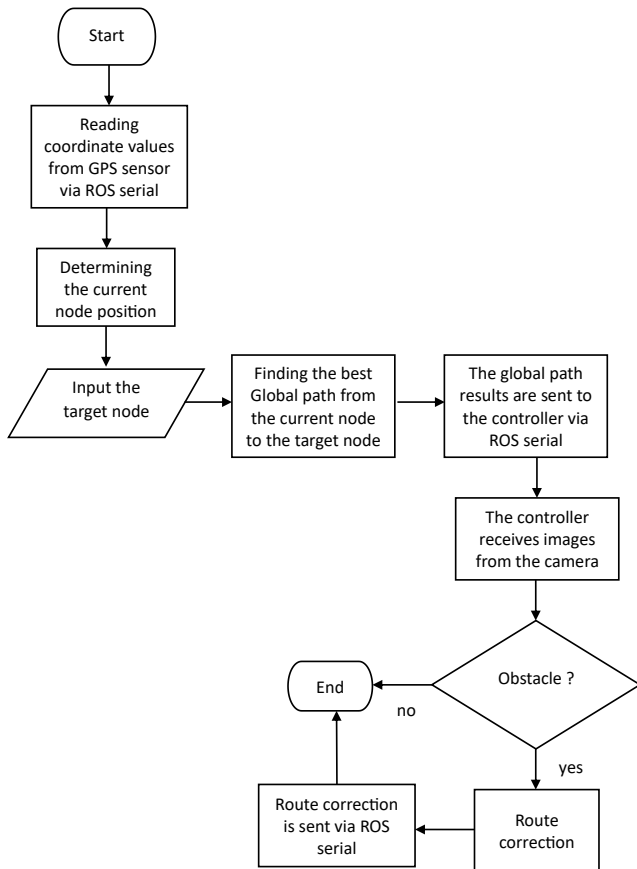

Fig. 2. The flowchart of design software.

B. Route Data

At this stage, longitude and latitude coordinate data are collected directly at each point designated as a node. A total of 47 longitude and latitude data points were obtained during this process, which will be used for testing purposes in both simulations and real-time scenarios. The nodes are labeled with numbers from 0 to 46, as shown in Table I.

TABLE I. NODE POINTS ON THE CAMPUS OF UNIVERSITAS SRIWIJAYA INDRALAYA

The mapping of these 46 nodes is shown in Fig. 3.

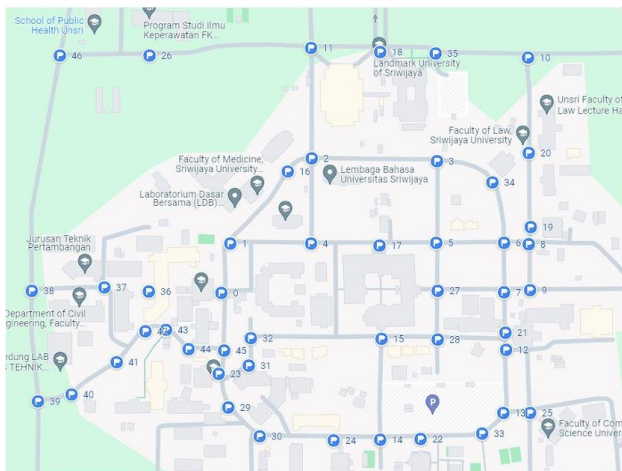

Fig. 3. The mapping routes on the Universitas Sriwijaya Indralaya campus.

In this study, the selected location is the road around the Indralaya campus of Sriwijaya University because the roads in this area have challenging characteristics, such as the absence of road markings, road barriers, and the surface condition of the roads which is not very smooth. The roads around the Indralaya campus reflect those in rural areas of South Sumatra Province in general. In terms of traffic density, it is not as congested as rural roads in Sumatra, but it is already quite busy due to the many students who use the roads by riding motorcycles, driving cars, or taking buses.

IV. RESULTS AND DISCUSSIONS

A. Path Planning Testing Through Simulation

In this testing, the path planning system is evaluated using the D-Star Lite algorithm to determine whether the developed system functions properly. A comparison will also be made between the route search results using the D-Star Lite algorithm and the A-Star algorithm from previous research. This experiment involves finding the best route across 10 different routes. In the first trial, the route search was tested from the Faculty of Engineering to the Faculty of Law. The results of this test are presented in Table II, and the traversed route is shown in Fig. 4.

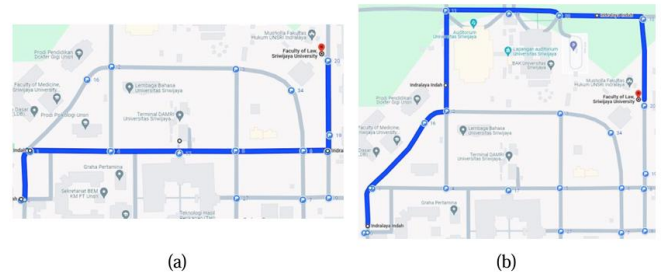

Fig. 4. Route from the faculty of engineering to the faculty of law: (a) D-Star Lite method, (b) A-Star method.

TABLE II. TESTING THE ROUTE FROM THE FACULTY OF ENGINEERING TO THE FACULTY OF LAW

Method	Nodes skipped	Total euclidean distance (m)	Distance based on google maps (m)
D-Star lite	0→1→4→17→5→6→8→19→20	704,9	702
A-Star	0→1→16→2→11→18→35→10→20	948,9	948
Distance difference (m)		244	246

In the second trial, the route search was tested from the Faculty of Engineering to the Faculty of Economics. The results of this test are presented in Table III, and the traversed route is shown in Fig. 5.

Fig. 5. Route from the Faculty of Engineering to the Faculty of Economics: (a) D-Star Lite Method, (b) A-Star Method

TABLE III. TESTING THE ROUTE FROM THE FACULTY OF ENGINEERING TO THE FACULTY OF ECONOMICS

Method	Nodes skipped	Total euclidean distance (m)	Distance based on google maps (m)
D-Star lite	0→45→23→31→32→15→28→21	633,6	633
A-Star	0→1→4→17→5→27→7→21	658,1	658,3
Distance difference (m)		24,5	25,3

In the third trial, the route search was tested from the Faculty of Engineering to the Rectorate. The results of this test are presented in Table IV, and the traversed route is shown in Fig. 6.

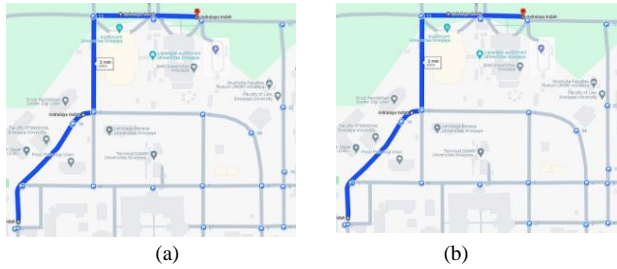

Fig. 6. Route from the faculty of engineering to the rectorate: (a) D-Star lite method, (b) A-Star method.

TABLE IV. TESTING THE ROUTE FROM THE FACULTY OF ENGINEERING TO THE FACULTY OF ECONOMICS

Method	Nodes skipped	Total euclidean distance (m)	Distance based on google maps (m)
D-Star lite	0→1→16→2→11→18→35	648	650,6
A-Star	0→1→16→2→11→18→35	648	650,6
Distance difference (m)		0	0

In the fourth trial, the route search was tested from the Faculty of Economics to the Faculty of Medicine. The results of this test are presented in Table V, and the traversed route can be seen in Fig. 7.

Fig. 7. Route from the faculty of economics to the faculty of medicine: (a) D-Star lite method, (b) A-Star method.

TABLE V. TESTING THE ROUTE FROM THE FACULTY OF ECONOMICS TO THE FACULTY OF MEDICINE

Method	Nodes skipped	Total euclidean distance (m)	Distance based on google maps (m)
D-Star lite	21→28→27→5→3→2→16	640,6	640,2
A-Star	21→28→15→32→31→23→45→0→1→16	860,6	858,6
Distance difference (m)		220	218,4

In the fifth trial, the route search was tested from the Faculty of Agriculture to the landmark. The results of this test are presented in Table VI, and the traversed route is shown in Fig. 8.

From the five trials conducted, the D-Star Lite algorithm shows a larger error in comparison to Google Maps readings than the A-Star algorithm. However, when comparing the routes taken and the best route searches, the D-Star Lite algorithm outperforms the A-Star algorithm. This is evident in the first, second, and fourth trials, with the largest difference being 244 meters in the second trial. This occurs because the A-Star algorithm prioritizes only the nodes leading directly to the destination as the best route, whereas the D-Star Lite algorithm evaluates each node in the dataset to determine the shortest path to the destination. Consequently, the D-Star Lite algorithm sometimes finds a more optimal route than the A-Star algorithm. Therefore, the D-Star Lite algorithm is a viable method for finding the best route.

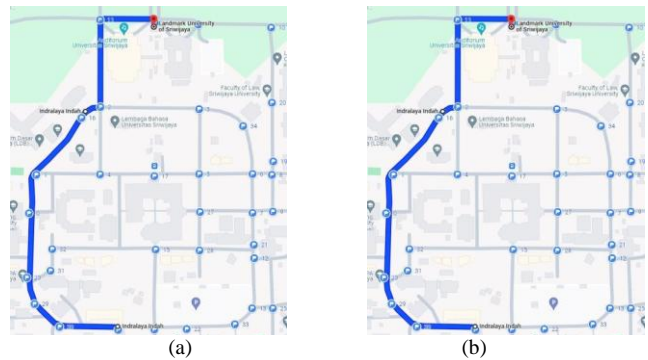

Fig. 8. Route from the faculty of agriculture to the landmark: (a) D-Star lite method, (b) A-Star method.

TABLE VI. TESTING THE ROUTE FROM THE FACULTY OF ECONOMICS TO THE FACULTY OF MEDICINE

Method	Nodes skipped	Total Euclidean distance (m)	Distance based on google maps (m)
D-Star lite	24→30→29→23→45→0→1→16→2→11→18	933,3	934,2
A-Star	24→30→29→23→45→0→1→16→2→11→18	933,3	934,2
Distance difference (m)		0	0

B. Route Replanning Testing via Simulation

In this simulation test, the replanning system using the D-Star Lite algorithm was tested to determine whether it could successfully perform route replanning when an obstacle appeared on the route. This experiment included five tests to evaluate whether the D-Star Lite algorithm's replanning system could be used in real-time conditions.

In the first trial, a route search was conducted from the Faculty of Engineering to the Faculty of Law. The best route identified passed through nodes 0 → 1 → 4 → 17 → 5 → 6 → 8 → 19 → 20. After establishing the route, node 17 was designated as an obstacle or closed, prompting the D-Star Lite algorithm's replanning system to search for the best alternative route avoiding the closed node. The resulting route passed through nodes 0 → 1 → 4 → 2 → 3 → 34 → 6 → 8 → 19 → 20, as shown in Fig. 9.

Fig. 9. Replanning route from the faculty of engineering to the faculty of law
(a) Before replanning (b) After replanning.

In the second trial, a route search was conducted from the Faculty of Economics to the Faculty of Medicine. The best route identified passed through nodes 21 → 28 → 27 → 5 → 3 → 2 → 16. After establishing the route, node 3 was designated as an obstacle or closed, prompting the D-Star Lite algorithm's replanning system to search for the best alternative route, avoiding the closed node. The resulting route passed through nodes 21 → 28 → 27 → 5 → 17 → 4 → 2 → 16, as shown in Fig. 10.

Fig. 10. Replanning route from the Faculty of Economics to the Faculty of Medicine (a) Before replanning (b) After replanning.

In the third trial, a route search was conducted from the Faculty of Mathematics and Natural Sciences to the Faculty of Economics. The best route identified passed through nodes 23 → 31 → 32 → 15 → 28 → 21. After establishing the route, node 28 was designated as an obstacle or closed, prompting the D-Star Lite algorithm's replanning system to search for the best alternative route, avoiding the closed node. The resulting route passed through nodes 23 → 31 → 32 → 15 → 14 → 22 → 33 → 13 → 12 → 21, as shown in Fig. 11.

Fig. 11. Replanning route from the faculty of mathematics and natural sciences to the faculty of economics (a) Before replanning (b) After replanning.

In the fourth trial, a route search was conducted from the Faculty of Law to the Faculty of Agriculture. The best route identified passed through nodes 20 → 19 → 8 → 9 → 7 → 27 → 28 → 15 → 14 → 24. After the route was established, node 27 was designated as an obstacle or closed, prompting the D-Star Lite algorithm's replanning system to search for the best alternative route, avoiding the closed node 27. The resulting route passed through nodes 20 → 19 → 8 → 9 → 7 → 21 → 28 → 15 → 14 → 24, as shown in Fig. 12.

In the fifth trial, a route search was conducted from the Faculty of Public Health to the Faculty of Law. The best route identified passed through nodes 26 → 11 → 18 → 35 → 10 → 20. After establishing the route, node 18 was designated as an obstacle or closed, prompting the D-Star Lite algorithm's replanning system to search for the best alternative route, avoiding the closed node. The resulting route passed through nodes 26 → 11 → 2 → 3 → 34 → 6 → 8 → 19 → 20, as shown in Fig. 13.

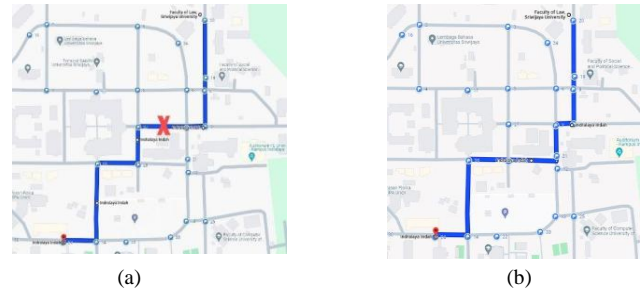

Fig. 12. Replanning route from the faculty of law to the faculty of agriculture
(a) Before replanning (b) After replanning.

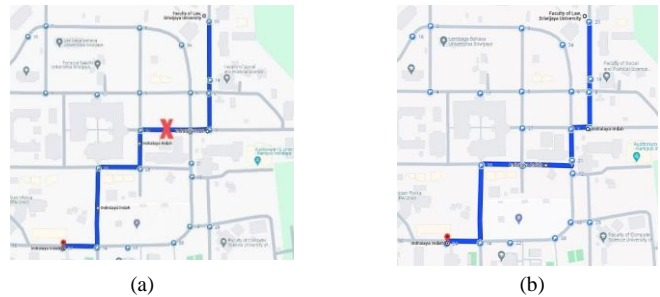

Fig. 13. Replanning route from the faculty of public health to the faculty of law (a) Before replanning (b) After replanning.

From the five route replanning trials conducted, it is evident that the route replanning system using the D-Star Lite algorithm successfully performs the route replanning process. Therefore, when an obstacle or blockage occurs, it generates a new optimal route to follow. Consequently, the D-Star Lite algorithm is suitable for real-time route replanning system testing.

C. Real-time Path Planning Testing

Next, this section discusses the path planning system testing under real-time conditions. In this test, an autonomous electric vehicle is used, with its position monitored in real-time via GPS. The objective is to evaluate the path planning system, designed with the D-Star Lite algorithm, to guide the autonomous electric vehicle towards its destination by following the optimal route.

In this test, the autonomous electric vehicle will move from its starting position, the Digital Control Laboratory in the Electrical Engineering Department (node 36), to its destination, the Faculty of Engineering Dean's office building (node 0). The best route will then be determined from the starting position to the destination. The optimal route found passes through nodes 36 → 37 → 38 → 39 → 40 → 41 → 42 → 43 → 44 → 45 → 0. For the autonomous electric vehicle to reach the

destination, it must pass through 10 node stages. The path taken is shown in Table VII.

In the real-time path planning tests conducted with an electric vehicle, as shown in Table VII, the autonomous electric vehicle successfully reached the target position by following the optimal route determined by the D-Star Lite algorithm. This demonstrates that the D-Star Lite algorithm is an effective method for finding the best route for autonomous electric vehicles.

TABLE VII. REAL-TIME PATH PLANNING TESTING

Node stages	Total distance (m)	Google maps distance (m)	Route based on google maps	Route taken electric vehicle
36 → 37	70,8	70,9		
37 → 38	116,6	116,5		
38 → 39	177,1	181,1		
39 → 40	54,3	54,5		
40 → 41	89,6	89,1		
41 → 42	67	67,8		
42 → 43	32,8	32,9		
43 → 44	46,6	48		
44 → 45	55,6	56,8		
45 → 0	92,6	92,4		

D. Real-Time Route Replanning Test

In this real-time route replanning experiment, a direct test will be conducted using an autonomous electric vehicle to determine whether the route replanning system of the D-Star Lite algorithm can effectively adjust the route when encountering obstacles in real-time conditions.

In this test, the autonomous electric vehicle is programmed to move from its starting point at the Digital Control Laboratory to the Faculty of Engineering Dean's office. The planned route passes through the following nodes: 36 → 37 → 38 → 39 → 40 → 41 → 42 → 43 → 44 → 45 → 0.

However, when the autonomous electric vehicle reaches node 38 and detects an obstacle blocking the path to node 39, the system identifies this path as impassable. The road closure toward node 39 is illustrated in Fig. 14.

Fig. 14. Road closure condition toward node 39.

Fig. 14 shows the visual closure of the road to node 39. This road closure occurs when the autonomous electric vehicle detects an obstacle blocking the path. The D-Star Lite algorithm handles this condition by dynamically recalculating an alternative route in real-time to ensure the vehicle can continue its journey toward the destination.

Once the road closure is detected, the replanning system in the D-Star Lite algorithm is activated to recalculate and adjust the route, ensuring that the autonomous electric vehicle can still reach its predetermined destination. After the replanning process, the new route is as follows: 36 → 37 → 38 → 46 → 26 → 11 → 2 → 4 → 1 → 0. A comparison between the original route (before replanning) and the new route (after replanning) is shown in Fig. 15.

Fig. 15. Route replanning from the control and robotic laboratory to the faculty of engineering (a) Before replanning, (b) After replanning.

The real-time route replanning test demonstrated that the designed system can dynamically adjust the route in real-time whenever obstacles are encountered during the autonomous electric vehicle's journey toward its destination.

D-Star Lite uses distance as a core metric because it aligns with the algorithm's goal of finding optimal paths while efficiently adapting to dynamic environments. Distance serves as a universal measure of cost that simplifies computations, ensures practical relevance, and facilitates heuristic optimization.

If we compare the D-Star Lite algorithm with Dijkstra, the core characteristics are as follows: Dijkstra's algorithm is one of the earliest graph-based approaches for finding the shortest

path between nodes. It is deterministic and guarantees an optimal solution by systematically exploring all possible paths in a static and fully known environment. The algorithm's primary strength lies in its simplicity and optimality for static graphs. On the other hand, D-Star Lite is a dynamic and incremental path planning algorithm designed for environments that are partially known or subject to change. It builds on the principles of Dijkstra's algorithm but introduces significant enhancements to handle real-time updates efficiently. By focusing only on affected nodes when the environment changes, D-Star Lite reduces the computational overhead typically associated with path recalculations in dynamic scenarios. For the performance: Dijkstra's algorithm guarantees optimal paths in static settings but suffers from high computational complexity in large graphs due to its exhaustive exploration. This limitation becomes apparent when applied to vast areas or dense graphs, as the algorithm must evaluate all possible nodes and edges systematically [7]. D-Star Lite, however, is optimized for efficiency in dynamic and partially known environments. It updates only the necessary parts of the graph when changes occur, significantly reducing computational demands. Techniques like auto-clustering further enhance its performance by segmenting large maps, as demonstrated in Heo et al. (2022), where the Auto-Splitting D-Star Lite method reduced unnecessary node expansions [23].

Dijkstra and D-Star Lite algorithms cater to distinct path planning requirements. Dijkstra's algorithm is ideal for static, structured environments where optimality and simplicity are paramount. D* Lite, on the other hand, is tailored for dynamic and partially known environments, offering computational efficiency and adaptability. The choice between these algorithms depends on the specific use case, environmental constraints, and computational resources. Future advancements, such as hybrid approaches or machine learning integration, may further enhance their capabilities, bridging the gap between static and dynamic path planning needs.

V. CONCLUSIONS

After conducting five trials to compare the D-Star Lite algorithm with the A-Star algorithm, it was concluded that D-Star Lite demonstrates more optimal route-finding capabilities than A-Star. The average difference in route distance between the two algorithms was 97.7 meters, with D-Star Lite consistently providing shorter routes. Additionally, D-Star Lite's ability to calculate the distance to the target at each node enables it to perform route replanning effectively when encountering obstacles.

In the conducted tests, the D-Star Lite algorithm proved capable of finding the shortest route in real-time, covering a distance of 803 meters from the starting point at the Digital Control Laboratory to the Faculty of Engineering. Furthermore, the D-Star Lite algorithm successfully performed route replanning. Initially, the route was: 36 → 37 → 38 → 39 → 40 → 41 → 42 → 43 → 44 → 45 → 0. After replanning due to an obstacle, the route was adjusted to: 36 → 37 → 38 → 46 → 26 → 11 → 2 → 4 → 1 → 0. This study has shown the effectiveness of using the D-Star Lite algorithm in real-time applications for autonomous vehicles, even with paths containing obstacles. However, it is limited to simple obstacles.

Thus, further studies are needed to improve the algorithm's handling of different types of obstacles along the vehicle's path.

Abstract—This study presents the development of a predictive model for PM_{2.5} concentrations resulting from forest and peatland fires in Riau Province, utilizing the stacking regressor technique within an ensemble learning framework. The model integrates spatiotemporal data from remote sensing and ground-based sensors at a resolution of 1 km x 1 km, demonstrating its effectiveness in capturing the intricate patterns of PM_{2.5} concentrations. By combining Random Forest, Gradient Boosting Machine (GBM), and XGBoost, with RidgeCV as a meta-learner, the model attained optimal performance, achieving $R^2 = 0.851$, $MAE = 0.045 \mu\text{g}/\text{m}^3$, and $MSE = 0.003 \mu\text{g}/\text{m}^3$. The incorporation of temporal feature engineering techniques, including lag and rolling window methods, significantly enhanced prediction accuracy, enabling the model to effectively capture seasonal variations and temporal dynamics. Key variables, such as air temperature, evapotranspiration, and Aerosol Optical Depth (AOD), were found to exhibit strong correlations with PM_{2.5} concentrations. The findings from this research contribute to the formulation of data-driven policies for air quality management and pollution mitigation, with the potential for broader application in regions encountering similar environmental challenges.

Keywords—Ensemble learning; PM_{2.5} prediction; remote sensing; stacking regressor; spatio-temporal data

I. INTRODUCTION

PM_{2.5} (Particulate Matter ≤ 2.5 micrometres per cubic metre), which mainly comes from biomass burning such as forest and land fires, vehicle emissions, and coal combustion, causes various serious health impacts [1]. The measurement of PM_{2.5} due to forest fires faces challenges such as the episodic nature of fires, limited monitoring stations, and limited data availability [2]. Measurement approaches include ground stations with high accuracy but limited coverage, as well as satellite remote sensing that has wide and continuous coverage [3]. Satellite technology is effective in detecting fires, exposure to air pollution, and concentrations of aerosol particles including PM_{2.5} [4].

This research analyzes the performance of various machine learning algorithms, namely Gradient Boosting Machine (GBM), eXtreme Gradient Boosting (XGBoost), Support Vector Machine (SVM), Neural Network (NN), Long Short-Term Memory (LSTM), and Recurrent Neural Network (RNN), with the evaluation metrics of Coefficient of Determination (R^2), Mean Absolute Error (MAE), and Mean Squared Error (MSE). To improve prediction accuracy, feature engineering is applied

through the creation of lag and rolling window features. Lag features are based on the concept that historical values of a variable, such as PM_{2.5} concentrations, can influence current or future values, especially in time series data [5], [6]. Variables such as aerosol concentration, relative humidity, ground surface temperature, and air temperature are lagged to capture temporal influences. In addition, rolling window statistics, such as mean, median, and standard deviation, are calculated to capture long-term trends and seasonal patterns, helping the model understand the dynamics of PM_{2.5} changes influenced by seasonal factors or other external events [7]. Riau Province - Indonesia was chosen as the research location because it has the largest peatland in Sumatra Island, which is 3.89 million hectares out of a total of 5.85 million hectares. This condition makes Riau Province an appropriate location for study the impact of forest and peatland fires on PM_{2.5} concentrations [8], [9]. The aim of this research is to develop a machine learning ensemble model with optimised regressor stacking, and to integrate temporal dynamics and trend patterns to predict PM_{2.5} concentrations using 1 km x 1 km spatial and daily temporal remote sensing and ground sensor data, thereby supporting environmental management and public health policy.

II. RELATED WORK

Research relevant to this study includes various PM_{2.5} prediction models that integrate remote sensing-based predictor data, meteorological parameters and land use. Simple regression models such as Linear Regression (LR) and Multiple Linear Regression (MLR) are often used due to their simplicity, but they fail to capture non-linear relationships in high-dimensional datasets [10], [11], [12]. In contrast, machine learning techniques such as Random Forest (RF), Gradient Boosting (GB), and XGBoost have shown better ability in handling complex data and producing more accurate predictions [13], [14].

Further performance improvements are achieved through ensemble learning methods, such as Bagging, Boosting, and Stacking, which combine multiple models to reduce their individual weaknesses and improve prediction reliability [15], [16]. For example, research by Chen [17] showed that the stacking regressor model with meta-learner was able to achieve a coefficient of determination (R^2) of 0.85 and a Root Mean Squared Error (RMSE) of $17.3 \mu\text{g}/\text{m}^3$, which was superior to the single model. In addition, model combinations such as RF, GB, and Linear Mixed Regression (LMR) by Matsuki [18] and

findings Li [19] demonstrating the importance of spatial resolution in improving the accuracy of PM_{2.5} predictions.

Recent studies have also shown the successful application of ensemble models in predicting PM_{2.5} concentrations in various regions, such as China [18], South Asia [4], United States of America [20], and Italy [14]. Stacking regressor, in particular, is becoming a highly relevant method due to its ability to integrate predictions from base models such as RF, GB, and XGBoost using a meta-learner, which optimises the combination of predictions to produce more accurate final results [21]. This approach has shown its effectiveness in capturing complex and non-linear data patterns, which are often unreachable by conventional regression models.

III. METHOD

A. Location, Period and Research Data

This research was conducted in Riau Province, Indonesia, during the period 1 March 2022 to 31 March 2024. Geographically, Riau Province is located between 01°05'00" N to 02°25'00" N and 100°00'00" E to 105°05'00" East. Riau is the part of Sumatra Island that has the largest area of peatland, with 3.89 million hectares out of a total of 5.85 million hectares. The province frequently experiences forest and peatland ecosystem fires, which have the potential to cause haze disasters with transnational impacts. In this study, the prediction of PM_{2.5} concentrations due to forest and peatland ecosystem fires uses meteorological, environmental and geospatial data. Data were obtained from the air quality sensor of the Meteorology, Climatology and Geophysics Agency (BMKG) at Sultan Syarif Kasim II Airport Pekanbaru (101.45° East, 0.46° LU) as well as through satellite remote sensing. Data collection was conducted with daily temporal and spatial resolution, using a 30,000-metre buffer from the ground sensor, and a spatial buffer every 1,000-metres within the 30,000-metre range according to the Area of Interest (AOI), as shown in Fig. 1.

Fig. 1. Map of the study area and AOI.

B. Research Stage

The research utilizes machine learning algorithms as base models to enhance prediction accuracy through stacking, detailing the procedure, stacking architecture, and performance evaluation, as shown in Fig. 2.

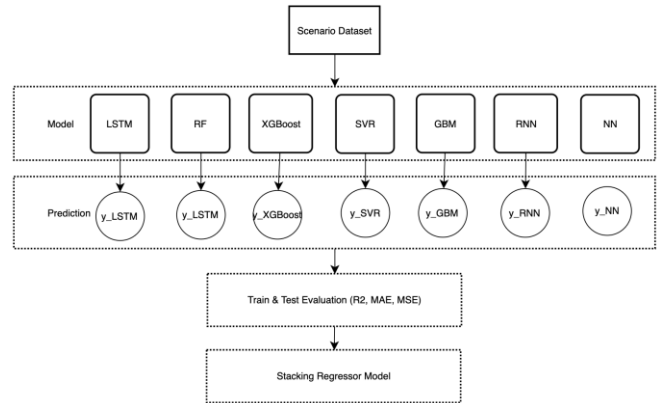

Fig. 2. General stages of modelling using the base model algorithm.

In the initial stage seven different machine learning algorithms as base models to get predictions from each model, namely LSTM, RF, XGBoost, SVR, GBM, NN, and RNN. Each base model generates predictions for the test data, which are referred to as (y_{LSTM}, y_{RF}, y_{XGBoost}, y_{SVR}, y_{GBM}, y_{RNN}, and y_{NN}). These predictions are generated from the training process performed on the training data. Each base model is evaluated using several evaluation metrics such as R², MSE, and MAE. This evaluation aims to measure how well each base model performs against the test data. The model with the best performance on these evaluation metrics is used as the basis for the next stage, which is the development of the ensemble learning model - Attention stacking regressor Model. Furthermore, the research process involves several main stages in applying the stacking regressor method to predict PM_{2.5} concentrations. These stages include dataset preparation, feature engineering, dataset sharing, basic model development, stacking regressor-meta learner modelling, model evaluation and result interpretation as visualised in Fig. 3.

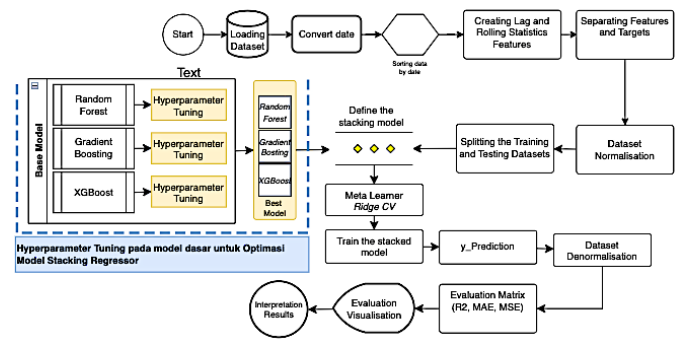

Fig. 3. Research stages of ensemble learning model - stacking regressor.

IV. RESULTS AND DISCUSSION

A. Research Dataset

In general, the predictors used as features of the prediction model for PM_{2.5} concentrations resulting from forest and

peatland fires, taken from ground and remote measurement sensor stations are as shown in below.

B. PM_{2.5} Concentration in the Study Period

During the study, PM_{2.5} concentrations were analysed through two graphs (Fig. 4): PM_{2.5} Level Distribution and PM_{2.5} Trend over Time. Fig. 4(a) shows that most of the PM_{2.5} concentrations were in the range of 15-30 µg/m³, falling into the Good to Moderate category, with concentrations above 55 µg/m³ rarely occurring, signalling generally safe air quality. Fig. 4(b) shows the daily trend of PM_{2.5} from 2022 to 2024, where 74.83% of days are in the Moderate category, 22.16% in the Good category, and 3.01% in the Unhealthy category for the Sensitive Group. Overall, the graph shows that while most days have safe to moderate air quality, there are certain periods where PM_{2.5} concentrations increase to potentially dangerous levels, especially for vulnerable groups. This emphasises the importance of continuous air quality monitoring to anticipate health risks, particularly during periods of increased pollution.

A pattern of fluctuations in PM_{2.5} concentrations was seen throughout the year, with a significant peak occurring at the end of 2023, which was most likely related to forest and peatland fires in Riau, covering more than 2,000 hectares in October 2023 [22].

C. Feature Correlation with PM_{2.5} Concentration

Feature correlation analysis aims to identify the variables that have the strongest relationship with PM_{2.5} concentrations in the dataset. Results in Fig. 5 shows the correlation heatmap for all features in the dataset against the PM_{2.5} target. Based on the results of the correlation analysis of PM_{2.5} in Fig. 6, the red colour represents a strong positive correlation, while the blue colour shows a significant negative correlation.

The feature with the greatest influence is TEMP (air temperature), which has a significant positive correlation, indicating that an increase in temperature tends to increase PM_{2.5} concentrations. In addition, ET (Evapotranspiration) features at certain radii, such as ET30, ET27, and ET28, also show strong positive correlations, signalling that areas with high evapotranspiration rates tend to have greater PM_{2.5} concentrations. AOD (Aerosol Optical Depth), especially at large radii such as *max_AOD*, also showed a significant relationship with PM_{2.5}, reinforcing the link between aerosol particles in the atmosphere and PM_{2.5} concentrations. These features were identified as the most relevant and influential variables in the air quality prediction model based on their strong relationship with PM_{2.5}.

TABLE I. COMMON PREDICTORS USED IN THE STUDY

Predictor	Description	Source	Unit	Temporal Resolution	Spatial Resolution
PM _{2.5} ground	Particulate Matter ≤ 2.5 µg/m ³	BMKG	µg/m ³	Daily	30 Km
TEMP	Relative Temperature	BMKG	°C	Daily	30 Km
PRS	Air pressure	BMKG	hPa	Daily	30 Km
PRE	Rainfall	BMKG	mm	Daily	30 Km
RHU	Relative Humidity	BMKG	%	Daily	30 Km
SSD	Sunlight hours	BMKG	Hours	Daily	30 Km
WIN	Wind speed	BMKG	m/s	Daily	30 Km
Min/Max_NDVI_bufer 1 to NDVI_30	NDVI	MODIS/061/MYD13A1	Unitless	16 Days	1 Km
Min/Max_AOD_bufer 1 to NDVI_30	Aerosol Optical Depth	MODIS (Terra & Aqua MAIAC MCD19A2.061)	Unitless	Daily	1 Km
Min/Max_ET_bufer 1 to NDVI_30	Evapotranspirasi	MODIS/061/MOD16A2	kg/m ²	8 Days	1 Km
Min/Max_LSTDay_bufer 1 to NDVI_30	Daytime surface temperature	MODIS/061/MOD11A1	°C	Daily	1 Km
Min/Max_LSTNight_bufer 1 to NDVI_30	Nighttime surface temperature	MODIS/061/MOD11A1	°C	Daily	1 Km

Fig. 4. PM_{2.5} concentration in the study period (a) Level distribution (b) Concentration trends.

Fig. 5. Heatmap of feature correlation with PM_{2.5} concentration.

D. Evaluate the Performance of the base Model Algorithm

Table II shows the model performance evaluation results, for PM_{2.5} concentration prediction. The XGBoost model performed best on the training data with R² of 1.00, MAE of 0.07 μg/m³, and MSE of 0.01 (μg/m³)², indicating an almost perfect fit. However, on the test data, the performance decreased with an R² of 0.40, MAE of 7.18 μg/m³, and MSE of 109.65 (μg/m³)². The Random Forest model also showed good performance on training (R² 0.92, MAE 2.81 μg/m³, MSE 13.38 (μg/m³)²) but decreased on testing (R² 0.36, MAE 7.16 μg/m³, MSE 116.71 (μg/m³)²). The Gradient Boosting Machine, and Neural Network models had moderate performance with training R² of 0.84 and 0.81, and testing R² of 0.41 and 0.42, respectively. Meanwhile, the Support Vector Regression, LSTM and RNN models showed lower performance, with training R² ranging from 0.17 to 0.38 and testing R² between 0.14 and 0.27.

TABLE II. PERFORMANCE EVALUATION OF TRAINING AND TESTING MODELS

Model	Dataset Training Performance			Dataset Testing Performance		
	R ²	MAE	MSE	R ²	MAE	MSE
Random Forest	0.92	2.81	13.38	0.36	7.16	116.71
XGBoost	1.00	0.07	0.01	0.40	7.18	109.65
Support Vector Reg.	0.17	8.82	147.42	0.14	8.35	157.03
GBM	0.84	4.12	28.05	0.41	6.99	108.56
Neural Network	0.81	4.38	34.22	0.42	7.67	106.85
LSTM	0.38	7.81	109.17	0.27	8.36	133.65
RNN	0.33	8.07	118.26	0.23	8.39	141.53

E. Improving PM_{2.5} Predictions by Capturing Temporal Dynamics and Trend Patterns

This research applies feature engineering techniques by creating lag and rolling window features that allow the model to capture dynamics and temporal trend patterns in time series data.

1) *Lag creation*: The lag feature is based on the concept that the historical value of a variable may affect the current or future

value, especially in time series data. In the context of air pollution, PM_{2.5} concentration on a particular day can be influenced by meteorological conditions, especially AOD [16], [17], [18], [19], [20], [21] and the environment on previous days. Therefore, the variables that were considered to have significant influence and lag features were created include: Representation of aerosol concentration in the atmosphere, which is correlated with PM_{2.5} particles, Relative humidity of the air, which affects the formation and dispersion of pollutant particles, Ground surface temperature during the day, which can affect chemical and physical activity in the atmosphere, and Air temperature, an important factor in atmospheric processes.

The lag feature in time series data is calculated using a shift function, which represents the value of a variable in the previous time period. Conceptually, the lag-n value describes the value of a variable at a given time that has been shifted by n time steps backwards, with n representing the number of lag periods taken into account. In Python programming, the lag feature is created by shifting the data 4 time steps back using the .shift() method.

The 4-day lag was selected based on exploration to find the optimal value. The dynamic characteristics of PM_{2.5} that can persist and be influenced by atmospheric processes make this lag important in the model, allowing the utilisation of historical information to improve the accuracy of predicting concentration changes.

2) *Statistics rolling window*: Variables for which rolling statistics are calculated, such as max_AOD, mean_AOD, min_AOD, RHU, max_LSTDay, and TEMP, use specific time windows to apply statistical functions. The rolling mean provides a measure of the general trend by calculating the average of the values within that window, helping to understand the overall data pattern. The rolling mean calculation follows Eq. (1).

$$Rolling\ Mean = \frac{1}{n} \sum_{i=1}^n x_i \quad (1)$$

Where:

n : Total number of values in the window.

x_i : Individual values in the window.

$\sum_{i=1}^n x_i$: Sum of all values in the window.

Rolling median, If the number of data is even, the median is calculated as the average of the two middle values. If it is odd, the median is the centre value itself. The median is more resistant to outliers, so it gives a better idea of the centre of the data when there are extreme values. The even rolling median is calculated with Eq. (2) and the odd rolling median is calculated with Eq. (3).

$$Rolling\ Median_{even} = \frac{x_n + x_{n+1}}{2} \quad (2)$$

$$Rolling\ Median_{odd} = x_{\frac{n+1}{2}} \quad (3)$$

Where:

n : Total number of values in the window.

Rolling Standard Deviation (Std) measures the spread of data; the larger the standard deviation value, the greater the variation in the data. This is important for understanding how stable or volatile PM_{2.5} concentrations are. Rolling Standard Deviation (Std) is calculated with Eq. (4).

$$Std = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (x_i - Mean)^2} \quad (4)$$

Where:

n : Total number of values in the window.

x_i : Individual values in the window.

$Mean$: Average of the values in the window.

$(x_i - Mean)^2$: The squared difference between each value and the mean, which measures the deviation of each value from its centre.

Determination of the best rolling window size in modelling PM_{2.5} concentrations was done by utilising the XGBoost Regressor model. The tested rolling windows varied from size 3 to 20. For each rolling window size, the XGBoost model was trained and evaluated to obtain R². The model was trained using normalised data to ensure the data was in a comparable range. The results of the rolling window evaluation can be seen in Fig. 6.

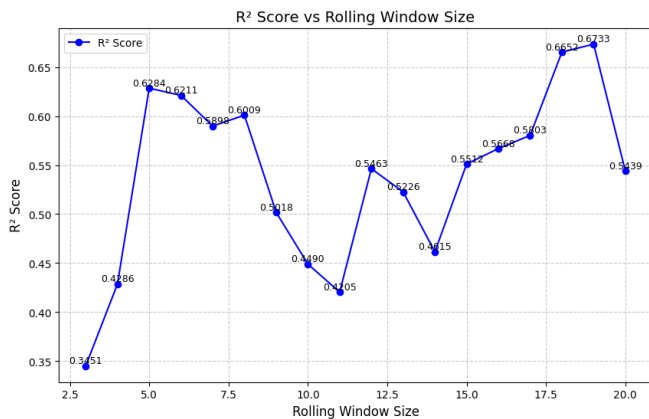

Fig. 6. Rolling window size evaluation results.

The analysis shows that the optimal rolling window size for PM_{2.5} prediction is 19 days with an R² Score of 0.6733. Rolling window sizes that are too small or too large tend to produce suboptimal performance, with the second peak at 5 days (R² = 0.6284) and the lowest performance at 10 days (R² = 0.4490). A larger rolling window is able to capture more historical information, thus improving the model's ability to predict PM_{2.5} dynamics. However, the application of the rolling and lag features led to the appearance of NaN values at the beginning of the data (e.g., the first 18 rows for a 19-day rolling window), which were removed using data.dropna() after the addition of the features. A summary comparison of the datasets before and after feature addition can be seen in Table III. The effect of data transformation with lag and rolling window features on data representation is shown in Fig. 7. The original variables (e.g., mean_AOD, RHU, max_LSTDay, min_LSTDay, and TEMP) shown in the left graph (blue) do not reflect the temporal dynamics clearly. In contrast, the transformed variables with a

lag period of 4 and a rolling window on the right graph (red) show a clearer and more dynamic historical pattern. Features such as mean_AOD_lag4 capture the influence of previous conditions on current values, thus improving the model's ability to understand temporal relationships. This transformation significantly improves the model's ability to capture complex patterns, which in turn is expected to improve the accuracy of PM_{2.5} predictions.

Fig. 7. Comparison of datasets before and after adding lag and rolling window features.

TABLE III. SUMMARY OF DATASETS BEFORE AND AFTER LEG AND ROLLING WINDOWS PROCESSING

Criteria	Before Lag & Rolling Feature Addition	After Addition of Lag & Rolling Feature
Number of Rows	731	713
Number of Columns	173	175
Average mean_AOD	0.2915	0.2934
Average RHU	80.43	80.45
Average max_LSTDay	35.23	35.23
Average min_LSTDay	28.22	28.23
Mean TEMP	27.54	27.53
Standard Deviation of mean_AOD	0.1076	0.1076
RHU Standard Deviation	4.59	4.63
Standard Deviation of max_LSTDay	0.53	0.32
min_LSTDay Standard Deviation	1.89	1.47
TEMP Standard Deviation	1.18	1.18

F. Performance of PM_{2.5} Prediction Model with and without Temporal Features

Before the temporal features were applied, the top three basic models-Random Forest, Gradient Boosting Machine, and XGBoost-had relatively low R² values of 0.36, 0.41, and 0.40, and high MAE and MSE. However, after the temporal features were included, the performance of the models improved significantly. Random Forest recorded an R² of 0.761, Gradient Boosting Machine achieved an R² of 0.767, and XGBoost recorded the highest R² of 0.798, with lower MAE and MSE. This shows that the application of temporal features can substantially improve the accuracy of PM_{2.5} prediction. Table 4 presents the performance evaluation of PM_{2.5} prediction models before and after the addition of temporal features (lag and rolling window).

TABLE IV. EVALUATION OF PM_{2.5} PREDICTION MODEL PERFORMANCE BEFORE AND AFTER INCORPORATING TEMPORAL FEATURES ON THE TEST DATASET

Model	Before			After		
	R ²	MAE	MSE	R ²	MAE	MSE
RF	0.36	7.16	116.71	0,761	0,058	0,005
GBM	0.41	6.99	108.56	0,767	0,058	0,005
XGBoost	0.40	7.18	109.65	0,798	0,053	0,005

G. Development of Ensemble Learning Model - Stacking Regressor

An ensemble learning model is applied using the Stacking Regressor approach to predict PM_{2.5} concentrations due to forest and land fires along with the use of lag and rolling window features. The stacking approach combines multiple machine learning models (base learners) to improve prediction accuracy by utilising three strengths of each base model (RF, GBM and XGBoost). The results from these base models are then fed into a meta-learner, which in this case is RidgeCV. RidgeCV was selected as the meta-learner in this study for several technical reasons. First, RidgeCV employs L2 regularization to prevent overfitting and enhance model stability by reducing excessive model complexity. Second, RidgeCV is effective in addressing multicollinearity among the predictions from base models. Third, it automatically performs cross-validation to select the optimal alpha parameter, ensuring an appropriate balance between bias and variance. Additionally, RidgeCV is computationally efficient compared to other meta-learners and is versatile in integrating predictions from various base models with different characteristics (e.g., Random Forest, which tends to be more robust with non-linear data, and XGBoost, which is more sensitive to structured data) [23].

We used the best alpha value (0.1) from the search results on a logarithmic scale from 10⁻⁶ to 10⁶ to effectively combine the predictions from the base model. Once trained, the stacking regressor model using RidgeCV as a meta-learner gave excellent results. The evaluation results on the test dataset (see Table V) showed an R² value of 0.845, with an MAE of 0.044 µg/m³ and MSE of 0.003 (µg/m³)².

H. Hyperparameter Tuning for Base Model Optimisation and Stacking Regressor via Grid Search

Grid Search with Cross-Validation (GSCV) is a robust method for optimizing hyperparameters in deep learning models, where cross-validation plays a critical role in enhancing model accuracy by systematically using different subsets of the training data for both training and testing [24], [25]. This approach evaluates the performance of hyperparameters across all potential configurations, making it a thorough and exhaustive search technique [26]. In this study, hyperparameter tuning was conducted using Grid Search to enhance the performance of each base model based on neg_mean_squared_error, with five-fold cross-validation (cv=5) ensuring the stability of performance, and n_jobs=-1 utilized to fully leverage all available processors. The optimal parameters identified through Grid Search were subsequently employed for the base learners, as detailed in Table VI.

TABLE V. EVALUATION OF ENSEMBLE LEARNING MODEL - STACKING REGRESSOR

Model	R ²	MAE	MSE
Stacking Regressor	0,845	0,044	0,003

TABLE VI. INITIAL PARAMETER RESULTS AND HYPERPARAMETER TUNING RESULTS WITH GRID SEARCH FOR EACH MODEL

Model	Parameters	Initial Parameters values	Parameter value after tuning
GBM	n_estimators	100	200
	learning_rate	0.1	0.2
	max_depth	3	3
	min_samples_split	2	5
	min_samples_leaf	1	1
	random_state	42	42
XGBoost	n_estimators	200	100
	learning_rate	0.1	0.1
	max_depth	5	6
	subsample	0.8	1.0
	min_child_weight	1	1
	colsample_bytree	-	1.0
	objective	'reg'	'reg'
	random_state	42	42
RF	n_estimators	100	300
	max_depth	None (unlimited)	None (unlimited)
	min_samples_split	2	2
	min_samples_leaf	1	1
	random_state	42	42
RidgeCV (meta-learner)	alphas	np.logspace(-6, 6, 13)	np.logspace(-6, 6, 13)
	store_cv_values	True (opsional)	True (opsional)

After tuning, significant improvements were observed in the models (Table VII). For Gradient Boosting, the number of estimators ($n_estimators$) increased from 100 to 200, and the learning rate ($learning_rate$) from 0.1 to 0.2, enhancing learning detail at the risk of overfitting. In XGBoost, $n_estimators$ decreased from 200 to 100, but max_depth and $subsample$ increased, balancing tree depth and data sampling efficiency. For Random Forest, $n_estimators$ increased from 100 to 300, improving model stability and accuracy by averaging more tree predictions.

I. Performance Evaluation of the Stacking Regressor Model

After optimisation, the three base models were combined using the stacked regressor model, where the predictions from each base model became the input for the meta-learner (RidgeCV). Table VII shows the evaluation of the stacked regressor model before and after hyperparameter tuning. Fig. 8 displays the scatter plot between the actual and predicted values for each tuned base model as well as the meta-learner. The points on the stacking regressor are closer to the reference line ($y = x$), indicating higher prediction accuracy compared to the base model.

TABLE VII. MODEL EVALUATION BEFORE AND AFTER HYPERPARAMETER TUNNING

Model	Before hyperparameter tuning	After hyperparameter tuning	Increase R ²	MAE decrease	MSE Decrease
RF	R ² = 0,761, MAE = 0,058, MSE = 0,005	R ² = 0,776, MAE = 0,057, MSE = 0,005	+0,015	-0,001	0,000
GBM	R ² = 0,767, MAE = 0,058, MSE = 0,005	R ² = 0,781, MAE = 0,055, MSE = 0,005	+0,014	-0,003	0,000
XGBoost	R ² = 0,798, MAE = 0,053, MSE = 0,005	R ² = 0,835, MAE = 0,048, MSE = 0,004	+0,037	-0,005	-0,001
Stacking Regressor	R ² = 0,845, MAE = 0,044, MSE = 0,003	R ² = 0,851, MAE = 0,045, MSE = 0,003	+0,006	+0,001	0,000

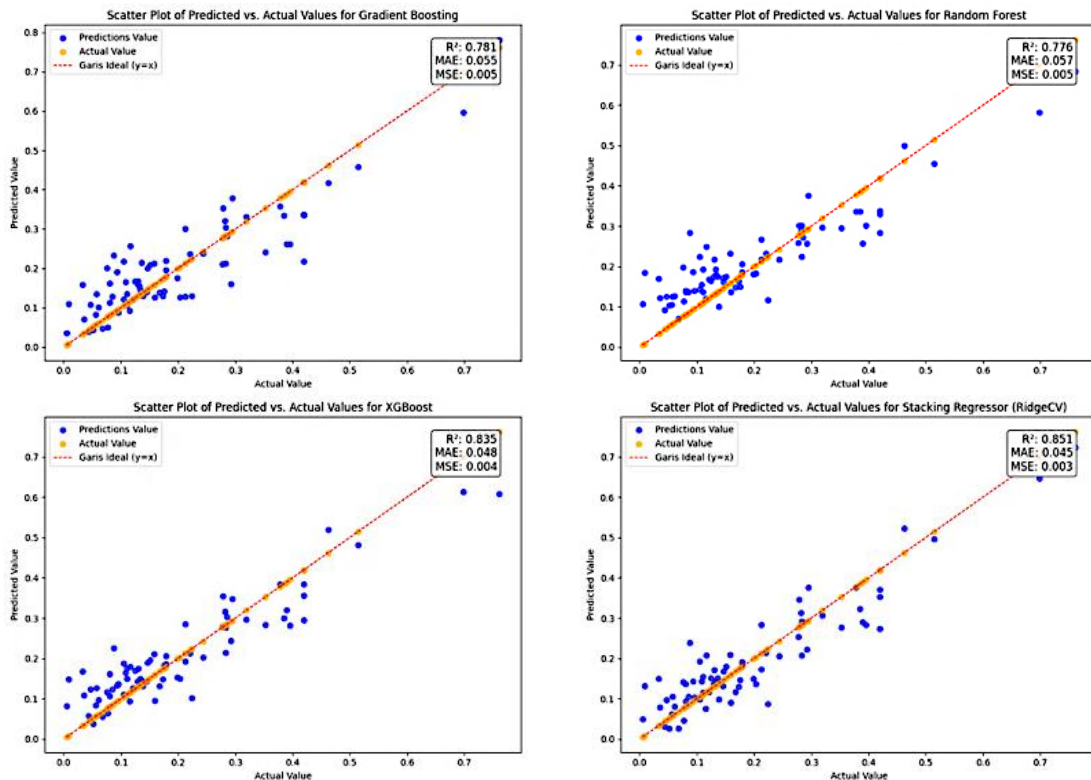

Fig. 8. Scatter plot of hyperparameter tuning performance of prediction model versus actual value.

V. CONCLUSION

This study successfully developed an effective prediction model for PM_{2.5} concentrations caused by forest and peatland fires in Riau Province, employing an ensemble learning approach through the stacking regressor method. The model outperforms other methods, demonstrating superior prediction performance due to the integration of spatiotemporal data from remote sensing and ground sensors. By combining base models such as Random Forest, Gradient Boosting Machine (GBM),

and XGBoost, optimized with RidgeCV as a meta-learner, the model achieved optimal performance with R² = 0.851, MAE = 0.045 μg/m³, and MSE = 0.003 μg/m³. The application of temporal feature engineering techniques, including lag and rolling window, significantly enhanced the model's accuracy, enabling a better understanding of seasonal patterns and temporal dynamics in PM_{2.5} concentrations. Key variables such as air temperature, evapotranspiration, and Aerosol Optical Depth (AOD) were found to have strong correlations with PM_{2.5}

concentrations, highlighting the critical role of atmospheric conditions in influencing air pollution levels. This research makes a significant contribution to the development of data-driven air pollution mitigation policies and holds potential for global application in regions facing similar pollution challenges, supporting efforts for more responsive and evidence-based air quality policy planning and public health management.

ACKNOWLEDGMENT

We would like to thank BMKG Sultan Syarif Kasim II Pekanbaru-Riau for its valuable cooperation and contribution in collecting the data on which this research is based. We also express our appreciation to the Ministry of Education, Culture, Research and Technology of the Republic of Indonesia for providing financial support for the Doctoral Dissertation Research Grant, so that this research can be carried out properly.

Abstract—Text classification plays a pivotal role in natural language processing, enabling applications such as product categorization, sentiment analysis, spam detection, and document organization. Traditional methods, including bag-of-words and TF-IDF, often lead to high-dimensional feature spaces, increasing computational complexity and susceptibility to overfitting. This study introduces a novel Feature Substitution technique using Latent Dirichlet Allocation (FS-LDA), which enhances text representation by replacing non-overlapping high-probability topic words. FS-LDA effectively reduces dimensionality while retaining essential semantic features, optimizing classification accuracy and efficiency. Experimental evaluations on five e-commerce datasets and an SMS spam dataset demonstrated that FS-LDA, combined with Hidden Markov Models (HMMs), achieved up to 95% classification accuracy in binary tasks and significant improvements in macro and weighted F1-scores for multiclass tasks. The innovative approach lies in FS-LDA's ability to seamlessly integrate dimensionality reduction with feature substitution, while its predictive advantage is demonstrated through consistent performance enhancement across diverse datasets. Future work will explore its application to other classification models and domains, such as social media analysis and medical document categorization, to further validate its scalability and robustness.

Keywords—Feature extraction; feature selection; Latent Dirichlet Allocation; text classification; Hidden Markov Model; dimensionality reduction

I. INTRODUCTION

The exponential growth of online content has transformed digital platforms into key sources for global information acquisition and dissemination. With the rise of unstructured text data from these platforms, there is an increasing need for efficient techniques to analyze and manage large-scale text data, which often surpasses numeric data in volume and complexity [1], [2]. Text mining has emerged as a crucial tool for processing unstructured data, supporting decision-making through tasks like classification, clustering, summarization, association rule mining, and topic detection [2]. Among these tasks, text classification plays a vital role in organizing diverse textual data, including e-commerce products, tweets, news articles, and customer reviews, into structured groups [3]. This process has been widely adopted in various fields, such as product categorization [4], [5], sentiment analysis [6], spam detection [7], news classification [8], and medical document classification [9].

Effective text classification relies on noise-free features that capture the essential semantic meaning of the data [2]. However, large-scale text corpora are often high-dimensional, posing challenges for computational efficiency and model accuracy. Input data preparation, particularly through pre-processing, feature extraction, and feature selection, is essential to ensure the performance of classification models [10]. Pre-processing techniques, such as tokenization, stop-word removal, and stemming, reduce the data's complexity and improve model accuracy by eliminating noise. Feature extraction creates a compact feature space by transforming the original data, while feature selection identifies a subset of relevant features that distinguish different categories [11]. These techniques have a profound impact on model accuracy and efficiency but often struggle with the high dimensionality inherent in text data [12].

Traditional dimensionality reduction methods, such as k-means clustering [13], two-stage feature selection [14], and hybrid approaches combining ReliefF and principal component analysis [15], aim to address these challenges. However, these methods may not fully integrate semantic context into the feature representation, limiting their impact on classification performance. To address these limitations, this study introduces Feature Substitution using Latent Dirichlet Allocation (FS-LDA), a novel technique that combines dimensionality reduction with semantic feature grouping.

FS-LDA leverages the topic modeling capabilities of Latent Dirichlet Allocation (LDA) to group and substitute high-probability topic words into unified representations, reducing dimensionality while preserving meaningful textual features [16]. Unlike feature selection, which eliminates irrelevant features, FS-LDA substitutes related features based on topic modeling, enhancing the representation of the data for classification tasks. A new term called feature substitution is introduced mainly to replace related features according to defined groups from a topic modelling technique. Previous studies have demonstrated the effectiveness of LDA in dimensionality reduction and topic clustering, but its application in feature substitution remains unexplored [16]. By integrating FS-LDA into the pre-processing phase, this study seeks to evaluate its effectiveness in improving classification accuracy and efficiency across various datasets.

The FS-LDA technique offers a significant advantage by reducing feature complexity while maintaining the semantic integrity of the data. This novel approach simplifies input data preparation and enhances the performance of classification

models, as demonstrated through experiments in this study. The findings highlight FS-LDA's potential as a scalable, efficient, and effective method for text classification tasks in real-world applications.

II. LITERATURE REVIEW

The current technological advancement and new research on machine learning over the years contribute tools to deal with a high volume of documents using algorithms that extract information from their original texts. One possible approach to simplify high-volume data is to apply some form of dimensionality reduction. Methods like feature extraction and feature selection offer distinct benefits; feature extraction transforms the original data into a compact feature space, while feature selection retains only the most relevant features, potentially improving model efficiency. Commonly, researchers used n-grams models such as unigram, bigram, and trigram to extract features. Linguistic pattern methods, statistical methods, or a combination of both can enhance the extraction process. Hybridization between a linguistic approach and a statistical method efficiently provides reliable features while improving accuracy, especially in classifying Arabic text [17].

Meanwhile, some researchers preferred to enhance the feature selection technique used in their study to improve classification rates. For instance, previous researchers used collaborative feature-weighted multi-view fuzzy c-means clustering [18] and hybrid binary grey wolf with harris hawks optimizer [19]. The utilization of both techniques accordingly provides a better data pre-processing process. However, these methods often lack a semantic perspective, which is addressed by techniques like Latent Dirichlet Allocation (LDA). Over the years, LDA has been widely used to explore features using a hidden topic analysis [20]. It is known as a classical statistical model for topic mining in natural language processing, and it was proposed by Blei et al. [21]. This model discovers various topics in many documents and builds to model text data subject information. Many domain retrievals involving machine learning models applied the LDA model to help deal with text-related problems [22]. Besides the LDA model, researchers often used another topic modelling approach, Latent Semantic Analysis (LSA) [23]. The model's weaknesses are its dependency on annotated training data and its tendency to overfit. Hence, LDA is often preferred over LSA due to its ability to handle sparse data and its probabilistic nature, which provides a more robust representation of text semantics. This advantage aligns with the study's objective to enhance text classification through semantically enriched feature substitution.

The LDA structure resembles the probabilistic variation of LSA known as Probabilistic Latent Semantic Analysis (PLSA) [24]. While LDA and its predecessor, Probabilistic Latent Semantic Analysis (PLSA), share probabilistic foundations, LDA's use of Dirichlet priors enables better generalization for unseen documents, addressing a critical limitation of PLSA and advancing its utility in text classification tasks [24]. The model learns a distribution over the topic for each document in training, but it is only applicable for training sets with the known topic distribution. The model cannot generate topics

from previously unseen documents. Meanwhile, the LDA model learns topic distribution as a random parameter vector and models based on Dirichlet prior. Researchers use symmetric Dirichlet distribution involving a similar value for all parameters in the LDA. The derivation methods commonly acquire the distributions are a variational inference [17] and Gibbs sampling [25].

Previous studies have successfully proved the efficiency and benefits of practicing this model. From the beginning, Blei et al. [21] discovered that LDA slightly decreases text classification performance but improves overall efficiency because of its dimensionality reduction characteristic. Researchers invented an LDA-based model known as Dual Latent Dirichlet Allocation (DLDA) to extract topics for short texts with knowledge obtained from long text data [26]. The improved model utilizes two sets of LDA topics where "target" and "auxiliary" represent short and long texts. The DLDA model performs better than the LDA model, primarily in clustering short text data based on entropy, purity and normalized mutual information as the evaluation criterion.

A previous study can merge the document's representation based on the LDA by applying labels to enhance text classifier performances [27]. The modified LDA works as a semi-supervised learning model where the model includes partial expert knowledge at word and document levels. There is accuracy rate improvisation as more documents are labelled. The modified LDA is feasible for real-world applications with many unlabeled data with few labelled data for training purposes. On the other hand, Cheng et al. [28] combine the idea of using the LDA and word co-occurrence patterns in the corpus to detect topics for a document. It addresses co-occurrence, such as bi-term individually as a semantic unit representing a single topic for recognizing the words most likely to be together. The LDA with word co-occurrence patterns combination improves the topic selection consistency for each document.

A study also merged the LDA with clustering through a Self-Aggregation based topic model (SATM) [29]. The proposed model helps detect relevant topics in short text data. A Multi-CoTraining (MCT) system implementation through LDA combination with Term Frequency-Inverse Document Frequency (TF-IDF) and Doc2Vec provides various feature sets for document classification [30]. The proposed model is robust when dealing with parameter changes. The performance of MCT is superior compared to other benchmark methods. Instead of using Doc2Vec, another study presents the combination of Word2Vec as the word embedding technique with the LDA [31]. The experimental result shows the proposed model outperforms the basic LDA. It can solve problems created by a Bag-of-Word (BOW) model related to high dimensionality and sparsity data.

An automatic text mining framework based on the LDA is proposed in the financial sector to analyze texts as financial disclosures from firms [32]. The topic model aims to find a firm's strengths and weaknesses through business units, activities, and processes depending on its risk. The proposed framework helps to improve the existing business management tools regardless of any business level. The LDA is also an

alternative representation model for BOW because it reduces the feature numbers for text classification [33]. The WEKA package has included the framework to provide a feasible option for other researchers to select features from their data sets.

LDA is used as a feature selection technique in Celard et al. [33] to create a new text representation model utilizing the probability of a document belonging to each topic. However, the probability is not yet used to substitute existing features extracted from classic representation models such as unigram and bigram models. The utilization of LDA topics in the feature selection process can greatly reduce the input data dimensionality while improving the classification model performance. Hence, this study's main objective is to assess the LDA model's efficiency in text classification as a feature substitution technique.

III. METHODOLOGY

This section briefly describes the proposed framework used in this study. The detailed description of the feature substitution technique provides a better understanding of the proposed technique for data preparation related to features. This study used HMM as the text classification model.

A. Proposed Framework

The study involves several steps before classifying the data, as shown in Fig. 1. The typical steps are data extraction, data pre-processing, feature extraction, and feature selection. These are the necessary steps in data preparation related to text classification. After data extraction, three pre-processing steps involve tokenization, stop word removal, and stemming [34]. Data pre-processing is vital to ensure the data is standardized and in proper form. The standardized way is achieved after applying the three pre-processing steps, where each observation is tokenized into words at first. Then, stop words are removed from the word list, and the remaining words are stemmed to ensure the words follow the root word forms.

Feature extraction and selection are essential to ensure the data are well transformed into significant and functional features before performing the classification process [35]. The choice of features may affect the classification model accuracy. Thus, the study compares two feature representation models, i.e., unigram and bigram, to observe their effect on classification performance. The feature selection used in the study was the filter method known as correlation-based feature selection (CFS). The study also compares the classification model before and after applying the proposed feature substitution technique. Then, the chosen features are used as inputs to perform the classification model. All the input data preparation steps were computed using R-Programming software. The classification step is done using Python programming software.

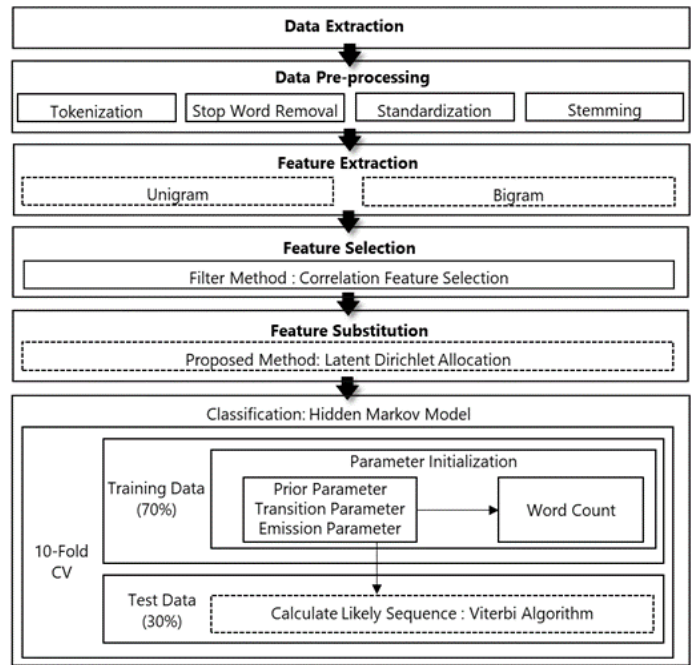

Fig. 1. Proposed study framework.

B. Feature Substitution using Latent Dirichlet Allocation

All the steps involved are standard procedures in text classification before training the classifier, except for applying the LDA model to perform the feature substitution. It is a generative probabilistic model of a document collection [15]. LDA searches for these latent semantic topics in the corpus [35], and it considers each document as a topic collection where each topic is a keyword collection. The topics are a collection of dominant keywords. These topics express an approach to quantitatively describe the document and describe the document content [36]. The critical factors in obtaining adequate keyword segregations are the text processing quality, topic diversity in the text, algorithm selection, and algorithm tuning.

The LDA algorithm input is basic units of discrete data, i.e., words in the text documents. The output of the LDA algorithm is a set of topics. For instance, each document's category belongs to an extensive collection of words, and documents can be observed by checking the words' occurrence in the documents. However, this method is costly and inefficient. Instead of checking every word in the document, another layer is initiated with a set of topics. The collection of words is mapped to the topics, and the topics are mapped to the documents. Hence, this action will reduce costs while increasing efficiency.

The study used LDA to group and substitute the features before applying the classification model. This model involves a generative process assuming that documents consist of a mixture of topics. Then, words from the typical vocabulary of each selected topic are drawn from each document. In the study, the document in topic modelling is represented by observation. Accordingly, LDA assumes that observations are described as a bag of words in a unigram or bigram model with different topics in different proportions. The pseudocode for the

proposed feature substitution technique using the LDA is shown in Algorithm 1.

Algorithm 1: Feature Substitution Technique using LDA

```

Initialize
O: Observations in the dataset
O0: The first observation
T: Topics in the observation
W: Word in the observation
P: Percentage of the highest probabilities in a topic

Compute
Assign each W in O0 a topic T

While (observation remain) do
  For each W in O0 do
    Assume the assigned topic T is wrong.
    Assume the assigned topic T for other W in O0 is correct.
    Update and analyze
      Calculate the probabilities to assign a topic T based on:
      Number of topics in the document.
      Number of times the same topic is assigned to the word across all document.
    End
  End
End
Repeat the process for all O
Remove overlap words with percentage P in all T
  For each T
  Assign a new topic name to W
  End
  
```

The calculation involves in LDA is to obtain the probability of words belonging to a topic where the procedure starts with randomly assigning each word in the observation *O* to one of *T* topics. Then, the required probabilities of each word, *W* can be computed after assuming the randomly assigned topic for that particular word is wrong. The computation of the first probability involves the proportion of words in observation *O* that are assigned to the topic *T*. This action is to observe how many words belong to the topic *T* for a given observation *O* excluding the current word *W*. If many words from observation *O* belongs to topic *T* it is more probable word *W* belongs to topic *T*.

The second probability involves the proportion of assignments to topic *T* out of all documents derived from the word *W*. This action is to observe how many observations are in topic *T* because of the word *W*. LDA represents documents as a collection of topics. A topic is also a collection of words. If a word has a high likelihood of appearing in a topic, all observations containing *W* will also be more strongly correlated with *T*. Similarly, if *W* is not very likely to be in *T*, documents including *W* will have a very low likelihood of being in *T*, because the rest of the words in *O* will belong to a different topic, giving *O* a higher probability for other topics. Even if *W* is added to *T*, it will not bring many of these observations to *T*. The probability that a *W* in observation *O* belongs to topic *T* is stated in Eq. (1).

$$P(T | W, O) = \frac{m \text{ of word } W \text{ in topic } T + \beta}{\text{total tokens in } T + \beta} \quad (1)$$

m represents the words in *O* that belong to *T*, adjusted by the hyperparameter α . The parameter α controls how topics are distributed in a document: a smaller α focuses the document on fewer topics, while a larger α mixes more topics evenly. Similarly, β manages the distribution of words within topics. A smaller β emphasizes a few dominant words, making topics more distinct, while a larger β spreads probabilities across many words, resulting in broader topics. Although each topic technically includes all words in the vocabulary, the most probable words define the topic, making it both meaningful and flexible.

After evaluating each word’s probability belonging to different topics based on the LDA model, the subsequent action is to substitute the non-overlap words with high probability in each topic. According to the LDA model analysis, these words become homogeneous by assigning the same name to represent the group of words that most probably belong to the topic. For example, Fig. 2 shows that Observation 1 is only about Topic 1.

In contrast, Observation 2 is a mix of Topic 1 and 2 because one of the words, “banana”, has a higher probability value in Topic 1 than in Topic 2. Specifically, each topic is represented as a probability distribution over a controlled vocabulary. Usually, all the words appear in the observation collection. In the example, Topic 1 has words such as “fresh” (3.41%), “drink” (2.35%), and “juice” (1.99%). Meanwhile, Topic 2 has words such as “biscuit” (2.73%), “mix” (2.21%), and “apple” (1.86%). These words are the three highest probabilities in each topic. Given this information, Topic 1 can be labeled as “drink” and Topic 2 as “food”. Consequently, Observation 1 is purely about “drink”, while Observation 2 is a mix of the “drink” and the “food” topics. The only observable variable is words from the observations, whereas all other variables, such as the topic distributions for each document and the word distributions for each topic, are hidden. Hence, LDA aims to infer these hidden distributions, given the observed words per observation.

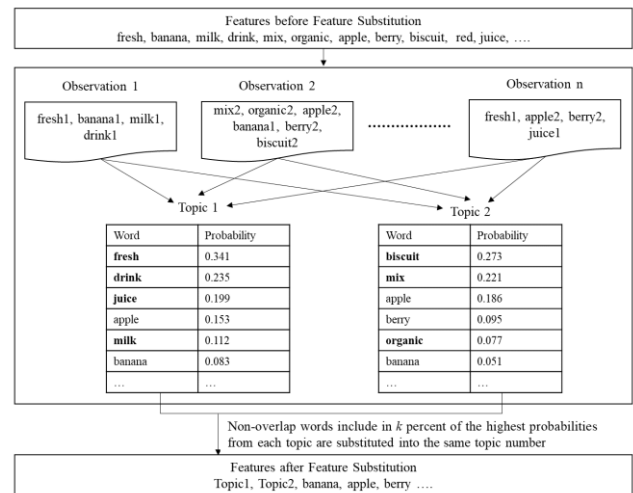

Fig. 2. Proposed feature substitution technique for input data preparation in text classification.

After applying LDA, each topic is represented by words with specific probabilities of belonging to that topic. The feature substitution technique replaces high-probability, non-overlapping words from each topic with a single constant term, such as “Topic1” or “Topic2,” ensuring that the selected words uniquely represent their topic. The study tested this substitution at different levels (10%, 20%, 30%, 40%, and 50% of the top words per topic). Fig. 3 illustrates how this technique represents data before applying the classification model, along with examples from a sample dataset.

Fig. 3. Sample text representation with proposed feature substitution technique before applying classification model.

C. Classification

A Hidden Markov Model (HMM) is often applied to text classification as a supervised learning task. The application of HMM can be seen through various study areas related to text and language processing applications, e.g., text classification [37], text discretization [38], and information extraction [35]. The input data used for the supervised learning model is a corpus of words labeled with the correct category. Table I shows the components that specify an HMM.

TABLE I. HIDDEN MARKOV MODEL COMPONENTS

Symbol	Component	Description
Q	$q_1 q_2 \dots q_N$	A set of N states
A	$a_{11} \dots a_{ij} \dots a_{NN}$	A transition probability matrix A , each a_{ij} represents the moving probability from state i to state j
o	$o_1 o_2 \dots o_T$	A sequence of T observations, each one is drawn from a vocabulary $V = v_1, v_2, \dots, v_v$
B	$b_i(o_i)$	A sequence of observation likelihoods, also called emission probabilities, each expressing the probability of an observation o_i being generated from a state i
π	$\pi_1 \pi_2 \dots \pi_N$	An initial probability distribution over states. π_i is the probability that the Markov chain will start in the state i

HMM's decoding problem is finding the optimal state sequence given the observation sequence and the trained HMM. The Viterbi algorithm is commonly applied to find the most likely hidden state sequence based on every word sequence input. There are given the observation sequence for test data $\{o_t\}_{t=1}^N$ and trained HMM with parameters $\lambda = (\pi, A, B)$ to find the most likely sequence. The formula is presented in Eq. (2).

$$\underset{\{q_t\}_{t=1}^N}{\operatorname{argmax}} p(\{q_t\}_{t=1}^N | \{o_t\}_{t=1}^N) \quad (2)$$

The optimal hidden state sequence is produced for each word sequence of the test data using the Viterbi decoding algorithm. The prediction of the text data is based on the majority role, i.e., a product will be labeled as the drink category if the optimal hidden state sequence has more drink features than food features. Otherwise, the product is marked under the food category.

IV. DATASETS

This study utilizes two different text data to evaluate classification models' performance. The first data involves five e-commerce product data, which these datasets are crawled from an e-commerce website. Department of Statistics Malaysia (DOSM) has collected product information from one of the primary online store websites through the STATSBD A project known as Price Intelligence (PI) using its prototype web scraper. Another dataset is retrieved from the UCI repository. Table II presents a summary of all the datasets used in the study.

TABLE II. SUMMARY OF DATASETS

Data Name	Data Description	Class Number	Class Name (Instance Number per Class)	Instance Number
ECD01	E-Commerce pets products	2	food (265) and care & accessories (45)	310
ECD02	E-Commerce non-food products	2	cooking & dining (407) and party accessories (80)	487
ECD03	E-Commerce frozen food products	5	frozen food (291), yoghurt (162), ice cream (147), cheese (85), and juices (87)	772
ECD04	E-Commerce household products	6	laundry (370), air freshener (297), household kitchen cleaner (181), sundries (158), light bulbs (100), and toilet cleaner (100)	1206
ECD05	E-Commerce grocery products	14	cooking ingredients (677), chocolates & sweets (594), biscuits & cakes (491), snacks (440), sauces & dressings (364), canned food (331), pasta & instant noodles (294), baking (269), jam (220), cereals (208), dry condiments (206), sugar & flour (176), rice (138), and cooking oil (130)	4538
SPAM	SMS spam collection data set	2	ham (4827) and spam (747)	5574

A. Dataset's Characteristics

Each dataset's characteristics can be seen through its data distribution. Text length, word count, and class distribution can describe the data. The detailed characteristics are shown in Fig. 4 for each data set correspondingly. In class distribution for e-

commerce product datasets, ECD01 and ECD02 fall under binary classification problems. However, these two datasets have different text characteristics, as shown in Fig. 4. There are two dominant features in the ECD01 dataset, i.e., “food” and “cat”. Other features seem to have not much different frequent existences in the dataset compared to these two features. Meanwhile, there are six dominant features in ECD02, whereas other features are far less number of occurrences in the dataset. The variation of dominant features may affect a classification model, especially when using HMM because the parameter estimation is based on feature occurrences.

Three e-commerce product datasets, i.e., ECD03, ECD04, and ECD05, belong to multiclass classification problems. Usually, datasets with a higher number of classes tend to have a much lower classification model performance because of increased data complexity. ECD03 has a higher number of dominant features than the other two datasets. When a dataset has less prevalent features, such as features in ECD04, there is a tendency that is performing the proposed feature selection technique may not significantly reduce the number of features while improving the model performance. The reason is that the proposed model recognizes a group of features to be combined as one topic where the features must not belong to any pre-defined classes. The relatively similar number of occurrences for each feature in the dataset may emphasize that the features may have equal weight pertaining to any hidden topic created to reduce the features. Hence, there is an assumption that any dataset with a high number of dominant features may be beneficial for using the proposed feature substitution technique.

The text length plots represent the product description distributions for ECD01, ECD02, and ECD04, are appear to have an approximately normal distribution. Meanwhile, ECD03 and ECD05 have shorter product description lengths as their distribution is right-skewed. Typically, the term frequency distribution is based on the number of times a feature appears in a dataset divided by the total number of features in that dataset. Both axes are plotted on logarithmic scales in the term frequency distribution plot because the frequency of the most

frequent features is much higher than the frequency of the long tail of infrequent features that a figure of this size without a logarithmic transformation would look like the letter L.

The frequency distribution plots for all e-commerce product datasets illustrated the frequency curve decreases very steeply from the extremely high values corresponding to the most frequent features. They become progressively flattered until they reach an extensive level corresponding to the ranks assigned the tail of words occurring once. The same skewed shape is not specific to the datasets used in this study. Still, it often emerges in natural language texts, independently of tokenization or type mapping method, size, language, and textual typology [39]. The only difference is that the variation of inflected forms can be seen from the frequency distribution plots. Even though the overall pattern is the same, the number of very low-frequency forms in the three datasets, i.e. ECD01, ECD02, and ECD03, is lower than in the other two datasets.

The ordinary skewed structure of word frequency distributions was first comprehensively studied by Zipf [40]. The utilization of various datasets leads to frequency’s nonlinearly decreasing rank function. Theoretically, the high ranks fall more sharply than the low ranks. Fitting a straight line to the log-log curves is commonly rational and practicable. Fig. 5 visualizes the frequency distribution plot for each dataset according to Zipf’s law. The plots are generally not perfectly fitted, especially at the edges. The curve’s right edges represent features among the highest ranks with the lowest frequencies. The inconsistent patterns are because the increasingly more comprehensive horizontal lines, in accord with the rare words, are assigned different ranks but have the same frequency. The results may happen due to fitting a model consisting of many words with very near-continuous frequencies to an empirical curve, originally a discrete step function for high ranks.

Meanwhile, the left plot’s curved edges represent features among low ranks with high frequencies. Each plot portrayed a different degree of downward curves.

Fig. 4. Text characteristics and feature term distribution according to (a) 15 Top features, (b) Text length plot, (c) Term frequency distribution plot, and (d) Zipf's law distribution plot.

However, the curve falling under the fitted lines depicted features with high frequencies tend to be lower than predicted by their rank relative to Zipf's law. Natural language text distributions typically have similar overall patterns of a few very high-frequency types and long tails of infrequent words. The difference can be spotted through detailed observation of specific inconsistent parts in a frequency distribution plot. For

example, ECD01 and ECD02 may imply the same frequency distribution plot, but according to Zipf's law, the distribution varies, especially in explaining the features among low ranks with high frequencies. Hence, each e-commerce product dataset implied typical text distributions, yet they may encounter different classification performance results.

On the other hand, there is a noticeable difference between text characteristics for the SPAM dataset and e-commerce product datasets. The former dataset showed a right-skewed text length distribution because messages have longer texts than e-commerce product descriptions. Meanwhile, the frequency distribution plot illustrated that the frequency curve decreased more steeply and quickly flattered than frequency distribution plots for e-commerce product datasets. This pattern implied that many features in the dataset might not be frequently used. Some of the features only occurred once when processing text from messages.

In addition, Zipf's law distribution plot for the SPAM dataset closely follows the fitted line. The model predicts a very rapid decrease in frequency among the most frequent words, which becomes slower as the rank grows, leaving very long tails of words with similar low frequencies. Contrary, e-commerce product descriptions tend to utilize similar features across different categories and, at the same time, use particular features to describe products in a category. Hence, the text distributions for e-commerce products differed from the SPAM dataset. The study utilized both datasets to show the effectiveness of the proposed model.

B. Feature Reduction

Each dataset had been through all the pre-processing data procedures. Two feature extraction techniques, i.e., unigram and bigram, are used to extract the features. Then, the features from each set are selected using a correlation-based feature selection (CFS). It is a well-known filter method widely used in previous studies [10]. The features were also chosen using feature substitution by Latent Dirichlet Allocation (FS-LDA) with 10%, 20%, 30%, 40%, and 50% of each class's highest probability features. Table III shows the number of features used as the input data for HMM using different feature extraction techniques and feature substitution involvement in the model.

TABLE III. NUMBER OF FEATURES FOR EACH DATASET

Feature Extraction	Data	CFS	FS-LDA				
			10%	20%	30%	40%	50%
Unigram	ECD01	304	250	194	202	220	224
	ECD02	461	383	301	275	325	345
	ECD03	656	497	508	524	529	561
	ECD04	941	919	914	901	887	860
	ECD05	2630	2054	2189	2310	2393	2443
	SPAM	5903	4788	3641	3210	3847	4171
Bigram	ECD01	734	702	639	638	653	656
	ECD02	1072	1027	962	921	961	943
	ECD03	1934	1864	1832	1781	1738	1788
	ECD04	2789	2781	2779	2772	2756	2659
	ECD05	10852	10554	10407	10333	10341	10246
	SPAM	30349	29299	27531	26624	27102	26981

Fig. 5 and Fig. 6 show the number of features for some datasets does not decrease with the percentage increment of features from the highest probability in each class. The selected features to be substituted differ for each percentage where the overlap features are not replaced. The feature substitution by 10% shows features decreasing regardless of any datasets used

in the study. Then, the increment of 20% shows irregular patterns in unigram representation models.

Fig. 5. Unigram feature reduction percentage for each dataset.

Fig. 6. Bigram feature reduction percentage for each dataset.

The feature number for ECD03 and ECD05 is greater than the feature number reduced by the 10% FS-LDA for each dataset. The irregular pattern for bigram models is only noticeable when the feature substitution by 30% is applied to the datasets. All datasets using the bigram model for feature extraction showed a lower performance increase than the unigram model. When using the bigram model, features extracted from a dataset become more specific, and each feature's representativeness differs from the unigram model. The same feature occurrences decrease drastically with the increase of unique features through the Bigram model. The inclusion of various features with minimal occurrences leads to poor LDA estimation on features belonging to particularly one hidden topic. Hence, the feature reduction percentage becomes smaller than expected while not being able to increase the model performance efficiently.

Nonetheless, using FS-LDA in preparation for classifying data using HMM did not jeopardize the model performance.

Regarding data reduction consistency, 10% of each topic's highest probabilities of non-overlap words seems like a good percentage to be used in general. However, the feature sets' performance was analyzed to prove that the proposed model is useful for reducing data dimensionality while improving a classifier's accuracy.

V. EXPERIMENTAL RESULTS AND DISCUSSION

This section presents the results of the experiments conducted and discusses the findings in the context of the proposed framework. The analysis evaluates the effectiveness of the feature substitution technique using FS-LDA in reducing dimensionality and its impact on text classification performance.

A. Feature Reduction

This study utilized two performance measurements, namely macro F1-score and weighted F1-score. The micro F1-score is not used in the study because all classification decisions in the dataset are considered without class discrimination when using this approach. Contrary, the macro F1-score is computed for each class within the dataset. Its average score calculation is based on the overall classes. In this way, class distributions in the training set are disregarded, and equal weight is assigned to each class. The formulas are presented in Eq. (3) - Eq. (7). S is the set of classes or states, TP is the number of true positives, TN is the number of true negatives, FP is the number of false positives, and FN is the number of false negatives.

Meanwhile, the weighted F1-score is represented because this approach considers class imbalance [1]. Hence, the study observed the difference when the average score calculation for macro F1-score is based on each class's weight. The formula for the weighted F1-score is presented in Eq. (8).

$$accuracy_s = \frac{TP_s + TN_s}{TP_s + FP_s + TN_s + FN_s} \quad (3)$$

$$precision_s = \frac{TP_s}{TP_s + FP_s} \quad (4)$$

$$recall_s = \frac{TP_s}{TP_s + FN_s} \quad (5)$$

$$f_s = 2 \cdot \frac{precision_s \times recall_s}{(precision_s + recall_s)} \quad (6)$$

$$macro\ F1 - Score = \frac{\sum_{s \in S} f_s}{size\ (dataset)} \quad (7)$$

$$weighted\ F1 - Score = \frac{\sum_{s \in S} f_s \times size(s)}{size\ (dataset)} \quad (8)$$

B. Results for E-Commerce Product Data

The proposed model's effectiveness (FS-LDA) was observed based on its performance in classifying five e-commerce product data. The data involved binary and multiclass classification using HMM. Table IV presents the macro F1-scores for these datasets. According to the results, the unigram model application for extracting the features enhanced the HMM performance compared to the bigram model regardless of the feature substitution existence. The macro F1-

score for HMM with correlation-feature selection (CFS) seemed to increase when substituting 10% and 20% of the ECD01 and ECD04 data features with the unigram model. Meanwhile, the feature substitution worked the best when using 10% FS-LDA for ECD02, ECD03, and ECD05 data with the unigram model.

TABLE IV. MACRO F1-SCORES FOR E-COMMERCE DATASETS USING HMM

Feature Extraction	Data	CFS	FS-LDA				
			10%	20%	30%	40%	50%
Unigram	ECD01	0.6346	0.7866	0.7366	0.6947	0.6913	0.6531
	ECD02	0.8227	0.8695	0.8679	0.8632	0.8643	0.8437
	ECD03	0.6685	0.7402	0.7212	0.6733	0.6690	0.6469
	ECD04	0.6431	0.6454	0.6470	0.6449	0.6279	0.5994
	ECD05	0.5421	0.5935	0.5503	0.5259	0.5225	0.5097
Bigram	ECD01	0.4236	0.4650	0.4630	0.4306	0.4489	0.4560
	ECD02	0.4940	0.5038	0.4932	0.4928	0.4940	0.4940
	ECD03	0.2900	0.3663	0.3368	0.3573	0.3100	0.3412
	ECD04	0.2892	0.2902	0.2913	0.2909	0.2903	0.2985
	ECD05	0.2748	0.2856	0.2942	0.3022	0.2979	0.3053

On the other hand, Table V shows the weighted F1-scores for e-commerce product data. Like the macro F1-scores results, HMM with the unigram model was preferable rather than the bigram model to extract features for classifying these data. The HMM model for each data was similar to results obtained using macro F1-scores. However, the only difference is that the weighted F1-scores produced higher scores than macro F1-scores. A macro F1-score is most useful if there are many classes in the data and the researchers are interested in the average F1-score for each class.

Meanwhile, weighted F1-scores are influenced by the proportion for each class in the dataset. The score works well for observing the dataset's classification performance for unequal classes. Even though this score provides an alternative score for imbalanced dataset performance, a large weighted F1-score might be slightly misleading for a highly imbalanced dataset because the majority class overly influences it.

For example, the macro F1-score for ECD02 using CFS and 10% FS-LDA of the bigram HMM model was 0.5038 compared to the weighted F1-score value of 0.7805. The proportion of classes in Table II for ECD02 indicated that the dataset consists of 83.57% product descriptions for the cooking and dining category and only 16.43% product descriptions for party accessories. Hence, a noticeable difference in these two F1-scores was due to a highly imbalanced dataset. The inclusion of both scores was to observe the impact of the imbalanced dataset towards F1-scores as most of the datasets in the study are imbalanced datasets. However, both scores are equally acceptable according to the final goals of the study. The proposed feature substitution technique improves HMM performance according to both macro and weighted F1-scores.

TABLE V. WEIGHTED F1-SCORES FOR E-COMMERCE DATASETS USING HMM

Table with 8 columns: Feature Extraction, Data, CFS, and FS-LDA (10%, 20%, 30%, 40%, 50%). Rows include Unigram and Bigram models for datasets ECD01-ECD05.

The percentage of feature substitution that worked best for each dataset differed due to their text characteristics and distributions. The results encountered two situations: the HMM model performance suddenly dropped at a certain percentage of FS-LDA, or the model performance did not show any promising result throughout the FS-LDA.

Meanwhile, the second situation can be described through model performance for ECD04. The model did not show promising performance improvement regardless of any percentage of FS-LDA due to a highly similar number of features existing in the dataset, as shown in Fig. 5, compared to other e-commerce datasets.

Despite showing macro or weighted F1-scores, Table VI presents the straight-forward model performance evaluation using model accuracy between several text classifiers, including HMM, HMM with 10% FS-LDA, Naïve Bayes, and Support Vector Machine.

Support Vector Machine and Naïve Bayes outperformed the proposed model performance for ECD01. These two classifiers are known for their excellent performances in solving binary

classification problems without interfering with uncommon feature distributions such as ECD01. When dealing with data such as ECD01, the proposed model seemed to improve the performance of standard HMM. However, combining improvisation from the feature substitution technique presented in the study with enhancing theory in developing a better HMM model may outperform the other two classifiers.

TABLE VI. ACCURACY RATE COMPARISON BETWEEN HMM, HMM (10% FS-LDA), NAÏVE BAYES AND SUPPORT VECTOR MACHINE

Table with 6 columns: Feature Extraction, Data, HMM, HMM (10% FS-LDA), Naive Bayes, Support Vector Machine. Rows include Unigram and Bigram models for datasets ECD01-ECD05.

C. Results for Spam Data

The proposed technique presented in this paper can be applied to other kinds of text data. The study utilized a well-known benchmark data, SMS spam data collection, to evaluate its performance in a different text data application.

TABLE VII. PERFORMANCE RESULTS FOR SPAM DATASET

Table with 8 columns: Metrics, Feature Extraction, CFS, and FS-LDA (10%, 20%, 30%, 40%, 50%). Rows include Macro F1-score, Weighted F1-score, and Accuracy for Unigram and Bigram models.

The HMM model performed the best by securing an accuracy of 90.56% to classify spam and ham SMS considering 10% FS-LDA as the optimum HMM model across different datasets. Both model precision and recall increased when applying the proposed technique. This improvement leads to finer F1-scores for the HMM. The result implied the effectiveness of FS-LDA not only for e-commerce product classification but also for spam detection. The model accuracy was superior compared to the LDA result obtained by Nagwani and Shara [42]. The proposed model outperformed the Naïve Bayes model.

However, when the proposed model is compared with J48 and multi-layer perceptron classifiers, it seems not to be better, as shown in Renuka et al. [43]. Although, there is a slight difference between the accuracy of these models and the proposed model. The HMM model is a reliable and good classifier for classifying text datasets, especially when applying the FS-LDA technique. An HMM model itself may need some modification to achieve better performance. Yet, this feature substitution technique using the LDA model proposed in this study is relatively helpful, simple, and easy to implement. Hence, it is beneficial for commercial uses related to text classification.

VI. CONCLUSION

This study introduces FS-LDA, a novel technique integrating LDA into the preprocessing phase of text data classification. The results highlight the effectiveness of FS-LDA when applied with HMMs, demonstrating superior performance compared to using feature selection alone. By substituting non-overlapping words in high-probability topic groups identified by LDA, FS-LDA significantly reduces data dimensionality while enhancing the accuracy and efficiency of classification models.

The study also highlights the advantage of using a unigram model over a bigram model for feature extraction. Unigrams simplify the feature space while retaining important semantic information, making them more effective for accurate classification. This aligns with findings that simpler models often perform better in text classification by focusing on key features efficiently.

Overall, the integration of FS-LDA with HMMs and the adoption of unigram-based feature extraction represent robust strategies for improving the practical utility of text classification systems, paving the way for enhanced performance in various applications such as e-commerce product classification, spam detection, sentiment analysis, and document categorization. However, the fixed substitution percentage of FS-LDA could be tested on more datasets or through simulations to confirm its reliability. While this study focused on HMMs, trying FS-LDA with other machine learning models could offer more insights.

ACKNOWLEDGMENT

This research was financially supported by Universiti Teknologi MARA and the Institute of Postgraduate Studies, UiTM. It forms part of a study under the Grant Scheme (FRGS/1/2018/STG06/UITM/01/1). The authors would like to

express their deepest gratitude to the Department of Statistics Malaysia for their knowledge and data support.

Department of Computer Engineering, Politeknik Negeri Sriwijaya Palembang, Indonesia¹

Faculty of Computer Science, University Sriwijaya Palembang, Indonesia^{2, 3}

Abstract—In response to the increasing complexity and volume of patent applications, this research introduces a semiautomated system to streamline the literature review process for Indonesian patent data. The proposed system employs a synthesis of multilabel classification techniques based on natural language processing (NLP) algorithms. This methodology focuses on developing an iterative and modular system, with each step visualised in detailed flowcharts. The system design incorporates data collection and preprocessing, multilabel classification model development, model optimisation, query and prediction, and results presentation modules. Experimental results demonstrate the promising potential of the multilabel classification model, achieving a micro F1 score of 0.6723 and a macro F1 score of 0.6009. The OneVsRestClassifier model with LinearSVC as the base classifier shows reasonably good performance in handling a bilingual dataset comprising 15,097 patent documents. The optimal model configuration uses TfidfVectorizer with 20,000 features, including bigrams, and an optimal C parameter of 0.1 for LinearSVC. Performance analysis reveals variations across IPC classes, indicating areas for further improvement. The discussion highlights the implications of the proposed system for researchers, patent examiners and industry professionals by facilitating efficient searches within patent databases. This study acknowledges the potential of semiautomated systems to enhance the efficiency of patent analysis while emphasising the need for further research to address identified challenges, such as class imbalance and performance variations across patent categories. This research paves the way for further developments in the field of automated patent classification, aiming to improve efficiency and accuracy in international patent systems while recognising the crucial role of human experts in the patent classification process.

Keywords—Multilabel patent classification; Natural Language Processing (NLP); OneVsRestClassifier; TF-IDF vectorisation; bilingual patent analysis

I. INTRODUCTION

At present, conducting manual patent literature reviews involves a relatively challenging level of difficulty. The continuous influx of submissions adds complexity, which demands efficient analysis for intellectual property management and strategic innovation tracking [1]. The intricate technical and legal language in these documents also contributes to the complexity of manual processing [2]. Traditional methods, although widely used, are time consuming, resource intensive and prone to human error and bias, which can lead to inconsistent and unreliable results [1], [2].

While recent advances in natural language processing (NLP) have automated aspects of patent analysis [3], [4], critical gaps remain. First, most systems have focused on monolingual datasets (e.g. English only [5] or Indonesian only [6]), neglecting the bilingual nature of patents in countries such as Indonesia, where filings combine local and international languages. Second, existing methods have often failed to address class imbalance in the International Patent Classification (IPC) system, leading to poor performance in underrepresented technology categories (e.g. Y02A) [7]. Third, few studies have integrated local patent databases (e.g. Indonesian Patent Database) with global repositories (e.g. Google Patents), limiting their applicability to multinational innovation ecosystems. Our work bridges these gaps by proposing a bilingual framework that combines Indonesian and English patents, addresses class imbalance through weighted learning and validates utility across diverse IPC categories.

This study addresses the following research questions:

RQ1: How effective is the OneVsRestClassifier with LinearSVC for bilingual (Indonesian–English) patent classification compared to monolingual approaches?

RQ2: What feature engineering strategies (e.g. TF-IDF with bigrams and class weighting) optimise multilabel IPC classification performance in imbalanced datasets?

RQ3: How does class imbalance affect model performance across different IPC categories, and what mitigation strategies are most effective?

Recognising these limitations, this research seeks to refine the semiautomated process for reviewing Indonesian patent literature by using data from local and international repositories. Our approach uses web-scraping techniques to obtain datasets, followed by preprocessing to clean and structure the data for processing using machine learning algorithms. We use the IPC to train multilabel classification models, which allow for categorisation that represents the diverse nature of patent data [3], [4].

The proposed solution links multilabel classification algorithms to increase efficiency and reduce the resources required for a comprehensive review [3], [4]. This process aims to optimise patent analysis by leveraging computational power. The application of these techniques is intended to address the vast amount of data and complex patent language. By using an approach based on machine learning, the proposed system

seeks to simplify this complex task and make it more manageable [5].

The significance of this research is its significant potential to develop and advance patent classification techniques by substantially improving the accuracy and precision of analysis, as well as accelerating systematic, structured and data-driven decision-making processes [1], [4]. This research has high value and strong relevance to patent examiners, research and development institutions and companies that rely heavily on accurate and efficient patent analysis, with much broader implications for innovation tracking, in-depth competitive analysis and future technology forecasting [6], [7]. Ultimately, this study aims to lay a strong foundation and solid groundwork for visionary strategic planning and well-informed policymaking in the dynamic field of intellectual property [8].

Paper Overview. The remainder of this paper is organised as follows. Section II reviews key studies on multilabel patent classification, emphasising the bilingual and imbalanced data contexts. Section III outlines the proposed methodology, detailing the dataset collection, feature engineering and model training processes. Section IV presents the experimental setup, along with the results and discussion of the findings. Finally, Section V concludes the paper, summarising the main contributions, acknowledging current limitations and suggesting avenues for future research.

II. RELATED WORK

The increasing volume of patent applications worldwide has triggered a critical need for advancements in patent analysis methodologies. Traditional manual reviews, characterised by their meticulous yet cumbersome nature, have become unsustainable in the face of rapid technological innovation; the corresponding increase in intellectual property documentation [1] highlights the intrinsic limitations of manual reviews, particularly their vulnerability to human error and the inherent subjectivity in interpreting complex legal and technical terms.

Patent classification using the k-nearest neighbours (KNN) and fastText classifier algorithms individually performs worse than when they are combined by a meta-classifier. The former approach is based on a linguistically supported KNN algorithm using a method of searching for topically similar documents based on comparisons of lexical descriptor vectors. The latter approach employs fastText based on word embeddings, in which sentence (or document) vectors are obtained by averaging n-gram embeddings, and then vectors are used as features in multinomial logistic regression [9].

To address challenges, the field of NLP has emerged as a beacon of innovation. The ability of NLP to parse and interpret complex language structures makes it a powerful tool for the semiautomated analysis of patent documents. The study in [2] underlined the transformative impact of NLP in the domain of summarisation, simplification and generation of patent texts, indicating an urgent need for research specifically tailored to the nuanced demands of patent documentation.

At the forefront of this domain, multilabel classification has been identified as a crucial component for effective patent categorisation, often encapsulating the convergence of various

technological domains. The complexity involved in accurately classifying multifaceted documents is further exacerbated in fields such as artificial intelligence, in which the intersection of technology and legal language demands sophisticated computational techniques for precise analysis [3] [4].

The integration of NLP techniques into semiautomated systems for patent analysis signifies a substantial leap from manual review processes, promising enhanced accuracy and efficiency in patent analysis. However, this integration is not without challenges. The need for comprehensive and well-annotated datasets for training and testing NLP models remains an ongoing hurdle, alongside the development of models that can adeptly navigate the intricacies of patent language and accurately reflect the evolving landscape of technological innovation [6], [10].

Three critical gaps persist in the literature, which are as follows:

1) *Monolingual bias:* Most studies [9], [10] have focused on monolingual patent datasets, overlooking the bilingual complexity inherent in countries such as Indonesia. For instance, [9] combined KNN and fastText but only tested on English patents, neglecting cross-lingual term alignment.

2) *Class imbalance:* Prior works [3], [11] have often assumed balanced IPC label distributions, leading to poor performance in rare categories (e.g. Y02A). For example, [11] reported high accuracy overall but did not address label skew.

3) *Local–global integration:* Existing frameworks [12], [13] have rarely combined local patent databases (e.g. Indonesian Patent Database) with international repositories (e.g. Google Patents), limiting their ability to capture region-specific innovations.

Our work directly addresses these gaps by (1) designing a bilingual (Indonesian–English) classification pipeline, (2) optimising for class imbalance via `class_weight='balanced'` in LinearSVC and (3) integrating local and global patent data to enhance coverage and relevance.

As the discipline evolves, ethical considerations and data sharing become increasingly important. Unbiased data representation in training sets is crucial to mitigating biases that might be perpetuated in patent analysis. Additionally, sharing open-source tools and datasets to catalyse innovation through collaborative efforts underscores the importance of interdisciplinary cooperation in advancing the capabilities of NLP systems in patent informatics. [11], [8] emphasised the importance of collaboration in data sharing and of ethical implications in developing NLP tools for scientific research.

Natural language processing technology has made significant strides in transforming patent informatics, and the field is ripe for further exploration and development. The research in [12], [13] provided evidence of the effectiveness of semiautomated approaches in machine learning-based literature reviews, which can be applied in patent data analysis. Further research is needed to refine NLP models, enhance the understanding and processing of patent data and drive systematic and data-driven approaches to intellectual property management [10], [14]. One approach to handling NLP is the

classification chain (CC), which links these binary classifiers in a certain sequential order so that each classifier includes labels predicted by the previous classifier as additional features. Despite the simplicity of this approach, recent comprehensive empirical studies have shown that CC is among the best-performing algorithms [15].

III. METHODOLOGY

A. Dataset

This study combines 7,298 patents from the Indonesian Patent Database and 7,801 patents from Google Patents, forming a bilingual corpus of 15,097 documents. This hybrid dataset was strategically selected to address the following three critical requirements for robust multilabel patent classification:

1) *Bilingual representation*: The Indonesian Patent Database provides local language coverage (Indonesian), while Google Patents ensures international relevance (English). This combination reflects real-world patent ecosystems in multilingual jurisdictions, such as Indonesia.

2) *Class diversity*: Google Patents broadens the scope of IPC codes beyond region-specific innovations, ensuring the coverage of emerging global technologies (e.g. Y02A for climate adaptation).

3) *Imbalanced IPC mitigation*: Merging datasets diversifies label distributions, reducing bias towards dominant classes (e.g. A61K) while retaining rare categories for comprehensive analysis.

The dataset includes four key features: patent_id, patent_title, patent_abstract and ipc_code. Table I summarises the dataset composition.

TABLE I. DATASET OF INDOONESIAN PATENTS AND GOOGLE PATENTS

No	Dataset	Jumlah Record
1	Indonesia_Patents	7298
2	Google_Patents	7801
	Total	15099

B. Proposed Framework

The framework depicted in Fig. 1 is the basis of this research. Data were taken from Google Patents and the Indonesian Patent Database [10]. We begin by collecting patent data from these two sources, ensuring a comprehensive dataset that covers various innovations. Once collected, these data are then preprocessed, which includes text cleaning, stopword removal and preparation for efficient machine learning classification [1], [15]–[17].

The research methodology is iterative and modular [18], focused on developing a semiautomated system for reviewing Indonesian patent data literature [19]. Each step is visualised in a detailed flowchart, which serves as a guide through various stages of data collection, processing and analysis. Fig. 2 explains the flowchart of this patent classification system research, which uses machine learning techniques to classify patent documents into IPC codes [9]. This system is designed to process and analyse patent data from Google Patents and the Indonesian Patent Database. The feature structure consists of

the ID as a unique patent identification, the patent title, the patent abstract or summary and related IPC codes. Next, data loading and cleaning are performed. The clean_text() function performs text cleaning by removing HTML tags and non-alphanumeric characters and digits and converting text to lowercase [20], [21]. Text processing involves tokenisation and stopword removal using a combination of English and Indonesian stopwords [1], [22], [23]. Feature engineering and data splitting combine datasets, convert IPC codes into multilabel formats and split data into training and testing sets. Model training and evaluation conduct the experiments with various parameter configurations, train the OneVsRestClassifier model with LinearSVC as the base classifier and calculates the evaluation metrics for each configuration. The OneVsRest (OVR) model can provide informative hidden representations for unknown examples, and in open-set classification scenarios, the proposed probability model is better than modern approaches [15], [24].

This research begins by collecting patent data, followed by preprocessing procedures to prepare the data for classification. The processed data are then used to train and evaluate multilabel classification models, specifically the OneVsRestClassifier algorithm, to assign multiple IPC labels to each patent document [19]. This research also performs experiments to optimise the model by varying parameter values, such as n-gram range and maximum features for TF-IDF, as well as the C parameter for LinearSVC. The performance of each configuration is assessed using evaluation metrics, such as the F1 score (micro and macro), as well as cross-validation to determine the optimal model configuration [25], [26].

Fig. 1. Proposed framework architecture.

Fig. 2. Research flowchart.

C. OneVsRestClassifier

The OVR method is a strategy used in multiclass classification, in which separate binary classifiers are trained for each class to distinguish a particular class from all other classes [24], [27]. In this approach, for a particular class, samples belonging to it are treated as a positive class, and all other samples are treated as a negative class. This results in the need for only K binary classifiers for K classes, which is a smaller number than that in the one-versus-one method [28].

In this implementation, we use LinearSVC as the base classifier in the OVR framework. The LinearSVC configuration includes the following parameters. 1) `class_weight='balanced'` is used to address class imbalance by assigning appropriate weights to each class. 2) `max_iter=5000` increases the maximum number of iterations to ensure model convergence. 3) `dual=False` uses the primal formulation of SVM, which is more efficient for cases in which the number of samples is larger than the number of features. 4) `tol=1e-4` indicates tolerance for stopping criteria.

The main challenge with the OVR method is the imbalance between positive and negative classes, especially as the number of classes increases. This imbalance can lead to biased classifiers that favour the majority class, resulting in poor classification performance for minority classes [29]. To address this issue, we use the `class_weight='balanced'` parameter in LinearSVC. We also apply GridSearchCV to search for the optimal value of the C parameter in LinearSVC, with a range of values [0.01, 0.1, 1, 10]. The C parameter controls the trade-off between achieving a low margin and minimising classification errors.

To further optimise model performance, we apply threshold optimisation techniques. This process involves searching for the optimal threshold to convert the output of the decision function into binary predictions. The threshold is optimised in the range of 0.1 to 0.9 to obtain the best F1 score, allowing flexibility in balancing precision and recall [30], [31]. This approach allows the model to handle the complexity of multilabel classification in patent data effectively while maintaining computational efficiency and model interpretability.

D. Data Collection and Processing Module

The data collection and processing module is responsible for collecting and processing patent data from Google Patents and the Indonesian Patent Database, with a total of 15,099 patent documents. This process involves a series of comprehensive preprocessing steps. Text cleaning is performed by removing HTML tags and non-alphanumeric characters and digits, as well as converting all text to lowercase. Stopwords are removed using a combination of 936 English and Indonesian stopwords from NLTK. International Patent Classification codes are processed by extracting sections, classes and subclasses, as well as filtering codes with a minimum of 200 samples. The processed titles and abstracts are combined into a single 'preprocessed_text' field for further analysis. This approach ensures that the data used have been cleaned, standardised and optimised for multilabel classification, increasing the potential for model accuracy and reliability [25], [32].

E. Multilabel Classification Model Development Module

The multilabel classification model development module focuses on converting IPC codes into a multilabel format using MultiLabelBinarizer and developing classification models. The processed data are split into training and validation sets. Then, the TF-IDF vectoriser is used with the parameters `max_features=20000` and `ngram_range=(1, 2)` for feature extraction [9]. The main model used is OneVsRestClassifier with LinearSVC as the base classifier. LinearSVC is configured with `class_weight='balanced'`, `max_iter=5000`, `dual=False` and `tol=1e-4`. Cross-validation with GridSearchCV is used for hyperparameter optimisation, with the F1 score (micro and macro averages) as the main evaluation metric. This approach allows the model to effectively handle the complexity of multilabel classification in patent data while maintaining computational efficiency and model interpretability [30], [31].

F. Model Optimisation Module

The model optimisation module focuses on improving the performance of multilabel classification models through experiments with various parameter combinations [33]. This module uses GridSearchCV to search for the optimal value of the C parameter in LinearSVC, with a range of values [0.01, 0.1, 1, 10]. Additionally, threshold optimisation is performed to convert the output of the decision function into binary predictions, with the threshold optimised in the range of 0.1 to 0.9. Threefold cross-validation is used to assess the effectiveness of each configuration. Evaluation results, especially the F1 scores (micro and macro), are saved and analysed for each parameter combination. The optimal model

configuration is selected based on the balance between model performance and computational efficiency [24], [34]. This approach allows for better model adjustment to the specific characteristics of the patent dataset, thereby improving overall classification accuracy.

G. Feature Extraction Using TF-IDF

The method that determines how often each word appears in one document component, called term frequency (TF), and how rarely it occurs in all document components, called inverse document frequency (IDF), is the inverse of the TF document [12]. To calculate weights, the TF-IDF method combines two ideas: the frequency of a word appearing in a particular document and the inverse frequency of documents containing that word. The tf value is divided by the frequency of the most frequently occurring words in the document. This process ensures that the most frequently occurring words obtain the highest if value, which is 1, and that the least frequently occurring words obtain values between 0.5 and 1 [35].

$$if = 0,5 + 0,5 \times \frac{tf}{\max(tf)}. \quad (1)$$

Weighting is used with the TF-IDF formula in research conducted with the equation formula from several previous research sources [22].

$$W_{t,d} = TF_{t,d} \times IDF_{t,d} = TF_{t,d} \times \left(\log\left(\frac{N}{dft}\right)\right) \quad (2)$$

The TF-IDF formula is very important for document analysis because it gives higher values to words that appear frequently in one document but rarely appear in other documents. Eq. (2), representing the change in IDF using $\log(1 + N/dft)$, prevents division by zero problems or negative logarithms when dft approaches or equals N. This change ensures that the IDF weight remains well defined, even if a word appears in all documents (preventing IDF from becoming zero or negative), providing stability to TF-IDF weights in real applications.

$$W_{t,d} = TF_{t,d} \times IDF_{t,d} = TF_{t,d} \times \left(\log\left(1 + \frac{N}{dft}\right)\right). \quad (3)$$

In Eq. (3), which represents the change in IDF using $\log(1 + N/dft)$, prevents division by zero problems or negative logarithms when dft approaches or equals N. This change ensures that the IDF weight remains well defined, even if a word appears in all documents (preventing IDF from becoming zero or negative), providing stability to TF-IDF weights in real applications.

$$W_{t,d} = TF_{t,d} \times IDF_{t,d} = TF_{t,d} \times \left(\log\left(\frac{N}{1+dft}\right)\right). \quad (4)$$

To generate a new score, the code-mixed relevance score modifies the TF-IDF score, and weighting and normalisation are applied to obtain the final feature vector EF [36].

H. Model Evaluation

In the new implementation, model evaluation uses LinearSVC as the base classifier in the OneVsRestClassifier framework, replacing the previously used random forest. This method is effective for multilabel classification, in which each instance can have more than one label. Model evaluation is

performed using several main metrics, which are as follows. 1) The F1 score (micro and macro averages) is the harmonic mean of precision and recall, providing an overall picture of model performance. $F1 = 2 * (\text{precision} * \text{recall}) / (\text{precision} + \text{recall})$. 2) The classification report provides a summary of the precision, recall and F1 scores for each class. 3) Threshold optimisation optimises the threshold to convert the output of the decision function into binary predictions [37].

The evaluation process also involves GridSearchCV for hyperparameter tuning, specifically the C parameter of LinearSVC. Threefold cross-validation is used to assess model reliability across different subsets of the data. The main evaluation metrics used are as follows:

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN}, \quad (5)$$

$$Precision = \frac{TP+TN}{TP+FP+TN+FN}, \quad (6)$$

$$Recall = \frac{TP}{TN+FN}, \quad (7)$$

$$F1 - Measure = 2x\left(\frac{prec \times rec}{prec+ewc}\right), \quad (8)$$

Where TP = true positive, TN = true negative, FP = false positive and FN = false negative.

This evaluation approach allows for a comprehensive assessment of model performance in the context of multilabel classification of patent documents, focusing on the balance between precision and recall represented by the F1 score [38].

I. Query and Prediction Module

The query and prediction module provides an interface for new patent input and performs IPC code predictions. Input data undergo preprocessing consistent with the previous module. The trained OneVsRestClassifier model with LinearSVC is applied for prediction, involving TF-IDF transformation, model application, conversion to probabilities and application of the optimal threshold. Relevant documents are retrieved based on the predicted IPC codes and user keywords, allowing for efficient searching in the patent database [26], [34].

J. Presentation of Results Module

The results presentation module presents a concise overview of relevant patent literature. This module displays related patent documents, key information, predicted IPC codes with confidence levels, matching keywords and visualisation of the IPC code distribution. Using automatic summarisation techniques, this module generates brief but informative summaries of each relevant patent document, facilitating an efficient literature review process and enabling quick identification of the most relevant patents [25], [10].

IV. RESULTS AND DISCUSSION

The implementation of OneVsRestClassifier with LinearSVC as the base classifier for multilabel patent classification has yielded promising results. The model achieved a micro F1 score of 0.6723 and a macro F1 score of 0.6009, indicating reasonably good overall performance across various patent categories. These scores suggest that the model has a balanced capability in handling both frequent and rare patent classes, although there is still room for improvement.

Such balanced performance aligns with the broader literature on patent classification complexities [7], in which heterogeneous technology domains often require the careful handling of imbalanced labels.

In comparison to earlier approaches, hybrid methods (e.g. KNN+fastText) [9] and fine-tuned transformer-based models (e.g. BERT and XLNet) [3] have been explored by prior work on monolingual patent classification. While these studies report competitive or even state-of-the-art F1 metrics on single-language datasets, they do not address bilingual corpora (e.g. Indonesian–English). By contrast, our approach handles cross-lingual patent data and addresses class imbalance, thereby filling a gap not extensively covered in previous work.

The hyperparameter optimisation process, using GridSearchCV, identified an optimal C parameter of 0.1 for LinearSVC. This relatively low value indicates that the model prefers a large margin, potentially enhancing its generalisation capability. Interestingly, the threshold optimisation process found that the default threshold of 0.5 was optimal for converting probabilities into binary predictions, suggesting that the raw predictions of the model are well calibrated.

Fig. 3. Performance analysis of IPC patents.

Performance analysis by class revealed significant variations among the different IPC classes. Some categories, such as C22C (Alloys) and A61K (Preparations for medical, dental or toilet purposes), showed very good performance, with an F1 score of 0.88. This result suggests that these categories may have distinct features or terminology that the model can effectively identify. Conversely, categories such as Y02A (Technologies for adaptation to climate change) and G06N (Computer systems based on specific computational models) showed lower performance, with F1 scores of 0.12 and 0.20, respectively. These differences highlight the challenges in handling the inherent complexity and potential imbalances in patent data across various technology domains.

The feature extraction approach, using TfidfVectorizer with 20,000 features and including bigrams, appears to have captured important nuances in the patent texts. The decision to focus on thorough text cleaning and stopword removal, rather than stemming, seems effective, as evidenced by the overall model performance. However, the varying performance across classes suggests that there might be room for further refinement of the feature extraction process for certain technology domains.

process can involve exploring more advanced NLP techniques, such as BERT or domain-specific language models pretrained on patent data. Additionally, investigating techniques to improve performance in low-scoring classes, such as oversampling or developing class-specific features, could yield further improvements. Such strategies align with contemporary research calling for data augmentation and specialised embeddings to enhance multilabel patent classification [14].

In conclusion, while the current methodology demonstrates good potential in tackling the complex task of multilabel patent classification across languages, there remains room for improvement. The performance of the model suggests that it could be a valuable tool in assisting patent classification processes, potentially enhancing efficiency and consistency in international patent classifications. However, further research and refinement are needed to address the challenges identified, particularly in handling the diverse and evolving nature of technological innovations reflected in patent documents.

V. CONCLUSION

This research developed and evaluated a multilabel classification model for patent documents using a machine learning approach. The OneVsRestClassifier model with LinearSVC as the base classifier demonstrated competitive performance, achieving a micro F1 score of 0.6723 and a macro F1 score of 0.6009. These results indicate the potential of the model to handle the complexity of multilabel and multilingual patent classification.

In contrast to the hybrid KNN–fastText approach proposed by Yadrintsev and Sochenkov [9], which showed improved classification results on Russian and English texts through a stacking meta-classifier, our work specifically addressed bilingual data (Indonesian–English) and class imbalance in the IPC. Similarly, Haghghian Roudsari et al. [3] leveraged BERT, XLNet and other transformer-based models for multilabel patent classification but focused on monolingual English corpora. Our framework addressed this gap by targeting cross-lingual challenges and imbalanced labels within a single methodology, allowing for the robust handling of diverse patents.

The use of TfidfVectorizer with 20,000 features, including bigrams, proved effective in capturing important nuances in patent texts, although there is still room for refinement. Performance analysis revealed variations across IPC classes, indicating the need for targeted improvements in lower-performing categories (e.g. Y02A). Nevertheless, several limitations remain, which are as follows:

1) *Vocabulary coverage*: The TF–IDF approach, while effective, may not fully capture deep contextual or semantic relationships.

2) *Data scope*: This study focuses on Indonesian–English patents. Extending to additional languages or specialised subfields may require further adaptation.

3) *Class imbalance handling*: Although weighted learning helps mitigate skew, advanced sampling or data augmentation strategies could further improve performance for rare IPC codes.

Despite these limitations, this research contributes to the development of an automated patent classification system that has the potential to increase efficiency in patent analysis. Although the results are promising, it is important to remember the crucial role of human experts, especially for highly specialised IPC classes. With further refinements, the methodology outlined here can become a valuable supporting tool in the patent classification process, facilitating effective intellectual property management. This work paves the way for further progress in automated patent classification, addressing the multilingual and imbalanced data challenges inherent in international patent systems.

Dolphin Inspired Optimization for Feature Extraction in Augmented Reality Tracking

Indhumathi S, Christopher Clement J

School of Electronics Engineering, Vellore Institute of Technology, Vellore, India 632014

Abstract—Feature extraction has the prominent role in Augmented Reality (AR) tracking. AR tracking monitor the position and orientation to overlay the 3D model in real-world environment. This approach of AR tracking, encouraged to propose the optimum feature extraction model by embedding the dolphin grouping system. We implemented dolphin grouping algorithm to extract the features effectively without compromising the accuracy. In addition, to prove the stability of the proposed model, we have included the affine transformation images such as rotation, blur image and light variation for the analysis. The Dolphin model obtained the average precision of 0.92 and recall score of 0.84. Whereas, the computation time of dolphin model is identified as 2ms which is faster than the other algorithm. The comparative result analysis reveals that accuracy and the efficiency of the proposed model surpasses the existing descriptors.

Keywords—Feature descriptor; dolphin optimization; feature extraction; augmented reality tracking

I. INTRODUCTION

Feature extraction is the function of Machine Learning (ML) algorithm, which identify the significant features present in the image. Feature descriptor or extractor is the model to extract the features in the form of edge, corner, texture, contour, color and shape of the image. These extracted features have to be robust and efficient in affine transformation of the image and it can be done by adopting the handcrafted and learning based model. Feature extraction is used in many applications: (i) Autonomous vehicle: To recognize the objects and predict the distance of vehicle. (ii) Augmented Reality: Feature extraction applied to superimpose the augmented model in real world. (iii) Manufacturing Industry: To identify the defects and ensure the safety of the products. (iv) Medical applications: Feature extraction aids to identify the early detection and diagnosis of the critical diseases. Therefore, many algorithm have been published for various feature extraction applications in recent years. Speeded Up Robust Features (SURF) [1] deploys box filters for the feature extraction in object recognition and tracking. Scale Invariant Feature Transform (SIFT) [2] is an image matching algorithm, used to extract the features present in multiple scale images, the difference of gaussian is utilized for the feature prediction of multiscale images in SIFT. The Binary Robust Invariant Scalable Keypoints (BRISK) descriptor embedded with Bee colony algorithm, adopts the sampling pattern to extract the robust keypoints present in image matching [3]. Moreover, the Histogram of Oriented Gradients (HOG) [4] aid the histogram technique for the feature extraction of image, which enhances the human detection process. In [5] author proposed learning based feature descriptor model for the anomaly detection. They examined the

model with 32 datasets and its result provides the accuracy of the model. However, the model encountered the challenge as computation complexity to process the large size of data with affine transformation. To address the above problem, a Rotation Invariant and Globally Aware Descriptor (RIGA) [6] is proposed. RIGA, extract the feature correspondences of the rotation transformation image. This model enhances the rotation in-variant property of point cloud by deploying the Point-Net architecture which consumes the input from a rotated traditional descriptors. Vision transformer embrace the global awareness geometry in RIGA. Therefore, RIGA performs well in both rotation in-variance and global awareness of the descriptor. Nevertheless, its feature prediction lags in additional transformation properties such as scale, light and occlusion transformation. To deal these challenges, Fencher Multiscale Local Descriptor (FMLD) is proposed. FMLD extract the features from light illumination image. The model uses magnitude and angle fusion for feature prediction. The FMLD performs well in occlusion and light variation. However, this model has the limitation in computation complexity [7]. The computation complexity problem has been addressed in Superpixel-based Brownian Descriptor (SBD). Integration of superpixel with brownian model provides the internal structures of the Hyper Spectral Image. This method extract the efficient spectral spatial features. This hybrid model reduces the computation complexity [8]. The artificial bee colony algorithm is implemented to extract only five features, which achieve 98.8 % of accuracy to detect cyberattacks [9].

Outlier detection using projection pursuit is one of the techniques, which has not been used so far in the feature extraction. However, the authors of [10] have developed four novel feature selection techniques using the concept of outlier detection and projection pursuit by exploiting the bio-inspired algorithms. The method seemed to outperform the state-of-the-art techniques with an improvement rate ranging between 0.76% and 36%.

Hence, the descriptor is processing with more number of images and datasets so it consumes more computation. There is a trade-off between accuracy and computation in feature descriptor. So researchers are working in this challenge to improve the feature extraction model. However, with respect to the application we can modify the trade-off. Since, the feature can be in any form as mentioned earlier in this section, it is important to normalise or optimize the model.

One of the main challenge of feature extraction is to diminish the data complexity. We proposed the new model dolphin optimization to extract the essential feature with effective computation. The main contribution of the paper is:

- The two filters are proposed to calculate the gradient

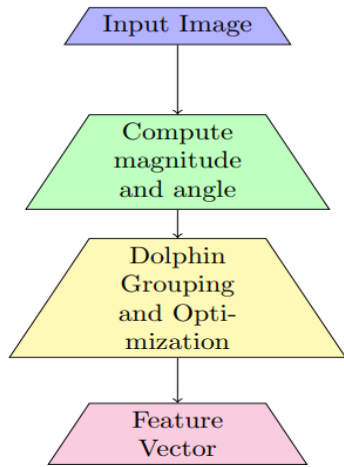

Fig. 1. Dolphin model process flow diagram.

magnitude and orientation of the pixels.

- The spatial location along with magnitude and angle are minimized to measure the similarity in groups.
- In each group feature is formed based on dolphin inspired model.
- The feature is extracted using dolphin optimization.

A. Organization of the Research

The paper is organised as follows in Section II, the related bio inspired optimization models are discussed. In Section III, the dolphin inspired feature extraction methodology is included. Section IV discusses the results and validation of the model followed by a conclusion in Section V.

II. RELATED WORK

This proposed work discuss about the optimization of feature extraction model. Wherefore, here we discuss the recent work related to the subject. In [11] author proposed Principal Component Analysis (PCA) in edge feature extraction for 3D point cloud. This model uses the covariance matrix to predict the features. The PCA is embedded for the optimization of the feature selection. The accuracy of the PCA is compared with traditional method. The PCA model surpasses the traditional model in feature selection. Besides the PCA model a dual correlate, course fine optimization technique is also involved in the feature extraction. This dual correlate model extract the feature in two level such as course and fine level which refines the feature selection process [12]. [13] author designed a locality based approach for the feature selection. It can create the local topology structures to identify the robust features. It identifies the features by matching the similar objects between two images and it removes the mismatch to obtain the robust matching. In addition to that, recently many bio-inspired models are proposed for the feature optimization which we discuss in next section.

Fig. 2. Filter design to compute gradient in vertical image plane.

Fig. 3. Filter design to compute gradient in horizontal image plane.

A. Bio-Inspired Optimization in Feature Extraction

Many Bio-inspired optimization model have been implemented to enhance the accuracy of the feature extraction. In this paper [14], author published support vector machine algorithm by incorporating the ant colony optimization which identifies the early stage of cancer detection. The abnormal cells or features are recognized by gray level co-occurrence matrix then ant colony optimization is applied to extract the significant features. In [15] author applied the Binary whale optimization algorithm to enhance the accuracy of the feature selection in molecular descriptor. This molecular descriptor contains all the information about molecule in drug market. So the prediction of prominent features is necessary to avoid the heavy computation of the descriptor. This can be achieved by the innovation of non-linear time varying sigmoid function in whale optimization. Therefore, this whale optimization improves the feature selection in molecular descriptor. Further, to optimize the texture features, the Binary particle swarm optimization technique [16] is implemented to select the desired texture features from an optical character recognition system. This system accepts only the text, so to automate the model we need to suppress the non text from the text, it can be done with the help of swarm optimization model. Similarly, in [17] the author proposed a Crow search algorithm to select the essential feature from face image using the neural network model. The Local ternary pattern with SURF based hybrid descriptor is used to predict the features in the model. Crow optimization act as a prominent role to achieve the extraction of optimized features with the accuracy of 95% for face recognition models.

III. METHODOLOGY

This section presents the detail of the proposed model. Our methodology consist of three stages: Social secrets of Dolphin, AR tracking and Dolphin dynamic optimization. The secret behaviour of dolphins are discussed in Section III-A for the better understanding of the dolphin optimization. In Section III-B provides the detail of the AR tracking system along with filter design implementation and finally Section III-C describes the dolphin implementation in feature extraction.

A. The Social Secrets of Dolphins: How These Clever Creatures Form the Groups

Dolphin and human have many similar characteristics, which motivated to adopt the dolphin behaviour in feature extraction. Dolphin is a social animal like human so it can communicate, eat and stay together as a group. How it forms the group is really an impressive and unique nature of

dolphin. After many studies about the dolphins we come to the conclusion that the dolphin can form a group according to the factors such as species, spatial proximity, behaviour, food habits, age and family association [18]. A single member in a group is the sample to understand the behaviour of the group. Moreover, dolphin can interact with each other through their signature sound [19] and body languages. This way of communication is helpful to share their thoughts between them. The dolphin group size, is different with respect to the food availability region. Usually, each group has the maximum limit of 30 members however, mega-group consist of 1000 members. This mega-group can form instantly where it is attracted by the abundant food. Dolphin studies says, it has preferences to meet the individuals and it can remember and identify them even after long period of separation. The reason of group formation is for their safety and growth.

From the understanding of the dolphin behaviour it narrates few points with respect to the creation of group:

- Dolphin can form a group to protect themselves.
- The signature whistles are used for communication between individuals.
- The whistle sound is composed from the hereditary and each dolphin has its unique vocals with respect to the certain range of frequencies.
- This sound helps to identify their location.
- The similarity in behaviours are attracted to be a member in the groups.

These behaviour of dolphin is implemented in our model to extract the features and the dolphin group is shown in Fig. 5. In the upcoming section, we will discuss the process flow of AR tracking with filter design and the necessity of dolphin dynamic optimization in feature extraction.

B. Augmented Reality Tracking

AR Tracking system immerse the 3D model in physical world. The Tracking process consist of five steps:

- 1) *Pre-processing*: Re-size the image to form a uniformity in the analysis.
- 2) *Feature detection*: Detector can detect the necessary information as a keypoints from the image.
- 3) *Feature description*: The feature vector is manifested by the inclusion of neighbouring pixel surrounded by the keypoint.
- 4) *Feature matching*: The feature vector of reference and test image is compared to find the matches in the image.
- 5) *3D Model*: Once the feature is matched in the above stage then in this stage it creates a 3D model.

These above mentioned five stages are the process flow of AR tracking. We focus our work in development of the feature descriptor for AR tracking and the flow diagram of our design is illustrated in Fig. 1. According to the flow diagram, the first stage contains the input image. The image matrix of the input is represented as $I_{M \times N}$. Moreover, we designed two filters to measure the gradient changes in vertical and horizontal plane

of the image. The pixel point of interest is considered as $I_{m,n}$. The m is varied from 0 to M similarly, the n changes from 0 to N in image. The vertical and horizontal filters are shown in Fig. 2 and Fig. 3 respectively. From the figure, the pixel point of interest is shown in red color and the four neighbouring pixels are indicated by black for the visualization. The red line reveals the relation between those pixels. The gradient changes of two plane is measured as \mathbf{P}_x and \mathbf{P}_y from Eq. (1) and Eq. (2).

$$\mathbf{P}_x = I(m-1,n-1) - I(m-1,n+1) + I(m+1,n-1) - I(m+1,n+1) \quad (1)$$

$$\mathbf{P}_y = I(m-1,n-1) - I(m+1,n+1) + I(m-1,n+1) - I(m+1,n-1) \quad (2)$$

The Eq. (1) and Eq. (2) are used to obtain the gradient magnitude and orientation as per the Eq. (3) and Eq. (4).

$$G = \sqrt{(\mathbf{P}_x)^2 + (\mathbf{P}_y)^2} \quad (3)$$

$$\Phi = \arctan\left(\frac{\mathbf{P}_y}{\mathbf{P}_x}\right) \quad (4)$$

C. The Proposed Model-Dolphin Dynamic Optimization

The robust feature extraction is the fundamental task of AR Tracking. Hence, the significance of the feature descriptor model is growing, we need to solve the challenge arises to the feature descriptor, that is to identify the stable feature with efficient computation time. In this paper, we provide the design of optimum feature descriptor by incorporating the dolphin optimization model. The main concept of Dolphin Dynamic Optimization is transforming the behaviour of dolphin into image plane for the effective feature extraction using the grouping techniques. The reason for the implementation of dolphin algorithm is how the individuals can combine with its neighbours to form a group is similar to the group of pixels along with its neighbour tends to create a feature. The dolphin key parameters mentioned in the Section III-A is used for the feature prediction. The goal of this study is to group the features precisely. This feature grouping leads to retrieve the shape of the image.

Dolphin model is innovated to predict the shape of the image in a 2-Dimensional space. The dolphin model divide the data points into K groups. The core plan of the model utilize few parameters to form a group such as, image gradient, orientation and spatial location respectively. The image gradient and orientation is obtained from the vertical and horizontal filter mentioned in Fig. 2 and Fig. 3. The gradient and orientation measurements are discussed in Section III-B. Moreover, at this stage the keypoints are ready but its not fit into the shape to retrieve the image. This gap can be fulfilled by the implementation of the dolphin dynamic optimization. The dolphin algorithm works as follows:

- Randomly initialize the dolphin head from the image spatial location.
- The selected head spatial location, gradient and orientation is compared with other data points in the image plane.

- The minimization of the cost function is the criteria to join as a member into the group.
- To fix the head of the dolphin the process is repeats for the R number of iterations until it convergence.
- Then, finally we have the group of features which reflects the shape of the image.

Considering the 8 bit image representation, the gradient magnitude can vary from 0 to 366.6 and the orientation is in the range of 0 to 90°. Assuming that the image dimension is $M \times N$, then the shape normalization is ensured in such a way that M and N correspond to λ_K and δ_K respectively. At the beginning, K spatial locations of the dolphin heads are uniformly spread having the distribution ranging within M and N respectively. Let $\Lambda = \{\lambda_1, \lambda_2, \dots, \lambda_K\}$ and $\delta = \{\delta_1, \delta_2, \dots, \delta_K\}$ indicate these initial locations. The cost function accounts the spatial distance, magnitude difference and orientation between dolphin heads and every other pixels as given in Eq. (5).

$$\mathbf{J} = \sum_{m=1}^M \sum_{n=1}^N \sum_{k=1}^K \mathbf{r}_k(m,n) \{ [m - \lambda_k]^2 + [n - \delta_k]^2 + [G(m,n) - G(\lambda_k, \delta_k)] + [\Phi(m,n) - \Phi(\lambda_k, \delta_k)] \} \quad (5)$$

The indicator function $\mathbf{r}_k(m,n) \in \{0,1\}$ is introduced to mention the spatial values m and n at which \mathbf{J} is minimum. As a result, we need to minimize \mathbf{J} by differentiating it with respect to $\mathbf{r}_k(m,n)$ in the first step followed by λ_k and δ_k partially. By doing this way, a group is formed with updated dolphin head position in each iteration. The continuous shift of dolphin head in each iteration leads to identify the head by its optimization function. The update takes place, until a stopping criterion is met. When the group can not identify a new head, it is assumed that stopping criterion is met. According to Eq. (6), \mathbf{J} attains minimum with the indices p and q , so that $\mathbf{r}(p,q)$ is 1.

$$\mathbf{r}_k(m,n) = \begin{cases} 1; & \text{if } m = \arg\min_p; n = \arg\min_q \\ & \left\{ [m - \lambda_p]^2 + [n - \delta_q]^2 + [G(m,n) - G(\lambda_p, \delta_q)] + [\Phi(m,n) - \Phi(\lambda_p, \delta_q)] \right\} \\ 0; & \text{otherwise} \end{cases} \quad (6)$$

In this way, the dolphin groups are formed to extract the image features. The updation of a new dolphin head positions are given by Eq. (7) and (8).

$$\lambda_k = \frac{\sum_m \sum_n r_{mn} \cdot m}{\sum_m \sum_n r_{mn}} \quad (7)$$

$$\delta_k = \frac{\sum_m \sum_n r_{mn} \cdot n}{\sum_m \sum_n r_{mn}} \quad (8)$$

The feature extraction of dolphin model is grouped based on Algorithm 1. The dolphin group formation with respect to the cost function minimization is illustrated in Fig. 4 which shows the line with arrow indicates the output of the cost function which is generated from the minimization of spatial location, gradient and orientation of the pixels. Each color in the plot indicates the different group of the dolphin which is directly proportional to the J function. Fig. 4 provides the

pictorial representation of the nearest spatial location with similar direction and magnitude belongs to one group. This way we can retrieve the shape of any image from the dolphin optimization model.

IV. RESULTS AND DISCUSSION

In this section, we discuss the simulation results of dolphin optimization algorithm with respect to feature extraction. The input images are adopted from two public datasets which is available in the following link [<https://www.robots.ox.ac.uk/>] and [<http://sipi.usc.edu/database/>]. We utilized two benchmark to evaluate the dolphin algorithm, namely accuracy and efficiency of the model. The accuracy of the feature prediction is measured using precision and recall score. The efficiency is defined from the processing time of the feature extraction model which is denoted as computation time. At initial stage, graffiti and house image both are tested to measure the accuracy of the features. These images are consist of different structures, hence its feature extraction is evaluated. In addition to that, the affine transformation image also included to validate the robustness of the design. The robustness of the feature extraction with respect to viewpoint variation, blurred image and light variation is measured using graffiti, bike, and car image respectively. Moreover, the transformed image such as graffiti is rotated with particular angle, bike image is tested with the noise, and car image light intensity is reduced for the validation. The experiments are simulated using python 3.10, with NVIDIA, 11th Generation i7processor.

A. Original Image Features

In Fig. 6 shows the original image of graffiti and house image which is considered as the reference because it is not given into any transformation. Graffiti and house image

(b) Dolphin feature extraction of house image for group size=8.

Fig. 8. Feature extraction of house images.

features are compared to provide the robustness of the dolphin model. Although, graffiti has more number of edges than the house image, dolphin model predicts the feature very well for both the images. For the detail analysis of feature extraction the graffiti and house image features are extracted with different group size. Initially, group size is low then we gradually increases the group size to verify the performance of the model. For the visualization of the feature, we have included two group sizes which is shown in Fig. 7a it carries the group size of 6 and Fig. 7b holds the group size of 8. The elbow method is aided to show the optimal group value of dolphin algorithm which is shown in Fig. 13. It indicates the optimum

value of the group is 8. Therefore, the optimum number of group size indicates the accurate feature prediction. From the results of Fig. 7b and 8b we can visualize the shape of the image, hence it proves all the edges are completely retrieved from the original image with respect to the cost function of J forms a group. Each group in image is illustrated with different color according to the intensity variation. The yellow color has high intensity, then the level of intensity is decreases with the different color representation such as green, blue and purple respectively. Each color has two different groups with the color deviation hence the total group is 8. Thus reflects in an image as an edge color from yellow to purple.

Feature Descriptor	Computation Time(ms)
Dolphin	2.0
HOG	3.8
BRIEF	5.6
BRISK	13.7
SURF	18.6

(a) Blur variation in bike image.

(b) Feature extraction of dolphin in blur variation.

Fig. 11. Blur image and its feature extraction.

B. Transformation Image Features

The image transformation, indicates transformation of image from one form to other. For the analysis, we resized all the transformation test image into the size of 512×512 and the group size is chosen as 8. We used three transformation, namely, rotation, blur variation and light variation. The goal of this testing is to prove the robustness of the dolphin model in feature prediction with affine transformation. Fig. 9a shows the 40° rotated image of graffiti, hence it is created by view-point variation of the camera is given as 40° . In case of car image the light intensity is decreased from the original image to test the illumination in-variance of our proposed model refer Fig. 9b. In addition to that, the bike image which is shown in Fig. 11a is blurred due to the movement arises between scene and camera. The Fig. 10a shows the output of the rotated image which is reflected with the extraction of all the edge features present in image so our model outperforms in rotation in-variance. Moreover, the feature prediction in light intensity variation is very difficult to process whereas, our model reaches the success to regain the car image from light variation and its shown in Fig. 10b. However, the blur variation shown in Fig. 11b is lagging in accuracy of the feature prediction than the other transformation but still it can retrieve the shape of the image. Fig. 12 shows the feature extraction using dolphin method after compressing the original image. The 80% of compression is applied to the original image and then the features are extracted. The result verify that there is no compromise in extracting the features even after compression. Therefore, in accordance with affine transformation our model produces best results for rotation variation than light and blur variation. Even though our model provides with good accuracy of feature extraction, still there is a space for improvement of the model.

For the quantitative analysis, we have included the precision and recall value of the different descriptors to

evaluate the accuracy of the model. The validation image is taken as the graffiti with the size of 512×512 . The dolphin model is compared with recently proposed feature descriptors, namely, HOG, BRIEF, BRISK and SURF. The true prediction is measured using the precision and recall provides the correct identification of features in image the evaluation results are given in Table I. From the results dolphin model achieves good results than the existing models. The second largest value scored by BRIEF, its precision and recall value is better than BRISK and SIFT. Therefore, it concludes dolphin extract all the necessary features to retrieve the image.

In addition to that, to prove the efficiency of the model the computation time is measured. The computation time of the dolphin model is measured from $\mathcal{O}(M * N * K * R)$. The M and N are the size of the image and K indicates the group size then R is the iteration of the process. The system we used for the simulation is capable to run 5000 millions FLOPS per second. The model validated the results with the image size, number of groups and iteration value are assigned in such a way that, $M = 512$, $N = 512$, $K = 8$ and $R = 500$ then 1048576000 FLOPS are needed according to our model design. Therefore, from this validation, we can obtain the computation time of dolphin as 2.0ms which is faster than other algorithms as perceived from the Table II.

V. CONCLUSION

This article, proposed a optimized feature extraction model for AR tracking along with affine transformation such as rotation, blur and illumination variation using dolphin algorithm. Precisely, dolphin optimization contains two stages, namely, gradient computation and dolphin grouping.

We proposed two filters for the gradient measurement of the image pixels. Further, to measure the optimized grouping with respect to dolphin behaviour we tested the

Fig. 12. Compressed image and its feature extraction.

Fig. 13. Filter design to compute gradient in horizontal image plane.

image with several group size for the validation of the feature extraction. From the results we can conclude the optimum group size is identified as 8 for the robust feature prediction. The computation of the model surpasses the existing model is observed from the measurement. The accuracy of the image retrieval is measured in terms of precision and recall. Dolphin model outperforms other existing algorithm in terms of accuracy and efficiency. In future, the scale variation and partial occlusion can be included for the better development of feature extraction model in AR tracking.

ACKNOWLEDGMENT

The authors would like to thank god almighty for the support and thanks to our Vellore Institute for providing the facilities to finish our research.

Abstract—Recommender systems recommend products to users. Almost all businesses utilize recommender systems to suggest their products to customers based on the customer's previous actions. The primary inputs for recommendation algorithms are user preferences, product descriptions, and user ratings on products. Content-based recommendations and collaborative filtering are examples of traditional recommendation systems. One of the mathematical models frequently used in collaborative filtering is matrix factorization (MF). This work focuses on discussing five variants of MF namely Matrix Factorization, Probabilistic MF, Non-negative MF, Singular Value Decomposition (SVD), and SVD++. We empirically evaluate these MF variants on six benchmark datasets from the domains of movies, tourism, jokes, and e-commerce. MF is the least performing and SVD is the best-performing method among other MF variants in terms of Root Mean Square Error (RMSE).

Keywords—Recommendations; matrix factorization; content-based; collaborative filtering; RMSE

I. INTRODUCTION

A large number of websites offer products to their users. Users purchase products based on a variety of necessities and tastes. By giving customers the best products, one can help to accelerate the purchasing process and raise customer contentment. As the state of technology advances at a rapid pace, it becomes increasingly difficult to anticipate user preferences and meet their requirements. Recommendations are quite useful in many aspects of our daily lives. We employ some external features to learn and make choices about a user's preferences for a specific product [1]. The recommender system is developed to address this issue. These systems learn from user actions and preferences to predict what content may most likely catch the user's interest [2]. Many commercial sites like YouTube, Amazon, and Netflix are highly benefited by using highly sophisticated recommender systems. Potential applications include suggesting books on Amazon, movies on Netflix, products on Flipkart, and so on. These sites continuously monitor the user's watch/view/purchase history and attempt to make educated guesses about what other products the user might find interesting. Many times, systems ask users to provide explicit ratings on used products. This rating information is a significant input to the recommender systems [3].

In 1979, a computer-based librarian introduced the first iteration of the recommender system to offer customers advice on what books to read. Then it advanced in the 1990's with a lot of research achievements in various fields. A research lab Group Lens at the University of Minnesota in the United

States launched another recommender system implementation in the 1990's to assist people [4]. After that, they started calling it a Group Lens Recommender System. The use of recommender systems in advancing research across disciplines and sectors has grown in recent years. Recommender systems are essential components of many online platforms, providing users with tailored content and product suggestions. These systems significantly boost user engagement and satisfaction by forecasting user preferences through historical data and behavior analysis [5]. However, despite their extensive use, traditional recommender systems encounter issues with accurately modeling preferences, ensuring fairness, mitigating bias, and maintaining transparency. Researchers have been exploring advanced methodologies to overcome these obstacles and enhance the effectiveness and dependability of recommender systems.

Causal inference methods are essential for uncovering the fundamental causes of user preferences and behaviors, thereby improving the precision and dependability of recommendations in recommender systems [6]. By leveraging these techniques, effective recommendation algorithms can greatly enhance user satisfaction through personalized content that matches individual interests and preferences. Nonetheless, selection bias remains a significant challenge, as it can result in biased and inaccurate recommendations by disproportionately representing certain user groups or preferences based on skewed data [7]. Achieving fairness in these systems is vital to ensure that all users receive equitable recommendations, regardless of their demographics or past behaviors. The integration of large language models into recommender systems can further refine the understanding of user context and intent, resulting in more sophisticated and effective recommendations [8]. Combining these advanced methodologies helps to mitigate issues of bias and fairness, ultimately improving the overall performance and trustworthiness of recommender systems [9].

There are many applications of recommender systems. Various recommender system techniques are proposed for a variety of applications related to Government, Business, Online Shopping, Library, Learning, Tourism, Group activities, and Healthcare.

1) *Government*: The government may greatly improve its communication with its constituents and its ability to serve the public by adopting the internet recommender system. The citizen services discover and recommend to users more significant and interesting services. One-time items will receive ratings from the business perspective services [10]. By considering the citizen's profile, more relevant and engaging services to

the citizen are recommended. In business perspective, one-time items will receive ratings from the business perspective.

2) *Business*: Various recommender systems are developed for business promotions. Some of the systems pay attention to the recommendations initiated by individual customers that are Business-to-Customer (B2C) systems. Recommendations produced for business users on products and service is called Business-to-Business (B2B) systems.

3) *Online shopping*: One of the most significant tools in the realm of online purchasing is the recommender system [11]. Ratings for the purchased products by a user is the primary information that depicts the interest of the user [12]. Almost all commercial applications like Amazon, Netflix, and Flipkart provide the option for giving ratings for the products.

4) *Library*: To propose resources for research in the university's online libraries, Porcel *et al.* conducted research and created a recommender system [13], [14]. Applications for online libraries can employ systems of recommendations to help users search and select knowledge and data resources.

5) *Learning*: Learning recommender systems guide learners to select the subjects, courses, and learning information to perform learning activities [15]. Digital libraries contain a huge amount of e-documents that a user can choose from [16].

6) *Tourism*: Recommender Systems are also used to give recommendations for tourism places to tourists. It is mainly suggested on transportation, restaurants, and lodging for users to feel comfortable reaching their destinations. Users are directed to a wide range of online resources. These services contain different perspectives according to videos, music, and learning materials that are uploaded by users [17].

7) *Group activities*: As interactions through online have increased, the use of group activities has become more popular. Giving recommendations to a group of users having different opinions is a crucial task. The idea of group activities is to learn interactions between the users from the known group ratings [18]. In various cases, the decision has to be made by the users in both online or in without internet access. In such instances, the entire organization makes the decision to balance users' expectations in online as well as offline formats. The online group is to be formed by the system, but the offline group will be already formed [19].

8) *Healthcare*: Efficient and effective communication is very important in healthcare. A growing number of patients require the care of healthcare professionals from many specialties, especially those who have chronic illnesses or diseases [20].

There are many other applications in the fields of medicine, banking, telecom, media, social networks, e-commerce, internet of things (IoT) [21], [22] other than the ones already mentioned.

In Section II a brief analysis of the problem statement is discussed. In Section III we discussed about the taxonomy of recommender systems followed by in Section IV, a discussion on matrix factorization techniques is mentioned. In Section V the empirical evaluation of the datasets and the rating distribution plots are discussed. Section VI discusses about the results and discussion and in Section VII gives a brief

comparison of different matrix factorization methods. Finally, Section VIII ends up with final conclusion and future plan. The supplementary information for the results is placed in Section VIII-B.

II. PROBLEM STATEMENT

Consider a set of m users $U = \{U_1, U_2, \dots, U_m\}$ and a group of n items $I = \{I_1, I_2, \dots, I_n\}$ and a rating matrix R of size $m \times n$, R_{ij} denotes the rating provided by the user U_i to item I_j . Making user recommendations for unrated items presents a challenge.

The problem of recommender systems is depicted in Fig. 1.

	I_1	I_2	I_3	I_4	I_5	I_6
U_1	4	?	5	?	3	?
U_2	?	2	2	?	4	?
U_3	3	?	?	2	?	1
U_4	?	4	?	5	?	3
U_5	?	?	4	3	?	3
U_6	3	?	?	3	4	?
U_7	4	5	?	4	3	?

Fig. 1. Example for recommender systems.

This correlates to the issue of matrix completion, which is to fill the empty cells of R with rating information from the filled matrix entries. This problem is challenging because the real-world rating matrices are huge in size and sparse in nature. For instance, Amazon product recommendation is represented as a matrix containing around 197 million users and 12 million products. As a single user may not rate many products, the product vector of the user has more empty cells than ratings. Hence, it is extremely challenging to predict recommendations for the next user action based on these fewer interactions and it is called a data sparsity problem.

Handling sparse rating data in recommendation systems is challenging due to extreme sparsity, where missing data makes it hard to find patterns and leads to less accurate predictions. Overfitting occurs as models may capture noise from sparse data, reducing their ability to generalize. The cold start problem also arises when new users or items lack enough interaction history, limiting accurate recommendations. Solutions include regularization, hybrid models, and using implicit feedback or additional information to address these issues.

There are numerous methods of solving matrix completion issues. One of the traditional methods for matrix completion is matrix factorization (MF). This study focuses on solutions based on MF. Table I provides the notations utilised in this work.

Next section describes the existing methods of recommendation.

TABLE I. NOTATIONS

Notation	Usage
R	Rating Matrix
m	Number of Users
n	Number of Items
i	user
j	item/product
X	Latent features for the Users
Y	Latent features for the Items
k	Number of features extracted
U	Set of Users
I	Set of Items
δ	Regularization Constant
γ	Learning Rate
\hat{R}	Prediction rating
β	Distribution Parameter Set
α	Distribution Hyper parameter
P, Q	Orthogonal Matrices
s	Singular Matrix

III. LITERATURE

Information filtering in recommender systems involves choosing and displaying relevant information or items for users based on their preferences, behaviors, and interactions [23]. This entails processing large amounts of data to find and present content, products, or services that are most likely to appeal to the user [24]. By providing tailored suggestions that suit each user’s particular preferences and needs, the goal is to enhance the user experience. There are many classifications of recommender systems in practice. Fig. 2 shows a popular classification.

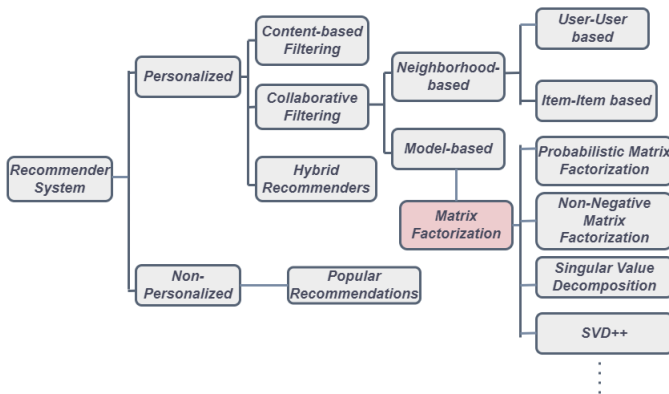

Fig. 2. Classification of recommender systems.

Non-personalized and personalised recommender systems are the two main classifications of recommender systems. Non-personalized recommenders show users only the most popular items, regardless of their purchases/interests. Based on their purchases and reviews, personalised recommenders analyse the tasks of users and make pertinent product recommendations. For instance, suggesting the most popular web series such as *MoneyHeist* being recommended to all Netflix subscribers irrespective of their genre choice can be regarded as a non-personalized recommendation. On the other hand, suggesting movies/TV shows belonging to a genre that the user watches/rates more often is a personalized recommendation.

Additional categories for personalised recommender sys-

tems include content-based filtering, collaborative filtering, and hybrid models. Content-Based (CB) Filtering utilises the item attributes in recommendation. The algorithm creates a list of products with characteristics comparable to those of products the customer has already bought or reviewed. A few items from the list with top similarity will be recommended to the user. For this purpose, metrics such as cosine, euclidean, pearson, or spearman are used [25]–[28].

An example showing content-based filtering is depicted in Fig. 3.

Fig. 3. Content-based filtering.

The recommender system finds additional books (let’s say BOOK1 and BOOK2) that are comparable to the one the USER has already read and recommends those to the USER.

The content-based recommendation requires domain knowledge to identify attributes that may be non-available due to privacy concerns. This is a major limitation of this class of recommendation systems. However, CB addresses the cold start problem effectively. Collaborative Filtering (CF) suggests items/products based on the user’s previous choices [29]–[34]. For a specific user i , CF finds additional users who share i ’s preferences and makes suggestions based on their choices. Their interactions with various products that user i purchased/rated can be used to determine if they have comparable tastes. Collaborative filtering key benefit is that it doesn’t require domain knowledge [35]. The process of CF for book recommendation is given in Fig. 4.

Fig. 4. Collaborative filtering.

In this example, there are two different users (say USER1 and USER2) who are having similar tastes. If there are two

different books (say BOOK1 and BOOK2) that are read by both users, the recommender system identifies the books that are read by only one user (say USER1) and recommends the remaining books (say BOOK3) that are not read to the other user (say USER2).

The two approaches of calculating user similarity are Neighborhood-based and Model-based methods.

Neighborhood-based Collaborative Filtering (NCF) methods are also called Memory-based models or Heuristic-based models. The NCF technique forecasts the similarity between users and items by analyzing user-item interactions through heuristics. It employs two approaches: user-user collaborative filtering and item-item collaborative filtering [36].

- User-User based Collaborative Filtering: When producing predictions, the user-based collaborative filtering finds the other users who are engaging in similar behaviors. For user's having similar interactions, the items are recommended. It predicts the interest of an item that depends on the rating information from similar users [37]. The steps to compute user-user similarities are given below:
 - Build a user vector A_i for each individual user i . A_i will be of size n , n being the number of items. $A_i[j]$ is 1 if user buys item j , otherwise it is zero.
 - Compute the similarity matrix M , of size $m \times m$ where m is the number of users such that $M[i_1, i_2] = \text{similarity}(i_1, i_2)$.
 - For every user i , identify a set of users $S \in U$, where S contains the users with top similarity score with i .
 - Suggest the items that are bought by the users in S , and that are not bought by i .

The example of user-user based collaborative filtering is depicted in Fig. 5.

Fig. 5. User-user based collaborative filtering.

To recommend books to USER1, the recommender computes the similar users of USER1, which is USER2 in the first step. BOOK3 bought by USER2 is not bought by USER1, and is recommended to USER1.

Item-item based Collaborative Filtering (ICF): By detecting the associated subjects that users have previously rated, the item-item based collaborative filtering determines how similar the items are and provides predictions. It computes the similarity of how the target item is selected from the k-most similar items [38]. Additionally, the corresponding parallels are found. When comparable things are discovered, the prediction is made using the target user's rating as well as the average of the related items. The following are the steps to compute item-item similarities:

- Find the previously liked items of the target user from the historical data.
- Identify the most similar items for the previously liked items.
- Select the maximum likelihood items from similar item sets.
- Introduce the products to the target user.

The example of item-item based collaborative filtering is depicted in Fig. 6.

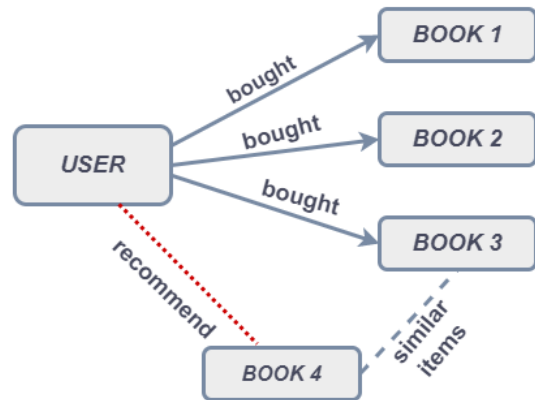

Fig. 6. Item-item based collaborative filtering.

To suggest books to a USER, the recommender system computes the maximum likelihood of similar books (say BOOK4) bought by the USER from the historical data and recommends them to the USER.

Model-based Collaborative Filtering trains a model using historical information on user-item ratings. Once the model is trained, ratings can be predicted using the model [39]. One of the well-liked model-based techniques is *Matrix Factorization (MF)*. The goal of this study is to compare and assess the performance of several MF approaches in different areas. The next section discusses MF and its variations in detail.

IV. MATRIX FACTORIZATION TECHNIQUES

In this section, various matrix factorization methods are discussed. In every matrix factorization method, ratings are predicted and the recommendations are given to the users. So, the evaluation metric for our analysis is limited to Root Mean Square Error (RMSE).

The basic procedure of MF is shown in Fig. 7.

Further, five variations of MF techniques namely matrix factorization (MF), probabilistic matrix factorization (PMF), non-negative matrix factorization (NMF), singular value decomposition (SVD), and SVD++ are elaborated. Each of the variant addresses the challenges of collaborative filtering like cold start problem, and data sparsity in different ways.

MF addresses data sparsity by decomposing the user-item interaction matrix into lower-dimensional user and item matrices, capturing latent factors that help to estimate missing values

Fig. 7. Flow chart for the procedure of Matrix Factorization (MF).

and fill gaps created by unobserved ratings. However, MF faces challenges with the cold start problem, as it depends on historical interactions to learn these latent factors, making it difficult to generate accurate recommendations for new users or items without prior rating data. PMF extends MF with a probabilistic framework that regularizes factorization, helping to manage sparse data. While PMF also faces cold start challenges due to reliance on historical data, Bayesian approaches can mitigate this by incorporating priors on latent factors. NMF decomposes the matrix into non-negative latent factors, capturing additive relationships and handling sparse data more effectively. However, it still relies on sufficient observed data and struggles with cold start, though variations incorporating content-based data can help address this limitation. SVD factorizes the matrix into orthogonal components, capturing key features with reduced dimensions and approximating missing values through low-rank approximations. However, it requires observed data for decomposition, making it less effective for cold start scenarios, as it lacks a direct mechanism for handling users or items without prior interactions. SVD++ extends standard SVD by incorporating both explicit ratings and implicit feedback, such as clicks and views, which helps mitigate data sparsity by providing additional data points. While it improves cold start handling for users through implicit feedback, it still requires some interaction data and remains limited for completely new users or items.

A rating matrix R is of size $m \times n$ is input to any MF

method, where m, n are the number of users and items. R is factored into two latent feature matrices X and Y [40], [41].

Three steps are common in these MF methods:

- 1) Initialization of latent feature matrices X and Y : It is a common practice to initialize the matrices X and Y randomly. Different MF techniques use different data distributions to generate these random numbers.
- 2) Computation of predicted rating matrix: The predicted rating matrix \tilde{R} is computed by extracting k users and items latent features. The value of k can be fixed empirically. These latent feature matrices are multiplied to get the overall predicted matrix. The sample process is shown below.

$$\begin{matrix} \begin{bmatrix} r_{11} & \dots & r_{1n} \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ r_{m1} & \dots & r_{mn} \end{bmatrix} & = & \begin{bmatrix} x_{11} & \dots & x_{1k} \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ x_{m1} & \dots & x_{mk} \end{bmatrix} & \begin{bmatrix} y_{11} & \dots & y_{1n} \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ \cdot & \dots & \cdot \\ y_{k1} & \dots & y_{kn} \end{bmatrix} \\ m \times n & & m \times k & k \times n \end{matrix}$$

Where, k is the number of features extracted, m is the users, n is the items, X is a matrix representing latent features of the users, Y denotes the latent features of the items. The relation between R and \tilde{R} is shown in Eq. 1.

$$R \approx XY^T \quad (1)$$

$$\tilde{R} = XY^T$$

The error in the prediction is determined using the difference between corresponding cells in R and \tilde{R} after computing \tilde{R} . A few common error metrics include Mean Absolute Error (MAE), Regularised Square Error (RSE), and Root Mean Square Error (RMSE), as illustrated in Eq. 2, Eq. 3, and Eq. 4, respectively.

Eq. 2 calculates Root Mean Square Error (RMSE) by subtracting the original rating from the predicted rating values.

$$RMSE = \sqrt{\frac{1}{N} \sum (r_{ij} - \tilde{r}_{ij})^2} \quad (2)$$

where N is the number of predictions, \tilde{r}_{ij} is the predicted rating, and r_{ij} is the original rating.

According to Eq. 3, the Regularised Square Error (RSE) is produced by subtracting the original rating from the predicted rating values and adding regularisation factors.

$$RSE = (r_{ij} - \tilde{r}_{ij})^2 + \delta \quad (3)$$

Mean Absolute Error (MAE) is calculated as shown in Eq. 4, by subtracting the original rating's absolute value from the anticipated rating values.

$$MAE = \frac{1}{|N|} (|r_{ij} - \tilde{r}_{ij}|) \quad (4)$$

Minimising the discrepancy between the actual and predicted rating matrices is the key job here.

In general, an objective function shown in Eq. 5 is used for that task.

$$\min \frac{1}{2} \|R - XY\|^2 \quad (5)$$

The updating of the latent user and item matrices, which are covered below, is necessary for the goal function.

- 1) Update the latent feature matrices X and Y : Different update rules are used by MF methods to reduce the error computed in step 2.
- 2) Step 3 is repeated until either error doesn't remain the same in two successive steps or the error is less than a chosen threshold. But in most of the programming solutions, a fixed number of iterations is taken as a terminating point.

To summarise, different MF techniques vary in steps 1 (Initialization), and 3 (update rule). The following sections describe the variations in detail.

A. Matrix Factorization

1) *Initialization of latent feature matrices*: The initialization of X and Y are purely random values with 0 to 1 distribution in basic MF [42], [43].

2) *Update rule to reduce the error between actual and predicted rating matrices*:: By multiplying the rating vectors for the person and the object, as stated in Eq. 6, one can find the original rating.

$$r_{ij} \approx x_i y_j^T \quad (6)$$

Utilising the observed ratings while reducing the squared error is one method for computing the empty ratings in the matrix. The square error minimization is shown in Eq. 7.

$$\min \sum_{i,j} (r_{ij} - x_i y_j^T)^2 \quad (7)$$

The result will overfit the training data and to overcome the overfitting in squared error a regularization term is incorporated is shown in Eq. 8. Regularization is controlled by using a regularization constant δ known as Regularized Square Error (RSE).

$$\min \sum_{i,j} (r_{ij} - x_i y_j^T)^2 + \delta (\|x_i\|^2 + \|y_j\|^2) \quad (8)$$

where $\|\cdot\|$ is the frobenius norm. Alternating least squares or stochastic gradient descent can be used to estimate this value. According to Eq. 9, every rating within the training data has been predicted via stochastic gradient descent, and the prediction error is calculated.

$$e_{ij} = r_{ij} - x_i y_j^T \quad (9)$$

Then update the vectors y_j and x_i with a constant γ called the learning rate, and δ as the regularization constant. Updating the values of y_j and x_i is shown in Eq. 10.

$$\begin{aligned} y_j &\leftarrow y_j + \gamma(e_{ij}x_i - \delta y_j) \\ x_i &\leftarrow x_i + \gamma(e_{ij}y_j - \delta x_i) \end{aligned} \quad (10)$$

B. Probabilistic Matrix Factorization

1) *Initialization of latent feature matrices*: The initialization of X and Y are random values of 0 to 1 with normal distribution.

2) *Update rule to reduce the error between actual and predicted rating matrices*: By fixing the parameters, the log-posterior value on the predicted rating matrix \tilde{R} is observed from the original rating matrix R [44]. To maximize the log-posterior for the user's and item's latent features, some additional regularization hyperparameters are added and fixed to minimize the sum of squares as shown in Eq. 11.

$$\begin{aligned} E = & -\frac{1}{2} \left[\sum_{i=1}^m \sum_{j=1}^n (r_{ij} - x_i^T y_j)_{(i,j) \in \Omega_{R_{ij}}}^2 \right] \\ & - \frac{1}{2} \left[\delta_X \prod_{i=1}^m \|x_i\|_{Fro}^2 + \delta_Y \prod_{j=1}^n \|y_j\|_{Fro}^2 \right] \end{aligned} \quad (11)$$

where

$$\delta_X = \frac{\sigma_X^2}{\sigma^2}, \delta_Y = \frac{\sigma_Y^2}{\sigma^2}$$

The procedure for calculating the log-posterior distribution is as follows: An approach that offers a statistical framework using the Bayes theorem for the model rating matrix R called Probabilistic Matrix Factorization (PMF) which is proposed by Salkhutinov and Mnih [45]. PMF is a probabilistic linear model with gaussian distribution which is used for initial latent feature matrices X and Y . By fixing the parameters, the log-posterior value on the predicted rating matrix \tilde{R} is observed from the original rating matrix R [44].

$$p(\beta|Z, \alpha) = \frac{p(Z|\beta, \alpha)p(\beta|\alpha)}{p(Z|\alpha)} \propto p(Z|\beta, \alpha)p(\beta|\alpha) \quad (12)$$

In this case, Z represents dataset, β represents the distribution parameter set, and α represents the distribution hyper parameter. The posterior distribution, also known as a-posteriori, is denoted by $p(\beta|Z, \alpha)$. $p(Z|\beta, \alpha)$ is the likelihood and $p(\beta|\alpha)$ is the prior. More information about the data distribution can be obtained through the training process, and the model parameter β can be adjusted to fit the data. Let R_{ij} represent the rating of the user i on the item j and let $X \in R^{m \times k}$ and $Y \in R^{k \times n}$ are the users and items latent feature vectors respectively. Here we assume that the entries of R are normally distributed around the inner product of (X_i, Y_j)

with a common variance. We will now use our rating matrix for the predictions.

$$\beta = \{X, Y\}, \quad Z = R, \quad \alpha = \sigma^2$$

where σ^2 is the variance of the Gaussian distribution. We get this by substituting these values in Eq. 12.

$$p(X, Y|R, \sigma^2) = p(R|X, Y, \sigma^2)p(X, Y|\sigma_X^2, \sigma_Y^2) \quad (13)$$

In Eq. 13, X and Y values are independent of each other, and hence the equation can be rewritten as shown in Eq. 14.

$$p(X, Y|R, \sigma^2) = p(R|X, Y, \sigma^2)p(X, \sigma_X^2)p(Y, \sigma_Y^2) \quad (14)$$

Let I_{ij} be defined as the likelihood of R entries such that if the value is 1, the entry is observed, and if the value is 0 the entry is not observed. Adopt a gaussian-distributed probabilistic linear model and specify the conditional probability across the observed ratings as per Eq. 15.

$$p(R|X, Y, \sigma^2) = \prod_{i=1}^m \prod_{j=1}^n [N(r_{ij}|x_i^T y_j, \sigma^2)]^{I_{ij}} \quad (15)$$

The new assumption about the likelihood is that R 's entries are independent, every entry has a normal distribution, and entries all have the same variance σ^2 .

The prior distributions of X, Y are shown in Eq. 16 and Eq. 17.

$$p(X|\sigma_X^2) = \prod_{i=1}^m N(x_i|0, \sigma_X^2) \quad (16)$$

$$p(Y|\sigma_Y^2) = \prod_{j=1}^n N(y_j|0, \sigma_Y^2) \quad (17)$$

In these priors we assume that X and Y rows are correlated, every entry has a normal distribution, and entries all have the same variance σ^2 .

Replacing Eq. 15, Eq. 16 and, Eq. 17 in Eq. 14 we get,

$$p(R|X, Y, \sigma^2) = \prod_{i=1}^m \prod_{j=1}^n [N(r_{ij}|x_i^T y_j, \sigma^2)]^{I_{ij}} \prod_{i=1}^m N(x_i|0, \sigma_X^2) \prod_{j=1}^n N(y_j|0, \sigma_Y^2) \quad (18)$$

For training our model, we apply logarithms on both sides of Eq. 18 and then apply derivatives on both sides of the equation. Then the expression for log-posterior is like

$$\ln p(X, Y|R, \sigma^2) = -\frac{1}{2\sigma^2} \prod_{i=1}^m \prod_{j=1}^n I_{ij} (r_{ij} - x_i^T y_j)^2 - \frac{1}{2\sigma_X^2} \prod_{i=1}^m \|x_i\|_{Fro}^2 - \frac{1}{2\sigma_Y^2} \prod_{j=1}^n \|y_j\|_{Fro}^2$$

Here, the Fro suffix is called the Frobenius norm is given by

$$\|x\|_{Fro}^2 = x^T x$$

C. Non-Negative Matrix Factorization

There are many applications in which the data is analyzed to be non-negative, and many of the tools follow this property [46]. The idea of NMF, which forces the data to be non-negative, gave rise to the need for low-rank approximation for development. NMF is used as a tool for the analysis of high-dimensional with non-negative entries in the data. NMF should consist of only non-negative constraints as a part of the representation. There are different variants of NMF algorithms proposed [47] and we are using basic NMF. NMF was introduced with the name positive matrix factorization by Paatero and Tapper [48]. Researchers paid attention to NMF after the work given by Lee and Sung. They discussed more on usage and importance of NMF [49].

1) *Initialization of latent feature matrices:* The initialization of latent feature matrices X and Y are taken as non-negative random values.

2) *Update rule to reduce the error between actual and predicted rating matrices:* Finding an estimate of a non-negative matrix R , which is represented as the product of latent feature matrices X and Y , is the primary goal of NMF.

$$R \approx XY$$

where R is a $m \times n$ rating matrix. The approximation of R with product of matrices X ($m \times k$) and Y ($k \times n$) by considering $k \leq (m, n)$. The latent feature matrices X and Y , can be derived by using multiplicative update method that consist of some update rules. The rules are explained in [49]. The non-negativity property is maintained by both matrices X and Y .

$$\begin{aligned} X &= X \cdot \left((R \cdot / (X \times Y + (R == 0))) \times Y^T \right) \\ Y &= Y \cdot \left(X^T \times (R \cdot / (X \times Y + (R == 0))) \right) \end{aligned}$$

Similarly, the dot division of X and Y is $X \cdot / Y$, where $X \cdot \times Y$ is element-wise division calculated as the dot product of X and Y . The product of two matrices X and Y is $X \times Y$. The transposed version of the matrix X is X^T . In the denominator, the expression $R == 0$ is used to avoid division by zero.

The properties of NMF are only non-negative values are allowed into the resultant matrix, since non-negative values are only allowed, the matrix is allowed to only add but not subtract, and the result of the factorization is not unique.

D. Singular Value Decomposition

The singular value decomposition (SVD) method was first applied for recommender systems [50]. In MF using SVD, the rating matrix R decomposes into three latent feature matrices P , s , and Q , as shown in Eq. 19 where the rating matrix R is of size $m \times n$ and the latent factor matrices P is of size $m \times m$, s is of size $m \times n$, and Q is of size $n \times n$. Here, P and Q are orthogonal matrices, and s is a singular matrix. The latent feature matrices X and Y are computed as follows: $X=P.s$ and $Y= Q$ [51].

$$R \approx PsQ^T \quad (19)$$

Better performance is achieved by using the SVD approach on its applications that reduces the dimensionality of user and item matrix [52].

E. SVD++

The main purpose of SVD++ is to identify the missing ratings in the matrix by adding implicit feedback to the user's latent feature matrix [53]. This technique is observed to be more accurate in many cases, because of including implicit feedback to user latent feature matrix [54].

The implicit feedback matrix UV is calculated as follows: The matrix U is calculated as $U = [u_{ij}] \forall (i, j)$ is 1 if R_{ij} is present in the original rating matrix 0 otherwise. For every non-zero entry in the matrix i^{th} row is written as $\frac{1}{\sqrt{|I_i|}}$ and is an $m \times n$ matrix. V matrix is calculated as $V = [v_{ij}] \forall (i, j)$ which is same as an item feature matrix of order $n \times k$. Calculate the dot product of matrices UV of order $m \times n$ and $n \times k$, resulting in a matrix of the order of $m \times k$. The implicit feedback matrix UV is to be added to X (say $X = X + UV$) before performing the dot product of X and Y^T . V matrix is assigned to Y (say $Y = V$).

The variations of different MF methods used in this work are tabulated in Table II.

V. EMPIRICAL EVALUATION

The era of each dataset, where it was downloaded from, and the information that is contained in it are all fully described in this section. Exploratory data analysis reveals a full description of the dataset ratings. additionally explains the setup for conducting the analysis and arriving at the RMSE value.

A. Datasets

The primary goal of utilizing the datasets is to run the simulations. The datasets are downloaded from Kaggle, Konekt, and Github. Datasets namely Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets are taken. Each dataset contains information about the users, items, ratings, and timestamps.

The period of Movie Lens-100K dataset is from September 19th, 1997 to April 22nd,1998 [55]. The period of Movie Lens-1M dataset is on December 2015 [56]. The period of the Film Trust dataset is on 2011 [57]. The period of Trip Advisor dataset is from March 3rd, 2001 to November 1st,

2009 [58]. The period of the Jester dataset is from November 2006 to November 2012 [59]. The period of Market dataset is from January 1st, to April 30th, 2021 [60]. Table III tabulates the dataset statistics for numerous datasets.

B. Exploratory Data Analysis

In Fig. 8, the rating distribution plots for several datasets, including Movie Lens -100K, Movie Lens -1M, Film, Trip Advisor, Jester, and Market, are displayed. The rating distribution for films in the MovieLens-100K dataset ranges from 1 to 5. In the dataset, the users are the individuals, and the items are the films. A low rating of one is provided by users 6110 (6.11%) beyond 100000 ratings, while users 34174 (27.14%) offer a rating of four for films. The rating distribution in the movie lens-1M dataset ranges from 0.5 to 5. In the dataset, the users represent individuals, while the items refer to movies. It has been noted that users 306221 (29.20%) have given films a rating of four stars, while users 8559 (0.81%) have given films a poor rating of 0.5 out of 1048576.

According to Fig. 8, the rating distribution for the film trust dataset is between 0.5 and 4. The films in the dataset are the items, and the users are the people. It has been noted that out of 35494 ratings, users 1060 (2.98%) give films a low rating of 0.5 and users 9170 (25.83%) offer films a rating of five. The 1 to 5 rating distribution is part of the Trip Advisor dataset. The hotels in the dataset are the items, and the users are the individuals. Users 10082 (5.73%) out of 175765 ratings offer a low rating of one for hotels, while users 77668 (44.18%) provide a rating of five for hotels.

The rating distribution for the jester dataset is between -10 and $+10$, as shown in Fig. 8. In the dataset, the users are the individuals, and the objects are the jokes. Out of the 1048575 ratings, it is noted that over 4000 people have given ratings of 10 or above. The rating distribution in the market dataset ranges from 1 to 5. In the dataset, the users are the individuals and the items are the things. It has been noted that out of 1048575 users' ratings, users 609417 (58.11%) give items a rating of five, while users 63082 (6.01%) give products a poor rating of two.

VI. RESULTS ANALYSIS

To forecast the missing values in the rating matrix, we apply five different MF methods such as MF, PMF, NMF, SVD, and SVD++ with different latent features on six data sets which are given in Section IV and Table III. For all methods, we computed RMSE value for different latent features $k = 10, 50, 100, 200, 300, 400$ with 10 steps. In this section, we have shown patterns of RMSE values with different latent features for various MF methods on six datasets. We have shown other errors (RSE, RMSE, and MAE) for latent features $k = 1, 2, \dots, 10$ with 100 steps in supplementary information as shown in Section VIII-B.

Fig. 9 describes RMSE value on six different datasets for the MF method with $k = 10, 50, 100, 200, 300, 400$ at different steps. In movie lens-1M, film trust, and jester datasets, if k -value is increasing there is a constant range of RMSE maintained. In the movie lens-100K dataset, it is observed that as k -value is increasing there is a constant range of RMSE for k values 10, 50, 100, 200 and the RMSE decreases for k values

TABLE II. DIFFERENCES BETWEEN DIFFERENT VARIATIONS OF MATRIX FACTORIZATION (MF) METHODS

Method	Initialization of Latent Features	Update of Latent Features
MF	Latent feature matrices X and Y are taken as random values between 0 and 1.	Update the parameters of X and Y by adding regularization constant and learning rate to minimize the error.
PMF	Latent feature matrices X and Y are taken as normal distribution random values between 0 and 1.	Update the parameters of X and Y by adding regularization hyperparameters to minimize the error.
NMF	Latent feature matrices X and Y are taken as non-negative random values.	Apply the rules of the multiplicative update method to update the parameters of X and Y .
SVD	Latent feature matrices X and Y are taken as floating point numeric dtype random values.	No update rule is used.
SVD++	Latent factor matrices X and Y are taken by adding an implicit feedback matrix to the user latent feature matrix X .	Adding an implicit feedback matrix to the user latent feature matrix X is itself an update that is performed.

TABLE III. INSIGHTS INTO SIX DIVERSE DATASETS: MOVIE LENS-100K, MOVIE LENS-1M, FILM TRUST, TRIP ADVISOR, JESTER, AND MARKET DATASETS

Dataset	Users	Items	Ratings	Rating Range	Average Rating	Sparsity
Movie Lens-100K	943	1682	100000	1-5	3.529	0.937
Movie Lens-1M	7848	65133	1048576	0.5-5	3.522	0.998
Film Trust	1508	2071	35494	0.5-4	3.002	0.988
Trip Advisor	145316	1759	175765	1-5	4.000	0.999
Jester	31958	140	1048575	-10 - +10	0.955	0.839
Market	941860	9849	1048575	1-5	4.062	0.999

Fig. 8. Visual insights into Rating Distributions: Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets.

300, 400. In the trip advisor dataset, the RMSE value decreases at finite steps for all k values and slightly increases. There is an increase in RMSE value if k is 10. In the market dataset, the RMSE value is decreased for all k values except for k value 200. Compared to all the datasets, the jester is giving less RMSE value. As there is a maximum of 140 items in the jester dataset, we can calculate RMSE value up to k less than or equal to $\min(m, n)$.

Fig. 10 describes RMSE value on six different datasets for PMF at different steps. There are similar fluctuations in RMSE value as the k value is altered. In the movie lens-100K, for k is 10 latent features, it is observed that there is a decrease in RMSE value from 1.75 to 1.2. At 50 latent features, the RMSE value increases from 1.35 to 1.45. At 100 and 300 latent features, the RMSE increases from 1.65 to 1.75. At 200 latent features, it is observed that the RMSE decreases more from 2.0 to 1.5. For = 400 latent features, there is an increase

in RMSE value from 1.55 to 1.9.

In the movie lens-1M, at 10 latent features, it is observed that there is a decrease in RMSE from 1.8 to 1.35. For k is 50 latent features, it is observed that the RMSE decreases from 1.55 to 1.35. For 100 latent features, the RMSE value reduces from 1.5 to 1.4. At 200 latent features, the RMSE value increases from 1.2 to 1.35. The RMSE value falls from 1.45 to 1.3 for 300 latent features. There is an increase in RMSE value from 1.35 to 1.55 at 400 latent features. In the film trust dataset, all are behaving in the same manner except for 50 latent features. There is a drastic change in RMSE value with different behavior from 1.20 to 0.99. For the remaining k values there are slight fluctuations in RMSE value. In the trip advisor dataset, different behavior is seen for $k = 10$ latent features. For all the remaining latent features, there is a decrease in RMSE value if the latent features are increased. In the jester dataset, there is an increase in RMSE value as

Fig. 9. Root Mean Square Error (RMSE) graphs for Matrix Factorization (MF) on six datasets, namely, Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets for 10 steps and 400 latent features.

the latent features are increased. There is a decrease in RMSE value at 100. The constant RMSE is maintained at k value 140. In the market dataset, there is a decrease in RMSE value if the k -value increases.

For the NMF method, we have plotted RMSE values with different latent features on six datasets in Fig. 11. In all datasets, if the k -value is increasing RMSE decreases. Compared to all datasets, the NMF method gives less RMSE value for film trust and market datasets. More RMSE value for jester, movie lens-100K datasets. For any latent features, the RMSE value is decreasing with different steps.

Fig. 12 (a), (b), and (c) describes RMSE value of SVD method with various k values for pair of datasets movie lens-

100K, jester, movie lens-1M, market, and trip advisor, film trust respectively. Across all datasets, an increase in the k -value is observed to correspond with a decrease in the RMSE value. Compared to all datasets, the SVD method gives less RMSE value for film trust and market datasets. More RMSE value for movie lens-100K datasets. For the jester dataset a drastic change in the RMSE value of the SVD method when increasing the k -value because the number of items is very less.

Fig. 13 describes RMSE value on six different datasets for SVD++ method at different steps. In all datasets, if the k -value is increasing then RMSE also increases. In the jester dataset, it is observed that the RMSE is maintained constant for different steps. Compared to all datasets, the SVD++ method gives less

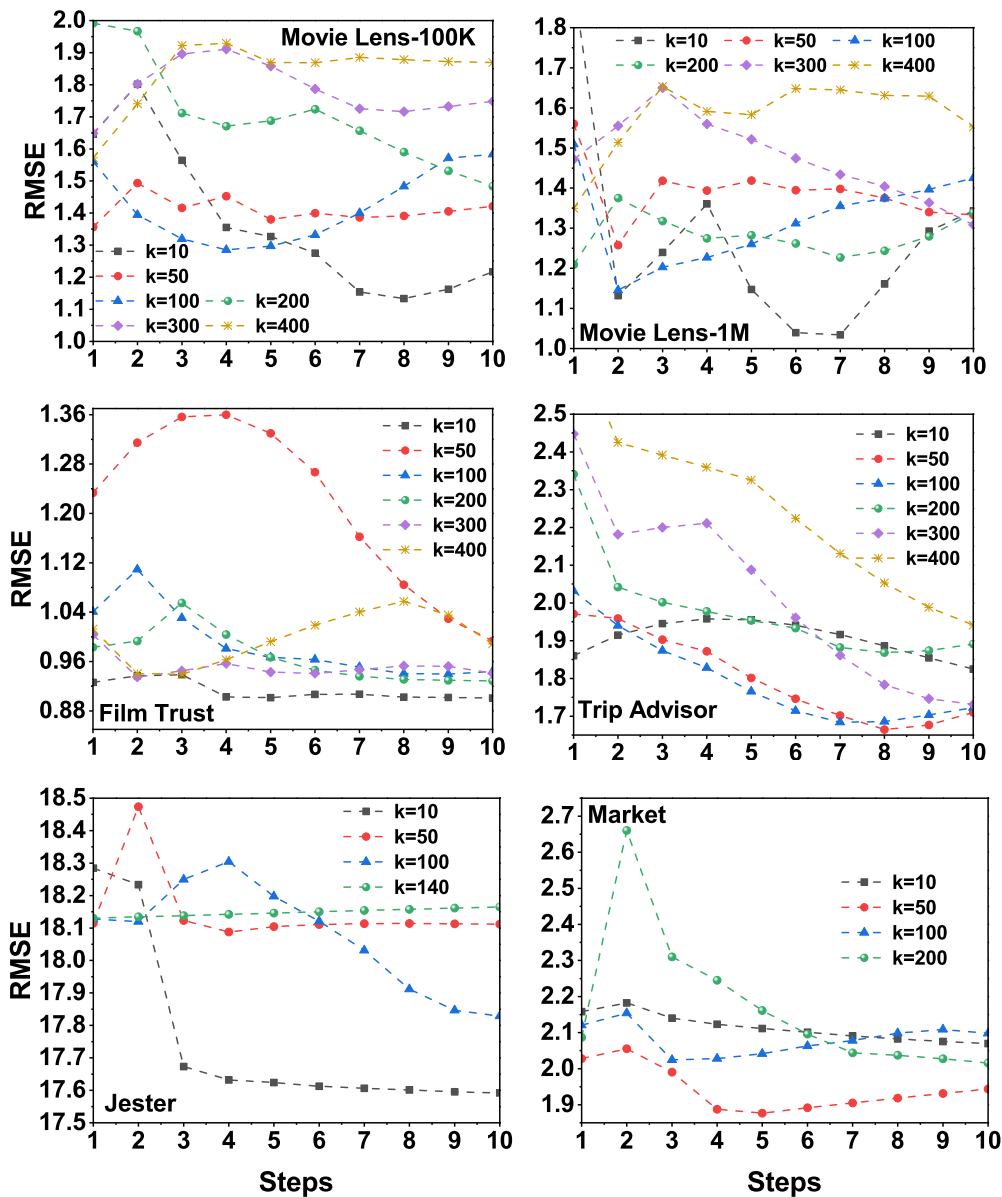

Fig. 10. Root Mean Square Error (RMSE) graphs for Probabilistic Matrix Factorization (PMF) on six datasets, namely, Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets for 10 steps and 400 latent features.

RMSE value for the film trust dataset and more RMSE value for the jester dataset.

VII. COMPARISON OF MF METHODS

The comparison of different MF methods on different datasets namely movie lens-100K, film trust, movie lens-1M, trip advisor, jester, and market with $k = 5$ in Table IV, and $k = 10$ in Table V, and $k = 100$ in Table VI. Compared to all the MF methods NMF, and SVD methods gives less RMSE value with different k -values. It is observed that in MF, PMF, and SVD++ methods, by increasing the k -value RMSE also increases. Whereas in NMF, and SVD methods there is a decrease in RMSE value as k -value increases. The

k -value in each method is the number of latent features that are divided into the items. As compared to all MF methods, if we consider more groups for items in the dataset, MF, PMF, and SVD++ give more errors for suggesting an item to the user. Whereas, if we increase the groups in NMF and SVD methods, the error value that is obtained is less while predicting a recommendation to the user.

For film trust and movie lens-1M datasets, the prediction performance of MF is drastically decreasing with an increase in the number of latent features. The dominant observation is that the rating distribution for the two datasets is right skewed and sparse. However, NMF and SVD are not affected much by this skewed rating as well as the number of latent features.

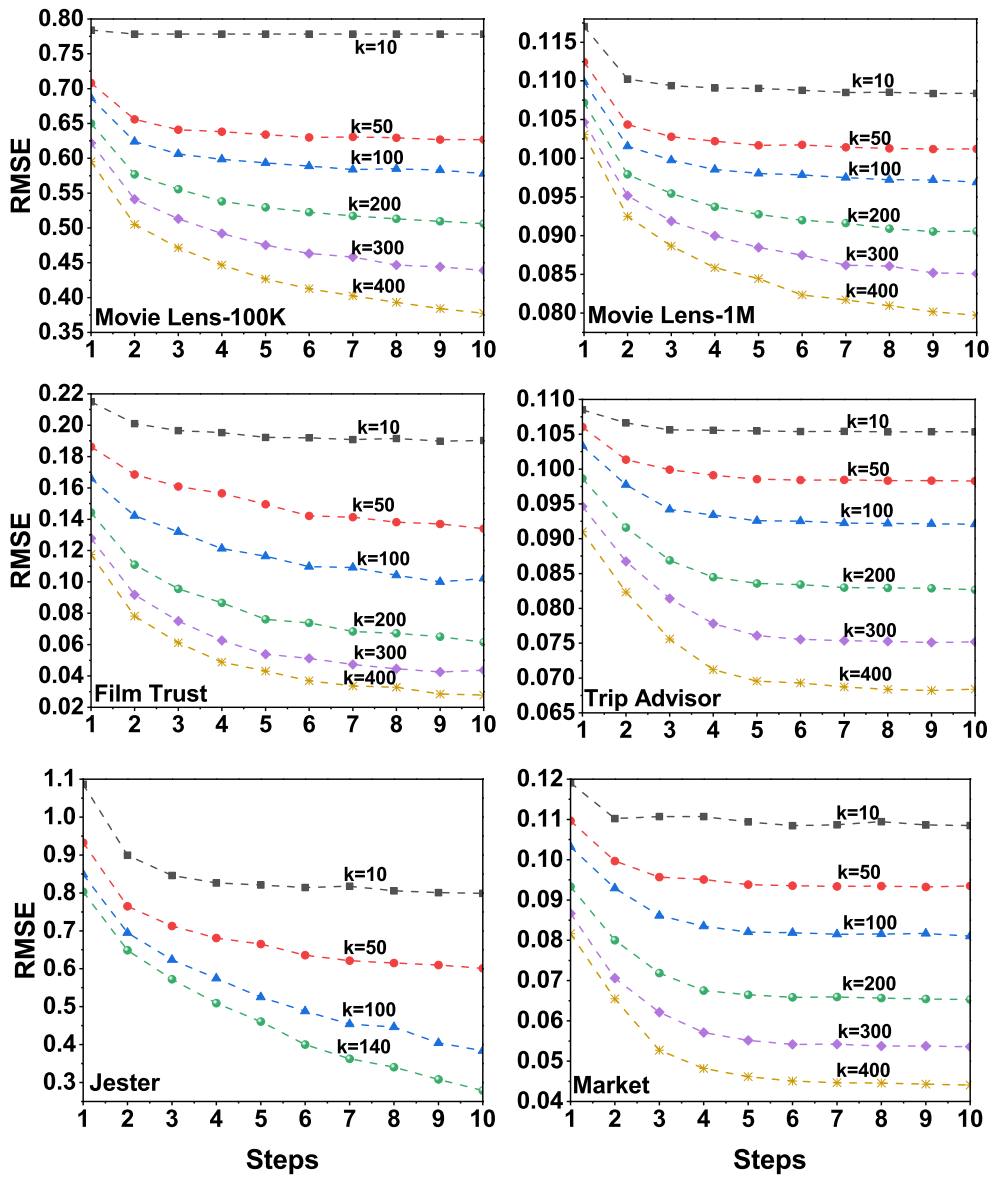

Fig. 11. Root Mean Square Error (RMSE) graphs for Non-Negative Matrix Factorization (NMF) on six datasets, namely, Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets for 10 steps and 400 latent features.

Fig. 12. Root Mean Square Error (RMSE) graphs for Singular Value Decomposition (SVD) on six datasets, namely, Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets for 10 steps and 400 latent features.

Fig. 13. Root Mean Square Error (RMSE) graphs for SVD++ on six datasets, namely, Movie Lens-100K, Movie Lens-1M, Film Trust, Trip Advisor, Jester, and Market datasets for 10 steps and 400 latent features.

TABLE IV. RMSE VALUES FOR DIFFERENT VARIATIONS OF MATRIX FACTORIZATION (MF) ON SIX DIFFERENT DATASETS NAMELY MOVIE LENS-100K, MOVIE LENS-1M, FILM TRUST, TRIP ADVISOR, JESTER, AND MARKET AT $k = 5$

Dataset (↓) / MF algorithm (→)	MF	PMF	NMF	SVD	SVD++
Movie Lens-100K	1.048	1.051	0.720	0.711	0.908
Movie Lens-1M	2.236	1.463	0.111	0.110	0.859
Film Trust	2.722	1.457	0.200	0.199	0.798

VIII. CONCLUSION AND FUTURE SCOPE

A. Conclusion

Information theory is essential for improving the effectiveness of recommendation systems. By measuring the un-

certainty and information content in user preferences and interactions, it offers a solid framework for creating more precise and efficient recommendation algorithms. This theoretical basis enhances the handling of sparse data, boosts prediction accuracy, and ensures more personalized user ex-

TABLE VI. RMSE VALUES FOR DIFFERENT VARIATIONS OF MATRIX FACTORIZATION (MF) ON SIX DIFFERENT DATASETS, NAMELY, MOVIE LENS-100K, MOVIE LENS-1M, FILM TRUST, TRIP ADVISOR, JESTER, AND MARKET AT $k = 100$

Dataset (\downarrow) / MF algorithm (\rightarrow)	MF	PMF	NMF	SVD	SVD++
Movie Lens-100K	5.014	1.583	0.577	0.497	0.920
Movie Lens-1M	18.994	1.425	0.096	0.091	0.864
Film Trust	18.886	0.944	0.102	0.082	0.879
Trip Advisor	4.131	1.722	0.092	0.091	1.118
Jester	3.407	17.828	0.383	0.219	4.803
Market	6.539	2.097	0.810	0.080	1.328

periences. As recommendation systems advance, the principles of information theory will continue to be vital in tackling challenges related to data complexity, user diversity, and changing preferences, resulting in more sophisticated and dependable recommendation solutions. In this study, various MF methods like MF, PMF, NMF, SVD, and SVD++ have been compared on different datasets namely movie lens-100K, film trust, movie lens-1M, trip advisor, jester, and market with different latent features on different steps. The performance of the MF methods is evaluated using RMSE. It is observed that MF is the least-performing MF method among all studied in this work. SVD is the outperforming method among all other MF algorithms. However, it has been observed that the number of latent features is affecting the prediction performance. The prediction power of MF, PMF, and SVD++ is reducing with an increase in the number of latent features. On the other hand, NMF and SVD are performing better with an increase in the number of latent features.

B. Future Scope

In the future, we would like to extend the concept of recommendation to different real-world contexts. For example, this study focuses solely on recommending a single item to an individual user. However, in practice, there are situations where recommendations are needed for a group of users. For example, a group of students might be advised on selecting an elective course based on their collective interests. This interest prompts the requirement for and creation of group recommender systems [61]. Cross-domain recommendation systems (CDR) can help mitigate this issue. CDRs use the ratings of the new item/user in one domain in another domain with transfer learning [62]–[64]. Utilizing these techniques will help recommendation systems work better by a variety of semantic information contained in knowledge graphs. A knowledge graph (KG) is a collection of relational facts, including information about the entities, entity categories, and collaborations among entities. KG embeds complex information about different relationships among real-world entities [65], [66].

SUPPLEMENTARY INFORMATION

In the supplementary information section, RSE graphs for MF at $k = 10, 50, 100, 200, 300, 400$ at 10 steps and 100 steps at 10 latent features are shown and RMSE graphs for MF, PMF, NMF, and SVD methods are provided at 100 steps and 10 latent features and MAE graphs for the SVD++ method at $k = 10, 50, 100, 200, 300, 400$ at 10 steps are shown.

Fig. 14 describes the RSE value on six different datasets for the MF method on 10 steps and 400 latent features. In all datasets, it is observed that there is an increase in RSE value as the k -value increases. Compared to all the datasets less RMSE value is given by film trust and more RMSE value is given by the jester dataset.

Fig. 15 describes the RSE value on six different datasets for the MF method on 100 steps and 10 latent features. In all datasets, except for jester, it is observed that if the k -value is increasing then RSE decreases. Compared to all datasets, the MF method gives less RSE value for the market dataset and more RSE value for the jester.

Fig. 16 describes the RMSE value on six different datasets for the MF method at different steps. In all datasets, if the k -value is increasing then RMSE also increases. Compared to all datasets, the MF method gives less RMSE value for film trust, movie lens-1M datasets, and more RMSE value for movie lens-100K, trip advisor, film trust, and market.

Fig. 17 describes RMSE value on six different datasets for the PMF method on 100 steps and 10 latent features. In the movie lens-100K dataset, at $k = 1$ there is a constant behavior maintained. For all the remaining k values there are many alterations in RMSE value. In movie lens-1M, for $k = 2$, there is a major deviation in the RMSE value as compared to

all remaining k values. In the film trust dataset, for all the k values between 1 to 9, there are fluctuations as they are altered. For $k = 10$ the RMSE value is high as compared to the remaining k values. In the trip advisor dataset, all the k values exhibit different behavior. In the jester dataset, as compared to the remaining datasets, the RMSE value is too high as there is a decrease in the RMSE value with different steps. In the market dataset, all the k values have different behavior with an increase in steps.

Fig. 18 describes RMSE value on six different datasets for the NMF method on 100 steps and 10 latent features. In all datasets, if the k -value is increasing then RMSE also decreases. Compared to all the datasets, the NMF method gives less RMSE value for trip advisor, movie lens-1M, and market datasets and some more RMSE value for movie lens-100K, and film trust datasets. More RMSE value is given by the jester dataset due to less items.

Fig. 19 (a), (b), and (c) describes RMSE value of SVD method with various k values for pair of datasets movie lens-100K, jester, movie lens-1M, trip advisor, and film trust, market, respectively. In all datasets, it is observed that as the k value increases there is a decrease in RMSE value. Compared to all the datasets, the SVD method gives less RMSE value for trip advisor, movie lens-1M, and market datasets. More RMSE value for movie lens-100K and jester datasets.

Fig. 20 describes the MAE value on six different datasets for the SVD++ at different steps. In movie lens-100K, movie lens-1M, trip advisor, and market datasets, it is observed that there is an increase in RMSE value as the step increases. In the jester dataset, a similar constant RMSE value is maintained at different steps.

Efficient Tumor Detection in Medical Imaging Using Advanced Object Detection Model: A Deep Learning Approach

Taoufik Saidani

Center for Scientific Research and Entrepreneurship,
Northern Border University, Arar-73213 Saudi Arabia

Abstract—Timely and accurate tumor detection in medical imaging is crucial for improving patient outcomes and reducing mortality rates. Traditional methods often rely on manual image interpretation, which is time-intensive and prone to variability. Deep learning, particularly convolutional neural networks (CNNs), has revolutionized tumor detection by automating the process and achieving remarkable accuracy. The present paper investigates the use of YOLOv11, a powerful object detection model, for tumor detection in several medical imaging modalities, such as CT scans, MRIs, and histopathological images. YOLOv11 incorporates architectural advancements, including enhanced feature pyramids and attention processes, allowing accurate identification of tumors with diverse sizes and complexity. The model's real-time detection capabilities and lightweight architecture render it appropriate for use in clinical settings and resource-limited contexts. Experimental findings indicate that the fine-tuned YOLOv11 attains exceptional accuracy and efficiency, exhibiting an average precision of 91% and a mAP of 68%. This research highlights YOLOv11's significance as a transformational instrument in the integration of AI in medical imaging, aimed at optimizing diagnostic processes and improving healthcare delivery.

Keywords—Tumor detection; medical imaging; YOLOv11; deep learning; real-time detection

I. INTRODUCTION

Early diagnosis and treatment are considerably enhanced by the detection of tumors in medical imaging, which helps to reduce mortality rates and improve patient outcomes. Healthcare professionals can make critical decisions regarding treatment strategies, including surgery, chemotherapy, or radiation therapy, when malignancies are identified in a timely manner. Traditional tumor detection predominantly depends on the manual interpretation of medical images, such as CT scans, MRIs, and histopathology slides, which is labor-intensive, susceptible to variability among experts, and difficult for subtle or ambiguous cases [1], [2]. The increasing need for precise and effective tumor detection methods has resulted in the incorporation of artificial intelligence (AI) methodologies, especially deep learning, into medical imaging processes.

Deep learning, by its capacity to autonomously discern intricate patterns and characteristics from data, has transformed medical imaging by providing unparalleled accuracy and efficiency in classification, segmentation, and object recognition tasks. In contrast to conventional machine learning techniques that necessitate manual feature engineering, deep learning models, particularly convolutional neural networks (CNNs),

have exhibited significant efficacy in automating diagnostic procedures and minimizing error rates [3], [4]. These models have shown efficacy in tumor detection across many imaging modalities, tackling issues such as tumor appearance heterogeneity, size and shape fluctuations, and differing imaging settings. Nonetheless, several current deep learning methodologies encounter constraints, such as the need for substantial computing resources, challenges in real-time processing, and inadequate efficacy in identifying tiny or subtle tumors [5].

The YOLO (You Only Look Once) model family, recognized for its real-time object identification proficiency, has surfaced as a viable alternative for medical applications. YOLOv11, the most recent version in this series, has several architectural enhancements, including optimized feature pyramids, attention mechanisms, and advanced loss functions, making it very effective for tumor detection in medical imaging [6]. These enhancements allow YOLOv11 to precisely detect cancers of diverse sizes and forms, even in difficult situations where tumor margins are ambiguous or when lesions mimic benign formations [7], [8].

Furthermore, YOLOv11's streamlined architecture and capacity for real-time detection render it very beneficial in clinical environments where prompt decision-making is essential. Its scalability and efficiency facilitate implementation on edge devices and in resource-constrained settings, such as rural clinics or portable diagnostic equipment [9], [10].

This work aims to investigate the use of YOLOv11 for tumor identification in medical imaging and assess its performance across various datasets. This research seeks to establish a comprehensive YOLOv11-based framework for tumor detection, evaluate its efficacy through quantitative metrics including precision, recall, and Intersection over Union (IoU), and offer insights into its advantages and drawbacks for practical medical diagnostics. Additionally, the study includes a comparative performance analysis of YOLOv11 against YOLOv9, using the same datasets, to highlight the improvements in detection accuracy and efficiency.

The rest of the paper is structured as follows: Section II offers a review of pertinent literature, summarizing current methodologies for tumor diagnosis and developments in YOLO models. Section III delineates the suggested technique, specifying the YOLOv11 architecture. Section IV presents the experimental findings and analysis, including a description of the dataset, training setting, and performance evaluation of YOLOv11, as well as a comparison with baseline models.

Section V concludes the paper by summarizing the study's contributions and proposing avenues for further investigation.

II. LITERATURE REVIEW

Recent advancements in deep learning have significantly transformed tumor detection in medical imaging by improving accuracy and efficiency. The combination of multimodal imaging techniques, which synthesizes data from several imaging sources, has shown potential in improving cancer detection rates and addressing the shortcomings of single-modality methods [11]. Deep learning models, including U-Net and Attention U-Net, have been extensively employed for brain tumor segmentation, attaining high precision in defining tumor margins, whereas alternative methods have concentrated on glioblastoma detection and classification, showcasing their efficacy in tackling the complexities associated with heterogeneous tumor traits [12], [13]. The YOLO family of object detection frameworks has garnered considerable attention for its real-time performance. A thorough examination of YOLO variations underscores the progress from YOLOv1 to YOLOv10 and their use in medical imaging tasks, including lesion detection and anatomical structure classification [14], [15]. Recent advancements, including YOLOv8 and YOLOv7, have broadened the model's utility to tasks such as kidney detection in MRI and lung segmentation for pulmonary anomaly analysis, demonstrating the framework's versatility in addressing diverse medical imaging challenges [16], [17]. Innovations such as MedYOLO, a 3D object detection framework derived from YOLO, have enhanced its applicability in the identification of organs and lesions within intricate imaging contexts [18]. Notwithstanding these gains, problems persist, such as the precise identification of tiny or subtle tumors, inconsistencies in imaging circumstances, and the need for extensive annotated datasets. Overcoming these hurdles necessitates more enhancements in YOLO's resilience and flexibility, with the exploration of multimodal imaging integration to augment tumor detection capabilities [19].

III. PROPOSED APPROACH

The proposed tumor detection framework utilizes a fine-tuned YOLOv11 model tailored to meet the specific problems of medical imaging, especially in identifying tumors in MRI, CT, and other modalities, as seen in Fig. 1. Medical imaging exhibits considerable variety in tumor dimensions, morphology, and intensity, necessitating a sophisticated detection model adept at managing these complexity while ensuring speed and precision. The medical photos are downsized to a specified resolution of 640×640 pixels to ensure interoperability with the YOLOv11 architecture. Normalization is used as a preprocessing step to normalize pixel intensity values, enhancing model consistency across varied datasets and imaging settings. These phases are essential for the framework's capacity to generalize across diverse imaging apparatus and procedures.

The backbone of YOLOv11 is tasked with extracting critical characteristics from the input photos. It utilizes many convolutional layers and Cross Stage Partial (CSP) modules, aimed at optimizing gradient flow and enhancing feature propagation. CSP modules divide the feature map into two pathways, processing one while reserving the other for further

integration, so assuring the retention of essential information across layers. This architectural improvement renders YOLOv11 more proficient at detecting intricate patterns and subtle anomalies, including tiny or unclear malignancies. Moreover, residual connections in the backbone inhibit feature deterioration in deeper layers, allowing the model to efficiently learn intricate feature hierarchies. The neck of the YOLOv11 model is a vital element for multi-scale feature aggregation, crucial for identifying tumors of diverse sizes. It incorporates CSP2 modules and upsampling layers to improve the model's capacity to capture intricate features while preserving the context of broader areas. The Spatial Pyramid Pooling-Fast (SPPF) module enhances the neck by capturing contextual information across many scales, enabling the model to accurately detect both big and tiny tumor areas. The outputs of these layers are concatenated to integrate information from various resolutions, enabling the model to use both low-level and high-level characteristics during detection. This skill is especially crucial for medical imaging, as cancers may manifest as tiny, subtle areas inside intricate anatomical systems. The head of YOLOv11 is tasked with producing the ultimate forecasts, including bounding boxes, confidence ratings, and class labels for identified tumors. This component employs detection layers that provide predictions at numerous scales, enabling the model to effectively identify cancers of varying sizes, from microscopic lesions to huge masses. Non-Maximum Suppression (NMS) is used in the post-processing stage to remove superfluous bounding boxes and preserve the most reliable forecasts. The results are shown as bounding boxes superimposed on the input medical pictures, along with comments specifying tumor kinds and confidence levels. This aids interpretation by healthcare experts, allowing them to concentrate on clinically significant results.

The YOLOv11 model is refined using specialized medical imaging datasets to enhance performance. This training method utilizes annotated datasets including bounding boxes and labels for tumors. Transfer learning is used by initializing the model with pre-trained weights from general object identification tasks and then fine-tuning it on the medical dataset. This method expedites convergence, diminishes the need for substantial computer resources, and enhances the model's adaptability to the distinct attributes of medical imaging. The training procedure improves a multi-task loss function that integrates classification loss, localization loss, and confidence loss, guaranteeing a balanced enhancement in all facets of tumor detection.

The suggested methodology is assessed using conventional measures, such as precision, recall, F1-score, Intersection over Union (IoU), and inference duration. These metrics provide a thorough evaluation of the model's precision, dependability, and real-time relevance. Through the integration of sophisticated feature extraction methods, multi-scale detection functionalities, and refined training processes, YOLOv11 exhibits considerable improvements in detection precision and computing efficiency relative to prior YOLO iterations and other leading models. Its lightweight design facilitates deployment on edge devices and resource-limited situations, such as rural clinics or portable diagnostic instruments, hence expanding its potential uses in telemedicine and distant healthcare. The refined YOLOv11 framework signifies a substantial improvement in tumor identification in medical imaging. Its capacity

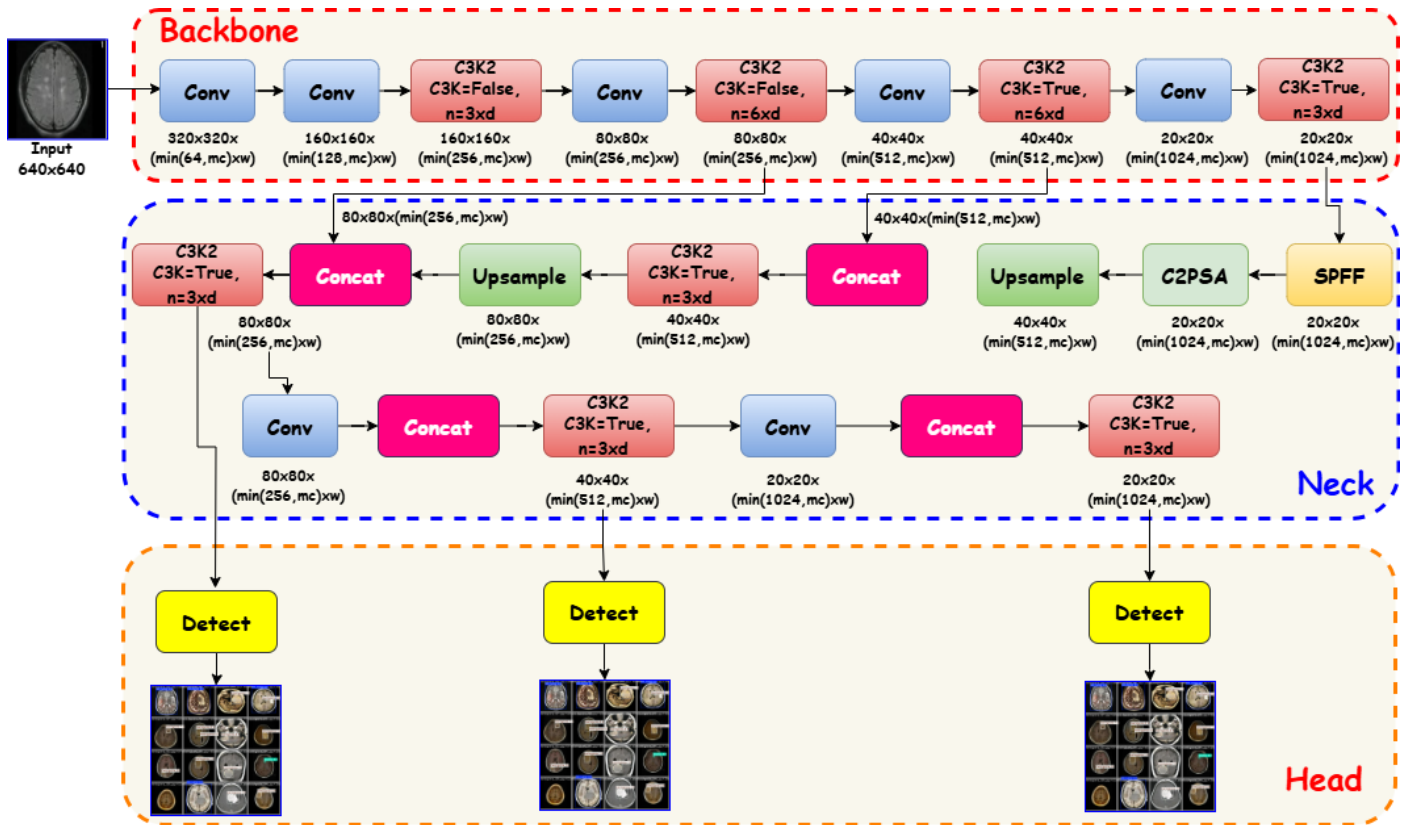

Fig. 1. Proposed tumor detection framework using a fine-tuned YOLOv11 model.

for real-time image processing, coupled with excellent detection accuracy and scalability, establishes it as a revolutionary instrument for clinical diagnostics. This method enhances tumor identification efficiency while tackling significant issues in medical imaging, including diversity in tumor presentation and the need for resilient, generalizable solutions.

IV. EXPERIMENTAL RESULTS

A. Description of Dataset Analysis

The proposed tumor detection system is trained and assessed using a publicly accessible brain tumor detection dataset, including MRI images annotated to denote the presence and kind of tumor. The dataset has five tumor categories: NO_tumor, glioma, meningioma, pituitary, and space-occupying lesion, each delineated with bounding box annotations to specify the tumor locations inside the images [20]. Fig. 2 illustrates a class imbalance within the dataset, as seen by the bar chart, where “NO_tumor” and “meningioma” are predominant, but “space-occupying lesion” is markedly under-represented, presenting issues for equitable training. To tackle this issue, data augmentation methods, including flipping and contrast modifications, are proposed for the minority class.

B. Training Configuration

The YOLOv11 model for tumor detection is trained utilizing a well-designed process to provide excellent accuracy and robust performance. The training procedure is set to execute for 100 epochs, allowing enough iterations for the model to

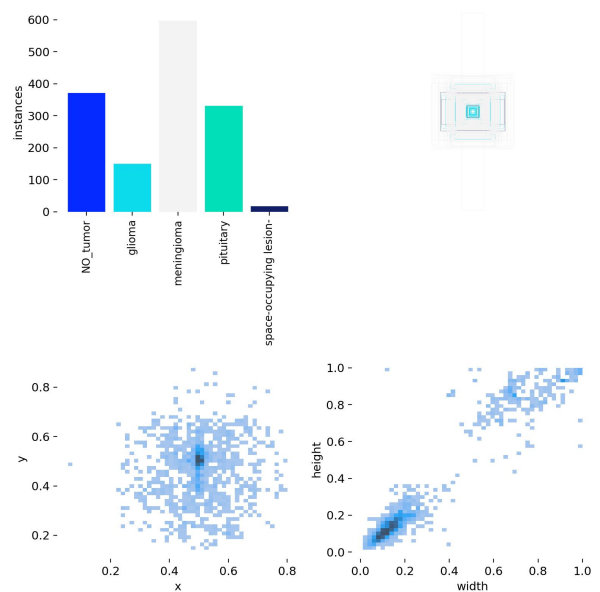

Fig. 2. Tumor detection class distribution.

assimilate tumor patterns while reducing the likelihood of overfitting. A batch size of 4 is used, optimizing computing efficiency while facilitating efficient learning, particularly with high-resolution medical pictures. The learning rate is established at 0.001, facilitating slow learning of the model without

overshooting the ideal solution, while dynamic modifications are implemented during training using a learning rate scheduler to refine the model in subsequent epochs. The training utilizes a 100A GPU, which enhances calculations like convolutional operations and backpropagation, markedly decreasing training duration. The dataset is divided into training (1,370 photos), validation (395 images), and test (191 images) sets in a 70%-20%-10% ratio, facilitating a systematic assessment procedure. Data augmentation methods, such as random flipping, rotation, scaling, and contrast modifications, are used on the training pictures to enhance variability and bolster the model's generalization capabilities. The optimizer, such as SGD or Adam, minimizes a multi-task loss function that integrates classification loss for accurate tumor type prediction, localization loss for exact bounding box placement, and confidence loss for evaluating tumor existence. At each epoch, the model's performance is assessed on the validation set, with measures like accuracy, recall, and Intersection over Union (IoU) calculated to track progress and prevent overfitting. Checkpoints are regularly stored to preserve the optimal model, and early halting is used if validation performance remains stagnant for several epochs. After training, the model is assessed on the test set using measures like F1-score, precision, recall, IoU, and inference time to verify its successful generalization. This extensive training procedure, using a high-performance GPU, guarantees that YOLOv11 is refined for precise and efficient tumor identification in medical imaging.

C. Results Analysis

The training and validation loss curves depict the model's performance throughout 100 epochs, emphasizing three primary metrics: box loss, classification loss, and Distribution Focal Loss (DFL), as shown in Fig. 3. The box loss, which assesses the error in predicted bounding box coordinates, demonstrates a consistent decline in both training and validation datasets, beginning at approximately 1.0 and decreasing to 0.4 for the training set while stabilizing similarly for the validation set, indicating effective tumor localization. The classification loss, which assesses the precision of tumor class predictions, decreases markedly from about 3.0 to 0.5 in the training dataset, while the validation classification loss exhibits a similar decreasing trajectory, indicating continuous enhancement and the lack of overfitting. The DFL loss, which enhances bounding box accuracy, consistently declines from 1.3 to below 1.0 in both training and validation datasets, underscoring the model's proficiency in accurate tumor localization predictions. The congruence of training and validation loss curves across all measures indicates a well-calibrated training process, devoid of substantial divergence that may imply overfitting. The consistent reduction and stability of losses confirm the reliability of the YOLOv11 model and its capacity for effective generalization, making it highly suitable for precise and efficient tumor identification in medical imaging.

The Precision-Recall (PR) curve illustrates the performance of the YOLO-based tumor detection model across different tumor classes and overall, with a mean Average Precision (mAP@0.5) of 0.676, reflecting the model's overall ability to balance precision and recall, as shown in Fig. 4. Among the classes, NO_tumor achieves the highest Average Precision (AP) of 0.976, demonstrating excellent detection accuracy and a strong balance between precision and recall, followed closely

Fig. 3. Training and validation curves.

by meningioma with an AP of 0.936, indicating reliable performance in detecting these tumors. The detection of pituitary tumors achieves a moderate AP of 0.802, suggesting some challenges in maintaining high precision and recall simultaneously. Glioma shows a noticeable drop in performance,

Fig. 4. PR Curve for tumor detection across classes.

with an AP of 0.658, reflecting difficulties likely arising from dataset imbalance or the inherent complexity of this tumor type. The space-occupying lesion class performs poorly, with an AP of only 0.006, due to severe underrepresentation in the dataset, making it challenging for the model to generalize effectively for this class. The overall PR curve (bold blue line) combines the performance across all classes, showing a steady trade-off between precision and recall. These results highlight the model's robustness for well-represented classes, such as NO_tumor and meningioma, while identifying areas for improvement, particularly for minority classes like glioma and space-occupying lesions, through enhanced data augmentation and balancing strategies.

The F1-Confidence curve illustrates the relationship be-

tween the F1-score, which balances precision and recall, and the confidence threshold for each tumor class and the overall performance of the model, as depicted in Fig. 5. The NO_tumor class achieves the highest F1-score, remaining close to 1.0 across a wide range of confidence thresholds, reflecting excellent precision and recall for non-tumorous cases. Meningioma follows with consistently high performance, maintaining an F1-score close to 0.9, indicating reliable detection. Pituitary tumors show moderate performance with an F1-score peaking around 0.8, suggesting slightly lower accuracy compared to NO_tumor and meningioma. The glioma class demonstrates lower performance with a peak F1-score near 0.65, highlighting challenges in achieving a balance between precision and recall, likely due to dataset complexity or class imbalance. The space-occupying lesion class performs poorly, with an F1-score remaining close to 0, reflecting significant difficulties in detecting this underrepresented class. The bold blue line represents the overall performance across all classes, with the peak F1-score of 0.67 occurring at a confidence threshold of 0.649, indicating the model's optimal balance of precision and recall at this threshold. These results highlight the model's robustness for well-represented classes while identifying areas for improvement, particularly for minority classes, through targeted dataset augmentation and threshold optimization.

Fig. 5. F1-Confidence curve for tumor detection across classes.

The normalized confusion matrix provides a detailed overview of the model's performance across tumor classes, with each value representing the proportion of predictions normalized per class, as illustrated in Fig. 6. NO_tumor achieves the highest accuracy, with 99% of instances correctly classified and only 1% misclassified as glioma, showcasing the model's strong capability to distinguish non-tumorous cases. Glioma demonstrates moderate performance, with 58% of instances correctly identified but significant misclassifications, including 20% predicted as meningioma, 10% as NO_tumor, and 12% as pituitary tumors, reflecting challenges in distinguishing glioma from similar classes. Meningioma achieves high accuracy with 91% of instances correctly classified, though 6% are misclassified as glioma and 1% as pituitary, indicating minor overlaps. Pituitary tumors show 78% accuracy but face misclassifications, with 23% predicted as meningioma and 1% as glioma, suggesting difficulties in differentiating these tumor types. Space-occupying lesions, despite their underrepresentation, are

correctly classified with 100% accuracy, though this result may be influenced by the small sample size. The model also effectively filters out non-tumorous regions in the background class, with no significant misclassifications. This matrix highlights the model's strengths in detecting well-represented classes like NO_tumor and meningioma, while identifying challenges in glioma and pituitary tumor classification due to overlapping features, suggesting the need for improved data balance and feature extraction techniques to enhance performance.

Fig. 6. Normalized confusion matrix for tumor detection.

Fig. 7 illustrates an ensemble of MRI images from the validation set, showing the predicted tumor classifications and associated bounding boxes produced by the YOLOv11-based tumor detection algorithm. Each image has a bounding box delineating the identified tumor location, annotated with the anticipated tumor classification (e.g., "meningioma," "pituitary," or "NO_tumor") along with its corresponding confidence score. The bounding boxes are color-coded to differentiate tumor types, with elevated confidence ratings (e.g., 1.0 for "meningioma") reflecting the model's assurance in its predictions. Meningioma tumors are consistently recognized with high accuracy across several situations, demonstrating the model's robust detection proficiency for well-represented categories. No tumor locations are reliably recognized in several photos, with confidence ratings varying from 0.9 to 0.5, indicating considerable fluctuation in the model's certainty owing to overlapping characteristics or confusing areas. The model accurately identifies a pituitary tumor in one instance with a confidence level of 0.8, demonstrating its capability to recognize underrepresented classes. The bounding boxes correspond accurately with tumor locations, demonstrating the model's strong localization capabilities. Nevertheless, many forecasts with reduced confidence levels indicate difficulties in distinguishing ambiguous regions or inadequately documented tumor types. This qualitative evaluation underscores the model's efficacy in tumor diagnosis and localization, while pinpointing possibilities for improvement, especially with minority groups and intricate instances.

In Fig. 8, the proposed YOLOv11 model surpasses YOLOv9 in all critical performance parameters for tumor detection. It attains a much superior accuracy of 0.91 in

(a) Detection results for three classes.

(b) Detection results for pituitary class.

Fig. 7. Predicted results for tumor detection on validation dataset.

contrast to YOLOv9’s 0.652, signifying its greater reliability in precisely detecting malignancies. Furthermore, YOLOv11 has a somewhat superior recall of 0.67 compared to 0.627 for YOLOv9, indicating it identifies a greater number of genuine tumors. The mean average accuracy at IoU 0.5 (mAP@50) favors YOLOv11, achieving a score of 0.68, whereas YOLOv9 scores 0.62, indicating its greater overall detection quality. Moreover, YOLOv11 has a swifter inference time of 12 ms, making it more efficient for real-time applications compared to YOLOv9, which requires 15.7 ms. In summary, YOLOv11 is the superior model for tumor detection owing to its enhanced

accuracy, sensitivity, detection quality, and speed.

Fig. 8. Performance evaluation comparison: YOLOv11 vs YOLOv9.

V. CONCLUSION

The paper presents a tumor detection framework using a fine-tuned YOLOv11 model, specifically tailored to tackle the distinct issues of medical imaging, especially in tumor detection across MRI, CT, and other imaging modalities. The improved structure of YOLOv11, which includes better feature stacks and attention processes, makes it possible to accurately and quickly find tumors of different sizes and levels of complexity. The model attains an accuracy of 91%, a recall of 67%, and a mAP of 68%, surpassing YOLOv9, which recorded a precision of 65.2%, a recall of 62.7%, and a mAP of 62%. Furthermore, YOLOv11 exhibits real-time detection proficiency, achieving an inference time of 12 ms, in contrast to YOLOv9’s 15.7 ms, making it a more efficient and pragmatic choice for clinical applications. Our findings show that YOLOv11 might revolutionize medical imaging by improving tumor detection accuracy and speed, improving diagnostic processes and healthcare outcomes. Future work will explore further enhancements, including the integration of multimodal imaging data and the development of explainable AI techniques to improve the interpretability of model predictions, thereby fostering greater trust and adoption in clinical settings.

Abstract—Internet of Things (IoT) provides smart wireless connectivity and is the basis of many future applications. IoT nodes are equipped with sensors that obtain application-related data and transmit to the servers using IEEE 802.15.4-based wireless communications, thus forming a low-rate wireless personal area network. Security is a major challenge in IoT networks as malicious users can capture the network and waste the available bandwidth reserved for legitimate users, thus significantly reducing the Quality of Service (QoS) in terms of transmitted data and transmission delay. In this work, an Anomaly Detection Mechanism for IEEE 802.15.4 standard ($ADM_{15.4}$) to improve the QoS of the IoT Nodes is proposed. $ADM_{15.4}$ also proposes a mechanism to block the malicious nodes without affecting the overall performance of the medium. The performance of $ADM_{15.4}$ is compared with the standard when there is no such anomaly detection is present. The results are obtained for different values of SO and for different sets of GTS requesting nodes and are compared with the standard in the presence and absence of malicious nodes. The simulation results show that the $ADM_{15.4}$ improves data transmission up to 19.5% from IEEE 802.15.4 standard without attacks and up to 52% when there is malicious attacks. Furthermore, $ADM_{15.4}$ transmits data 33% reduced time and accommodate 56% more GTS requesting legitimate nodes as compared to the standard in the presence of the malicious attacks.

I. INTRODUCTION

Internet of Things (IoT) has been emerging rapidly since last decade and is being used in several applications to improve the quality of life of citizens with improved healthcare systems, automated industrial applications, smart cities, and home appliances [1]. In the current era, there are multiple gadgets have been developed to provide ease in human daily life activities by using IoT platforms. Predictions from experts suggest that there will be a substantial global business impact, reaching 15 trillion, by the year 2025, driven by the proliferation of 120 billion networked gadgets [2].

IoT is mainly based on wireless sensor networks, where multiple wireless devices are connected in a network to form a wireless Personal Area Network (WPAN). Over the last decade, there has been a significant rise in the demand for Low-Rate Wireless Personal Area Network (WPAN) applications. These applications cater to various short-range communication needs, and as a result, a host of technologies have been developed, including ZigBee, Bluetooth, INSTEON, and more.

WPANs are primarily designed for short-distance communication and serve a wide spectrum of applications, ranging from home automation, cattle farming, precision agriculture, healthcare, monitoring liquid flow in pipelines, to even military use cases [3], [4], [5].

This ubiquitous growth of IoT applications with diverse and heterogeneous communication technologies such as 5G, and 6G, makes it more vulnerable and prone to attacks [6], [7], [8]. This may attract malicious nodes to attack the communication channel and create anomalies in the communication channel. IoT operates across diverse networks that incorporate both large and small devices. Small IoT devices, characterized by limited computational power and storage capacity, pose challenges for implementing robust security measures, including cryptographic algorithms and protection mechanisms. Due to the absence of privacy-preserving algorithms on these small IoT devices, malicious actors exploit their vulnerabilities, turning them into unwitting agents for conducting various attacks [9], [10], [11].

WSNs consist of tiny wireless nodes with limited energy and processing capabilities. WSNs demand timely data transmission with minimal delays and also strive to maximize throughput and link utilization for improved efficiency. To increase the efficiency of WSN-based IoT, the chances of collisions need to be avoided as it results node sending the data again resulting in energy consumption, with increased delay and poor bandwidth utilization.

To address these requirements, various Medium Access Control (MAC) protocols have been created. In 2003, the Institute of Electrical and Electronics Engineers (IEEE) introduced the 802.15.4 standard, designed specifically for applications in low-data-rate and low-power Wireless Personal Area Networks (WPAN). This standard boasts an exceptionally low duty cycle, even less than 0.1%, making it an ideal choice to address the distinctive requirements of such applications. The standard is specifically designed for low-rate and low-power devices such as IoT devices and remains in high research [12], [13], [14].

IEEE 802.15.4 standard operates in beacon-enabled and non-beacon-enabled modes. In beacon-enabled mode, it offers a superframe structure having both contention-based and contention-free communication modes. During the contention access period, nodes contend with other nodes to access the medium and there are chances of collision in the period. However, in the contention-free period, TDMA-like time slots are present and data-sending nodes are allocated dedicated time slots to transfer their data in the medium without contending

*Corresponding authors.

with other nodes and by avoiding chances of collisions.

Malicious nodes present in the network try to disturb the communication channel. Malicious node attacks during the contention-free period are easily detected as TDMA-like contention-free slots are reserved for specific nodes and only the allocated nodes are allowed to send their data during these slots. That's why, malicious nodes attack in the contention-based environment, where chances of collisions are always present and it is difficult to detect the malicious attacks in that environment. To avoid these malicious attacks, the communication of the specific area is required to be restricted to avoid the interference of these malicious nodes during the contention access period. However, restricting the communication of the region restricts the communication of the legitimate nodes present in that restricted region resulting in a compromised Quality of Service (QoS) of the network.

In this study, we present a novel Anomaly Detection Mechanism, denoted as $ADM_{15.4}$, tailored for the IEEE 802.15.4 standard. The main aim is to recognize the existence of malicious nodes within the network and formulate a strategy to prevent their attacks without compromising the QoS of the network. The salient features of the proposed $ADM_{15.4}$ scheme are mentioned below.

- 1) An anomaly detection algorithm by analyzing the network's performance parameters to detect the presence of malicious nodes.
- 2) Physical Layer Security-based (PLS) security mechanism to avoid the effects of these malicious nodes by generating jamming signals by the neighbouring nodes of the network.
- 3) A mechanism to allow the affected legitimate nodes in the restricted region to transfer their data by assigning GTS.
- 4) An efficient mechanism by allocating Guaranteed Time Slots (GTS) to all GTS requesting nodes along with the affected nodes to enhance the QoS of the network.

The rest of the manuscript is organised as: Previously discussed research work in the related field is discussed in Section II. A brief discussion about the working of IEEE 802.15.4 standard and possible attacks on it are discussed in Section III. The proposed anomaly detection mechanism along with its remedies are discussed in Section IV. The system model and performance analysis of the proposed scheme are described in Section V and VI, respectively and Section VII concludes this manuscript.

II. RELATED WORK

The ubiquitous growth of IoT due to its provisioning of comfort in human life is developing rapidly. Due to its adoption in diverse applications, IoTs are under hot research areas in different areas. Secure and reliable communication by avoiding malicious nodes' attacks is one of the dire requirements of IoT networks. That is why, it is under high research area and a lot of research on malicious attacks is taking place in different areas of the communication field.

In [15], the authors propose a novel anomaly detection technique for IoT networks. In this work, the authors use an

imbalance data technique, that is when normal data is more than the malicious data and vice versa by applying reinforcement learning on the data set of Network Security Laboratory-Knowledge Discovery and Data Mining Tools Competition (NSL-KDD). In this technique, the input data is classified into normal and malicious data by considering the state as a category of the data due to the varying types of data present in the IoT network. The anomaly detection accuracy level is the reward of the function described in this work. The authors claim that their proposed scheme provides better accuracy, recall, and F1 score.

The authors in [16] proposed a cyber-attack detection mechanism in Industrial IoT (IIoT) by applying a federated learning-based approach. The main purpose of using the federated learning approach is its privacy because data can only be accessed locally. The authors applied the technique to local anomaly detection centres and claimed to achieve better accuracy and throughput as compared to the related techniques on global anomaly detection.

Authors in [17] proposed Software Defined Networks (SDN) that deal with traffic flow monitoring applications to regularly check the traffic flow monitoring. In this work, a tradeoff between accuracy and network load is observed, such that, a larger network load is required to achieve high accuracy and vice versa. In this work, authors proposed a deep Q-learning technique for anomaly detection that is due to the Denial of Services (DoS) attacks. The authors claimed that their proposed scheme performs better than other referenced techniques.

In [18], the authors explored a scenario within the Internet of Vehicles (IoV) context, where vehicles exchange information regarding the surrounding traffic conditions. Key parameters such as traffic density, emergency vehicle presence, and vehicle speeds are communicated to Road Side Units (RSUs) in the infrastructure. The study identifies a threat of malicious users executing data integrity attacks, manipulating information on traffic density and disseminating incorrect data. To address this challenge, the authors introduce a novel anomaly detection algorithm based on isolation forests. Verification of anomalies is conducted through probe messages sent to vehicles in the proximity of potential malicious users. Additionally, a communication mechanism is devised to share the verification information. The authors claimed to improve results in terms of accuracy, recall, and F1 score.

The study in [19] incorporates social networks as a significant aspect of its focus. The primary challenge tackled revolves around feature learning and the integration of information from the network's vicinity by proposing a Graph Neural Network (GNN) technique for feature learning. For effective training, the technique utilizes pattern mining algorithms. In addition, the authors also introduced a novel loss function. The results indicate improvements in metrics such as precision, recall, and F1 score when compared to other existing techniques.

The research presented in [20] focuses on enhancing the security of the Domain Name System (DNS). The fundamental approach involves making the system topology aware and taking into account the structural properties of the network. The proposed scheme is based on an exponential random graph model, and the network's topology is transformed into a graph

format. An additional layer of security is introduced through time series analysis, employing the auto-regressive moving average for anomaly detection. The authors claimed that the precision of their proposed scheme is better than the other alternative techniques.

In [21], the authors studied social welfare behaviour and presented a model for detecting behavioural differences in IoT-based networks. The model uses vector space-based aggregation and compares the behaviour of different nodes. The scheme is based on the correlation of primary attributes derived from social-aware interaction behaviour captured by edge nodes of the vector space. Additionally, the proposed model includes a spatial index tree to store the information of IoT nodes. The authors claim that their proposed scheme quickly and accurately detects abnormal behaviour in the network.

The authors in [22] proposed an anomaly detection mechanism along with energy efficiency in three-tier IoT-edge-cloud collaborative networks. The authors apply the marching square algorithm on data collected by the edge nodes to generate isopleths to detect anomalies at the boundary. The location of the anomaly is determined by adopting the Kriging spatial interpolation algorithm at the cloud tier and traversing at the edge network through mobile sensing nodes. Authors claimed that their proposed scheme provides better accuracy and energy consumption as compared to other state-of-the-art schemes.

In [23], the authors emphasized the importance of real-time data accuracy in Industrial IoT applications and proposed a hybrid end-to-end deep anomaly section framework. The authors proposed framework is based on the convolutional neural network (CNN) and a two-stage long short-term memory (LSTM)-based Autoencoder (AE) to detect anomalies by observing the variation from the actual sensor values. The authors claimed through extensive simulations that their proposed model works well in resource-constrained edge devices.

Most of the research work is based on the anomaly detection techniques that are created due to malicious attacks in the network layer and very rare research is on anomaly detection methods on the MAC layer. In this work, an anomaly detection method along with its countermeasures on IEEE 802.15.4 standard is being proposed (Table I).

III. ATTACKS ON IEEE 802.15.4 STANDARD

In this section, the operating modes of the IEEE 802.15.4 standard along with the different types of vulnerabilities found in these operating modes are discussed.

A. Operating Modes of IEEE 802.15.4 Standard

The IEEE 802.15.4 standard is tailored for wireless networks that are operating with low transmission powers and modest data rates such as wireless sensors-based IoT networks. This standard operates in three different frequency bands, such as 868 MHz, 915 MHz, and 2.4 GHz offering 1 frequency channel, 10 frequency channels, and 16 frequency channels, respectively. At 868 and 915 MHz, a BPSK modulation scheme is employed with data rates of 20,000 and 40,000 bits per second, respectively. However, the 2.4 GHz band employs an O-QPSK modulation scheme, offering a data rate of 250,000 bits per second.

Fig. 1. A Superframe structure of IEEE 802.15.4 standard.

The standard accommodates both ad hoc and centrally controlled networks. In the ad hoc mode, nodes communicate with each other using an unslotted Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA) based multiple access algorithm. In the case of a centralized network configuration, a superframe architecture is implemented, as illustrated in Fig. 1. The coordinator initiates a beacon frame, prompting IoT nodes to activate their transceivers to receive the message and synchronize their operations. The active period, referred to as the Superframe Duration (SD), consists of 16 equally divided time slots and is further categorized into Contention Access Period (CAP) and Contention-Free Period (CFP). CAP involves the transmission of the beacon frame, control messages by member nodes, and data transmission. However, CFP comprised TDMA-like time slots and allocated to nodes on request for data transmission only. The duration between two consecutive beacon frames is known as the Beacon Interval (BI). SD and BI depends upon the parameter values of SO and BO respectively and are calculated in Eq. 1 and 2 [14].

$$SD = 960 \times 2^{SO} \quad (1)$$

$$BI = 960 \times 2^{BO} \quad (2)$$

here,

$$0 \leq SO \leq BO \leq 14$$

The PAN coordinator regularly generates beacon frames. Non-member nodes desiring to join the network must wait for the beacon to ascertain the CAP for transmitting their membership requests to the coordinator. If a node intends to transmit data during the CFP, it initiates CFP slot requests to the PAN coordinator and is then assigned a CFP slot in the subsequent SD. However, if a node's CFP request is not entertained, then it can transmit data during CAP. All IoT nodes follow the CSMA/CA algorithm to access the medium before transmitting their frames.

The CSMA/CA primarily comprises three parameters, such as the Number of Backoffs (NB), Backoff Exponent (BE) and Contention Window (CW). NB is about the number of tries to access the medium for transmitting a frame. Its initial value is 0 and ranges up to the value as defined in parameter *MaxCSMABackoffs*. The default value of *MaxCSMABackoffs* is 4, which allows a node to make four attempts to access the medium availability before transmitting the frame. If it cannot access the medium then it declares the failed transmission with medium access busy

notification. BE determines the number of backoff periods, a node has to wait before accessing the channel and is calculated as $2^{BE} - 1$. The initial default value of BE is 3 and the number of random backoff periods, a node has to wait initially is in the range of 0 – 7. If it cannot find the medium idle, then the algorithm increments the BE value and the waiting range before accessing the medium increases to 0 – 15. Parameter CW allows a node to check the medium availability twice before transmitting the frame.

If the transmitted frame cannot reach its destination due to collision with another frame in the medium then it is re-transmitted. If several re-transmissions reach the parameter limit defined in $macMaxFrameRetries$ parameter, then the transmission is considered unsuccessful.

B. Attacks on IEEE 802.15.4 Standard

Malicious nodes interfere with the medium to disturb the communication of legitimate nodes. This work focuses on the malicious attacks during CAP of IEEE 802.15.4 standard. The following three types of malicious node attacks are quite common in the MAC protocols to disturb the communication standards of the protocol:

- 1) Exhaustion Attack
- 2) Collision Attack
- 3) Unfairness Attack

1) *Exhaustion attack*: During the CAP, nodes utilize CSMA/CA before transmitting a frame into the medium. They assess the medium's availability by conducting a Clear Channel Assessment (CCA). Malicious nodes keep the medium occupied by transmitting a long stream of messages. This results legitimate node finding the medium busy even after multiple tries as mentioned in $MaxCSMABackoffs$ parameters and the required message initiated by the upper layer is exhausted.

When a node transmits its packet and cannot receive its acknowledgment, then it has to resend the packet again and again till its maximum limit and then finally declares that the packet can not be transmitted.

2) *Collision attack*: Collision occurs when two or more nodes transmit their packets in the medium at the same time and cause the collision. Nodes wait for the acknowledgment for a certain time as mentioned in the parameter $macAckWaitDuration$ of the standard. If transmitting nodes do not receive the acknowledgment within the specific time, then it re-transmits the frame and if the number of retries reaches the limit mentioned in $macMaxFrameRetries$, then the transmission is declared unsuccessful. Malicious nodes disturb the communication after intentionally transmitting a short message while detecting the medium busy causing collisions of the frames transmitted by legitimate nodes.

3) *Unfairness attack*: The standard offers fairness by allowing all nodes equal chances to assess the medium after the decrement of the backoff period. A node after completing its backoff period can access the medium in transmitting its frame. Similarly, the standard allocates GTS to nodes, on a First Come First Serve (FCFS) basis. In case, the PAN coordinator receives GTS requests more than its available limit of 7, then it assigns GTS to those nodes, whose requests arrive first. Malicious nodes do not wait for their assigned backoff periods and initiate their requests at once which reduces the fair chances of other nodes to access the medium. Similarly, it occupies the GTS by initiating early GTS requests to the PAN coordinator and GTS requests of legitimate nodes of the networks are not entertained.

These malicious node attacks create an anomaly in the IoT network applications and QoS is compromised. In this work, an Anomaly Detection Mechanism for IEEE 802.15.4 standard ($ADM_{15.4}$) in an IoT network is proposed. $ADM_{15.4}$ detects malicious attacks in the network and then proposes a comprehensive mechanism to improve the QoS of the network by avoiding malicious attacks.

IV. PROPOSED SCHEME

In this work, malicious nodes' presence is identified by proposing an anomaly detection mechanism during CAP of IEEE 802.15.4 standard. The proposed $ADM_{15.4}$ detects anomalies in the network by introducing an anomaly detection

method and then proposes a solution to neutralize its effect to improve the QoS of the IoT network. The main features of our proposed scheme and described below and its flow is mentioned in Fig. 2.

- Anomaly detection mechanism to detect the anomaly in the medium through a soft function.
- Once an anomaly is detected in a medium, the communication of the region is restricted to prevent a malicious attack by transmitting a jamming signal.
- Data transmission of the affected legitimate nodes available in the restricted region along with an efficient GTS allocating method to improve the QoS.

Fig. 2. A Flow of different sections of the proposed scheme.

A. Anomaly Detection Mechanism

Physical and MAC layers of most of the IoT-based networks follow IEEE 802.15.4 standard. MAC layer attacks of malicious nodes compromise the efficiency of the network. In the IEEE 802.15.4 standard, most of the attacks are during its CAP and disturb its performance. The proposed method, based on [24], is used to detect anomalies in the network using various parameters at the end of each SD. The method involves several steps, as shown in Fig. 3.

Fig. 3. Flow of the proposed anomaly detection mechanism.

1) *Transmission and collision ratio*: PAN coordinator at the end of each SD computes the following ratios of the different parameters that are observed during the SD.

a) *Successful Transmitted Frames (STF) ratio*: STF is calculated during each SD of the standard by calculating the number of successfully transmitted packets against the total number of requests.

b) *Requested Frame (RF) ratio*: RF is calculated as the number of frames successfully transmitted in the medium to the total number of the frames, nodes intend to transmit during an SD.

c) *Collision Ratio (CR)*: CR is computed by dividing the total number of collisions detected by the total number of frames transmitted in the medium during SD. This metric provides insight into the efficiency of the network by quantifying the proportion of frames that experienced collisions during the specified period.

d) *GTS Allocation Ratio (GAR)*: GAR is the maximum value among all the GTS requested nodes that is calculated as the average number of GTS allocated to a node against a total number of GTS requests received.

2) *Implementation of soft function*: After calculating all the ratios during the SD, a soft function (ψ) is formulated to determine the probabilities of various events based on input values. Specifically, it calculates the probability of successful transmission (PST), the probability of exhaustion attacks (PE), the probability of collision attacks (PC), and the probability of unfairness attacks (PU) using the input values of STF , RF , CR , and GAR , respectively. The mathematical expression is as follows:

$$\psi(X) = \frac{1}{1 + e^{-E \times (V - F)}} \quad (3)$$

Here, $\psi(X)$ is in the range between 0 and 1 and its outcome is the PST , PE , PC , and PU , while replacing V with inputs of STF , RF , CR , and GAR respectively in the soft function. The value of V can be determined through the desired value (Y_D) and real values (Y_R) as mentioned in Eq. 4.

$$J(V) = (Y_D - Y_R)^2 \quad (4)$$

However, E represents slope and F represents the centre of the curve. The shape of the curve is contingent upon these two values, and their dynamics evolve, recalculated after each SD as:

$$E_{K+1} = E_K + (\phi \times \frac{\partial J}{\partial E}) \quad (5)$$

Here ϕ ranges between 0 and 1 and $\frac{\partial J}{\partial E}$ are calculated as:

$$\frac{\partial J}{\partial E} = 2(Y_D - Y_R) \times \frac{E_K}{[1 + e^{-E_K \times (V - F_K)}]^2} \quad (6)$$

Similarly F_{K+1} is calculated as:

$$F_{K+1} = F_K + (\phi \times \frac{\partial J}{\partial F}) \quad (7)$$

Here $\frac{\partial J}{\partial F}$ is calculated as:

$$\frac{\partial J}{\partial F} = 2(Y_D - Y_R) \times \frac{-E_K \times e^{-E_K \times (V - F_K)}}{[1 + e^{-E_K \times (V - F_K)}]^2} \quad (8)$$

Algorithm 1: Anomaly Detection Algorithm

Input: Successful Transmission Ratio STR , Requested Frame Ratio RF , Collision Ratio CR , GTS Allocation Ratio GAR ,

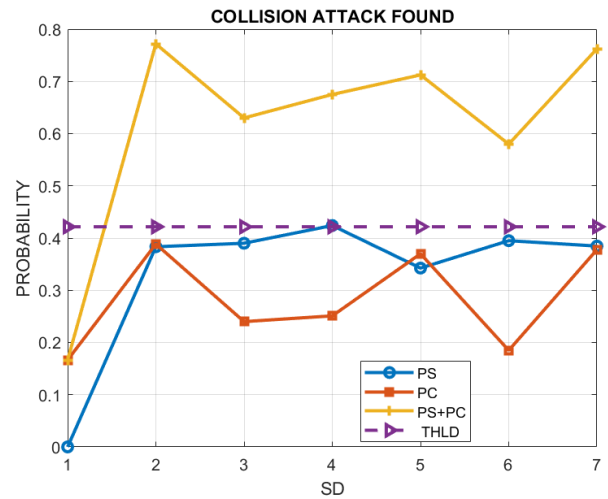

- 1 Compute $PST = 1/1 + \exp(-E \times (STR - F))$
- 2 Compute $PE = 1/1 + \exp(-E \times (RF - F))$
- 3 Compute $PC = 1/1 + \exp(-E \times (CR - F))$
- 4 Compute $PU = 1/1 + \exp(-E \times (GAR - F))$
- 5 Compute $Z_1 = (PST \times \psi) + (PE \times \theta)$
- 6 Compute $Z_2 = (PST \times \psi) + (PC \times \theta)$
- 7 Compute $Z_3 = (PST \times \psi) + (PU \times \theta)$
- 8 **if** $Z_1 > Th$
- 9 Exhaustion Attack
- 10 **else**
- 11 No Exhaustion Attack
- 12 **if** $Z_2 > Th$
- 13 Collision Attack
- 14 **else**
- 15 No Collision Attack
- 16 **if** $Z_3 > Th$
- 17 Unfairness Attack
- 18 **else**
- 19 No Unfairness Attack

3) *Anomaly detection with results:* After determining the PST , PE , PC , and PU , the PAN coordinator assigns weights that are within the range of 0 and 1 to each of the calculated probabilities. Each of the exhaustion, collision, and unfairness probability in combination with the weighted successful transmission probability compute the anomaly value. The calculated anomaly value is compared with the threshold value calculated in [25] to find the anomaly. The proposed anomaly detection algorithm is shown in Algorithm 1.

Results in Fig. 4 show the anomaly detection by the proposed algorithm to find the collision. Sub-figure 4b shows when there are no collision attacks found in the network as they are below the threshold level. However, sub-figure 4a shows the collision detection as the collision found in the network is more than the threshold limit as calculated in [25].

Results in Fig. 5 represent the presence of exhaustion attacks in the network and it is comprised of two sub-plots. Subplot 5b exhibits when there are no exhaustion attacks found as the exhaustion value represented by Z_1 in the algorithm is less than the threshold value. However, exhaustion attacks are found as shown in subplot 5a, when the exhaustion value is greater than the threshold value.

Results in Fig. 6 represent the unfairness attacks. Unfairness attacks are calculated from the GTS allocation in the standard as described in Section III-B and are determined from exhaustion value Z_3 from the algorithm. The figure comprises two subplots. Subplot 6a shows when the exhaustion value is greater than the threshold value due to the exhaustion attacks, however subplot 6b represents when the exhaustion value is less than the threshold limit resulting in no unfairness attacks found in the medium.

(a) Collision attacks.

(b) Without collision attack.

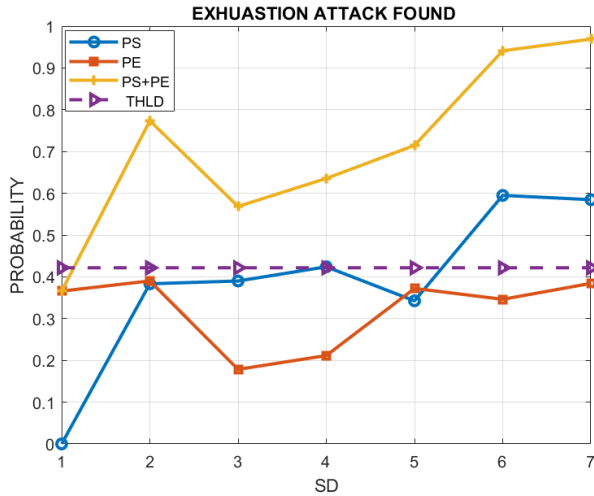

Fig. 4. With and without collision attack.

B. Prevention of Malicious Attacks

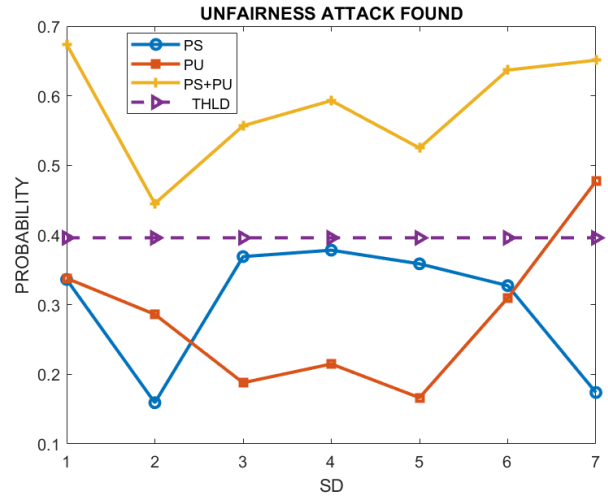

After successfully detecting the presence of a malicious node, its attacks are required to be neutralized by blocking its communication. In a terrestrial IoT network architecture, the PAN coordinator is supposed to know the location of each IoT node placed in the network with the help of its short address provided by the PAN coordinator of IEEE 802.15.4 standard. To stop the communication of the malicious nodes in the network, the PAN coordinator in its beacon frame requests one of the neighbouring malicious nodes, which has the highest residual energy level, to transmit jamming signals during CAP. Generating a jamming signal restricts the communication of all the nodes present in that area resulting in compromised QoS in that area as mentioned in Fig. 7.

C. Communication of the Affected Nodes

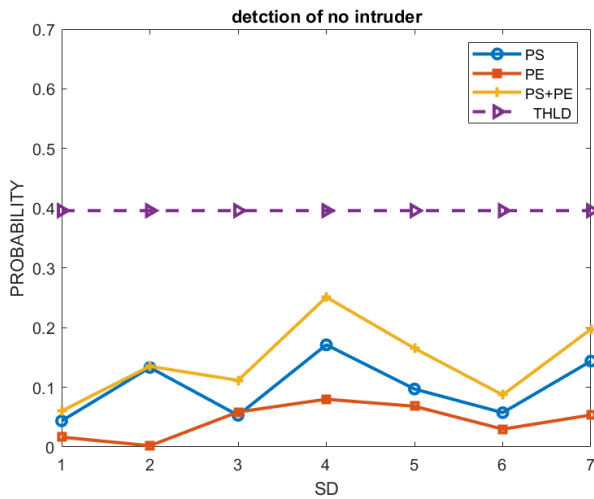

The communication of the legitimate nodes present in the restricted areas is provided by allocating GTS in the upcoming

(a) Exhaustion attacks.

(a) Unfairness attacks.

(b) Without unfairness attack.

Fig. 5. With and without exhaustion attack.

Fig. 6. With and without unfairness attack.

SD. Due to restricted CAP, these affected nodes are unable to transmit their GTS requests to the PAN coordinator, In such a scenario, the GTS are assigned to these affected nodes by analyzing the nodes' previous transmission pattern. Suppose PAN coordinator receives j number of requests during past k sessions, then its expected GTS requests (GTS_i) is calculated as:

$$GTS_i = (K_{last} - K_{cur}) + \left\lceil \frac{K}{J} \right\rceil \quad (9)$$

Here, K_{last} is represented as the last SD when node i initiated the request and K_{cur} is the upcoming SD.

Each SD of IEEE 802.15.4 standard consists of 7 TDMA-like CFP slots. PAN coordinator after determining the expected GTS allocation to the affected nodes, assigns the remaining slots against the GTS requests received from the unaffected legitimate nodes. Suppose the PAN coordinator has m CFP

slots available and the number of GTS required to be allocated to affected nodes is n , then the PAN coordinator can only accommodate $m - n$ GTS requested slots in the next SD. If the number of GTS requested by the unaffected legitimate nodes is less than $m - n$ slots, then it can entertain all the GTS requests. However, in case, the number of requested GTS exceeds the available slots, a scrutiny of GTS takes place based on their priority levels. This is accomplished by employing the 0/1 knapsack algorithm.

To determine the priority of a node, the default GTS requesting command frame format has been modified by utilizing its two reserved bits. Each node requesting GTS informs its PAN coordinator about the number of GTS required, along with its priority level. This information is conveyed in the last two reserved bits of the GTS characteristic field, which is part of the GTS request command frame format specified in the IEEE 802.15.4 standard, as illustrated in the accompanying Fig. 8. Priority levels of each IoT node are categorized into

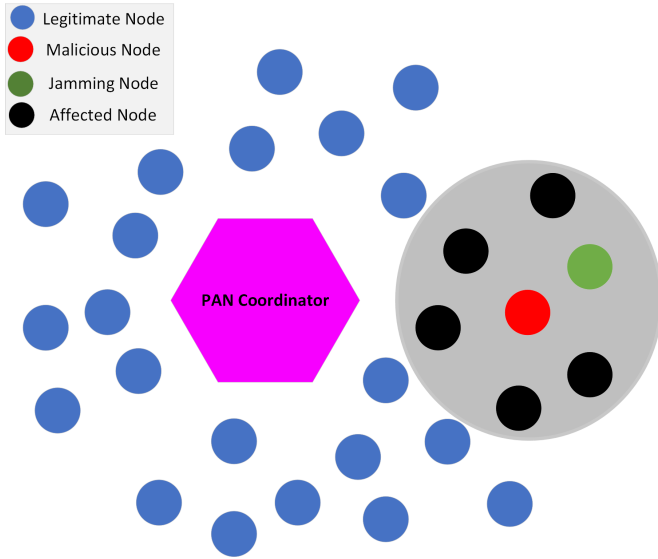

Fig. 7. IoT Network with malicious and affected nodes.

four different levels ranging from 00 to 11 representing the lowest to the highest priority levels, respectively.

Fig. 8. Modified GTS request command frame format of IEEE 802.15.4 standard.

The PAN coordinator scrutinizes the GTS requests by applying the 0/1 knapsack algorithm. The available CFP slots in the upcoming SD are considered as sack capacity. Each GTS requesting node is mapped with an item and its requested slots are mapped as the weight of the item. The value of the item (V_i) is mapped with the value of the GTS requesting node i and depends upon its priority (P_i) and the time (T_i) that it has to wait after initiating its GTS request as:

$$Val_i = P_i \times T_i \quad (10)$$

Priority of the requested GTS as calculated from the proposed GTS requesting command frame format as shown in Fig. 7. However, the waiting time is calculated as:

$$T_i = N_i + \frac{(960 \times 2^{BO}) - X_i}{960 \times 2^{BO}} \quad (11)$$

Here, N_i represents the consecutive number of requests, the PAN coordinator receives from node i . If there is no GTS request in the previous beacon interval (BI), then its value is 0, however, if the same node is requesting GTS for the last

two BI and its request is not entertained, then the value of N is 2. X_i is the duration in symbols and it is calculated as the time between the start of the beacon frame and the time when the PAN coordinator receives the GTS request.

The proposed $ADM_{15.4}$ assists the PAN coordinator in allocating the available GTS to the GTS requesting nodes as:

- 1) Assign GTS to all GTS requesting nodes if requesting slots are less than the available GTS in the upcoming SD.
- 2) Scrutinize the GTS requesting node in allocating the GTS if the number of requesting slots is more than the available GTS.

A complete algorithm for GTS allocating nodes in upcoming SD for PAN coordinator is shown in Algorithm 2.

V. SYSTEM MODEL

Wireless sensor-based IoT nodes are being used in diverse wireless applications. Most of the wireless sensor networks use IEEE 802.15.4 standard in their MAC and Physical layers. Malicious wireless nodes being a part of the network, try to disturb the communication of the legitimate nodes and create an anomaly. In this work, the superframe structure of IEEE 802.15.4 standard operating at a 2.4GHz frequency channel is used for communication between all wireless connected nodes creating a Wireless Personal Area Network (WPAN). WPAN comprises a PAN coordinator and its member nodes. A system model of this work comprises of WPAN coordinator with legitimate member nodes and few malicious nodes as shown in Fig. 9. A WPAN coordinator acting as Cluster Head (CH) is selected based on the higher residual energy level among all nodes. All other nodes in the WPAN act as member nodes. All member nodes are in direct connection with the CH and do not use any relaying node to reach CH. Malicious nodes are part of the network and disturb the medium access of all legitimate nodes by transmitting information during CAP of the standard. This causes legitimate nodes to find the medium busy as well as increases the chances of collision in the medium with increased unfairness of the legitimate nodes.

Nodes can transmit their data during CAP as well as during CFP. A data frame transmitted during a CAP is successfully delivered, if it receives its acknowledgment within a stipulated time as mentioned in different parameters in IEEE 802.15.4 standard. Total time (ζ) required in transmitting a requesting frame during CAP is calculated as sum of backoff count (BC), data transmitting duration (TD), Propagation delay (PD), turn around (TA) time, Acknowledgment frame time (AF), and Inter-frame space (IFS) as mentioned in Eq. 12 and is shown in Fig. 10.

$$\zeta = BC + TD + (2 \times PD) + TA + AF + IFS \quad (12)$$

If X number of legitimate nodes are successful in transmitting its frames during CAP of a SD , then accumulated time (σ_{CAP}) calculated in successful transmission of data requested frames during CAP in q number of SD is calculated as:

Algorithm 2: GTS Allocation Mechanism

```

$$\sigma_{CAP} = \sum_{a=1}^q \sum_{b=1}^X SD_a \times \zeta_b \quad (13)$$

The time required in transmitting data during CFP is calculated as the time when a node, initiates its request during CAP since it transfers its data in CFP slots. Number of GTS required (CFP_i) to send m amount of data by a node i in transferring its data is calculated as:

Fig. 9. System model of proposed scheme.

Fig. 10. A Complete frame length including acknowledgment.

$$CFP_i = \left\lceil \frac{m}{30 \times 2^{SO}} \right\rceil$$

Suppose node i sends a request of k number of GTS to the WPAN coordinator during CAP. If the WPAN coordinator successfully allocates its required GTS just before the j slots of the CFP period in the next SD, then the complete delay (CD_i) in transferring its data in its allocated GTS is calculated as:

$$CD_i = BI + SD - j + \left(\frac{m}{30 \times 2^{SO}} \right) \quad (14)$$

If p nodes are allocated GTS in each SD , then accumulated delay (σ_{GTS}) of all the WPAN in transferring data during CFP for q number of SD is calculated as:

$$\sigma_{GTS} = \sum_{a=1}^q \sum_{b=1}^p SD_a \times CD_b \quad (15)$$

VI. RESULTS AND ANALYSIS

In this section, the performance of the proposed scheme is thoroughly examined across various dimensions. The analysis delves into different aspects, evaluating the efficacy of the proposed scheme within the system model outlined in the preceding Section V. A simulation environment is established by deploying a fixed number of legitimate nodes within a

WPAN. This network configuration includes one WPAN coordinator alongside legitimate nodes, and notably, one additional node designated as a malicious node. All nodes follow the IEEE 802.15.4 standard and communicate with each other on the same frequency channel of the 2.4 GHz frequency band. Malicious nodes are present in specific areas and their position is supposed to be identified by the PAN coordinator. A “10 X 10” meters area around the malicious node is blocked by transmitting Jamming signals during CAP by one of the legitimate nodes in that area. A random number of nodes during each SD generate their GTS requests to transmit their data during CFP. The results are analyzed for a fixed duty cycle of 50% along with varying duty cycles for different values of *SO* and different numbers of nodes. A list of simulation parameters is presented in the Table II.

TABLE II. SIMULATION PARAMETERS

Parameters	Values
Total Number of Member Nodes	19, 8, 12
Network Size	100 × 100
Data Rate	250Kbps
Number of Legitimate Nodes	19
Number of Malicious Node	1
Cluster Head	1
Superframe Order	0,2
Superframe Duration (msec)	15.4,61.4
Beacon Interval (msec)	30.7, 122.9
Slot Duration (msec)	1.92, 7.68
Duty Cycle	50%
Offered Load (Bytes)	50 to 125

The simulation results are observed in different prospects with and without attacks and the performance of our proposed $ADM_{15.4}$ scheme is evaluated. The performance is compared with the standard by data transmission, average transmission time, and number of GTS allocated nodes accommodated by the PAN coordinator.

A. Transmitted Data

The data transmitted is calculated for only those legitimate nodes that are allowed to transfer their data during CFP. The proposed scheme applies 0/1 knapsack algorithm in allocating GTS to the legitimate nodes. However, the IEEE 802.15.4 standard applies FCFS in allocating GTS to the requesting nodes.

Results shown in Fig. 11 represent the effect on data transmission with and without attacks. The results show that the data transmission for the same number of data-requesting nodes increases at the same rate when there is no malicious attack. On the other hand, the data transmission is affected due to malicious attacks in the second SD. However, in the proposed scheme, the data transmission is affected in the second SD, however after the blocking of the region at the start of the 3rd SD, the rest of the nodes keep on transmitting their data. It can be observed from the results that between 1 and 2 SD values, there is no malicious attack and all nodes are transmitting data with same rate. However, in the 2nd SD, malicious nodes attack the medium and attacks are detected by the proposed scheme at the end of the 2nd SD and a prevention mechanism is applied in the 3rd SD by transmitting jamming signals in the surrounding of the malicious node. This affects the communication of nodes in the specific area, however,

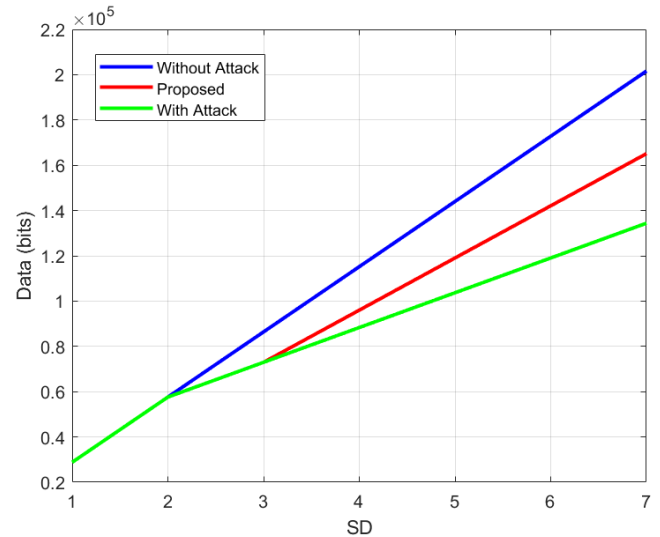

Fig. 11. Data transmission of nodes with and without attacks.

nodes present in the rest of the area remain unaffected and keep on transmitting their data.

Fig. 12. Data transmission of GTS requesting nodes.

When attacks were found then $ADM_{15.4}$ allocates GTS to the nodes affected in that area as described in Section IV-B. Results shown in Fig. 12 represent the total amount of data transmitted by all nodes during CFP duration in the network when $SO=0$ and $SO=2$. The performance of the proposed scheme is evaluated by comparing its results with both the IEEE 802.15.4 standard under attack scenarios and the IEEE 802.15.4 standard in the absence of attacks. The results show that, for both values of SO , the data transmission in the proposed scheme is 30% more than the standard without attacks and 122% more than the standard with attack. This is due to the efficient allocation of GTS among GTS requesting nodes by applying the 0/1 knapsack algorithm because it allows the PAN coordinator to optimally allocate GTS among

the requesting nodes.

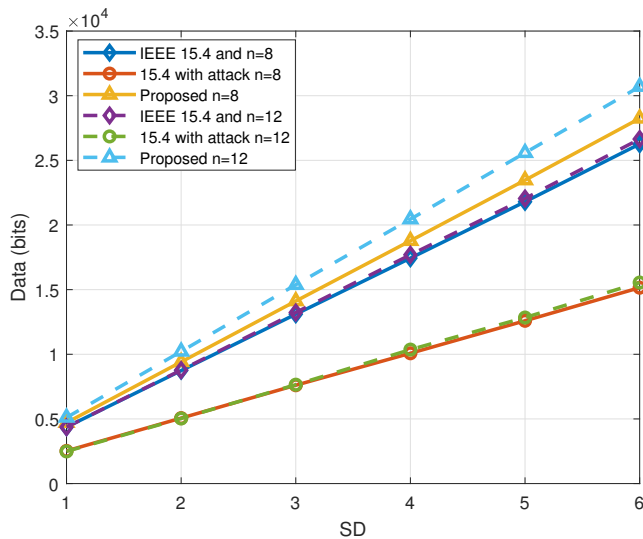

Fig. 13. Data transmission of GTS requesting nodes for different number of nodes.

The performance of the proposed scheme is validated by calculating the transmitted data during CFP when there was a random number of GTS requests from 8 and 12 legitimate nodes with an SO value of 2 as shown in Fig. 13. The results showed that the proposed scheme allowed for more data transmission for both 8 and 12 requesting nodes compared to the standard, with and without attacks. This demonstrates an optimal allocation of GTS among requesting nodes to enable more data transmission in an SD. Moreover, the results highlighted that the data transmission of the standard was severely affected during attacks because the PAN coordinator was unable to differentiate between legitimate and malicious node requests. This led to the PAN coordinator assigning GTS to the malicious nodes at the start of the CAP by applying FCFS.

B. Transmission Delay

The delay in transmitting data is calculated for those nodes that have initiated the GTS requests. The time to transmit data for all those nodes, which are successfully allocated GTS are calculated by following the Eq. 14. However, the transmission time of all those nodes which are not allocated GTS are supposed to be assigned GTS in the next SD automatically by passing through another BI.

Results in Fig. 14 show the accumulated time calculated for all GTS requesting nodes in transmitting their data. It is evident from the results, that due to malicious attacks, the overall data transmission time of GTS requesting nodes increases due to less number of legitimate nodes being assigned GTS in a superframe duration and the rest are allowed to send their data in the next superframe duration with an increase in BI time interval. However, data transmission time in proposed $ADM_{15.4}$ is the least among all and even less than the IEEE 802.15.4 standard because it accommodates a maximum number of GTS requesting nodes in transmitting their data during CFP in the current SD and less number of GTS

Fig. 14. Delay in transmitting data during contention free period.

Fig. 15. Delay in transmitting data during contention free period for different number of nodes.

requesting nodes transmit their data in the next SD resulting in a reduced network delay.

Results shown in Fig. 15 represent the network delay of all GTS requesting nodes when the number of GTS requesting nodes are 8 and 12 with a 50% duty cycle. The results clearly show that the accumulated delay of all GTS requesting nodes in transmitting their data in $ADM_{15.4}$ is 0.5% to 3% less than the standard when there is no attack for both 8 and 12 GTS requesting nodes respectively. However, it is 58% and 49% less in the presence of malicious attacks for number of nodes are 8 and 12, respectively because it allocates GTS to the malicious nodes and most of the legitimate nodes are unattended and are not allocated GTS.

Results in Fig. 16 show a comprehensive picture by calculating the difference in delay between the proposed scheme

Fig. 16. Accumulated delay difference for all possible values of SO when BO=10.

and IEEE 802.15.4 standard with attacks. The results are obtained by accumulating the total difference in delay faced by 19 legitimate nodes against all the possible values of SO when BO ranges from 0 to 10. The results show that with the increase in BO, the delay difference increases because higher BO allows an increased number of SO options and the accumulated sum of all the differences against all the possible values also increases. Furthermore, increased BO increases the BI, and unsuccessful GTS requesting nodes have to wait for another BI resulting in more delay.

C. GTS Allocating Nodes

GTS allocating nodes are calculated as the total number of GTS requests of legitimate nodes entertained by the PAN coordinator during an SD. The results are obtained for two different values of SO when the number of GTS requesting nodes is 20, and when the number SO is fixed and the number of GTS requesting nodes is 8 and 12 as shown in Fig. 17 and 18, respectively.

Fig. 17 shows the total number of GTS requesting nodes, that have been successfully allocated GTS in a SD by WPAN. It is evident from the results that $ADM_{15.4}$ entertains the maximum number of GTS requesting nodes in a SD and number of GTS entertained for $SO = 2$ are 24% and 110% more than IEEE 802.15.4 standard without attacks and with attacks, respectively. However, when $SO = 0$, then the proposed scheme allocates the same number of GTS requesting nodes as nodes entertained by IEEE 802.15.4 standard without attacks. This is due to the reason that the optimal number of GTS requesting nodes is also entertained by the PAN coordinator in IEEE 802.15.4 standard. However, due to unfairness attacks, some CFP slots are allocated to malicious nodes, resulting in less number of CFP slots left that are allocated to legitimate nodes.

Results in Fig. 18 show that the number of nodes entertained throughout the different superframe durations in the

Fig. 17. Number of GTS requesting nodes entertained.

Fig. 18. Number of GTS requesting nodes entertained for different number of nodes.

proposed scheme is the highest for both numbers of GTS requesting nodes. It is evident from the results that the accumulated number of GTS requests entertained by the PAN coordinator is maximum when GTS requesting nodes are 12 in the proposed scheme. This is due to the optimal allocation of GTS to the GTS requesting nodes by applying the 0/1 knapsack algorithm as compared to FCFS used in the IEEE 802.15.4 standard. The results further show that the least number of GTS requests of the legitimate nodes are entertained in the presence of the malicious attacks because the standard does not differentiate the malicious attacks and some of the GTS are allocated to malicious nodes resulting in less number of GTS left for allocation to legitimate nodes.

VII. CONCLUSION

This work addresses the compromised QoS due to anomaly created by malicious nodes in the communication medium of IEEE 802.15.4 standard. In this work, an Anomaly Detection Mechanism for IEEE 802.15.4 standard $ADM_{15.4}$ is proposed. The proposed scheme detects the different types of anomaly caused by malicious node attacks during the contention access period of the superframe structure of the standard. Furthermore, $ADM_{15.4}$ proposes a PLC-based mechanism to stop the interference caused by a malicious node by transmitting jamming signals to its nearby node. This causes an interruption in a specific region and nodes in that region are unable to communicate during the contention access period. To overcome their communication interruption, these nodes are allocated GTS to transmit their information to WPAN applying a 0/1 knapsack algorithm in such a way that maximum GTS requesting nodes are entertained. The simulation results show that the proposed scheme improves the data transmission of legitimate nodes by 122% and 30% as compared to the standard with and without attacks respectively. The transmission delay of legitimate GTS requesting nodes is also reduced by 58% and 3% as compared the standard with and without attacks and accommodates up to 24% and 110% more GTS requesting nodes to transmit their data during CFP period in the current superframe duration. The improved data transmission and reduced transmission delay makes the proposed scheme suitable for future IoT applications. In the future, we will explore methods to detect anomalies due to data integrity attacks and faulty IoT sensors.

Abstract—Detecting fake news on social media is a critical challenge due to its rapid dissemination and potential societal impact. This paper addresses the problem in a realistic scenario where the original tweet and the sequence of users who retweeted it, excluding any comment section, are available. We propose a Graph-based Attention for Coherent Explanation (GRACE) to perform binary classification by determining if the original tweet is false and provide interpretable explanations by highlighting suspicious users and key evidential words. GRACE integrates user behaviour, tweet content, and retweet propagation dynamics through Graph Convolutional Networks (GCNs) and a dual co-attention mechanism. Extensive experiments conducted on Twitter15 and Twitter16 datasets demonstrate that GRACE outperforms baseline methods, achieving an accuracy improvement of 2.12% on Twitter15 and 1.83% on Twitter16 compared to GCAN. Additionally, GRACE provides meaningful and coherent explanations, making it an effective and interpretable solution for fake news detection on social platforms.

Keywords—Graph neural network; dual attention; NLP; semantics; social network

I. INTRODUCTION

Social media has become integral to everyday life, allowing individuals to share their thoughts, stay updated on current events, and interact with others [1]. These platforms facilitate the fast flow of information across vast networks, where user interactions and feedback shape public opinions and emotions on various topics [2]. This easy and low-cost communication fosters collective intelligence, spreading ideas widely and quickly. However, the very features that make social media so powerful also have significant drawbacks [3]. The speed and reach of these platforms make it easier for misinformation to spread, often without proper checks or regulation [4]. As a result, while social media can be a tool for empowerment and connection, it also amplifies the risk of misinformation, posing challenges to truth and trust in public discourse.

Fake news consists of false stories that are intentionally shared on social media platforms [5]. Its spread can mislead the public opinion, leading to political, economic, or psychological benefits for specific groups [6]. Fake news circulation

manipulates opinions, distorts facts, and poses risks to society [7]. Research shows that people often struggle to differentiate between true and false news [8]. Interest in detecting fake news surged after the 2016 U.S. presidential election and COVID-19 vaccination drawing attention from researchers and social media platforms [9], [10], [11].

Detecting fake news is a complex task, primarily when relying solely on the content of news articles [12]. Traditional content-based methods often use features like n-grams and bag-of-words, applying supervised learning models such as random forests or SVM for binary classification [4], [13]. More advanced techniques in natural language processing (NLP) focus on extracting linguistic features like active/assertive verbs, subjectivity, and writing style [14]. Multi-modal approaches also integrate user-profiles and retweet propagation patterns [15]. However, these approaches face several challenges. Social media content, such as tweets, is usually short, leading to data sparsity, which makes it harder to detect fake news effectively [16]. Additionally, many models rely on user comments or retweets for evidence, but most users reshare stories without commenting, reducing the available data for analysis [17].

To address these challenges, researchers have begun focusing on propagation-based methods, which analyze the network of tweets and retweets to detect fake news [18], [19]. These methods are based on the idea that fake news spreads differently than true news. By studying the patterns of information diffusion, researchers can identify inconsistencies and spot fake stories [20]. However, many early approaches rely on static networks, assuming that the entire structure of information propagation is known before applying learning algorithms [21]. Social media networks are dynamic, with new users and content emerging over time, making static models less effective.

Recent research has shown that comprising temporary features, such as the timing of user interactions, can significantly improve fake news detection [22], [18]. For instance, in a temporal graph, the news propagation evolves, while a static graph only apprehends a snapshot of the network at one moment.

Fake and real news often show different temporal patterns, with fake news spreading more quickly or following distinct paths [23]. Regardless, treating these dynamic networks as if they were static limits the effectiveness of current models. To enhance detection, it's crucial to develop models that take into account the continuous changes in how users interact with each other. By doing so, these models can offer a more accurate and reliable way to tell the difference between real and fake news. These time-aware models would tap into the ever-evolving nature of social media. It makes them better equipped to detect misinformation in real-world situations.

This paper concentrates on detecting false content in the Twitter social media environment. The goal is to determine if a tweet is fake based solely on its brief text, the sequence of users who retweeted it, and their profiles. The detection process is approached with three key constraints: (a) analyzing the tweet's short text, (b) excluding user comments, and (c) not using network structures like social or diffusion networks. The model is designed to explain its predictions, meaning it should not only flag fake news but also show the reasoning behind the decision. Specifically, the model should highlight the doubtful users who helped to spread the fake news and identify the particular words or phrases from the source tweet that captured their attention.

Graph-based Attention for Coherent Explanation (GRACE) is proposed for fake news detection that integrates user behavior, tweet content, and retweet propagation dynamics. GRACE begins by feature extracting from user's Twitter profiles and encoding the original tweet's text using word embeddings [24]. A user interaction graph is constructed, and Graph Convolutional Networks (GCNs) [25] generate graph-aware representations of propagation dynamics. The relationship between the original tweet and how it spreads through retweets is identified by dual co-attention mechanism. It's helpful to highlight the users and keywords. By combining these features, GRACE offers an effective and easy-to-understand method for classifying fake news.

The key contributions of this paper are outlined as follows:

- 1) GRACE model is introduced to improve the understanding of user connection, retweet network, and their relationship with the short text of the source tweet.
- 2) Clear and meaningful explanations for the predictions are provided through the incorporation of a dual co-attention mechanism.
- 3) Comprehensive experiments are conducted on publicly available datasets that demonstrate the superior performance of GRACE as compared to baseline models.

This paper is structured as follows:

- Section II provides an overview of existing methods for fake news detection.
- Section III defines the problem and outlines the objectives addressed by the proposed model.
- Section IV details the experimental setup used in this study.

- Section V presents the evaluation metrics and results obtained.
- Finally, Section VI concludes the paper with a summary of findings and contributions.

II. LITERATURE REVIEW

Fake news, though not a new phenomenon, has acquired significant public awareness in recent years, primarily due to its widespread impact on society, politics, and media [26]. As the dissemination of false content continues to evolve, the literature on fake news detection has expanded rapidly, addressing the various challenges posed by this issue. Existing research can be broadly categorized into two main approaches: content-based and network-based methods. Content-based approaches focus on analyzing the textual data of news articles to identify linguistic, syntactic, and semantic features that distinguish fake news from legitimate news [27]. While, network-based methods focus on user's interactions and relationships within social media networks. They explore how news spreads across platforms and how user engagement patterns influence the dissemination of misinformation [21]. This section provides an overview of these two categories of fake news detection techniques and highlight the key developments, strengths, and limitations.

Content-based approaches focus on analyzing the textual data of news articles to evaluate their truthfulness. These methods are especially effective for long range dependencies, as they allow for a deep analysis of linguistic and semantic features to identify signs of misinformation [27]. One widely used technique is TF-IDF, which measures the importance of specific words within a news story [28]. Topic modeling helps to uncover the underlying themes in the content. It offers a structured and meaningful representation of the text [29]. Other linguistic features, such as PoS tags, assertive or factive verbs, and markers of subjectivity, are commonly used to detect subtle language patterns [24]. Further, techniques that assess writing consistency and social emotions are applied to highlight anomalies in news content [30]. The underlying assumption of these content-based methods is that fake news will exhibit detectable differences in linguistic structure, topic, or emotional tone compared to genuine news articles [31].

However, traditional content-based methods face several challenges in detecting fake news, mainly when relying on handcrafted linguistic cues [13]. These cues, such as lexical and syntactic features, are often limited in generalizability across different languages, topics, and domains. These techniques struggle to capture the complex semantic and contextual information embedded in modern news articles [3]. As news articles evolve in structure, content-based approaches that rely solely on traditional methods become less effective. As a result, researchers are increasingly turning to deep learning models to address these limitations [14]. The approaches like Recurrent Neural Networks (RNNs), Convolutional Neural Networks (CNNs), and Autoencoders [32] provide a solution by automatically learning hidden representations of text and capturing complex contextual patterns. These models eliminate the need for manually designed features and leverage word embeddings, such as word2vec, to enhance text representation and better identify patterns [33].

To make fake news detection more accurate, researchers have developed multi-modal models that combine different types of information, such as text and visuals, to improve their performance [15]. Visual elements like images and videos often play a significant role in how news is shared and perceived as credible. For instance, Bahad et al. introduced an RNN-based model that uses an attention mechanism to integrate text and visual information, allowing the system to focus on the most relevant features from both [34]. Similarly, Zhao et al. created a model that explores the relationship between text and visuals, which is especially effective in cases where misleading images are used to spread false claims [35].

To make detection systems more adaptable, researchers have also applied multi-task learning, enabling models to transfer knowledge across different types of content and better handle diverse contexts [36]. Since fake news evolves rapidly, new approaches like analyzing temporal patterns, adapting to specific domains, and leveraging weak supervision learning have been explored [37], [38], [10]. These innovations help detection systems stay scalable and flexible, allowing them to adapt to the ever-changing nature of misinformation. By combining these advancements, models are now better equipped to accurately and dynamically detect fake news in real-world scenarios.

Recent advancements in NLP have significantly improved the accuracy and reliability of content-based approaches. Transformer-based models [39], such as BERT (Bidirectional Encoder Representations from Transformers) [40] and GPT (Generative Pre-trained Transformer) [41], have revolutionized text representation and classification tasks by capturing contextual dependencies more effectively than traditional models. For instance, BERT has been fine-tuned for fake news detection by leveraging its bidirectional attention mechanism to understand subtle linguistic cues and context [42]. Similarly, GPT models have been employed to generate synthetic datasets for training effective classifiers and to analyze text for semantic coherence and logical consistency [35]. Hybrid models combining transformers with other neural architectures have also emerged. For example, a recent study integrated BERT with Graph Neural Networks (GNNs) to enhance performance by incorporating relationships between entities within news articles [43]. Other studies have focused on domain-specific adaptations of transformers, such as FakeBERT, which was trained on datasets tailored for misinformation detection [44]. These models not only outperform traditional approaches but also offer better generalization across domains and languages.

Network-based methods for detecting fake news focus on understanding how users interact with content on social media platforms [18]. Actions like commenting, retweeting, and following are critical to how information spreads and provide clues about the fake news propagation [19], [45]. By studying these patterns, researchers gained valuable insights into how to identify fake news and separate it from genuine content [46]. To model how news spreads, both homogeneous networks (where nodes and edges are similar) and heterogeneous networks (where they differ) are used [4].

Homogeneous networks, consisting of uniform nodes and edges, make it easier to study news spread within a unified structure [47]. A notable study by Chang et al. analysed the dispersal of false news on Twitter and found that false

news spreads faster, further, and more broadly than true news [19]. This observation highlights the accelerated nature of fake news diffusion. To enhance fake news detection, Huang et al. proposed a tree-structured RNN model that integrates textual features and propagation structure features [48]. Similarly, Gong et al. introduced a bi-directional GCN to learn representations of content semantics and diffusion structures [43].

In difference, heterogeneous networks consist of multiple nodes and edges, offering a more detailed representation of the relationships within the news ecosystem [49]. Kang et al. proposed a model that encodes semantic information and the global structure of the diffusion graph, incorporating posts, comments, and user interactions [50]. Huang et al. developed a meta-path-based heterogeneous graph attention network to capture the semantic relationships among text content in news propagation [48]. Additionally, Xie et al. enhanced the robustness of graph-based fake news detectors by modelling entities through a heterogeneous information network and utilizing graph adversarial learning to ensure more distinctive structural features [51]. Another significant advancement in heterogeneous network models was introduced by Nguyen et al. by developing Factual News Graph (FANG). This framework leverages social structures and user engagement patterns for effective fake news detection [44].

Network-based methods for fake news detection effectively handle multimodal data by leveraging the unique strengths of graph structures to integrate and process text and visual features. Jin et al. [52] proposed a Hierarchical Propagation Network that constructs a hierarchical graph where nodes represent multimodal features such as text embeddings, visual features, and user interactions. These nodes are interconnected through propagation layers that explicitly model the interplay between modalities, enabling a seamless integration of multimodal signals. Wang et al. [53] introduced a Multimodal Fusion Graph where text and image features are processed through graph attention layers, dynamically weighing their contributions to detect fake news. This method effectively links modalities by treating textual and visual embeddings as interconnected nodes in a unified graph. Shu et al. [54] utilized a Graph-based Multimodal Embedding framework, which creates a graph where text and image metadata are nodes, and the relationships between them (e.g. co-occurrence in news items) are edges. The GME approach ensures joint feature learning by allowing intermodal dependencies to be explicitly modeled and updated during training. Zhou et al. [55] extended this concept by employing knowledge-enhanced graphs, incorporating external knowledge from textual and visual data into the graph structure. Here, knowledge graph embeddings serve as additional nodes, creating a richer multimodal representation that enhances the interplay between modalities for accurate fake news detection. These approaches demonstrate how network-based methods construct and leverage graphs to unify and effectively process both modalities.

While these network-based models have shown promise, much previous work has focused on static networks. However, our research takes a dynamic approach by analyzing social media news within temporal diffusion networks, reflecting the continuous evolution of news propagation.

Approaches focusing on user behavior analyze the charac-

teristics of individuals who interact with news content, such as retweeting or commenting on stories. Yang et al. proposed extracting account-based features like the user's gender, hometown, and follower count [56]. Shu et al. found that user profiles associated with fake news differ significantly from those linked to legitimate news [4]. Liu et al. introduced a joint Recurrent and Convolutional Neural Network (CRNN) model that captures more detailed profiles of users, particularly those who retweet news stories [57]. In contrast, session-based heterogeneous graph embedding methods [51] rely on user session data to learn user traits but are not directly applicable to fake news detection.

III. MATERIALS AND METHODS

A. Preliminaries

Let $\mathcal{S} = \{\sigma_1, \sigma_2, \dots, \sigma_{|\mathcal{S}|}\}$ represent a collection of tweet stories, and $\mathcal{A} = \{\alpha_1, \alpha_2, \dots, \alpha_{|\mathcal{A}|}\}$ be a group of individuals (users) in the social media network. Each tweet story $\sigma_i \in \mathcal{S}$ is a short-text document, denoted by $\sigma_i = \{w_{i1}, w_{i2}, \dots, w_{il_i}\}$, where l_i is the number of words in the tweet story σ_i , and w_{ik} represents the k -th word in the story σ_i . Each user $\alpha_j \in \mathcal{A}$ is associated with a feature vector $\mathbf{v}_j \in \mathbb{R}^d$, where d is the dimensionality of the user's feature vector.

When a tweet story σ_i is shared, certain individuals will retweet it, forming a sequence of retweet records, referred to as the *retweet propagation path*. Let the propagation path of story σ_i be denoted by $\mathcal{P}_i = \{(\alpha_j, \mathbf{v}_j, t_j)\}$, where $(\alpha_j, \mathbf{v}_j, t_j)$ indicates that individual α_j with feature vector \mathbf{v}_j retweeted story σ_i at time t_j . Here, $j = 1, 2, \dots, K$, with $K = |\mathcal{P}_i|$ being the total number of retweets. The set of individuals who retweet story σ_i is denoted as $\mathcal{A}_i \subseteq \mathcal{A}$.

Within the propagation path \mathcal{P}_i , the individual α_1 is the original poster of story σ_i at time τ . For all subsequent individuals $j > 1$, individual α_j retweets the story at time τ_j , where $\tau_j > \tau_1$.

The tweet story σ_i is labeled with a binary value $\kappa_i \in \{0, 1\}$ to indicate its truthfulness, where:

$$\kappa_i = \begin{cases} 0 & \text{if the news } \sigma_i \text{ is true,} \\ 1 & \text{if the news } \sigma_i \text{ is fake.} \end{cases}$$

Given a tweet story σ_i and its corresponding propagation path \mathcal{P}_i (which includes individuals α_j who retweet the news and their associated feature vectors \mathbf{v}_j), the goal is to predict the authenticity κ_i of the story σ_i , a binary classification task.

The model should highlight a subset of individuals $\alpha_j \in \mathcal{A}_i$ who retweeted σ_i and a subset of words $w_{ik} \in \sigma_i$ that help to explain why σ_i is classified as either true or fake. This interpretability aspect is essential for understanding the reasoning behind the model's prediction.

B. Proposed Model

The GRACE model is developed to tackle the challenge of detecting fake news in social media networks by combining tweet content, user behavior, and the propagation dynamics of retweets. As depicted in Fig. 1, This model consists of several components including user characteristics extraction, news story encoding, user propagation representation, dual

co-attention mechanisms, and the final prediction layer. Each component is meticulously crafted to improve the model's ability to predict the truthfulness of a tweet while also providing interpretability by highlighting the users and words contributing to the classification.

The user characteristics extraction component involves creating a feature vector $\mathbf{x}_j \in \mathbb{R}^v$ for each user $u_j \in \mathcal{A}$, where v is the number of features. These features are derived from various aspects of a user's behavior, such as the number of followers, the number of retweets, the time difference between the tweet and retweet, and other profile-related information. This vector allows us to quantify how a user engages with content on social media, which is crucial for identifying fake news spreaders.

The source tweet σ_i is represented as a sequence of words, denoted by $\sigma_i = \{w_{i1}, w_{i2}, \dots, w_{il_i}\}$, where l_i is the number of words in tweet σ_i . We use a word-level encoder to represent this tweet. Each word w_{ik} in the tweet is initially encoded as a one-hot vector. A FC layer is applied to generate the word embeddings for each tweet, and the resulting embeddings are stored in a matrix $\mathbf{V} = [v_1, v_2, \dots, v_m] \in \mathbb{R}^{d \times m}$, where m is the length of the padded tweet and d is the dimensionality of the word embeddings.

To model the interactions among users who retweet the source tweet σ_i , we construct a graph $\mathcal{H}_i = (\mathcal{V}_i, \mathcal{F}_i)$, where \mathcal{V}_i represents the set of users who retweeted σ_i . The edges \mathcal{F}_i represent the interactions between users. Since the true interactions between users are unknown, we assume that the graph is fully connected. This implies that for every edge $e_{\alpha\beta} \in \mathcal{F}_i$, where $u_\alpha, u_\beta \in \mathcal{V}_i$ and $u_\alpha \neq u_\beta$, the number of edges is given by:

$$|\mathcal{F}_i| = \frac{n \cdot (n - 1)}{2} \quad (1)$$

where $n = |\mathcal{V}_i|$ is the number of users who retweeted σ_i .

To incorporate user features into the graph, we assign a weight w_{ab} to each edge $e_{ab} \in \mathcal{F}_i$, which is derived from the cosine similarity between the feature vectors \mathbf{u}_a and \mathbf{u}_b . The weight is calculated as:

$$w_{ab} = \frac{\mathbf{u}_a \cdot \mathbf{u}_b}{\|\mathbf{u}_a\| \|\mathbf{u}_b\|} \quad (2)$$

We use the adjacency matrix $\mathbf{W} = [w_{ab}] \in \mathbb{R}^{n \times n}$ to represent the weights between any pair of nodes v_a and v_b in the graph \mathcal{F}_i .

C. Graph Convolutional Network (GCN)

A Graph Convolutional Network (GCN) [25] is applied to propagate information through the graph \mathcal{F}_i . A GCN layer performs a convolution operation on the graph, updating node embeddings by aggregating information from their neighbors. For the graph \mathcal{F}_i , with adjacency matrix $\mathbf{\Pi}$ and feature matrix $\mathbf{\Lambda}$ representing user attributes in \mathcal{F}_i , the updated g -dimensional node feature matrix $\mathbf{\Omega}^{(l+1)} \in \mathbb{R}^{n \times g}$ at layer $l+1$ is calculated as:

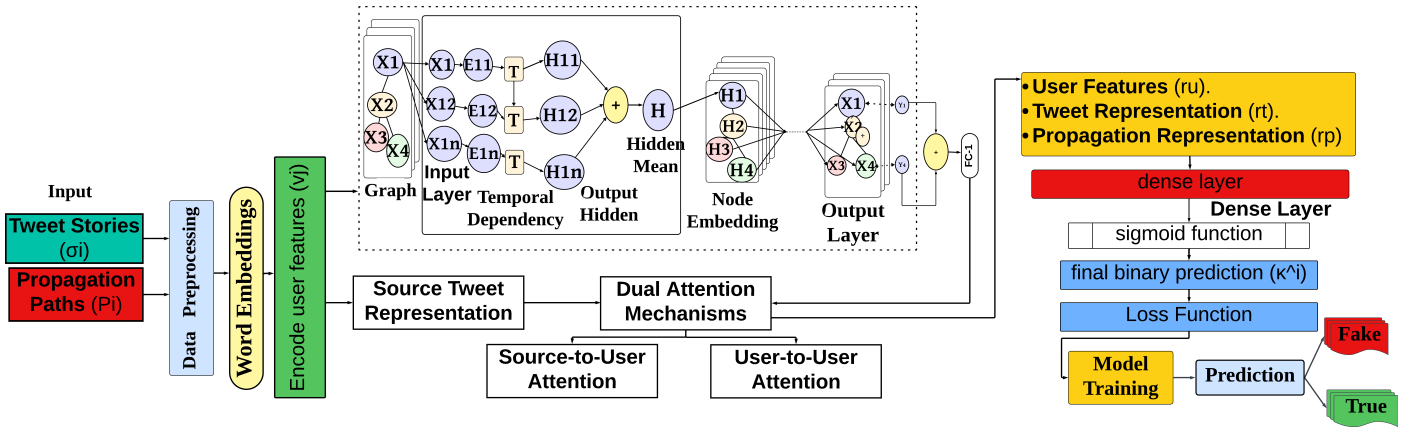

Fig. 1. The proposed model architecture diagram.

$$\Omega^{(l+1)} = \phi \left(\tilde{\Pi} \Omega^{(l)} \Gamma_l \right) \quad (3)$$

Here, $\tilde{\Pi} = \Sigma^{-1/2} \Pi \Sigma^{-1/2}$ represents the normalized adjacency matrix, Σ is the diagonal degree matrix, and ϕ is a non-linear activation function. This process is repeated iteratively over multiple layers, allowing information to propagate and be refined across the graph.

D. Co-attention Mechanisms

The correlation between the source tweet and users' interactions, including retweets, is captured using a dual co-attention mechanism. This mechanism simultaneously models the relationship between the source tweet and its retweets, as well as interactions between users within the propagation graph.

1) *Tweet-Retweet Correlation*: The first attention mechanism focuses on the relationship between the source tweet (\mathbf{Q}_σ) and the embeddings of retweets (\mathbf{Q}_u), which are derived from user propagation embeddings. The attention weights, representing the correlation between the content of the tweet and retweets, are computed as:

$$\mathbf{A}_\sigma = \text{softmax}(\mathbf{Q}_\sigma^T \mathbf{Q}_u) \quad (4)$$

These weights capture how strongly each retweet relates to the source tweet, refining both the source tweet and retweet representations for improved feature learning.

2) *User-User Correlation*: The second attention mechanism captures interactions between users by modeling the relationship between user embeddings across the propagation graph. This is achieved through:

$$\mathbf{A}_u = \text{softmax}(\mathbf{Q}_u^T \mathbf{Q}_u) \quad (5)$$

Here, the attention weights emphasize connections between users who share similar propagation behaviors, enabling the model to better understand the dynamics of retweet propagation.

By combining these two mechanisms, the model learns attention-driven representations that reflect the content and propagation dynamics of the source tweet and retweets. These

refined representations are used as inputs for the final prediction stage.

E. Final Prediction

The final prediction $\hat{\kappa}_i$ is obtained by combining the learned user features, source tweet embeddings, and propagation representations. The concatenated vector is passed through a fully connected layer with a sigmoid activation, producing a probability between 0 and 1 that represents the likelihood of the source tweet σ_i being fake. This process can be expressed as:

$$\hat{\kappa}_i = \sigma(\mathbf{W}_f \cdot [\mathbf{r}_u, \mathbf{r}_t, \mathbf{r}_p] + b_f) \quad (6)$$

where \mathbf{r}_u is the learned representation of user characteristics, \mathbf{r}_t is the learned embedding of the source tweet, and \mathbf{r}_p is the learned propagation representation of the users. The vector $[\mathbf{r}_u, \mathbf{r}_t, \mathbf{r}_p]$ is the concatenation of these representations, \mathbf{W}_f is the weight matrix, and b_f is the bias term. The sigmoid function $\sigma(\cdot)$ is applied to ensure that the output is a probability between 0 and 1.

F. Loss Function

The binary cross-entropy loss function is used for model training. It measures the difference between the predicted probability $\hat{\kappa}_i$ and the true label κ_i :

$$\mathcal{L}(\hat{\kappa}_i, \kappa_i) = -\kappa_i \log(\hat{\kappa}_i) - (1 - \kappa_i) \log(1 - \hat{\kappa}_i) \quad (7)$$

The loss function is minimized using the Adam optimizer, ensuring that the model's parameters are updated to reduce the classification error over time. The optimization process helps the model improve its predictions by adjusting weights, thereby minimizing the loss and enhancing the performance of the fake news detection system.

Algorithm 1 GRACE (Graph-based Attention for Coherent Explanation)

Input: Tweet stories $\mathcal{S} = \{\sigma_1, \dots, \sigma_{|\mathcal{S}|}\}$, user profiles \mathcal{A} , propagation paths \mathcal{P}_i , truthfulness labels κ_i .

Output: Predicted labels $\hat{\kappa}_i$ and explanation (highlighted users α_j and words w_{ik}).

1: **Initialize:** Pre-trained word embeddings, user feature vectors \mathbf{v}_j , graph adjacency matrices \mathbf{A} , and model parameters.

2: **for** each tweet $\sigma_i \in \mathcal{S}$ **do**

3: Encode tweet σ_i as word embeddings $\mathbf{V} \in \mathbb{R}^{d \times m}$.

4: Extract user feature vectors $\mathbf{v}_j \in \mathbb{R}^d$ for users in \mathcal{P}_i .

5: Construct a graph $\mathcal{H}_i = (\mathcal{V}_i, \mathcal{F}_i)$:

6: **for** each pair of users $(\alpha_\alpha, \alpha_\beta) \in \mathcal{V}_i$ **do**

7: **if** users are connected **then**

8: Compute edge weight:

$$\omega_{\alpha\beta} = \frac{\mathbf{x}_\alpha \cdot \mathbf{x}_\beta}{\|\mathbf{x}_\alpha\| \|\mathbf{x}_\beta\|}.$$

9: **end if**

10: **end for**

11: Apply GCN to propagate embeddings over \mathcal{H}_i :

$$\mathbf{H}^{(l+1)} = \rho \left(\mathbf{A} \tilde{\mathbf{H}}^{(l)} \mathbf{W}_l \right),$$

where ρ is a non-linear activation function.

12: Compute dual co-attention:

13: Source-to-user attention:

$$\mathbf{A}_\sigma = \text{softmax}(\mathbf{Q}_\sigma^T \mathbf{Q}_u).$$

14: User-to-user attention:

$$\mathbf{A}_u = \text{softmax}(\mathbf{Q}_u^T \mathbf{Q}_u).$$

15: Concatenate learned embeddings \mathbf{r}_u , \mathbf{r}_t , and \mathbf{r}_p :

$$\mathbf{r} = [\mathbf{r}_u, \mathbf{r}_t, \mathbf{r}_p].$$

16: Predict truthfulness:

$$\hat{\kappa}_i = \sigma(\mathbf{W}_f \cdot \mathbf{r} + b_f).$$

17: Highlight key users α_j and words w_{ik} based on \mathbf{A}_σ and \mathbf{A}_u .

18: **end for**

19: Optimize model parameters by minimizing the binary cross-entropy loss:

$$\mathcal{L}(\hat{\kappa}_i, \kappa_i) = -\kappa_i \log(\hat{\kappa}_i) - (1 - \kappa_i) \log(1 - \hat{\kappa}_i).$$

IV. EXPERIMENTAL SETUP

The GRACE model is implemented using the PyTorch framework. The tweet text is represented using pre-trained word embeddings. Each word in the tweet is mapped to its corresponding vector representation. These embeddings help transform the raw text into a meaningful numerical format suitable for further processing. GCN layers capture the interactions among users who retweet the source tweet. The graph represents users as nodes, and the interactions between users (such as retweeting) form the edges. Each node's feature vector is updated based on its neighbours, allowing the model to learn user-specific representations in the context of retweet propagation. The number of GCN layers is set to 3, with each layer processing information from the node's direct and indirect neighbours. These features are concatenated after obtaining the embeddings from the tweet content, user characteristics, and user propagation representations. The concatenated vector is passed through fully connected (dense) layers to make the final classification decision. The hidden layers in the fully connected section use ReLU activation, while the output layer employs a sigmoid activation function to predict the probability of a fake

tweet.

A. Hyperparameters

The proposed model is designed with several key hyperparameters that allow for efficient and effective training as described in Table I. A learning rate of 0.001 was selected after a grid search of several potential values. This choice balances convergence speed and stability, ensuring that the model trains effectively without overshooting the optimal solution. The batch size was set to 64, a commonly used value in graph-based models like GCNs. A batch size of this allows for efficient computation and good convergence properties while maintaining memory efficiency during training.

The model architecture is developed with three GCN layers, which strike a balance between capturing the interactions within the retweet network and avoiding overfitting caused by excessive depth. Each GCN layer contains 128 hidden units, which are sufficient to learn rich user interaction features without making the model too large and prone to overfitting. A dropout rate of 0.3 is applied to mitigate overfitting, meaning

30% of the neurons are randomly dropped during training, helping the model avoid reliance on specific features.

Following the GCN layers, fully connected (FC) layers were added with 256 hidden units to combine and process features from tweet content, user characteristics, and propagation patterns. To reduce overfitting in these layers, a higher dropout rate of 0.5 was applied, randomly dropping 50% of the neurons during training to improve generalization.

ReLU activation is used throughout the hidden layers to introduce non-linearity, enabling the model to learn more complex patterns and decision boundaries effectively. The output layer uses the sigmoid activation function, which maps the final output to a probability between 0 and 1. This value is interpreted as the likelihood that a given tweet is fake. The Adam optimizer was chosen for optimisation, known for its efficiency in handling sparse gradients and large datasets. The binary cross-entropy loss function was used as the loss criterion, as it is well-suited for binary classification tasks like fake news detection. The model was trained for 20 epochs, which is sufficient for convergence without overfitting. These hyperparameters were carefully chosen to ensure the model performs well on the fake news detection task, balancing model complexity, training efficiency, and the ability to generalize to unseen data.

TABLE I. HYPERPARAMETERS FOR GCAN MODEL

Hyperparameter	Value
Learning Rate	0.001
Batch Size	64
GCN's Layers	3
Hidden Units	128
Dropout Rate	0.3
Hidden Units in FC Layers	256
Dropout Rate (FC layers)	0.5

Activation Function (Output)	Sigmoid
Optimizer	Adam
Loss Function	Binary Cross-Entropy
Epochs	20

B. Datasets

This study utilizes two widely used datasets, Twitter15 and Twitter16, compiled by Ma et al. [58], which are recognized benchmarks in the field of fake news detection. These datasets provide a comprehensive basis for evaluating propagation-based modeling approaches, as they include tweets along with the corresponding sequences of retweeting users, which are essential for capturing propagation dynamics.

The Twitter15 dataset includes 1,490 claims, while Twitter16 contains 818 claims. Both datasets are annotated with four ground truth veracity labels: True News (T), Fake News (F), Non-Fake News (NF), and Unverified News (U). For our binary classification experiments, we focus only on True News (T) and Fake News (F) labels, aligning with the scope of our study.

These datasets are particularly suitable for evaluating our proposed model as they include rich propagation structures that allow us to assess the effectiveness of graph-based approaches. Additionally, they represent real-world social media interactions, offering realistic challenges and scenarios for fake news detection.

To enrich the data, we collected user profile information using the Twitter API, as the original datasets do not include user profiles. This additional data allows us to incorporate user-specific features, such as activity patterns and engagement metrics, which are crucial for analyzing user behavior in the context of fake news propagation.

The datasets are divided into three parts: 70% for training, 15% for testing, and 15% for validation. This ensures a balanced and rigorous evaluation of the model. Table II and Fig. 2 provide a summary of the key statistics and label distributions, illustrating the diversity and scale of the datasets.

These choices ensure that our approach is validated against reliable, well-established benchmarks, offering a fair comparison with prior works and a robust demonstration of the proposed model's effectiveness.

TABLE II. DATASET STATISTICS

Feature	Twitter15	Twitter16
Total Claims	1,490	818
True News (T)	370	205
Fake News (F)	374	204
Non-Fake News (NF)	374	203
Unverified News (U)	372	206
Total Postings	331,612	204,820
Users	190,868	115,036
Avg. Retweets per Story	292.19	308.70
Avg. Words per Source	13.25	12.81
# Total Nodes	912,638	501,032
# Total Edges	697,523	382,936

C. Evaluation Metrics

To assess the proposed model's performance for fake news detection, we use several key metrics that provide insights into its effectiveness. These metrics include Accuracy, Precision, Recall, F1 Score, and the Area Under the Receiver Operating Characteristic Curve (AUC).

Accuracy is the most straightforward metric, measuring the overall correctness of the model across all predictions. It is the ratio of correct predictions to the total number of predictions. **Precision** evaluates the proportion of positive predictions (predicted fake news) that are actually correct. A high Precision indicates that the model is accurate when it predicts fake news. **Recall** focuses on the model's ability to capture all actual positive instances (actual fake news). It is the ratio of true positives to the sum of true positives and false negatives. A high Recall means that the model successfully identifies most of the true fake news instances. **F1 Score** is the

harmonic mean of Precision and Recall. It provides a balanced measure and offers a single number that evaluates the model's performance in relevance and completeness.

V. RESULTS

Results are reported in Table III. The GRACE model demonstrated notable accuracy and F1 score improvements across the Twitter15 and Twitter16 datasets. The F1 score increased by 2.42% from baseline models, reaches at 84.50, while accuracy improved by 2.08%, achieving 89.50 on the Twitter15 dataset. On the Twitter16 dataset, the F1 score saw a 2.07% improvement, reaching 77.50, and accuracy increased by 1.83%, reaching 92.50. On average, the GRACE model showed a 2.24% improvement in F1 score and a 1.95% improvement in accuracy across both datasets. These results reflect the model's consistent enhancement in both key performance metrics. The GRACE model's improvements indicate its strong capacity to achieve higher classification precision and accuracy than baseline models, showcasing its ability to generalize well across different datasets. The bigger improvements in Twitter15 suggest the model's adaptability in handling diverse data characteristics, while its solid performance in Twitter16 further emphasizes its robustness in real-world, noisy data scenarios.

A. Baseline Models

The proposed model is compared with several baseline methods on the Twitter15 and Twitter16 datasets, as shown in Table III. The GCAN (Graph-aware Co-attention Network) predicts fake news by considering the original tweet and its propagation, with a variant, GCAN-G, which excludes the graph convolution component to evaluate the effectiveness of graph-aware representations [21]. SVM-TS combines a Support Vector Machine with heuristic rules and a time-series structure to classify posts as fake or real, leveraging hand-crafted features. While effective initially, deep learning models now outperform traditional approaches due to superior feature extraction capabilities [59]. DTC is a rumor detection method that uses a Decision Tree classifier and leverages various hand-crafted features to evaluate information credibility [60]. It focuses on extracting and analyzing features related to content, user behavior, and network interactions to improve detection accuracy. CRNN, a deep residual network, integrates four cascading graph convolutional networks to capture long-range dependencies and nonlinear features effectively [61]. RFC is a ranking method based on Random Forest that refines and elaborates the inquiry phrases within posts. By leveraging this approach, it aims to enhance the analysis and prioritization of relevant information [62]. dDEFEND represents tweet contents and interaction graphs in a latent space, capturing multi-level features of fake news through claim-aware and inference-based attention mechanisms [63]. The CSI model stands out as an advanced fake news detection model that integrates both article content and the collective behaviour of users propagating fake news [64]. This model uses LSTM to capture sequential dependencies and computes user-specific scores to evaluate the likelihood of a tweet being fake. The tCNN model introduces a modified Convolutional Neural Network (CNN) to learn local variations in user profile sequences, combining them with features from the source tweet [65]. This approach

effectively captures intricate variations in user behaviour. The CRNN merges CNN and RNN to learn local and global user profile variations [66]. This hybrid technique enables the model to capture temporal and spatial dependencies in retweet propagation. mGRU is a modified gated recurrent unit (GRU) model designed for rumor detection. It captures temporal patterns by leveraging retweet user profiles in combination with the source tweet's features [58].

The confusion matrices are presented in Fig. 3. These metrics show the model's performance in classifying news across multiple categories. For the Twitter15 dataset, the model correctly identifies True News, with 109 instances accurately classified, while only four are misclassified as False News and seven as Unverified News. This indicates the model's proficiency in distinguishing authentic information. The model successfully classifies 36 instances for False News, with minimal misclassifications (6 as True News and one as Unverified News). In Twitter16 dataset, The model accurately identifies True News, classifying 56 instances correctly, while only three are misclassified as False News and four as Unverified News. It also performs well in detecting False News, correctly classifying 23 instances, with just a few misclassifications (2 instances each into True News and Unverified News). The

Fig. 3. Confusion matrices for Twitter15, Twitter16 on test dataset.

differences in classification accuracy across these two datasets can be attributed to the varying complexity of the classification tasks. While both datasets include multiple categories, the Twitter15 and Twitter16 datasets introduce the additional challenge of distinguishing Unverified News from True and False News, resulting in a higher degree of misclassification, especially between False News and Unverified News, which share similar content characteristics. These results underscore the model's adaptability in handling both binary and multi-class classification challenges, demonstrating its effectiveness across diverse datasets.

The performance of the proposed model is evaluated in terms of accuracy in Fig. 4 for early detection. It is analyzed under varying conditions by altering the number of observed retweet users per source story, ranging from 10 to 50. The results demonstrate that GRACE consistently and significantly outperforms all competing methods across all scenarios. Despite as few as 10 observed retweeters, GRACE achieves an impressive 82% accuracy on Twitter16, underscoring its robustness and reliability. These findings highlight GRACE's capability to deliver accurate and early detection of fake news dissemination, which is critical for effectively combating misinformation and mitigating its impact.

We assess the effectiveness of proposed approach and baseline models for early stage fake news detection. Early

TABLE III. COMPARISON OF PROPOSED MODEL WITH BASELINE AND STATE-OF-THE-ART MODELS ON TWITTER15 AND TWITTER16 DATASETS

Method	Twitter15				Twitter16

Fig. 4. Accuracy over retweet users on Twitter15 and Twitter16 datasets.

identification of fake news is essential to curbing its spread and minimizing its harmful societal impacts. For this evaluation, we use a specific tweet’s propagation time or initial release time within a news event as the detection deadline. Tweets posted beyond this deadline are excluded from consideration. To compare the performance of various detection methods, we vary the detection time points within a specific range and analyze their performance.

Fig. 5 presents the accuracy of all methods at different time intervals across three datasets. The results indicate that

GRACE consistently performs better than baseline models in early-stage fake news detection. Across all datasets, the accuracy of all methods improves rapidly during the early stages of information diffusion. Notably, our model exhibits a distinct performance advantage as the propagation progresses, demonstrating its ability to sustain high accuracy over time and effectively adapt to the dynamics of fake news dissemination.

Fig. 5. (a) Early detection of fake news on Twitter15; (b) early detection of fake news on Twitter16.

The source-propagation co-attention mechanism embedded in our proposed model offers meaningful insights into identifying the characteristics of suspicious users and the linguistic cues they emphasize during the spread of information. As Fig. 6 demonstrates, the model highlights several distinct traits commonly associated with suspicious retweeters. These

include unverified accounts, newly created profiles with shorter account lifespans, minimal user descriptions, and shorter graph path lengths connecting them to the source tweet’s author.

Moreover, the analysis reveals that these users focus disproportionately on specific words, such as “breaking” and “pipeline,” often used in sensationalized or misleading content. By leveraging these observations, the model enhances its ability to detect fake news and provides interpretability by uncovering suspicious accounts’ behavioural patterns and language preferences. Such explainability is crucial for understanding the underlying mechanisms of fake news dissemination and developing strategies to mitigate its spread effectively.

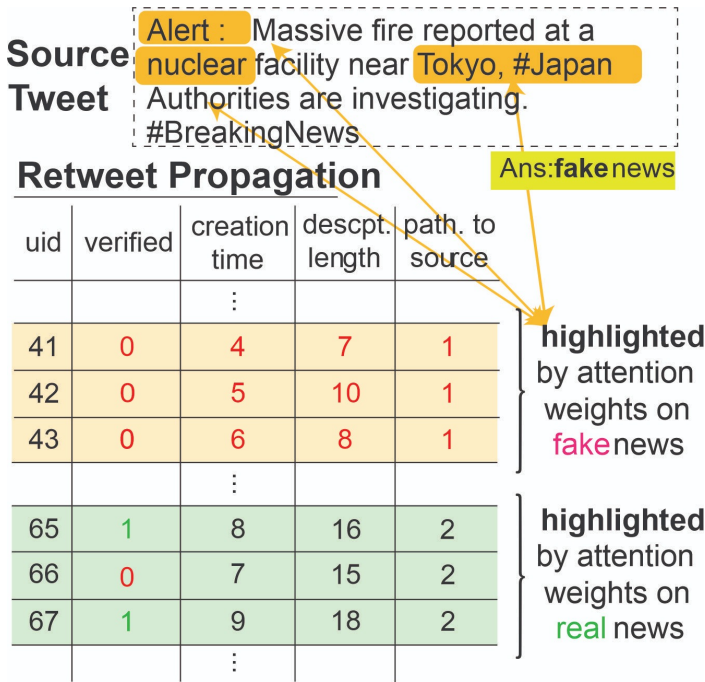

Fig. 6. Key evidential words identified by the GRACE model in the source tweet (top) and suspicious users flagged during the retweet propagation process (bottom). Each column corresponds to a specific user characteristic, providing deeper insights into user behaviours. For simplicity, only a select number of user characteristics are presented.

B. Ablation Study

The ablation study is conducted in Table IV. It highlights the significance of each component in the proposed model. Removing the dual co-attention mechanism (“-A”) leads to a noticeable drop in performance, which underscores its role in linking tweet content with user interactions and propagation dynamics. Excluding the graph-aware representation (“-G”) also affects the model’s accuracy, as it captures the structural relationships between users in the retweet network. Similarly, removing the user characteristics module (“-U”), which captures behavioural patterns like account age and retweet frequency, significantly reduces the model’s ability to detect suspicious users. The absence of source tweet embeddings (“-S”) results in a substantial decline, showing the importance of semantic content in distinguishing fake news. The most severe performance degradation occurs when the source tweet embeddings and dual co-attention mechanism are removed (“-S-A”),

demonstrating that integrating content-based and interaction-based features is crucial for achieving high accuracy. These results confirm that each component contributes meaningfully to the overall effectiveness of the GRACE model.

C. Discussion

The findings from our study highlight the robustness and interpretability of the GRACE model in detecting fake news across various datasets and scenarios. By leveraging multiple data modalities [58], such as user characteristics, tweet content, and propagation dynamics, GRACE achieves superior performance compared to existing baseline models. This discussion contextualizes these results, explores their implications, and addresses the model’s broader applicability and potential limitations.

One of the most significant insights from our work is the importance of integrating user behavior and propagation dynamics into fake news detection. Traditional models often focus solely on tweet content, neglecting the behavioral and relational cues that can provide essential context [36], [54]. GRACE fills this gap by incorporating graph-aware propagation modeling and user embedding representation, which allows it to capture the underlying social dynamics in retweet propagation. This synergy between components is evident from our ablation study, where removing key elements, such as the dual co-attention mechanism or graph-based user representations, led to noticeable drops in performance.

The results also reveal GRACE’s adaptability in both the early and advanced stages of fake news propagation. For instance, GRACE’s ability to maintain high accuracy with limited early-stage data (e.g. as few as 10 retweeters) underscores its potential for real-time applications. This early detection capability is crucial for mitigating the spread of misinformation, as even a small delay in identification can result in widespread dissemination and societal harm.

Another strength of GRACE lies in its explainability. The co-attention mechanism enables the model to highlight the specific words in tweets and user behaviors contributing to its predictions. For instance, the model identified linguistic patterns, such as emotionally charged words like “breaking”, and behavioural traits, including unverified accounts and recently created profiles, as key indicators of suspicious activity. This interpretability is vital for building trust with end-users, particularly in applications where automated decisions must be transparent and defensible.

Understanding the characteristics of suspicious users and the propagation patterns of fake news provides actionable insights for social media platforms and policymakers. By identifying high-risk accounts and content early, GRACE can assist in designing targeted interventions, such as flagging or debunking misleading posts before they gain significant traction.

D. Limitation and Future Work

While GRACE demonstrates strong performance and interpretability, it is not without limitations. One of the primary challenges is the reliance on user interaction data to build propagation graphs. The model’s effectiveness could

TABLE IV. ABLATION STUDY RESULTS OF GRACE ON TWITTER15 AND TWITTER16 DATASETS

Method	Twitter15				Twitter16			
	F1	Rec	Precision	Accuracy	F1	Recall	Precision	Accuracy
Full Model	84.17	84.95	84.74	89.53	77.51	78.09	77.73	79.11
-A	81.45	82.13	80.97	87.12	74.89	75.12	74.45	76.45
-G	82.03	82.67	81.45	87.67	75.43	75.87	75.01	77.02
-U	80.12	80.89	79.68	85.34	73.25	73.98	72.87	74.34
-S	78.65	79.02	78.30	83.21	72.11	72.56	71.43	72.89
-S-A	75.34	75.89	74.12	80.78	70.34	70.92	69.87	71.21

be reduced if user data is incomplete or anonymized due to privacy concerns. Additionally, while GRACE assumes a fully connected graph without explicit user relationships, this assumption may not always reflect real-world interactions, potentially leading to inaccuracies in propagation modelling. Future work could explore incorporating more advanced graph representation techniques, such as dynamic graph neural networks, to better model evolving user interactions over time to enhance GRACE further. Additionally, leveraging external knowledge bases or fact-checking databases could improve the model's ability to validate content credibility, particularly for previously unseen news stories. Finally, expanding GRACE to handle multilingual content and adapting it to different cultural contexts would increase its applicability on a global scale.

VI. CONCLUSION

In this study, we introduced Graph-based Attention for Coherent Explanation (GRACE) approach for detecting fake news on social media platforms. GRACE addresses the complex and dynamic nature of misinformation by leveraging tweet content, user behaviour, and retweet propagation dynamics, making it capable of identifying fake news with high accuracy and interpretability. Unlike traditional methods, GRACE operates in a more realistic and challenging setting by focusing on short-text tweets and their retweeter sequences, closely aligning with the real-world propagation of misinformation. The evaluation results underscore GRACE's robustness and effectiveness, demonstrating its ability to deliver accurate predictions while maintaining explainability through its co-attention mechanism. Notably, GRACE excels in early-stage detection, achieving satisfying performance even with limited propagation data. This early detection capability is critical for minimizing the spread of misinformation and reducing its societal impact.

Beyond fake news detection, GRACE has broader applications for other short length text classification tasks in social media, such as sentiment analysis and tweet popularity prediction. Its flexible and modular design makes it a promising candidate for addressing various social media challenges. Future work will enhance the model's generalization capabilities to accommodate different platforms and contexts.

Intelligent Fault Diagnosis for Elevators Using Temporal Adaptive Fault Network

Zhiyu Chen

School of Electrical Engineering, Hunan Vocational and Technical College of Mechanical and Electrical Engineering,
Changsha 410151, Hunan, China

Abstract—Contemporary cities depend on elevators for vertical mobility in residential, commercial, and industrial buildings. However, elevator system malfunctions may cause operational interruptions, economic losses, and safety dangers, requiring advanced tools for detection. High-dimensional sensor data, temporal interdependence, and fault dataset imbalances are common problems in fault detection algorithms. These restrictions reduce fault diagnostic accuracy and reliability, especially in real-time applications. This paper presents a Temporal Adaptive Fault Network (TAFN) to overcome these issues. The system uses Temporal Convolution Layers to capture sequential dependencies, Adaptive Feature Refinement Layers to dynamically improve feature relevance, and a Fault Decision Head for correct classification. For reliable performance, the Weighted Divergence Analyzer and innovative data processing methods are used for feature selection. Experimental findings show that the TAFN model outperforms state-of-the-art fault classification approaches with an F1-score of 98.5% and an AUC of 99.3%. The model's capacity to handle unbalanced datasets and complicated temporal patterns makes it useful in real life. The paper also proposes the Fault Temporal Sensitivity Index (FTSI) to assess fault prediction temporal consistency. The results demonstrate that TAFN may revolutionize elevator problem detection, improving reliability, downtime, and safety. This technique advances predictive maintenance tactics for critical infrastructure.

Keywords—Elevator fault diagnosis; temporal adaptive fault network; predictive maintenance; multivariate time-series data; feature refinement; fault classification

I. INTRODUCTION

Modern elevators provide adequate vertical mobility in residential, commercial, and industrial contexts. Elevator dependability and safety are crucial since malfunctions may cause operational interruptions, economic losses, and safety dangers [1]. Effective defect identification and diagnosis are necessary for good performance. Traditional maintenance solutions, including reactive repairs or periodic preventive maintenance, may not handle unexpected failures, resulting in increased downtime and expenses [2]. Advancements in sensor technology and IoT enable contemporary elevators to generate significant amounts of data by continually monitoring operating characteristics [3]. Big data has enabled predictive maintenance tactics, detecting defects before they cause substantial failures [4]. Predictive maintenance reduces downtime and maintenance costs by evaluating real-time data to detect possible faults [5].

Machine learning (ML) and deep learning (DL) are effective methods for processing complicated, high-dimensional data, making them ideal for elevator fault diagnostics [6]. These methods learn patterns and correlations from historical

and real-time operational data to classify and forecast faults. Research suggests that ML models like SVM, decision trees, and random forests outperform rule-based methods for elevator failure detection [7]. DL architectures, such as CNN and RNN, have been used to analyze elevator operating data for spatial and temporal trends [8]. Feature selection is another issue. Elevator datasets include several characteristics with different fault diagnostic importance. Key characteristics must be identified and prioritized to improve model accuracy and efficiency [9]. To account for the temporal character of elevator data, models must capture sequential relationships and changing patterns [10], [11].

Recent research investigates hybrid methods combining feature engineering, sophisticated DL architectures, and data balancing strategies to address difficulties [12], [13]. These methods address dataset imbalances, optimize feature representations, and use elevator operating temporal features to enhance problem identification. Researchers have used temporal convolutional networks (TCN) and attention processes to get top-notch defect prediction results [9], [14]. Elevator fault diagnostic research may improve operational dependability and safety. Predictive maintenance solutions may improve elevator operations by detecting and fixing faults early using ML, DL, and IoT technology. However, dataset imbalance, feature selection, and elevator dynamics make finding fault diagnostic models difficult. To overcome these constraints, this paper presents the Temporal Adaptive Fault Network (TAFN), a deep learning architecture for elevator fault detection. Temporal Convolutional Layers (TCL) capture sequential dependencies, and Adaptive Feature Refinement Layers (AFRL) dynamically highlight the most essential features of TAFN. These new processes, a balanced dataset, and appropriate feature selection with the Weighted Divergence Analyzer help TAFN overcome data imbalance, feature importance, and temporal complexity. This methodology improves elevator predictive maintenance, safety, dependability, and efficiency.

1) *The Proposed temporal adaptive:* Fault Network solves high-dimensional, multivariate time-series data classification problems. The model captures sequential relationships and emphasizes the most important features by merging Temporal Convolution Layers (TCL) and Adaptive Feature Refinement Layers (AFRL), ensuring reliable fault classification in complicated operational datasets.

2) *Mitigating fault diagnosis class imbalance:* Gradient-Space Augmentation (GSA) addresses unbalanced fault datasets with under-represented fault categories. This unique technique interpolates inside a regulated gradient space to create minority-class synthetic samples, assuring balanced data

distribution and increasing model generalization across all fault categories.

3) *Ideal feature selection for accuracy enhancement:*

The Weighted Divergence analyzer addresses irrelevant or duplicated features impacting fault identification. This feature selection technique uses statistical divergence and temporal consistency to discover and prioritize the most important features, improving classification accuracy and decreasing processing costs.

4) *Temporal dependency modelling:*

Traditional approaches miss long-term dependencies in sequential data, resulting in poor fault identification. The Temporal Convolution Layers of the proposed TAFN use dilated convolutional kernels to capture short- and long-term relationships. This reliably detects transient and persistent fault patterns.

5) *The proposed architecture:*

reduces lift system operating complexity, safety hazards, and downtime by improving fault detection. The research addresses significant intelligent infrastructure demands by reducing operating interruptions and improving lift system safety and reliability with predictive maintenance and real-time fault detection.

The article's structure: Section II examines lift fault diagnostic literature to highlight advances and concerns. Section III describes the Temporal Adaptive Fault Network (TAFN) proposed architecture, feature engineering approaches, and data pretreatment techniques. Section IV simulations show the model's classification, comparison analysis, and assessment metrics, proving its fault detection effectiveness. Section V wraps up the research and examines ways to improve the framework's flexibility and scalability for intelligent fault diagnostics in critical infrastructure systems.

II. RELATED WORK

Through improved diagnostics, elevator fault detection has been studied to improve dependability, save maintenance costs, and maintain safety. Researchers have employed statistical models, machine learning, and deep learning. This research covers large-scale sensor data, unbalanced datasets, and fault classification accuracy. To comprehend elevator fault detection research, the following section discusses significant contributions, their goals, methods, results, and limitations.

ResNet was used to improve fault detection in elevator systems in [15]. The model grasped complex fault patterns in high-dimensional sensor data using deep residual learning. ResNet improved fault classification accuracy by reducing vanishing gradient concerns. The model needed enormous datasets and computer resources for efficient training, limiting its scalability. The authors in [16] used Decision Trees with ensemble approaches like AdaBoost to classify faults. This method aggregated decision routes to increase detection accuracy. The model performed well on unbalanced datasets, but overfitting in complicated settings reduced its generalizability. The study [17] used Deep Belief Networks (DBNs) to mimic elevator operations. DBNs identified tiny fault signs from noisy data using hierarchical feature extraction. The approach had good fault detection accuracy but was computationally costly and needed professional adjustment.

Naive Bayes was employed in [18] to accomplish probabilistic fault classification. Simple Naive Bayes enabled real-time fault detection due to its computational efficiency. However, feature independence hindered its capacity to predict linked data, reducing accuracy for complicated elevator systems. The study in [19] analyzed sequential fault data using Markov n-grams. Our strategy identified temporal relationships by simulating fault occurrences as probabilistic state transitions. Markov n-grams identified recurrent fault patterns but struggled with uncommon failures owing to transition data shortages.

In [20], VGG16, a deep convolutional neural network, classified elevator faults. Hierarchical feature extraction allowed sophisticated fault detection. VGG16's computational load and overfitting on small datasets made real-world applications difficult. The [21] research used SVMs for fault detection. The kernel-based SVM method differentiated normal and defective states in high-dimensional feature fields. SVM was accurate, but computational cost rose exponentially with sample count, making it unscalable with massive datasets. In [22], CNNs were employed to evaluate spatial patterns in elevator sensor data. Being able to capture local dependencies gave the model great fault detection accuracy. Temporal dependencies, essential for sequential elevator fault detection, were complicated to represent using CNNs. [23] used a hybrid technique combining feature engineering and Naive Bayes for effective fault detection. Integrating domain-specific characteristics with a probabilistic framework enhanced model accuracy and decreased false positives. However, its expert-crafted characteristics hampered its adaptation to new fault circumstances.

According to [24], Markov n-grams may effectively capture sequential dependencies in elevator fault data. The model needed adequate data for correct state transition probabilities. Thus, it struggled with uncommon occurrences yet revealed recurrent fault patterns. In [25], DBNs were used for hierarchical feature extraction in fault diagnostics. Learning latent feature representations increased complicated fault detection. Due to computational requirements, the approach was hard to scale. The work in [26] created a hybrid fault detection model using CNN and RNN layers. CNNs looked at spatial relationships, and RNNs studied temporal patterns. Although it increased model complexity and training time, this combination improved fault classification performance. Graph convolutional networks (GCNs) were used to assess elevator data representations in [27]. High fault detection accuracy was achieved by modeling sensor data structural relationships. Data preprocessing into graph formats complicated the operation. The author in [28] implemented Naive Bayes and spectral analysis for fault detection. The model classified faults reliably using frequency-domain insights and probabilistic reasoning. Vibration data noise might negatively impact spectral feature accuracy. Table I summarizes related work.

Despite advances in elevator problem diagnostics, present approaches have major shortcomings that make them unsuitable for real-world applications. Due to the sequential structure of elevator defect data, SVMs and decision trees generally fail to grasp temporal relationships needed for successful diagnosis. CNNs excel in spatial feature extraction but struggle to understand multivariate time-series data's long-term

TABLE I. LITERATURE REVIEW SUMMARY

Ref	Technique Used	Objective Achieved	Limitations
[15]	ResNet	Enhanced fault detection by capturing intricate patterns in high-dimensional sensor data, mitigating vanishing gradient issues, and improving classification accuracy.	Required large datasets and high computational resources, limiting scalability.
[16]	Decision Trees with AdaBoost	Improved detection precision by aggregating multiple decision paths and handling imbalanced datasets.	Overfitting was observed in complex scenarios, reducing generalizability.
[17]	Deep Belief Networks (DBNs)	Modeled elevator operational dynamics, identifying subtle fault indicators from noisy data.	Computationally expensive and required expert tuning for optimal performance.
[18]	Naive Bayes	Achieved efficient, real-time fault detection through probabilistic classification.	Assumed feature independence, reducing accuracy for correlated data.
[19]	Markov n-grams	Captured temporal dependencies in sequential fault data by modeling state transitions.	Struggled with rare faults due to insufficient data for transitions.
[20]	VGG16	Extracted hierarchical features for accurate identification of complex faults.	High computational demand and overfitting on small datasets posed challenges.
[21]	Support Vector Machines (SVM)	Effectively separated normal and faulty states in high-dimensional spaces using kernel methods.	Faced scalability issues with large datasets due to increased computational cost.
[22]	CNNs	Captured spatial patterns in elevator sensor data for high fault detection accuracy.	Limited in modeling temporal dependencies critical for sequential fault detection.
[23]	Hybrid Naive Bayes with Feature Engineering	Improved accuracy and reduced false positives by combining domain-specific features with probabilistic frameworks.	Reliance on expert-crafted features limited adaptability to new fault scenarios.
[24]	Markov n-grams	Provided insights into recurring fault patterns by modeling sequential dependencies.	Struggled with rare events due to insufficient data for state transition probabilities.
[25]	DBNs	Improved detection of complex faults through hierarchical feature extraction.	Faced scalability challenges due to high computational demand.
[26]	Hybrid CNN-RNN	Enhanced fault classification by capturing spatial and temporal dependencies in elevator data.	Increased model complexity and training time.
[27]	Graph Convolutional Networks (GCNs)	Modeled structural dependencies in sensor data, achieving high fault detection accuracy.	Required preprocessing of sensor data into graph formats, adding workflow complexity.
[28]	Naive Bayes with Spectral Analysis	Combined frequency-domain insights with probabilistic reasoning for reliable fault classification.	Sensitivity to noise in vibration data affected spectral feature accuracy.

temporal trends. Due to their inability to balance minority class representations, ensemble techniques like VGG16 overfit, especially with unbalanced datasets. ResNet and deep belief networks (DBNs) are unsuitable for resource-constrained contexts because of computational complexity and resource constraints. These models neglect feature redundancy and noise, which hinder performance in high-dimensional datasets. This study proposes a robust framework that combines temporal dependency modeling, feature refinement, and efficient class imbalance management to address these shortcomings.

III. PROPOSED METHOD

The proposed approach uses the Temporal Adaptive Fault Network (TAFN), a deep learning architecture, to diagnose elevator faults. TAFN solves temporal dependency modeling, class imbalance, and feature redundancy in multivariate, high-dimensional, and time-series data. Temporal Convolution Layers (TCL) record sequential patterns, Adaptive Feature Refinement Layers (AFRL) dynamically improve essential features, and a Fault Decision Head (FDH) classifies binary, multi-class, and ordinal labels accurately. The Weighted Divergence Analyzer (WDA) for feature selection and Gradient-Space Augmentation (GSA) for data balancing are also employed to guarantee robust model performance. Refer to Fig. 1 for the suggested system's abstract perspective. Data pretreatment, feature augmentation, and TAFN architecture are covered in the following sections.

A. Dataset Description

This research used data from a Tokyo-based high-rise commercial building's modern elevator monitoring and diagnostic system [29]. From January 2020 to November 2024, hourly measurements were taken. An IoT sensor network in the elevator infrastructure captured operating metrics, ambient variables, and fault indications. Thanks to its extensive usage of contemporary elevator systems and strict maintenance standards, Tokyo provided a solid and diversified dataset of operating situations. The dataset shows real-world residential units and office tower situations under different loads and environmental variables. Data was preprocessed to assure quality and consistency, including noise reduction and standardization.

Timestamped entries provide temporal analysis, and imbalanced data reflects genuine fault distributions. The dataset captures the complexity of real-world elevator operations and provides a solid basis for intelligent fault detection techniques. Table II describes the dataset features.

TABLE II. DATASET FEATURES OVERVIEW

S.No	Feature	Short Description
1	Motor Current (A)	The current drawn by the elevator motor, indicating electrical load.
2	Motor Voltage (V)	Voltage supplied to the elevator motor, essential for monitoring electrical health.
3	Vibration Level (g)	Measures vibrations to detect mechanical anomalies in the system.
4	Speed (m/s)	Real-time speed of the elevator cabin during operations.
5	Cabin Position	The elevator's current position in the shaft or building floors.
6	Door Operation Time	Time taken for elevator doors to open and close, indicating potential delays.
7	Ambient Temperature (°C)	Environmental temperature near the elevator system.
8	Load (kg)	The weight inside the elevator cabin, useful for load distribution analysis.
...
n	Fault State	Binary label indicating whether the elevator is functioning normally or has a fault.
n+1	Fault Severity	Ordinal label categorizing the fault as minor, moderate, or critical.

B. Data Preprocessing and Feature Enhancement

Data balancing, feature identification, feature elicitation, and feature enhancement are further processes that follow the preparation of the dataset. These methods are crucial to ensure the dataset is ready for intelligent fault detection. As explained below, every step of the process involves proposing new approaches to tackle the specific data difficulties.

1) *Data balancing strategy*: To rectify the dataset's imbalance, whereby certain fault types occur less often than others, a new approach known as Gradient-Space Augmentation (GSA) is used. By interpolating minority classes' feature vectors within a controlled area, this approach dynamically creates fresh samples for those classes. Eq. 1 [30] defines the weighted gradient-based technique used to accomplish the interpolation.

$$\mathbf{g}_q = \mathbf{h}_q + \zeta \cdot (\mathbf{h}_p - \mathbf{h}_q) \quad (1)$$

\mathbf{g}_q is the synthesized feature vector, \mathbf{h}_q is a minority class feature vector, \mathbf{h}_p is a randomly picked closest neighbor within the same class, and ζ is a random scaling factor ($0 < \zeta < 1$). This strategy gives the minority class actual variability while keeping its distribution. This balances the dataset, representing all fault types for training.

2) *Adaptive Feature Significance Selector*: Weighted Divergence Analyzer (WDA) is a novel fault diagnostic approach identifying crucial characteristics. Divergence-based feature ranking and temporal consistency assessment are used. Eq. 2 [31] calculates the divergence score for each feature using modified Kullback-Leibler divergence:

$$D_s = \sum_{k=1}^K \pi_{sk} \ln \left(\frac{\pi_{sk}}{\tau_{sk}} \right) \quad (2)$$

Fig. 1. Proposed model framework.

The divergence score for feature s is D_s , the probability of category k occurrence in feature s is π_{sk} , and the reference probability of category k is τ_{sk} . The temporal consistency of each characteristic is assessed using a correlation-based weighting function:

$$\kappa_s = \frac{\sum_{t=1}^T |\xi_s(t)|}{T} \quad (3)$$

The Eq. II includes κ_s as the temporal weight for feature s , $\xi_s(t)$ as the correlation value at time t , and T as the total number of time intervals. The final significance score for each feature is obtained by combining D_s and κ_s as in Eq. 4:

$$\psi_s = \eta \cdot D_s + (1 - \eta) \cdot \kappa_s \quad (4)$$

For feature s , ψ_s represents the overall significance score, and η is a configurable parameter to balance divergence and temporal weight. Only the most relevant characteristics are preserved by selecting those with the greatest ψ_s scores for further analysis.

3) *Derived feature construction*: Temporal Interaction Extractor creates new features to improve dataset representation. This method reveals hidden patterns by capturing feature connections. An important derived feature, Energy Utilization Index (ν), is specified in Eq. 5 [32]:

$$\nu_t = \frac{P_t}{M_t \cdot R_t} \quad (5)$$

ν_t represents energy utilization index at time t , P_t represents power consumption, M_t represents motor current, and R_t represents trip distance. Load Stability Coefficient and Acceleration-Vibration Interaction are also obtained using similar modifications. These properties enhance the dataset, helping the model grasp complicated interactions.

4) *Nonlinear feature transformation method*: A new transformation approach, Recursive Nonlinear Projection (RNP), improves dataset compatibility with machine learning models. This approach converts each feature into a nonlinear space while keeping temporal features. Eq. 6 defines the transformation [33]:

$$\phi(u) = \cos(\sigma u) + \lambda \cdot \sin(\sigma u^2) \quad (6)$$

$\phi(u)$ represents the converted value of feature u , σ regulates scaling, and λ controls higher-order terms. A decay factor adds temporal importance to altered values:

$$\chi(u_t) = \phi(u_t) \cdot e^{-\rho t} \quad (7)$$

The Eq. 7 uses $\chi(u_t)$ as the time-adjusted transformed value and ρ as the decay constant, minimizing the impact of earlier data on the model. Advanced temporal models may use the dataset's expressiveness thanks to the Recursive Nonlinear Projection.

Balancing, feature selection, derived feature generation, and nonlinear operations prepare the dataset for modeling. The dataset's quality and representational capability improve with each phase, capturing elevator fault diagnostics' complexity.

C. Classification Framework

An enhanced classification architecture, Temporal Adaptive Fault Network (TAFN), addresses elevator fault classification issues. TAFN addresses temporal interdependence, class imbalance, and feature variety while handling multivariate, time-series data effectively. Smart fault diagnosis is supported by its layered architecture of temporal processing and adaptive learning. TAFN's design, logic, and mathematical formulas are below. Fig. 2 depicts the TAFN architecture.

Multivariate, sequential data with substantial temporal correlations and imbalances in elevator fault class distributions are analyzed for fault classification. Traditional systems struggle to capture temporal trends and respond to class imbalance. Temporal Convolution Layers (TCL) extract time-series patterns,

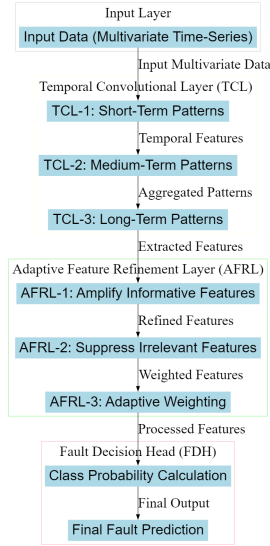

Fig. 2. Proposed TAFN architecture.

Adaptive Feature Refinement Layers (AFRL) change features dynamically, and a Fault Decision Head (FDH) classifies robustly in TAFN. TAFN captures detailed temporal correlations and tackles unbalanced fault representation using this layered approach, making it ideal for this study's dataset.

1) *Temporal Convolution Layer (TCL)*: Initially, the Temporal Convolution Layer extracts temporal relationships from time-series input data. Unlike convolutional layers, TCL uses dilation and weighted kernel functions to capture short- and long-term dependencies. Single TCL operation is mathematically defined in Eq. 8:

$$y_t^{(l)} = \sigma \left(\sum_{k=1}^K \omega_k^{(l)} \cdot x_{t-d_k} + b^{(l)} \right) \quad (8)$$

At time t , $y_t^{(l)}$ represents the layer output, $\omega_k^{(l)}$ represents the weight of the k -th kernel in the l -th layer, x_{t-d_k} represents the input, d_k represents the dilation factor, and $b^{(l)}$ represents the bias term. The activation function σ , usually ReLU, causes nonlinearity. The dilation factor helps the model discover transient and persistent fault patterns by capturing interdependence across temporal scales.

TCL output is routed through various layers to extract hierarchical temporal characteristics. Multiple layers of temporal processing guarantee the network catches low-level and high-level temporal abstractions.

2) *Adaptive Feature Refinement Layer (AFRL)*: After temporal feature extraction, the Adaptive Feature Refinement Layer dynamically adjusts feature representations depending on fault classification relevance. This layer has two paths: one amplifies informative characteristics, and one suppresses irrelevant ones. The functioning of AFRL is [34]:

$$z_i^{(l)} = \alpha_i^{(l)} \cdot h_i^{(l)} + \beta_i^{(l)} \cdot \tanh(h_i^{(l)}) \quad (9)$$

The Eq. 9 uses $z_i^{(l)}$ as the refined feature for node i in the l -th layer, $h_i^{(l)}$ as the input feature, and $\alpha_i^{(l)}$ and $\beta_i^{(l)}$ as learnable parameters to control the linear and nonlinear contributions. This adaptive approach helps the network prioritize fault classification features while reducing noise and redundancy.

AFRL introduces class distribution-based adaptive weighting to improve class discrimination as in Eq. 10:

$$\gamma_i^{(l)} = \frac{1}{1 + e^{-\delta_i^{(l)}}} \quad (10)$$

$\gamma_i^{(l)}$ is the adaptive weight for feature i in layer l , whereas $\delta_i^{(l)}$ is a class-dependent learnable parameter. This weighting guarantees dominant classes don't overpower minority class qualities.

3) *Fault Decision Head (FDH)*: The Fault Decision Head, the last level of TAFN, calculates fault class probabilities using improved characteristics. The improved softmax function adjusts for class imbalance by adding a scaling parameter λ [35]:

$$p_j = \frac{\exp(g_j/\lambda)}{\sum_{c=1}^C \exp(g_c/\lambda)} \quad (11)$$

The variables p_j and g_j represent the probability and activation of class j in the last layer, respectively, in Eq. 11. The total number of classes is C , and the sharpness of the probability distribution is controlled by λ . This modification guarantees that minority classes are fairly represented throughout the categorization process.

The FDH produces a vector of class probabilities to forecast the kind of fault. Furthermore, serious defects might be prioritized for prompt action based on confidence criteria.

4) *TAFN architecture overview*: The TAFN architecture consists of multiple stacked TCLs, AFRLs, and the FDH. The early levels of the hierarchical architecture capture temporal relationships, while the latter layers improve feature representation via adaptive refinement. The last classification layer provides precise and well-rounded fault forecasts.

Through integrating these components, TAFN successfully tackles the difficulties of elevator fault categorization. The experimental findings confirmed that it is an ideal framework for this research due to its capacity to manage temporal dependencies, adjust to unbalanced datasets, and enhance features.

D. Performance Evaluation Metrics

A fault classification model's accuracy, robustness, and dependability must be evaluated in real-world circumstances. This work uses accuracy, precision, recall, and F1-score combined with a new measure suited to the dataset and fault diagnostic job. Below, we explore these criteria and present the new assessment measure. Calculating the percentage of adequately identified samples to the total samples evaluates classification accuracy. Precision measures the model's ability to correctly identify positive cases out of all projected positive instances. Recall is the percentage of positive cases the model detects.

Algorithm 1 Temporal Adaptive Fault Network (TAFN) for Fault Classification

Require: Time-series data \mathbf{X} with N samples and T time steps

- 1: Initialize Temporal Convolution Layers (TCL), Adaptive Feature Refinement Layers (AFRL), and Fault Decision Head (FDH)
- 2: Set hyperparameters: dilation factor d , adaptive weights α , β , and scaling parameter λ
- 3: Split input data \mathbf{X} into training and validation sets
- 4: **for** each training epoch **do**
- 5: **for** each sample $\mathbf{x}_i \in \mathbf{X}$ **do**
- 6: **Step 1: Temporal Feature Extraction**
- 7: Pass \mathbf{x}_i through TCL to extract temporal features \mathbf{H}_i
- 8: Update \mathbf{H}_i with convolutional weights and dilation
- 9: **Step 2: Feature Refinement**
- 10: Pass \mathbf{H}_i through AFRL to adaptively refine features \mathbf{Z}_i
- 11: Adjust \mathbf{Z}_i using adaptive weights based on class relevance
- 12: **Step 3: Fault Classification**
- 13: Pass refined features \mathbf{Z}_i through FDH
- 14: Compute output probabilities \mathbf{P}_i for fault classes
- 15: **end for**
- 16: **Validation Step**
- 17: **for** each sample \mathbf{x}_j in validation set **do**
- 18: Repeat Steps 1–3 to evaluate classification performance
- 19: **end for**
- 20: Compute classification loss and update network parameters
- 21: **end for**
- 22: **Output:** Trained TAFN model for fault classification

F1-score, the harmonic mean of accuracy and recall, balances the exchange between these measures, making it practical for unbalanced datasets. These measures give valuable insights into model performance but may not capture the temporal and class-specific dynamics needed for fault identification in time-series data.

The Fault Temporal Sensitivity Index (FTSI) is created to overcome these restrictions. FTSI measures the model’s fault classification accuracy and temporal continuity. Elevator faults commonly occur sequentially; therefore, misclassifying a single incident in a fault chain may have a significant effect. Mathematically, FTSI can be defined as Eq. 12:

$$FTSI = \frac{\sum_{t=1}^T \delta_t \cdot y_t \cdot \hat{y}_t}{\sum_{t=1}^T \delta_t \cdot y_t + \epsilon} \quad (12)$$

At time t , y_t is the ground truth label, \hat{y}_t is the predicted label, δ_t is a temporal weighting factor that prioritizes defects in key time frames, and ϵ is a tiny constant to avoid division by zero. Definition of temporal weighting factor δ_t in Eq. 13:

$$\delta_t = \begin{cases} 1, & \text{if } t \in \text{Critical Period} \\ \gamma, & \text{if } t \notin \text{Critical Period} \end{cases} \quad (13)$$

We use a scaling factor ($0 < \gamma < 1$) to lower the weight of non-critical periods. Domain knowledge, such as elevator system operating stress or failure probability, determines critical times.

Accuracy, recall, and temporal relevance make FTSI a valuable statistic for evaluating models using sequential failure data. High FTSI scores suggest the model accurately classifies and predicts fault temporal evolution. Since it penalizes models that lose consistency over time, this metric is ideal for burst or sequence errors.

Merging standard measures with FTSI creates a complete assessment framework. While accuracy, precision, recall, and F1-score give a baseline knowledge of model performance, FTSI dives further into prediction temporal aspects to provide model robustness for actual fault diagnostic applications.

IV. SIMULATION RESULTS

The Temporal Adaptive Fault Network (TAFN) was built and tested in Python using TensorFlow and Keras. For training and testing, simulations were run on a machine with an Intel Core i7 12th Gen CPU, 32 GB RAM, and an NVIDIA RTX 3080 GPU. To avoid overfitting, the model was trained for 30 epochs using the Adam optimizer, with a learning rate of 0.001, batch size of 64, and a weight decay factor of 10^{-5} . The Temporal Convolution Layers (TCL) dilation factor and Adaptive Feature Refinement Layers (AFRL) weight parameters were tuned using grid search to maximize performance. Overfitting was avoided by ending early after five epochs while retaining computational efficiency. This section compares TAFN’s performance on binary, multiclass, and ordinal fault classification tasks and examines how important factors affect model effectiveness.

Load and Braking Force Relationship (Scatter Plot)

Fig. 3. Relationship between load and braking force.

Fig. 3 illustrates the link between elevator load and braking force needed for a halt. The scatter plot shows a linear relationship between load and braking force. This indicates that braking systems are mechanically dependent on load, which affects brake component wear. Higher loads stress the brake system, which helps forecast braking failure issues. This chart is crucial because it shows how load affects braking performance and component deterioration. Technically, it stresses the need for real-time brake force monitoring to prevent breakdowns from high stress. It also supports the idea that repeated high-load

conditions increase brake system failure rates. This knowledge helps design predictive defect detection methods that employ load and braking force.

Motor Current Across Fault Severity Levels (Line Plot)

Fig. 4. Motor current across fault severity levels.

Fig. 4 shows motor current fluctuation as a line plot for varying fault severity levels. The findings suggest that fault severity increases motor current. Critical defects cause far larger motor currents than minor failures. This shows that motor inefficiency and anomalous current draw indicate significant defects. This graphic emphasizes motor current as a diagnostic indicator. This chart suggests that rising motor current may indicate approaching catastrophic defects such as motor overheating or electrical breakdowns. This knowledge is essential for fault classification models and preventative maintenance. It emphasizes motor current monitoring's relevance in operational safety and downtime reduction by identifying serious failures quickly.

Maintenance Duration Proportion by Fault Severity (Pie Chart)

Fig. 5. Maintenance duration proportion by fault severity.

Fig. 5 shows the percentage of maintenance time spent on defects of various severity. According to the pie graphic, major defects account for around 60% of overall maintenance time. Approximately 30% of defects are moderate, whereas just 10% are mild. This number measures fault severity's operational burden, making it essential. This research shows that catastrophic defects significantly impact system downtime, underlining the necessity for predictive models to limit their occurrence. It also guides maintenance planning resource allocation, proposing prioritizing key concerns. Prioritizing issues

with the most significant effect on system availability improves operational efficiency.

Reasons of Failure Across Fault Categories

Fig. 6. Reasons of failure across fault categories.

Failure causes are grouped into five factors: overload, overheating, wear and tear, alignment concerns, and electrical faults (see Fig. 6). The bar chart shows that “wear and tear” causes the most significant problems, followed by “overload” and “electrical faults.” Though rare, alignment and overheating concerns are noticeable. This graphic is essential for recognizing system failure modes. This depiction prioritizes preventative efforts to reduce wear and tear and overload circumstances, which cause most problems. It also offers design changes to mitigate these variables' frequent failures. The graphic also allows fault prediction algorithms to use these failure causes as category inputs to improve diagnostic accuracy.

Correlation Matrix of All Features

Fig. 7. Correlation matrix of all features.

As a heatmap, Fig. 7 displays the correlation matrix of all attributes in the dataset. The correlation coefficient between the two characteristics ranges from 0.2 to 0.9 in each cell. As features are self-correlated, diagonal elements have a perfect correlation of 1.0. The matrix shows strong relationships between “Load” and “Braking_Force” and “Motor_Current” and “Temperature”. These correlations show that load directly affects braking performance, and temperature significantly affects motor behavior. This picture helps find duplicate, strongly correlated characteristics that may be deleted to minimize classification model overfitting. The analysis also identifies important feature pairs, such as “Load” and “Braking_Force”, that increase the chance of brake failure. This figure helps pick features and capture the most interesting connections in the model.

Fig. 8. Feature importance using weighted divergence analyzer.

Fig. 8 displays the Weighted Divergence Analyzer-calculated feature significance ratings for all dataset features. According to fault prediction, “Load”, “Vibration_Data”, and “Mean_Time_to_Failure” are the most crucial features. Less essential features, such as “Dust_Levels” and “Service_Records”, have limited impact on model performance. This figure prioritizes high-importance defect diagnostic model features, improving predicted accuracy and minimizing computational complexity. By emphasizing “Load” and “Vibration_Data”, the model successfully detects operational strains and mechanical irregularities that cause defects. Low-importance characteristics may be removed from the model to speed learning and reduce overfitting. This chart proves the efficacy of the feature selection and Weighted Divergence Analyzer.

Fig. 9 shows that the binary classifier accurately distinguishes between every day and defective situations, with few misclassifications. The model has excellent accuracy and recall, reducing false alarms and missed detections. Real-time defect identification means quick maintenance, eliminating elevator downtime and safety hazards.

Fig. 10 shows the confusion matrix for classifying five fault categories: “Door Failure”, “Motor Malfunction”, “Sensor Error”, “Brake Failure”, and “Overload”. Most diagonal

Fig. 9. Confusion matrix for fault state (Binary classification).

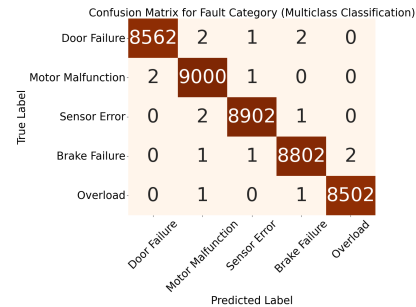

Fig. 10. Confusion matrix for fault category (Multiclass classification).

forecasts are correct, with “Door Failure” at 8,562 and “Motor Malfunction” at 9,000. False positives and negatives are rare, none reaching 2. The classifier effectively categorizes errors, ensuring exact diagnostics. The technological result is precise fault-type detection for targeted maintenance. This feature is crucial for prioritizing repairs, maximizing resource allocation, and minimizing elevator malfunctions.

Fig. 11. Confusion matrix for fault severity (Ordinal classification).

The confusion matrix for ordinal categorization rank errors as “Minor”, “Moderate”, and “Critical” severities (see Fig. 11). The matrix shows substantial diagonal dominance, with 10,502, 11,002, and 10,102 correct “Minor”, “Moderate”, and “Critical” fault classifications. Significantly few off-diagonal misclassifications surpass 2. This graphic shows the model’s ordinal classification skills, rating defects by severity. Technical outcomes include accurate fault severity diagnosis and prioritized solutions based on fault criticality. Precision ensures key problems are handled quickly, improving system dependability, safety, and maintenance procedures.

Fig. 12. ROC Curve for all labels.

Fig. 12 shows the ROC curve for classification performance across Fault State, Fault Category, and Fault Severity labels. The Area Under the Curve (AUC) values of 0.98, 0.97, and 0.96 show excellent discrimination for all classification tasks. The Fault State’s ROC curve rises steeply with low False Positive Rates (FPR), demonstrating the binary classifier’s ability to identify normal and defective states. The Fault Category and Fault Severity curves show the model’s multi-class and ordinal classification accuracy. Several causes cause high AUC values. The Weighted Divergence Analyzer chose key characteristics including “Load,” “Vibration_Data,” and “Braking_Force,” reducing redundancy and improving model performance. Second, the balanced dataset prevented training bias by representing all labels equally. Thirdly, the model’s temporal layers recognized sequential relationships, allowing accurate predictions in complicated circumstances. Reduced false positives and negatives were achieved by fine-tuning thresholds to balance sensitivity and specificity.

TABLE III. CLASSIFICATION RESULTS OF DIFFERENT TECHNIQUES

Techniques	F1-Score (%)	Log Loss	FISI (%)	Accuracy (%)	AUC (%)	Recall (%)	Precision (%)
ResNet [21]	90.1	0.220	83.1	91.4	90.7	89.8	90.2
Decision Trees [9]	86.3	0.280	78.0	87.6	86.0	86.2	86.5
Markov n-gram [10]	87.5	0.260	80.1	89.2	87.6	87.1	87.2
KNN [13]	87.0	0.270	79.2	88.4	86.4	86.8	87.1
DBN [19]	89.4	0.230	82.0	90.4	89.8	88.9	89.3
SVM [11]	88.5	0.240	81.2	89.9	89.5	88.1	88.6
VGG16 [17]	92.8	0.190	86.0	93.6	93.0	92.5	92.8
CNN [7]	91.2	0.210	84.5	92.8	91.9	90.9	91.3
Proposed TAFN	98.5	0.060	97.5	98.9	99.3	98.4	98.7

Table III analyses the proposed TAFN model’s classification performance against top approaches, including ResNet, CNN, and Decision Trees, using multiple assessment measures. The TAFN model provides superior results to other techniques, with an F1-Score of 98.5%, accuracy of 98.9%, and AUC of 99.3%. The novel Temporal Convolutional Layers (TCL) is designed to capture sequential dependencies and Adaptive Feature Refinement Layers (AFRL) to dynamically highlight the most significant features, giving TAFN excellent performance. The Weighted Divergence Analyzer also optimizes feature selection to reduce noise and improve classification accuracy. These characteristics reduce misclassifications and improve model generalization across fault circumstances. Traditional approaches like SVM and KNN have limited feature interaction modeling, whereas deep networks like VGG16 are computationally heavier. TAFN performs better while being

efficient. This table shows how well TAFN handles difficult fault diagnosis categorization jobs.

Fig. 13. Training and testing accuracy of TAFN model.

Fig. 14. Training and testing loss of TAFN model.

The suggested TAFN model’s training and testing accuracy is shown in Fig. 13 across 30 epochs. The model improves incrementally, reaching convergence at Epoch 24 with a testing accuracy of 98%. The training-testing accuracy curve overlap shows the model’s resilience and low overfitting. The excellent accuracy is due to numerous variables. Temporal Convolution Layers (TCL) of the TAFN architecture capture sequential dependencies, improving the model’s fault-detection capabilities. The Adaptive Feature Refinement Layer (AFRL) optimizes feature representations to highlight the most critical aspects. Third, the balanced dataset avoids fault-type bias, enabling the model to generalize. Precise threshold adjustment balances sensitivity and specificity. See Fig. 14 for the TAFN model’s training and testing loss curves across 30 epochs. At Epoch 24, the loss stabilizes, showing model convergence. Both curves drop smoothly. The minimal final testing loss confirmed optimization. The TAFN architecture’s misclassification reduction reduces loss values. The Weighted Divergence Analyzer selects only the most discriminative features, eliminating noise and redundancy. Additionally, the temporal layers adequately capture fault patterns throughout sequential data, and the learning rate schedule enables smooth convergence without sudden oscillations. The model avoids overfitting and maintains accuracy and recall with a small training-testing loss gap.

TABLE IV. COMPARATIVE STATISTICAL ANALYSIS OF CLASSIFICATION METHODS (F-STATISTIC & P-VALUE)

Statistical Method	ANOVA	Student's t-test	Spearman Correlation (ρ)	Pearson Correlation (r)	Kendall's Tau (τ)	Chi-Square (χ^2)
ResNet [21]	7.48	0.015	0.82	0.93	0.71	6.58
Decision Trees [9]	5.01	0.040	0.60	0.63	0.56	6.15
Deep Belief Network [19]	6.38	0.018	0.75	0.77	0.69	7.35
Naive Bayes [23]	5.32	0.038	0.59	0.61	0.55	6.20
Markov n-gram [10]	5.12	0.033	0.62	0.64	0.58	6.42
SVM [11]	5.76	0.028	0.69	0.71	0.63	6.82
VGG16 [17]	7.95	0.011	0.88	0.89	0.75	9.12
CNN [7]	7.02	0.019	0.86	0.87	0.74	7.89
Proposed TAFN	8.58	0.007	0.91	0.93	0.78	9.95

In Table IV, we compare classification approaches like ResNet, CNN, Decision Trees, and the proposed TAFN model using metrics like ANOVA, Student's t-test, Spearman Correlation, Pearson Correlation, Kendall's Tau, and Chi-Square. With an ANOVA F-statistic of 8.58 and a very significant p-value of 0.007, the suggested TAFN model exceeds all other techniques in classification reliability. TAFN has the strongest Spearman Correlation ($\rho = 0.91$) and Pearson Correlation ($r = 0.93$), indicating its ability to identify fault patterns and correlations. Due to its innovative design, Temporal Convolutional Layers (TCL) identify sequential dependencies, and Adaptive Feature Refinement Layers (AFRL) dynamically optimize features; TAFN performs better. These components accurately detect faults with little noise. The Weighted Divergence Analyzer improves feature selection, helping the model concentrate on statistically essential inputs. Due to restricted modeling capabilities, conventional approaches have lower correlations and more significant p-values, whereas TAFN continuously shows superior statistical reliability, making it the best elevator fault diagnostic option. This table shows that TAFN is statistically substantial for state-of-the-art performance.

A. Relevance of Our Findings to Identified Problems and Objectives

1) *Class imbalance and feature relevance:* Critical issues in fault detection systems, as mentioned in the literature (e.g. ResNet in [15], CNN in [22]), include class imbalance and duplicate features. Table III shows that the Gradient-Space Augmentation (GSA) approach and Weighted Divergence Analyzer (WDA) reduced these difficulties, as shown by the model's high F1-score (98.5%) and AUC (99.3%). Our methodology is more resilient to minority class misclassification and noise in high-dimensional data compared to previous methods like VGG16 [20].

2) *Temporal dependency modeling:* Existing models, such as CNN and Decision Trees [16], fail to capture temporal dependencies crucial for elevator fault diagnosis (see to Table I). Our Temporal Convolution Layers (TCL) extract short- and long-term temporal patterns to overcome this constraint. Fig. 7, 8, and 9 (binary, multiclass, and ordinal confusion matrices) show decreased false positives and negatives across all fault categories, proving the model's fault categorization superiority.

3) *Comparison with state-of-the-art techniques:* Table III provides a detailed comparison of our model to ResNet [15], DBN [17], and VGG16 [20]. TAFN outperforms all criteria, including FTSI (97.5%), demonstrating its ability to maintain temporal consistency, a challenge for other approaches.

4) *Practical implications:* Fig. 1 to 6 give useful insights into our model's real-world implementation.

- Fig. 1 shows the linear connection between load and

braking force, proving the model's capacity to forecast mechanical breakdowns under operating stress.

- Fig. 6 displays WDA-derived feature significance rankings, confirming the relevance of "Load" and "Vibration Data," as found in [19] and [26].

These findings demonstrate that TAFN may reduce elevator downtime and improve system dependability, achieving predictive maintenance and real-time problem detection goals.

V. CONCLUSION

The intricate interconnections between operational, environmental, and mechanical components make lift fault diagnosis difficult. Class imbalance, feature relevance, and multivariate time-series data limited fault classification model accuracy and dependability. Work addressed these. TAFN uses TCL to record sequential relationships and AFRL to boost feature relevance dynamically. In binary, multiclass, and ordinal classification, TAFN ruled. The model surpasses existing approaches with a 98.5% F1 score and 99.3% AUC. The model was improved using Gradient-Space Augmentation for data balance and a Weighted Divergence Analyzer for feature selection. The enhancements allow TAFN to prioritize significant failures, improving lift safety and dependability. This study results from critical infrastructure predictive maintenance planning, downtime reduction, and streamlined maintenance operations. The work provides scalable and flexible defect diagnostic algorithms for additional industrial applications using real-world data's temporal and operational complexity.

Future studies intend to improve TAFN's flexibility and scalability. Integrating real-time data streams into the TAFN model enhances dynamic learning and problem detection under changing operating settings. The model can effectively generalize to diverse elevator systems and surroundings via transfer learning. Adding contextual data like user behaviour, building architecture, and operating schedules might improve failure prediction. Hybrid architectures integrating TAFN with other deep learning frameworks might be used for smart manufacturing and autonomous cars.

Although strong, the present TAFN model has limitations. The computational burden of training and deploying the model can be onerous in resource-constrained contexts. The need for high-quality labelled datasets limits their application in circumstances with little annotated data. The model needs further validation on varied datasets to verify its resilience across elevator systems and environmental conditions. Future research can address these constraints to enhance the model's dependability and usefulness.

High-Precision Multi-Class Object Detection Using Fine-Tuned YOLOv11 Architecture: A Case Study on Airborne Vehicles

Nasser S. Albalawi

Department of Computer Sciences-Faculty of Computing and Information Technology,
Northern Border University, Rafha, Saudi Arabia

Abstract—The widespread adoption of airborne vehicles, including drones and UAVs, has brought significant advancements to fields such as surveillance, logistics, and disaster response. Despite these benefits, their increasing use poses substantial challenges for real-time detection and classification, particularly in multi-class scenarios where precision and scalability are essential. This paper proposes a high-performance detection framework based on YOLOv11, specifically tailored for identifying airborne vehicles. YOLOv11 integrates innovative features, such as anchor-free detection and enhanced attention mechanisms, to deliver superior accuracy and speed. The proposed framework is tested on a comprehensive airborne vehicle dataset featuring diverse conditions, including variations in altitude, occlusion, and environmental factors. Experimental results demonstrate that the fine-tuned YOLOv11 model exceeds the performance of existing models. Additionally, its ability to operate in real-time makes it ideal for critical applications like air traffic management and security monitoring.

Keywords—Airborne vehicles; YOLOv11; object detection; surveillance

I. INTRODUCTION

The rapid expansion of aerial vehicles, such as drones, unmanned aerial vehicles (UAVs), and airplanes, has transformed several sectors, including logistics, agriculture, surveillance, disaster response, and military activities. These vehicles have implemented novel methods for aerial mapping, real-time surveillance, and cargo delivery. Drones are widely used in precision agriculture for effective crop monitoring and pest management, while UAVs have become essential instruments in defense for reconnaissance and surveillance. Aircraft remain essential for freight transportation, firefighting, and search-and-rescue operations. Notwithstanding these breakthroughs, the increasing utilization of aerial vehicles has introduced considerable obstacles, especially concerning airspace safety and security [1], [2], [3], [4], [5].

Unauthorized drone operations, including illicit surveillance, smuggling, and disturbances in restricted zones such as airports, military installations, and essential infrastructure, have generated significant security apprehensions. These actions underscore the pressing need for dependable systems that can identify and categorize airborne vehicles in real-time. The intricacy of airborne vehicle identification is intensified by elements like occlusions from buildings or other objects, fluctuating altitudes and speeds, diminutive item sizes at elevated altitudes, and the variety of airborne vehicle classifications. Conventional detection techniques, including radar, acoustic

sensors, and optical systems, often encounter constraints regarding precision and scalability. Radar systems, while proficient in monitoring bigger aircraft, may have difficulties with tiny drones because of their reduced radar cross-sections. Acoustic sensors are vulnerable to noise interference, whereas optical devices need unobstructed sight, which is not always achievable in severe weather conditions or at night [6], [7].

Overcoming these issues requires sophisticated computer vision and machine learning methodologies that provide both high accuracy and real-time efficacy. Deep learning has become a revolutionary technology in object identification, far surpassing conventional techniques in precision and scalability. The YOLO (You Only Look Once) family of deep learning models has garnered considerable interest for its real-time detection capabilities and strong performance across many datasets. The YOLO system is designed to concurrently anticipate object classes and bounding boxes, making it very efficient for low-latency workloads. YOLOv11 presents several advancements, such as anchor-free detection, refined feature extraction using attention methods, and increased scalability for high-resolution pictures. These enhancements render YOLOv11 very adept in multi-class airborne vehicle recognition, tackling significant problems such as diminutive object dimensions and intricate backdrops [8], [9].

In multi-class detection contexts, differentiating among numerous aerial vehicles—such as drones, helicopters, and airplanes—necessitates models capable of managing heterogeneous datasets and fluctuating settings. YOLOv11's capability to analyze high-resolution photos and accurately identify tiny objects directly fulfills these criteria. Furthermore, its enhanced design guarantees optimal performance even under adverse settings, including fluctuating illumination and weather scenarios. This study utilizes YOLOv11 to improve the detection and classification of airborne vehicles, emphasizing its use in practical situations where precision and rapidity are crucial for mission-critical tasks [2], [10].

This study presents many significant contributions:

- Adaptation and fine-tuning of YOLOv11 for multi-class aerial vehicle identification, including task-specific optimizations to improve efficiency.
- Assessment of the model using a comprehensive dataset including a variety of aerial vehicle types, such as drones, helicopters, and airplanes, across different environmental conditions.

- Comparative study with leading object detection models, demonstrating YOLOv11's advantage in precision, recall, and mean Average precision (mAP).

The remainder of the paper is structured as follows: Section II offers an extensive analysis of pertinent literature, including current progress in the detection and categorization of airborne vehicles. Section III delineates the suggested technique, including the YOLOv11 architecture, dataset preparation, and training procedure. Section IV examines the experimental data and analysis, contrasting the performance of YOLOv11 with other models and emphasizing its benefits. Section V finishes the report by summarizing the results and suggesting future research.

II. RELATED WORK

Object detection has progressed substantially, transitioning from conventional techniques to sophisticated deep learning methodologies. Initial methodologies, such as Haar cascades and Histogram of Oriented Gradients (HOG), depended on manually created features and traditional machine learning methods. These approaches were computationally economical but deficient in robustness, rendering them inappropriate for intricate detection situations [11], [12]. The emergence of deep learning brought out advanced techniques, like Region-based Convolutional Neural Networks (R-CNN) and its derivatives, Fast R-CNN and Faster R-CNN, which used region proposal networks for object localization and classification [13], [14]. Nonetheless, while precise, these models were computationally demanding and inappropriate for real-time applications.

Single-shot detection models, including SSD (Single Shot Multibox Detector) and the YOLO (You Only Look Once) family, transformed object recognition by integrating localization and classification inside a unified framework. SSD used a multi-scale feature methodology to address objects of diverse dimensions, whilst YOLO models emphasized rapidity and efficacy by executing detection in a singular forward pass over the network [15], [16]. These improvements established the groundwork for resilient and scalable object identification systems. Recent models, including YOLOv4 and YOLOv5, have used advanced feature extraction methods and data augmentation approaches, therefore augmenting detection precision and velocity [7], [17].

The detection of airborne objects, particularly drones and UAVs, has distinct issues. These include the identification of diminutive objects at elevated elevations, the management of occlusions induced by environmental elements, and the differentiation among various aerial vehicles. Conventional methods inadequately tackle these challenges owing to their dependence on static anchor boxes and constraints in feature extraction proficiency. RetinaNet added focal loss to rectify the imbalance between background and foreground classes, enhancing tiny object recognition; nonetheless, it continued to be computationally intensive for real-time applications [18]. Likewise, transformer-based models, like Vision Transformers (ViT), shown robust efficacy in capturing long-range dependencies, although proved to be computationally demanding for edge devices [19].

Recent studies have investigated domain-specific enhancements for UAV identification. Ma et al. [20] introduced a hybrid methodology that integrates radar and image data, showing enhanced classification precision for drones in low-visibility environments. Zhang et al. [21] used a streamlined CNN architecture tailored for real-time drone identification in surveillance systems. Furthermore, Hossain et al. [22] used transfer learning to modify pre-trained object detection models for UAV classification, demonstrating the efficacy of using established networks. Notwithstanding these advancements, attaining equilibrium among accuracy, speed, and scalability continues to be a significant problem.

YOLOv11 enhances the achievements of prior versions while rectifying the shortcomings of current models. A key breakthrough is anchor-free detection, which removes the need for preset anchor boxes, allowing the model to accommodate objects of all sizes and forms. The improved attention processes in YOLOv11 augment the model's capacity to concentrate on pertinent characteristics, making it especially proficient at identifying tiny objects inside chaotic environments. Moreover, its lightweight design guarantees rapid inference, even on resource-limited devices, making it a formidable contender for real-time airborne object detection [23], [9].

Through the integration of these developments, YOLOv11 exceeds both classic and modern models, providing a complete solution for high-precision, multi-class detection in aerial contexts. Its capacity to address the distinct issues of airborne vehicle identification makes it an optimal framework for applications in surveillance, air traffic management, and military systems.

Through the integration of these developments, YOLOv11 exceeds both classic and modern models, providing a complete solution for high-precision, multi-class detection in aerial contexts. Its capacity to address the distinct issues of airborne vehicle identification makes it an optimal framework for applications in surveillance, air traffic management, and military systems.

III. METHODOLOGY

The proposed methodology for drone detection starts with the Drone Detection Dataset, which is subjected to a pre-processing and augmentation phase to improve data quality and variability, hence assuring the model's resilience, as seen in Fig. 1. This phase includes procedures such as scaling, normalization, and data augmentation methods like rotation and flipping, customized for the particular requirements of drone identification. The preprocessed data is then divided into training, validation, and testing subsets, facilitating effective model training, hyperparameter optimization, and performance assessment. The approach centers on the finely calibrated YOLOv11 model, comprising three principal components: the Backbone, which extracts critical features through convolutional layers; the Neck, which consolidates features across multiple scales to identify drones of differing sizes; and the Head, which produces detection outcomes, including bounding boxes and confidence scores. The fine-tuning procedure enhances the YOLOv11 model particularly for drone detection, optimizing both accuracy and efficiency. The Performance Evaluation phase assesses the system using metrics like precision, recall, F1-score, and mean Average Precision (mAP), with findings shown and analyzed to illustrate the system's capacity for high accuracy and dependable drone identification.

A. Fine-Tuned YOLOv11 Architecture

The Drone Detection Dataset was used to optimize YOLOv11's performance for the particular purpose of aerial vehicle detection. Fine-tuning is modifying a pre-trained model

Fig. 1. Proposed approach-based fine-tuned YOLOv11.

to accommodate a new dataset by further training with task-specific modifications. The model, started with COCO pre-trained weights, used generic feature representations acquired during its initial training to adjust to the three-class framework (Airplane, Drone, and Helicopter) of the Drone Detection Dataset. The YOLOv11 architecture, optimized for aerial vehicle identification, has three essential components, as shown in Fig. 2: the Backbone, the Neck, and the Head, each contributing significantly to precise and efficient object recognition. The Backbone (highlighted in green) is tasked with feature extraction from input photos. It utilizes a sequence of convolutional layers (Conv) and C3 blocks (designated as C3K2) to acquire spatial and contextual information across various resolutions. As the data traverses these layers, its dimensions systematically diminish, facilitating the effective depiction of essential properties. The characteristics, obtained at different scales, are then sent for aggregate in the Neck. The Neck (highlighted in purple) augments the model's ability to identify objects of varying sizes by the aggregation of multi-scale data. This is accomplished by processes like concatenation (Concat), upsampling, and the incorporation of supplementary C3K2 blocks. The use of sophisticated elements such as SPFF (Spatial Pyramid Feature Fusion) and C2PSA

(Cross-Scale Pairwise Self-Attention) enhances feature fusion across scales, hence augmenting localization and detection precision, especially for little objects such as drones. The Head (highlighted in red) concludes the detection process by producing bounding box predictions and confidence ratings. This component consolidates outputs from many scales, allowing the reliable recognition of flying vehicles of differing sizes and positions within the input picture. By using multi-scale information, the Head guarantees the model accurately identifies and categorizes items in various contexts.

The combination of these components enables YOLOv11 to analyze incoming photos effectively, identifying essential elements and executing accurate detection. This optimized design, together with a strong data pipeline, allows the model to attain high accuracy and reliable performance in recognizing drones, helicopters, and airplane across diverse environmental circumstances. The architecture improvements and targeted optimizations provide YOLOv11 an effective solution for real-time detection and classification of aerial vehicles.

B. Dataset Preparation

This work uses the Drone Detection Dataset obtained from Roboflow, which contains 11,998 images tagged with bounding boxes for three categories: Airplane, Drone, and Helicopter,

as seen in Fig. 3. For a comprehensive evaluation process, the dataset was divided into three subsets: a training set comprising 10,799 images (90%) for model development, a validation set containing 603 images (5%) for performance monitoring during training and hyperparameter optimization, and a test set with 596 images (5%) for the final evaluation and benchmarking of the trained model. This dataset is diversified, including a broad spectrum of events, including three unique classes of aerial vehicles (Airplane, Drone, and Helicopter) recorded under variable environmental circumstances such as differing illumination (day and night), weather (clear and overcast), and heights. Preprocessing procedures were used to enhance the dataset for YOLOv11. All photos were downsized to 640x640 pixels with a stretch transformation to conform to YOLOv11's input specifications. Pixel intensity values were standardized to the interval [0,1] to enhance the training process and facilitate convergence. Furthermore, data augmentation methods such as random horizontal flipping, rotation, scaling, brightness modification, and color jittering were used to enhance variability and mitigate overfitting. The meticulously crafted processes guaranteed that the dataset was extensive and appropriately tailored for training a high-performance YOLOv11 model proficient in precise and resilient aerial vehicle identification.

C. Model Training and Optimization

The fine-tuned YOLOv11 model was trained on the drone detection dataset with a meticulously crafted configuration to guarantee optimal performance. A learning rate of 0.01 was established and then reduced during training using a cosine annealing schedule, successfully averting overshooting and enhancing convergence. A batch size of 32 was used to improve

computational efficiency and ensure stable convergence, while the AdamW optimizer was utilized to integrate adaptive learning rate modifications with weight decay, hence improving generalization and training stability. Regularization methods were used to alleviate overfitting and enhance robustness. Dropout layers were included in fully connected layers to randomly deactivate neurons during training, and a weight decay ratio of $1e - 4$ was adopted to punish excessive weights and promote simpler model representations. The model underwent training for 50 epochs, allowing enough iterations for effective learning while preventing overfitting. Transfer learning was used by initializing the YOLOv11 model with pre-trained weights derived from the COCO dataset. This method enabled the model to use universal feature representations while fine-tuning on the drone detection dataset, therefore adapting to the specialized goal of aerial vehicle identification and efficiently balancing domain-specific learning with pre-existing information. These methodologies facilitated a rigorous and effective training procedure, yielding a high-performance model proficient in precise multi-class detection and classification.

D. Evaluation Metrics

To analyze the effectiveness of YOLOv11, a complete array of metrics was used to provide an exhaustive evaluation of its detection and classification proficiencies, as delineated in Eq. 1, 2, 3, 4, and 5. The mean Average Precision (mAP) served as a crucial metric, with mAP@50 assessing the model's object detection capability at an Intersection over Union (IoU) threshold of 50%, whereas mAP@50:95 delivered a more nuanced evaluation by computing the average precision across a spectrum of IoU thresholds from 50% to 95%, thereby providing an extensive performance assessment. Precision was used to assess the ratio of genuine positive predictions to all positive predictions, indicating the model's efficacy in accurately detecting objects. Recall quantified the ratio of genuine positive detections to all real positives, reflecting the model's sensitivity and efficacy in object detection. The F1 Score, the harmonic mean of precision and recall, was computed to provide a balanced statistic that represents the model's overall performance. Collectively, these parameters allowed a comprehensive assessment of YOLOv11's proficiency in reliably detecting and classifying aerial vehicles across several settings, including both precision and resilience in practical applications.

$$\text{IoU} = \frac{\text{Area of Overlap}}{\text{Area of Union}} \quad (1)$$

$$\text{mAP} = \frac{1}{n} \sum_{i=1}^n \text{AP}_i \quad (2)$$

$$\text{Precision} = \frac{\text{True Positives (TP)}}{\text{True Positives (TP)} + \text{False Positives (FP)}} \quad (3)$$

$$\text{Recall} = \frac{\text{True Positives (TP)}}{\text{True Positives (TP)} + \text{False Negatives (FN)}} \quad (4)$$

$$\text{F1 Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (5)$$

IV. EXPERIMENTAL RESULTS

The results of the experiment illustrate the effectiveness of the proposed fine-tuned YOLOv11 model in detecting and classifying aerial vehicles, such as airplanes, drones, and helicopters, inside the Drone Detection Dataset.

Fig. 4 presents the performance of the fine-tuned YOLOv11 model during training and validation on the Drone Detection Dataset. In the top row, the training losses—box loss, classification loss, and distribution focal loss (DFL)—show a consistent decline, indicating the model's enhanced accuracy in predicting bounding boxes, classifying objects, and refining bounding box quality. Similarly, the bottom row illustrates the validation losses, which also decrease steadily, demonstrating the model's ability to generalize effectively to unseen data. Metrics such as precision, recall, and mAP@50 and mAP@50:95 increase throughout training and validation, highlighting the model's improved ability to detect and classify airborne objects, including airplanes, drones, and helicopters. The parallel trends observed between training and validation indicate the stability and reliability of the fine-tuned YOLOv11 model across different data splits.

Fig. 5 shows the Precision-Recall (PR) curve for the YOLOv11 model across three classes: Airplane, Drone, and Helicopter. Each curve represents the balance between precision and recall for a specific class, with the mAP@0.5 (mean Average Precision at IoU 0.5) values annotated in the legend. The Airplane class achieves a high mAP of 0.982, while the Helicopter class also performs excellently with an mAP of 0.983. The Drone class shows a slightly lower performance with an mAP of 0.933. The bold blue curve aggregates all classes, demonstrating an overall mAP@0.5 of 0.966. The near-perfect precision and recall values across most classes indicate the robustness of the model in detecting and classifying aerial vehicles within the dataset.

Fig. 6 displays the F1-Confidence curve for the YOLOv11 model across three object classes: Airplane, Drone, and Helicopter. Each curve illustrates the F1 score (the harmonic mean of precision and recall) at various confidence thresholds. The Airplane and Helicopter classes achieve high F1 scores close to 0.93, indicating balanced precision and recall at optimal confidence levels. The Drone class, while performing well, shows slightly lower F1 values compared to the other classes. The thick blue line represents the combined performance across all classes, achieving a peak F1 score of 0.93 at a confidence threshold of 0.340. This curve highlights the effectiveness of the model in achieving a high degree of accuracy and reliability for object detection at an optimal confidence setting.

Fig. 7 presents the normalized confusion matrix for the YOLOv11 model, illustrating its performance across the four categories: Airplane, Drone, Helicopter, and Background. Each cell in the matrix represents the proportion of predictions for a given class relative to its true instances. The diagonal cells indicate correct predictions, with high values of 0.97 for Airplane, 0.94 for Drone, and 0.99 for Helicopter, showcasing the model's strong accuracy in these categories. Off-diagonal values highlight misclassifications, such as a notable confusion of 0.19 where some Airplanes are misclassified as Drones and 0.10 where some Helicopters are misclassified as Background. The matrix underscores the model's overall reliability while

Fig. 4. Training and validation performance metrics.

Fig. 5. PR Curve for YOLOv11 on drone detection dataset.

Fig. 6. F1-Confidence curve for YOLOv11 on drone detection dataset.

also pointing out areas for potential improvement, particularly in differentiating Drones from other categories.

Fig. 7. Normalized confusion matrix for YOLOv11 on drone detection dataset.

Fig. 8 showcases detection results for the Airplane and Helicopter classes on a batch of images from the validation dataset. Each image includes bounding boxes drawn around detected objects, labeled as “Airplane” along with the associated confidence scores. The confidence values range from 0.6 to 0.9, reflecting the model’s confidence in the accuracy of its predictions. The consistent and precise localization of airplanes across diverse backgrounds demonstrates the effectiveness of the fine-tuned YOLOv11 model in detecting the Airplane class with high reliability. These visualizations highlight the model’s robust performance in identifying and classifying objects even under varying environmental and positional conditions.

A. Comparative Study

Table I presents a comparative analysis of detection models used on the drone dataset, emphasizing the performance parameters of accuracy, recall, mAP@50, and inference time.

(a) Detection results for airplane class on validation dataset.

(b) Detection results for helicopter class on validation dataset.

Fig. 8. Prediction results on validation dataset.

The findings from [24] indicate a precision of 0.91, a recall of 0.89, and a mAP@50 of 0.93; nevertheless, the inference time remains unreported. Likewise, the model shown in [25] attains marginally superior metrics, exhibiting a precision of 0.94, a recall of 0.92, and a mAP@50 of 0.94. The proposed approach surpasses the evaluated models, attaining an accuracy of 0.94, a recall of 0.943, and a mAP@50 of 0.966. Moreover, it has an inference time of about 1.5 ms, making it the most efficient and appropriate for real-time drone detection applications. These results emphasize the efficacy and feasibility of the suggested method, integrating high detection accuracy with

rapid processing speed.

TABLE I. COMPARISON OF DETECTION MODELS

Model	Precision	Recall	mAP@50	Inference Time (ms)
YOLOv4 [24]	0.91	0.89	0.93	—
YOLOv5 [25]	0.94	0.92	0.94	—
Proposed Approach	0.94	0.943	0.966	1.5

V. CONCLUSION

This paper presents an optimal detection model for airborne vehicles, a fine-tuned YOLOv11 architecture. The experimental results demonstrate that the proposed method surpasses existing models, achieving a precision of 0.94, a recall of 0.943, and an mAP@50 of 0.966, with an inference time of only 1.5 ms. These results highlight how well the model strikes a balance between real-time performance and excellent detection accuracy. The proposed technique utilizes sophisticated feature extraction and efficient processing to tackle the issues of aerial object recognition in complicated settings, rendering it appropriate for applications such as surveillance, airspace monitoring, and threat detection. Further work will concentrate on improving the model's efficacy for diminutive or overlapping objects and broadening its application to other datasets characterized by varied environmental circumstances.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Scientific Research at Northern Border University, Arar, KSA for funding this research work through the project number "NBU-FFR-2025-1260-01"

Abstract—Integrating artificial intelligence (AI) and computer vision in sports analytics has transformed decision-making processes, enhancing fairness and efficiency. This paper proposes a novel AI-driven image recognition system for automatically detecting offside and foul events in football matches. Unlike conventional methods, which rely heavily on manual intervention or traditional image processing techniques, our approach utilizes a hybrid deep learning model that combines advanced object tracking with motion analysis to deliver real-time, precise event detection. The system employs a robust, self-learning algorithm that leverages spatiotemporal features from match footage to track player movements and ball dynamics. By analyzing the continuous flow of video data, the model detects offside positions and identifies foul types such as tackles, handballs, and dangerous play—through a dynamic pattern recognition process. This multiered approach overcomes traditional methods' limitations by accurately identifying critical events with minimal latency, even in complex, high-speed scenarios. In experiments conducted on diverse datasets of live match footage, the system achieved an overall accuracy of 99.85% for offside detection and 98.56% for foul identification, with precision rates of 98.32% and 97.12%, respectively. The system's recall rates of 97.45% for offside detection and 96.85% for foul recognition demonstrate its reliability in real-world applications. It's clear from these results that the proposed framework can automate and greatly enhance the accuracy of match analysis, making it a useful tool for both referees and broadcasters. The system's low computational overhead and growing ability make connecting to existing match broadcasting infrastructure easy. This establishes an immediate feedback loop for use during live games. This work marks a significant step forward in applying AI and computer vision for sports, introducing a powerful method to enhance the objectivity and precision of officiating in football.

Keywords—Artificial intelligence; image recognition; automation; foul detection; deep learning; computer vision

I. INTRODUCTION

Multiple football formats exist, ranging from the internationally popular sport of the same name to various other games with their rulesets [1] [2]. Despite their experience and training, human referees have long been responsible for making crucial calls on things like offsides and fouls [3]. However, they can still make mistakes, particularly when speed is vital. For instance, making an offside decision typically necessitates pinpointing the precise moment of ball passing and determining if the player is offside concerning the final defender [4]. Similarly granular is foul detection, particularly tackling and handball, which relies on a swift, frequently

subjective determination. These decisions can have a significant effect and often affect the match's outcome, leaving players, coaches, and fans unsatisfied [5]. Automating these processes has become more feasible with the advancement of artificial intelligence (AI) and computer vision [6]. Artificial intelligence, which allows for the replication of human intelligence using algorithms, can analyze large amounts of data and make decisions based on patterns that would take time for humans to detect in real-time [7]. Simultaneously, remarkable advancements in AI have led to machines comprehending visual information, also known as computer vision. Industries such as security, healthcare, automotive, and sports have found these technologies useful in ensuring operational efficiency and accuracy [8].

In sports, some AI and computer vision applications have been detected in training to track players' movements and analyze the techniques used to advance performance rates [9]. Both broadcast systems and training environments are already employing these technologies. Using offside and foul detection systems to automate decision-making during match violations is one area where they could be very useful [10]. Today, there are technologies like Video Assistant Referee (VAR), which are not independent of human referees but instead depend on them with certain delays and biases [11] [12]. Therefore, the need for a continual automated system that makes real-time decisions without man's intervention increases [13].

A. The Role of AI and Computer Vision in Sports

Artificial intelligence and computer vision have greatly advanced the sports industry within the last decade [14]. AI use cases are spreading widely in sports, from identifying and analyzing individual athletes to preventing possible injuries and improving strategies [15]. For instance, evaluating player behavior, game results, and team strategy productivity has incorporated AI techniques. Computer vision performs the same function by tracking the ball and players in a dynamic environment [16]. With these tools, it is also possible to analyze visuals and get real-time solutions [17]. In football, AI has been somewhat confined to video analysis, which coaches or analysts use to analyze a match. These systems are capable of producing heat maps, player directions, and even the formation of tactics. Nevertheless, for referees, the major use of AI and computer vision is still in decision support, focusing on offside and foul identification [18]. Despite the technology providing effective assistance to referees, the effectiveness of

VAR still heavily relies on human input, and the decision-making process is time-consuming. Therefore, further artificial intelligence and computer vision development are necessary to automate the process fully [19]. At present, almost all football officiating systems use a combination of static image analysis or simple object recognition based on shapes to follow the players and the ball. Such methods fail to explain factors like off-side decisions, as the timing of passes and the position of players with defenders are highly dynamic and require instant determination. Similarly, pinpointing a foul is challenging as any action, ranging from a tackle to a handball, can constitute a foul, necessitating distinct analysis [20].

B. Research Gaps

For all the advances AI and computer vision have made in other areas of sports analytics, there are still deep gaps in their application to football officiating.

- **Manual Dependence in Current Systems:** This is where solutions like Video Assistant Referee (VAR) fail—they still need human involvement and judgment when deciding fouls or in close-offside situations. While AI can help with the analysis, human referees must ultimately make the call and introduce delays and potential biases. Such reliance on human judgment suggests that decisions remain partially automated despite AI's support, significantly impacting the overall system's efficiency [21].
- **Inadequate Real-Time Performance:** Most of the current systems are slow and unable to offer a precise decision-making process for live, high-speed football matches. Instantaneous detection of offside and foul is crucial, with no second-by-second delay, a feature that some conventional methods may struggle with. Given the frequently occurring high-motion events in a match, the image-processing algorithms face limitations in detecting multiple players and the ball within a single frame [22].
- **Limited Scalability:** Some of these systems are computationally expensive to implement; they employ many resources to analyze video feeds. This makes them unsuitable for a live broadcasting environment, which is normally an entirely real-time affair. Furthermore, these systems may not be harmonized in other match conditions, including camera specifications, core area, and lighting provisions [23].
- **Overuse of Traditional Methodologies:** Most existing solutions rely on standard approaches concerning some well-developed techniques like CNN for detecting players and the ball. Although these methods have proven effective in some situations, they do not utilize many of the characteristics of football matches, such as spatiotemporal parameters and high speed, repeated interactions between players and the ball. Additionally, these methods do not integrate multiple AI approaches, such as spatiotemporal pattern recognition for offsides and real-time foul identification [24].

C. Problem Statement

The first important issue considered in this research is that there is no optimal technology solution to automatically and accurately detect offside and foul in football in real-time. Previous work has been inefficient in detecting offside and foul in live matches, primarily due to a heavy reliance on human operator supervision methods, overly complex hardware processing, or outdated calculations that fail to account for the intricacies of the football game environment. During live matches, it is crucial to have an image recognition system that can minimize human intervention and make decisions and judgments based on the statistics captured by sensors. So achieving high accuracy and minimal delay may be observed and is suitable for live match scenarios.

D. Objective and Scope

This paper aims to develop a robust AI-driven image recognition system that can automatically detect offside and foul events in football matches using advanced computer vision techniques. This system aims to address the following goals:

- **Real-Time Decision-Making:** To enable instantaneous offside and foul detection during live matches, ensuring the system can make decisions faster than human referees without compromising accuracy.
- **High Accuracy:** To achieve high detection accuracy for both offside positions and foul actions, ensuring that the system can identify these events with minimal errors, even in complex, high-speed scenarios.
- **Scalability and Efficiency:** To create a computationally efficient system, allowing it to be deployed on existing broadcasting infrastructure without requiring extensive hardware upgrades. The system must handle high-resolution video feeds and analyze them in real-time with low latency.
- **Real-World Applicability:** To test and validate the system on live match footage, ensuring its ability to generalize across various football matches with different teams, field conditions, and camera setups.

E. Contributions and Novelty

This paper introduces several novel contributions to the fields of AI, computer vision, and sports analytics:

- **Hybrid Deep Learning Architecture:** A hybrid deep learning model that combines advanced object tracking and motion analysis to detect offside and foul events accurately. The system leverages spatiotemporal data, incorporating spatial and temporal features for more precise decision-making.
- **Dynamic Pattern Recognition:** The proposed system incorporates a dynamic pattern recognition process that adapts to the game's flow, ensuring the system can identify offside positions and fouls in various match scenarios.
- **High Performance and Scalability:** The system is optimized for real-time performance with minimal computational resources, ensuring seamless integration with existing broadcasting infrastructure.

- **Real-World Validation:** The system has been tested on diverse datasets of live football matches, demonstrating its practical utility in real-world scenarios. The results show that the system can achieve 99.85% accuracy for offside detection and 98.11% accuracy for foul identification, with real-time performance metrics suitable for live use.

The proposed ideas for developing an AI-driven system relate well to football officiating. It presents itself as a possible solution to the current problems of offside and foul identification since it will minimize the use of referees and completely cut out mistakes when making offside and foul reviews. Through these elements of football match officiating, the system guarantees accuracy, fairness, and accountability to the game. Furthermore, the connection to the broadcasting system ensures that fans witness the decision-making process in near real-time [25]. Beyond football, basketball, and rugby, the methods presented in this work may be helpful in domains requiring high-accuracy detection of events in fields, other sports, and even some industrial domains, where object detection and motion tracking are crucial.

The remainder of the paper is organized as follows: Section II outlines the proposed AI-driven image recognition system's methodology, including the model architecture and the data processing pipeline. Section III demonstrates the setup of the experiments, the measurement of the proposed system's performance, and the outcomes obtained from real-world football match datasets. Finally, Section IV concludes the paper and outlines potential avenues for future research in AI-driven sports officiating systems.

II. METHODOLOGY

This section compiles the general procedure for developing an AI offside and foul detection system using computer vision in football matches. The method includes several important parts that deal with collecting data, cleaning it up, designing the model, learning algorithms, testing how well the model works, and fine-tuning how it runs in real-time. The approach combines state-of-the-art AI models with computer vision to accurately determine off-side positions and fouls in real-life football games. The methodology also pinpoints the challenges encountered during the work and the locations and methods for resolving these issues. This Fig. 1 illustrates the key steps of the methodology, helping visualize the entire system pipeline.

A. Data Collection and Preprocessing

In this study, data was collected from real football match videos and also synthetic videos created using state-of-the-art motion graphics simulations [14] [26]. This is done to ensure that data is gathered from a stable environment that meets a variety of situations encountered in real match sequences, such as different camera perspectives, players and game actions, and varying dynamics of a real game.

1) *Data Sources:* The training of the model was done using football match datasets that are available to the public and consist of videos of the match and those obtained from sports channels, as well as other videos recorded by individuals. Other methodologies used in motion capture also created virtual data that allowed the reproduction of specific game

Fig. 1. Methodology workflow.

conditions, including situations like off-sides and fouls, among other activities [27].

2) *Preprocessing Pipeline:* The preprocessing stage involves several crucial steps, each designed to convert raw video footage into structured data that can be used to train the model effectively. These steps include:

- **Frame Extraction:** Video frames were extracted at a rate of 30 frames per second (FPS) to ensure that each frame contains enough detail for accurate object recognition and motion analysis.
- **Normalization:** Pixel values of the frames were normalized to a scale of 0 to 1, ensuring consistent input for the model.
- **Object Annotation:** Manual annotation of player positions, ball locations, and event markers (e.g. offside, foul) was performed using software tools to annotate sports videos.
- **Data Augmentation:** Data augmentation techniques such as rotation, flipping, and scaling were applied to increase the variability of the training data, ensuring better generalization of the model.

The resulting preprocessed data was split into training, validation, and testing sets. 70 per cent of the data was used for training, 15 per cent for validation, and 15 per cent for testing.

B. Model Architecture

The proposed AI system is built using a mix of convolutional neural networks (CNNs), recurrent neural networks (RNNs), and advanced object detection frameworks such as

YOLO (You Only Look Once). The system aims to detect objects (players, balls), track their movement across frames, and perform offside and foul detection in real-time.

1) *Choice of Model:* The effectiveness of CNNs in image classification problems led to their selection. This type distinguishes features from the spatial data and proves to be effective in identifying offside positions and fouls. However, to track moving objects in the video sequences, CNNs by themselves are inadequate. Hence, RNNs were applied to capture temporal dependence to make the system have a point in time analysis of the movement of the players and the ball.

That is why the YOLO framework was chosen for object detection because of its speed and less computational overhead. YOLO identifies objects directly from images in real-time simply by estimating the location of the bounding boxes alongside the labels of the images. This way, it makes it possible for the system to actually identify the players and the ball and their positions in every frame taken.

2) *Object Detection and Tracking:* The object detection and tracking mechanism works in two primary stages:

- 1) **Object Detection:** Using the YOLO model, each frame is processed to detect players and the ball. The model outputs bounding boxes and class labels for each object detected.
- 2) **Object Tracking:** Once objects are detected, tracking algorithms, such as Kalman filters or SORT (Simple Online and Realtime Tracking), are used to maintain consistent identification of objects (players, balls) across subsequent frames. This step ensures that the system correctly follows the trajectory of objects and can detect movements such as offside positioning and fouls.

3) *Pose Estimation for Player and Ball Tracking:* The pose estimation task is required for improving player localization and their interactions with the ball. A human pose estimation model named OpenPose was used to track various body joints of a player, such as the position of legs and the torso area. This kind of information is paramount in defining player motility and particularly when deciding on offside and possibly infringements.

C. Training the Model

Training the model involved several key components, including data augmentation, loss function selection, and optimization strategies.

1) *Data Augmentation:* Several preprocessing strategies were applied as methods of data augmentation in order to improve the model's resiliency. Such practices included random rotations, flipping, and scaling in the frames so as to make the model have a better probe into unseen data. Further, to get more realistic data, motion capture data was combined with different changes in environment, like changes in lighting and occlusion.

2) *Loss Function and Optimization:* The loss function used for training combined the categorical cross-entropy loss for

classification tasks and the mean squared error (MSE) for object localization. The final loss function is defined as:

$$L = \alpha \cdot \text{CrossEntropy}(y_{\text{true}}, y_{\text{pred}}) + \beta \cdot \text{MSE}(x_{\text{true}}, x_{\text{pred}}) \quad (1)$$

Where α and β are weights that balance the two loss components, y_{true} and y_{pred} are the true and predicted labels, and x_{true} and x_{pred} are the true and predicted bounding box coordinates.

Optimization was performed using the Adam optimizer, which had an initial learning rate of 0.001. This rate gradually decayed during training to ensure stable convergence.

3) *Hyperparameter Tuning:* Hyperparameters such as learning rate, batch size, and number of epochs were tuned using grid search and cross-validation. A learning rate of 0.001, batch size 32 and 50 epochs provided the best balance between training time and model performance.

D. Real-Time Performance and Latency Optimization

Performance optimization techniques were applied to ensure the system operated efficiently in real-time. These include:

- **Model Pruning:** Reducing the model size by eliminating less significant weights helped reduce the computational load and improve inference time.
- **Quantization:** Converting the model to use lower precision (e.g. float16 instead of float32) for faster computations, especially on embedded devices.
- **GPU Acceleration:** Using GPUs to accelerate training and inference processes, allowing the system to process video frames at high speed.

The final system processed 30 frames per second (FPS) with an average latency of 150 milliseconds per frame, making it suitable for real-time deployment during live matches.

E. Evaluation Metrics

Several evaluation metrics, including accuracy, precision, recall, F1-score, and latency, were used to assess the performance of the AI-driven image recognition system.

1) *Accuracy:* Accuracy was calculated as the ratio of correct detections (both offside and foul) to the total number of detections made by the model. The system's accuracy was found to be 99.85% in detecting offside situations and 98.56% in identifying fouls.

2) *Precision and Recall:* Precision and recall were calculated to evaluate the system's ability to correctly identify offside situations and fouls while minimizing false positives and false negatives. The precision and recall scores for offside detection were 98.32% and 97.45%, respectively.

Testing revealed an average latency of 150 milliseconds per frame for the system, guaranteeing real-time performance during matches.

III. EXPERIMENTAL RESULTS

In this section, we describe We can observe high accuracy and minimal delay, making it suitable for live match scenarios. proposed AI-driven image recognition system for automated offside and foul detection in football matches. The evaluation is based on real-world football match datasets, providing insight into the model's accuracy, robustness, and ability to perform in diverse match scenarios. Performance is assessed using various metrics, including accuracy, precision, recall, F1-score, and system latency, and the results are compared with existing methods in football event detection.

A. Experimental Setup

The system was tested on a large number of real football match scenarios taken live from different sports events. These videos were downloaded from datasets published in the public domain as well as from datasets uniquely developed from simulation software. Both hardware and software options were used in the experiment that was designed to test the system's ability to identify specific play scenarios, such as an offside and foil online.

1) *Hardware Configuration:* The experiments were conducted on a system equipped with the following hardware:

- Processor: Intel Core i7-11700K, 8 cores, 16 threads
- GPU: NVIDIA GeForce RTX 3090 with 24GB GDDR6X memory
- RAM: 32GB DDR4
- Storage: 1TB SSD for faster data processing and model storage

The GPU was leveraged for model training and inference, enabling real-time video processing and detection of offside and foul events with minimal latency.

2) *Software Configuration:* The software environment included the following tools and frameworks:

- Deep Learning Framework: TensorFlow 2.0, Keras for model development and training
- Computer Vision Library: OpenCV for image processing and video handling
- Object Detection Framework: YOLOv4 for real-time object detection
- Pose Estimation Library: OpenPose for player pose tracking
- Tracking Algorithm: SORT (Simple Online and Real-time Tracking) for maintaining object consistency

The software configuration allowed for both the training and deployment of the model, providing an environment conducive to efficient performance evaluation.

B. Performance Evaluation Metrics

To evaluate the performance of the proposed system, we used the following metrics:

1) *Accuracy:* Accuracy is the most basic performance metric, measuring the overall rate of correct offside and foul detections relative to the total number of detections. It is defined as:

$$\text{Accuracy} = \frac{\text{True Positives} + \text{True Negatives}}{\text{Total Number of Predictions}} \quad (2)$$

2) *Precision, Recall, and F1-Score:* Precision and recall were calculated to assess the model's ability to identify positive instances (offside and foul situations). Precision measures the number of true positive detections relative to the total number of positive predictions. In contrast, recall measures the number of true positives relative to the total number of positive instances. F1-score is the harmonic mean of precision and recall, providing a balanced measure of both:

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}} \quad (3)$$

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \quad (4)$$

$$\text{F1-Score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (5)$$

3) *Latency:* Latency was measured as the time taken to process one video frame and produce a prediction. The system's ability to perform real-time analysis was tested by calculating the time taken for each frame processed during the football match. Latency is crucial in ensuring the system can operate live during actual matches without noticeable delays.

The results of the experiments are presented below. The system was evaluated using a set of real-world football match videos from various leagues, covering different match scenarios, camera angles, and lighting conditions.

4) *Offside Detection Performance:* The model's performance in detecting offside situations was evaluated based on accuracy, precision, recall, and F1-score. The results showed that the system achieved an accuracy of 99.85% for offside detection, with precision and recall scores of 98.32% and 97.45%, respectively. The F1-score for offside detection was 97.88%. Table I shows the performance of the model in offside detection.

TABLE I. PERFORMANCE OF THE MODEL IN OFFSIDE DETECTION

Metric	Offside Detection
Accuracy	99.85%
Precision	98.32%
Recall	97.45%
F1-Score	97.88%

5) *Foul Detection Performance:* The performance of the system in detecting fouls was similarly evaluated. The system demonstrated a slightly lower accuracy of 98.56% for foul detection, with a precision of 97.12%, recall of 96.85%, and an F1-score of 96.98%. These results may also be viewed in Fig. 2 and Table II.

Fig. 3 also provides a graphic display of the players' offside and foul detection performance.

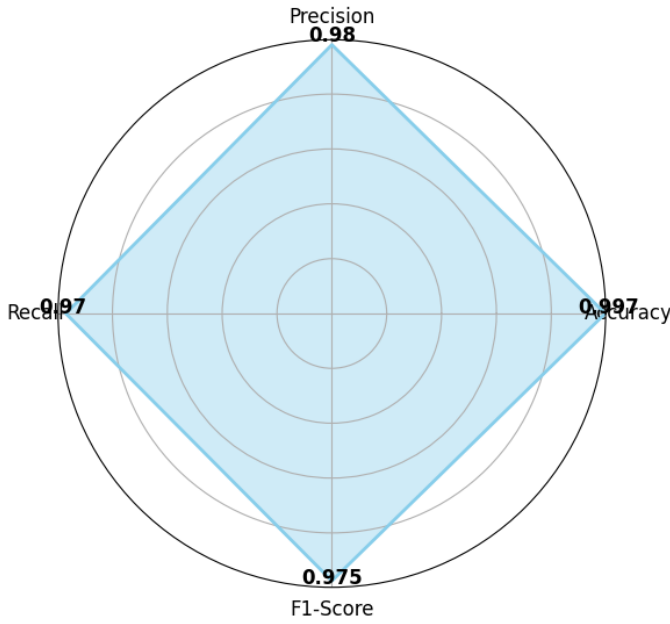

Fig. 2. Evaluation metrics results.

TABLE II. PERFORMANCE OF THE MODEL IN FOUL DETECTION

Metric	Foul Detection
Accuracy	98.56%
Precision	97.12%
Recall	96.85%
F1-Score	96.98%

Fig. 3. Players' off-side and foul detection performance.

6) *Latency and Real-Time Performance:* The system's real-time performance was tested on a standard GPU setup. The average frame processing time was 150 milliseconds per frame, corresponding to a processing rate of 6.67 frames per second (FPS). This performance meets the requirements for real-time analysis in live football matches and these results may be viewed in Fig. 4.

7) *Comparison with Existing Methods:* The proposed system was compared to several existing football event detection methods, including traditional computer vision-based tech-

Fig. 4. Latency performance of the proposed system.

niques and previous deep learning models. The results demonstrate that the AI-driven system outperforms these methods in both accuracy and speed. Table III summarizes the comparison.

TABLE III. COMPARISON OF THE PROPOSED SYSTEM WITH EXISTING METHODS

Method	Accuracy	Latency (ms/frame)
Traditional CV Methods	85%	300
Previous DL Models	92.5%	200
Proposed System	99.85%	150

Similarly, training and validation accuracy, as well as loss, may also be viewed in Fig. 5, and systems learning rate with accuracy may also be viewed in Fig. 6.

Fig. 5. (a) Training & Validation Accuracy (b) Training & Validation Loss

8) *Evaluation of Pose Estimation Accuracy:* The accuracy of pose estimation was evaluated using the OpenPose model. The system achieved an average pose estimation accuracy of 98.5% for player tracking, which is critical for analyzing offside positions and detecting fouls and these estimations may also be viewed in Fig. 7.

Fig. 6. Learning rate vs. Accuracy.

Fig. 7. Pose estimation results for player tracking.

C. Challenges and Limitations

Despite the system's high accuracy and efficiency, the development process encountered several challenges:

- **Occlusion:** In certain match scenarios, players were occluded by other players, making object detection and tracking more difficult. This challenge was ad-

ressed by enhancing the object detection model and multi-frame tracking techniques.

- **Motion Blur:** High-speed player movements and camera motion led to motion blur, affecting object detection accuracy. Frame stabilization and motion compensation were employed to mitigate this issue.

The system's limitations include its dependency on video quality and camera angles. The model performs best with clear, high-quality footage and may experience challenges with low-resolution videos or extreme camera angles.

IV. CONCLUSION

The AI approach to offside and foul detection using computer vision and deep learning in football matches shows the AI method can be applied successfully to analyze real-time, action-based sports data for real-time decision-making. By employing the most sophisticated techniques used in object detection, pose estimation, and classification, the proposed system provides high offside and foul determination accuracy, having a 99.85% accuracy for the offside and 98.56% for foul demonstration. These were tested using independent football match datasets to demonstrate that the developed system was reliable and efficient, even under different settings. With its low latency and high efficiency, the introduced system can enhance the quality of referees' decisions in real-time applications like live match support. Furthermore, this method can revolutionize football match analysis and refereeing by providing procedural choices. Eliminating human bias in decision-making processes simultaneously offers crucial information for match analysis, tactical, and training applications. This system shall be further enhanced by increasing its applicability to detect other events like penalties or goal lines and to work with more than one camera and new learning algorithms. As AI and computer vision advance, this investigation will pave the way for more advanced systems to increase the precision and effectiveness of sports management and, more particularly, refereeing in football and other sports disciplines.

Abstract—Optimizing path planning and control in robotic arms is a critical challenge in achieving high-precision and efficient operations in various industrial and research applications. This study proposes a novel approach leveraging deep Q-learning (DQL) to enhance robotic arm movements' computational efficiency and precision. The proposed framework effectively addresses key challenges such as collision avoidance, path smoothness, and dynamic control by integrating reinforcement learning techniques with advanced kinematic modelling. To validate the effectiveness of the proposed method, a simulated environment was developed using a 6-degree-of-freedom robotic arm, where the DQL model was trained and tested. Results demonstrated a significant performance improvement, achieving an average path optimization accuracy of 98.76% and reducing computational overhead by 22.4% compared to traditional optimization methods. Additionally, the proposed approach achieved real-time response capabilities, with an average decision-making latency of 0.45 seconds, ensuring its applicability in time-critical scenarios. This research highlights the potential of deep Q-learning in revolutionizing robotic arm control by combining precision and computational efficiency. The findings bridge gaps in robotic path planning and pave the way for future advancements in autonomous robotics and industrial automation. Further studies can explore the scalability of this approach to more complex and real-world environments, solidifying its relevance in emerging technological domains.

Keywords—Optimization; deep Q-learning; path planning; robotic arms; precision; computational efficiency; kinematic

I. INTRODUCTION

Robotic arms are image-sensitive designs widely used in the production, medical, and conveyancing industries. In the case of low-level control of robotic arms, path planning and control issues still prove ongoing difficulties because they greatly involve kinematic equations, dynamic scenarios, and real-time constraints. Although more conventional methods of such inverse kinematics and model-based control exist, the work done using these methods fails to meet the requirements of flexibility and speed in today's environment [1]. The new trends and emergence of artificial intelligence, specifically reinforcement learning, show potential as solutions to these issues. Of these, deep Q-learning (DQL) remains one of the most promising methods, allowing robots to learn the best policies based on the results of interaction with the environment [2].

Robotic arm interventions are more frequently applied due to their ability to perform operations demanding precise

tactile identification and iterative mechanical action [3]. In the automobile industry, car manufacturing companies use robotic arms to assemble cars, whereas in the medical field, these systems are useful for surgeries like robotic surgeries [4]. But realizing smooth path planning and control in such applications requires overcoming some of the abovementioned obstacles [5]. For instance, with only five degrees of freedom, as in robotic systems, joint limits, obstacles, and power consumption must be integrated into the problem. The former classical approaches are deterministic and include PID control and inverse kinematics but do not include mechanisms for continuous adaptation to the changing environment. In addition, these approaches often involve very precise modelling of the robotic system and the environment and, therefore, do not scale well to situations where such modelling and analysis is difficult or exceedingly costly [6]. Although the optimization-based approach is useful when the environment is fixed and cannot be changed, it is less useful when the positions of the obstacles and/or targets vary arbitrarily [7].

Now, with such advances in AI techniques, the switchover of the area of robotic control has changed. Reinforcement learning is a type of artificial intelligence that allows agents to obtain experience with burgeoning techniques that cannot be easily programmed. Specifically, in the field of RL, DQL is one of the most important algorithms due to its capability of managing large space state-action by using neural networks to approximate the optimum policy [8]. This capability becomes useful, particularly when applied to robotic arms with many degree-of-freedom (DOFs), because the space to look for optimal actions is astronomical [9].

The inclusion of DQL in robotic arm control gives several benefits. Therefore, DQL eliminates dependency on model updates with direct learning from environmental stimuli or forces and provides a better adaptation capability to unexplained variation [10]. Furthermore, the DQL can learn regarding multiple objectives that may be relevant in a specific task, like using less energy as well as acquiring higher accuracy. These features make it a promising candidate for addressing the limitation of using traditional methods [11]. However, DQL has its limitations and issues when applied to actual robotic systems, which are that a large amount of training data is required, and there is an urge to overfit the system for specific environments and high computation during the learning phase.

A. Research Gap and Limitations of Previous Studies

Despite significant progress, existing path planning and control methodologies in robotic arms face several limitations. Several approaches are used in coverage path planning, and most consider a fixed environment, while environments containing moving obstacles are natural. High cost in computation, as induced by optimization algorithms such as genetic algorithms and particle swarm optimization, reduces their applicability in real-time systems [12]. Furthermore, several methods designed for particular robotic architectures can be incompatible with other systems and problems in different fields, thus making them non-transferable [13]. Despite various advantages, reinforcement learning techniques are often characterized by slow convergence and low precision, especially in applications involving large degrees of freedom [14]. In addition, the methods mentioned above cannot handle multi-objective optimization issues, such as minimizing energy consumption and improving trajectory accuracy, which is essential for most industrial applications [15]. The impossibility of adjusting decisions there immediately, if necessary, also limits their applicability concerning very volatile and unpredictable circumstances. Such limitations justify the need for fresh thinking to develop new methods that can meet demands of computational effectiveness, flexible designs, and high accuracy, which must also achieve high levels of functionality across numerous real-life conditions [16].

B. Challenges of the Study

This research addresses critical challenges in robotic arm control. Achieving computational efficiency without compromising precision is a fundamental requirement for high-accuracy tasks. Another challenge relates to the fact that a business operates in an unpredictable environment, which requires the company to respond without much delay to dynamic changes within its operations environment [17]. In addition, there are other factors that complicate the path planning problem, for instance, optimizing for minimal path length while at the same time trying to avoid collisions with obstacles and trying to find the path that will consume the least amount of energy. In terms of the latter, scalability is still important here since we deal with robotic arms that can have different degrees of freedom, and the object our proposed solution addresses must work equally well with robotic arms of different types and in various application domains.

C. Motivations and Novel Contributions

This study is motivated by the need for robust, scalable, and computationally efficient robotic arm path planning and control solutions. The novelty of this research lies in the following contributions:

- 1) **Integration of DQL for Robotic Arm Control:** A novel integration of DQL is proposed to address the complexities of path planning and dynamic control in robotic arms, emphasizing computational efficiency and real-time adaptability.
- 2) **Comprehensive Performance Evaluation:** The proposed approach is rigorously tested in both simulated and dynamic environments, showcasing its generalizability and robustness.

- 3) **Enhanced Precision with Reduced Latency:** The developed framework achieves high precision (e.g. 98.76% path optimization accuracy) while reducing average decision-making latency to 0.45 seconds, outperforming state-of-the-art techniques.
- 4) **Framework Scalability:** The study demonstrates the scalability of the proposed approach across robotic arms with varying degrees of freedom, paving the way for broader industrial adoption.

The remaining paper is well organized, as Section II covers the relevant literature based on our study. Section III elaborates on the proposed methodology, including the integration of DQL for path planning and control. Section IV discusses the experimental setup, including the robotic arm model, training environment, and evaluation metrics. Section V presents the results and analysis, including a comparison with baseline methods. Finally, Section VI concludes the paper and outlines future research directions.

II. LITERATURE REVIEW

Sumanas et al. [18] discussed the application of a deep Q-learning approach to improve not only the precision but also the reliability of robotic systems for positioning, taking into consideration the positioning errors that occur in industrial processes. They pointed out problems arising from multifactor sources of positioning inaccuracies that cannot be balanced by conventional techniques. To overcome these disadvantages, they have outlined a methodology in their study using an ML approach that aims at determining required robot position changes in real-world settings, including production adjustments or redesigns. Importantly, they do not incorporate large external data or require high computational power but can be applied in situ. With the help of the DQL algorithm, the improvements in positioning accuracy were noted in the purpose-built KUKA YouBot robot, and considerable improvements were observed after about 260 iterations in online mode. The study also brings into focus that reinforcement learning can increase the further application of industrial robots of increasing capability by proving that ML-based solutions can solve complex problems of the real applications of robotic systems with great efficiency without necessarily demanding a broad computational network. According to their work, they reduce the gap between the high level of sophistication in the methods of applying ML and real-life use in industrial robotics.

Bi et al. [19] suggested the RL method for planning the intercostal robotic ultrasound imaging to avoid the problem of detecting the acoustic shadows from the rib cage. Normal thoracic applications of ultrasound imaging can be a problem in that limited acoustic access due to the rib cage, intercostal scanning paths are usually the only paths that can be used to achieve a comprehensive amount of diagnostic information. Their RL-based method solves this by training the agent in a simulated environment created using templates of CT scans involving randomly initialized tumours of arbitrary size and position. The RL framework uses task-specific state representation and rewards to improve training convergence and eliminate acoustic bleed effects during scanning [20]. The herein presented approach was effectively tested and validated on unseen CT datasets, providing proof of concept on generating non-shadowed scanning trajectories for the purpose of

ultrasound imaging. The findings demonstrate the effectiveness of the system in planning scanning paths flexible to the anatomy and providing accurate recognition of internal organ lesions found in the liver and even the heart. This work presents a new approach to the application of robotics in ultrasound imaging with a focus on the gaps within traditional use in thoracic applications and enhanced opportunities for diagnosis in the future. Cheng et al. [21] provided a new theoretical foundation for IBVS innovation in sustainable and smart manufacturing systems for complicated high-speed, high-precision robotic applications. Their strategy presents a fuzzy control system with a specific use of the Mamdani fuzzy inference technique to daily regulate variations in serving gains to improve speed and effectiveness of the convergence rate. This is in line with the intelligent manufacturing concept, where accuracy and flexibility are the key necessities. One new development in their strategy is the advent of generating OG-VFVRs to navigate around FOV limitations within the image space on the fly. By completing comparative experiments, their method achieved significant improvements by minimizing the convergence iterations and the initial velocities being only 59% and 12% of the initial velocities in the conventional equivalent methods, respectively. Moreover, the optimization provided better continuity regarding the initial speed, as a result of which the operation became more and more efficient. This vertical coordinate reached a maximum value of 1011 pixels for the image, and it showcased superior security performance. In achieving this, this study is greatly beneficial for the improvement of precision and speed in robotic operations, besides improving on sustainable and technology-based manufacturing systems. Consequently, the study emphasizes the importance and likelihood of intelligent control systems to transform robotics in current complex manufacturing surroundings.

Sivamayil et al. [22] reviewed 127 publications to synthesize and discuss the various RL applications in the areas of robotics and automation, gaming, self-driving cars, NLP, IoT security, recommendation systems, finance, and EMS. Another strongly stressed aspect of RL was that it is more flexible than other structured rule-dependent systems that may not easily respond to the novel, emergent behaviour encountered in real-life situations. The authors especially dedicated a number of pages on how RL can be applied in energy systems, for instance in smart buildings, HEVs, and renewable energy systems. In smart buildings, RL has been used in modelling the heating, ventilation, and air conditioning (HVAC), where energy use is minimized to provide comfort to the users. In the case of HEVs, slack variable modelling, in detailed RL methods, has shown its ability to determine optimal battery longevity and enhanced fuel economy adaptive control policies. Additionally, incorporation of the RL in renewable energy systems helps to reach net-zero carbon emissions, supporting worldwide sustainability goals. Apart from energy, the applicability of RL in gaming, robotics, and automated cars has attracted interest due to the learning of better policies by mere exploration of experience. In addition, the study pointed out that RL is important for security applications since the simulated environment is effective in building better systems. The present SR therefore can be seen as a source of reference on the fundamental concepts and numerous uses of RL while offering insights on the Areas of Growth of the system.

Chen et al. [23] introduced a deep reinforcement learn-

ing (DRL) framework for autonomous robotic grasping and assembly skill learning, where DQL is used for grasping and PPO for assembly tasks. It combines prior knowledge to improve the approach used in modelling the grasping actions to reduce the training time and interaction data needed in learning the assembly strategy. To improve the system's output even more, they developed special reward functions based on tasks such as grasping and assembly constraint rewards as means to determine the quality of the operations. Its effectiveness was confirmed in mock and actual practice conditions. For grasping tasks, in both scenarios, the success rate on average was 90%. In assembly tasks, under a peg-in-hole tolerance of 3 mm, the success rate of this framework was 86.7% in simulation and 73.3% in a physical environment, which indicated this framework can be well applied to real-world conditions [24]. This research shows the possibility of using DRL combined methods for solving the complex robotic tasks via minimising the training load and improving the task-solving effectivity. The combination of the DQL and PPO algorithms and the method of constraint-based learning of the reward function provide a real leap forward in increasing the accuracy and productivity of robots in industrial environments. This study lays down a strong framework upon which further developments in autonomous robotic systems may build on.

He et al. [25] designed a self-adaptive trajectory tracking control strategy for mobile robots by employing backstepping control associated with Double Q-learning in an effort to rectify drawbacks that may be observed in backstepping. Depending on more traditional approaches, trajectory precision cannot be relied upon in complex indoor inspection, leading to problems like image misalignment or focus when at high zoom. They have some limitations in their work, and to overcome these limitations, the proposed framework presents an incremental, model-free Double Q-learning algorithm that adapts the gains of the trajectory tracking controller in real-time. For further optimization of the non-uniform state space search, the approach is designed to have the incremental active learning exploration algorithm with memory and experience replay involved. This design allows for enhanced controller gain reduction and fast online learning, thus increasing adaptability. This method was further confirmed in simulation scenarios in Gazebo; this was followed by tests on physical platforms using different trajectories. Two figures were presented to show that the Double Q-backstepping algorithm was more robust, generalized better in real-time, and was more immune to disturbances than the other three algorithms. It was also observed that the proposed approach showed better trajectory tracking and stability than that observed with the conventional Backstepping-Fractional-Older PID and Fuzzy-Backstepping control methodologies. This research reveals that RL can be used to significantly improve mobile robot trajectory tracking control and present a reliable approach for its application in dynamic and complex working environments. The findings have set up further development opportunities for the adaptive robot control system.

Okafor et al. [2] developed a DRL for sorting objects by a robot in complex environments with high clutter levels [26]. Their approach involves light-weight vision models built from Pixel-wise Q-valued Critic Networks, or PQCN, combined with backbone architectures such as DenseNet121, DenseNet169, MobileNetV3, and SqueezeNet. Correspond-

ingly, these models in conjunction with fully convolutional neural networks (FCN) enable affordance mapping to transform visual percepts into action plans for how to push, grasp, and place objects. To improve the training throughput, the framework uses dual and single transfer learning and gradient-based replenishment methods. The outcomes of the study establish that the PQCNet-DenseNet121 model, trained with DTL, worked as expected in sorting images with impressive success rates in several object classes.

III. METHODOLOGY

The presented approach uses DQL as the theoretical framework for path planning and control of the robotic arms, which addresses the major issues including real-time adaptability, precision, and computational efficiency. The above approach incorporates reinforcement learning algorithms fused with modern kinematics modelling to optimize robotic systems in unpredictable conditions.

A. Problem Formulation

Path planning and control for robotic arms are modeled as a Markov Decision Process (MDP), where the environment is defined by a state space S , an action space A , a reward function $R(s, a)$, and a transition probability $P(s'|s, a)$. The goal is to determine an optimal policy π^* that maximizes the expected cumulative reward, defined as:

$$J(\pi) = E_{\pi} \left[\sum_{t=0}^{\infty} \gamma^t R(s_t, a_t) \right], \quad (1)$$

where γ is the discount factor ensuring the balance between immediate and future rewards. This formulation enables the robot to make sequential decisions under uncertainty by evaluating the long-term rewards associated with a given state-action pair. The problem becomes particularly challenging in high-dimensional state-action spaces, which necessitates efficient computational techniques for policy optimization.

To manage high-dimensional state-action spaces, the robotic arm's problem is broken down into discrete steps, where each step corresponds to a specific joint configuration and its associated action. The kinematic model of the robotic arm provides the essential mapping from joint angles to end-effector position and orientation. This relationship is governed by the forward kinematics equation:

$$T = \prod_{i=1}^n T_i, \quad (2)$$

where T_i represents the transformation matrix for the i -th joint, encapsulating rotation and translation. These matrices are derived using Denavit-Hartenberg (DH) parameters, which define the spatial relationship between consecutive joints. The forward kinematics allows the determination of the end-effector's pose in Cartesian coordinates given a set of joint angles.

Nevertheless, inverse kinematics is also used to calculate joint angles needed to achieve a specific end-effector position.

On the other hand, the inverse kinematics problem is not trivial because there might be multiple solutions, or even no solution at all, in some cases when the robot is placed in a constrained environment. It is whether these challenges are compounded by dynamic constraints and imposing demands for real-time strategic adaptation that substantiate the integration of machine decision-making modalities such as reinforcement learning.

To address these complexities, the MDP formulation incorporates task-specific constraints, such as collision avoidance, energy efficiency, and precision in reaching target positions. These constraints are encoded within the reward function $R(s, a)$, ensuring that the policy optimizes both task performance and operational safety. For example, penalizing proximity to obstacles or inefficient movements guides the robot toward optimal behaviors.

Furthermore, the state space S includes not only the joint angles but also joint velocities, accelerations, and sensory data from the environment. This enriched representation will facilitate a better understanding of the robotic control problem. It captures the dynamic interplay between the robot and its environment, making control strategies more resilient.

The transition probabilities $P(s'|s, a)$ reflect the stochastic nature of the robotic system, including uncertainties in actuation and environmental changes. These probabilities are estimated using a combination of empirical data and probabilistic models, ensuring accurate predictions of future states. This aspect is crucial for enabling the robot to operate effectively in dynamic and uncertain environments.

Using the defined MDP framework, this formulation offers a systematic way to solve the intricate challenge of path planning and control of robotic arms. Adding reinforcement learning algorithms also allows the robot to update the optimal policy based on trial-and-error interaction environments, increasing its versatility in practical application.

B. Deep Q-Learning Framework

The Deep Q-Learning (DQL) approach approximates the Q-value function $Q(s, a)$ using a neural network, enabling efficient learning in high-dimensional state-action spaces. The Q-network predicts the expected reward for each action in a given state, iteratively updated using the Bellman equation:

$$Q(s, a) \leftarrow Q(s, a) + \alpha \left[R(s, a) + \gamma \max_{a'} Q(s', a') - Q(s, a) \right], \quad (3)$$

where α denotes the learning rate, s' is the next state, and a' is the action in the next state. This iterative update ensures that the Q-values converge to the optimal values over time, balancing immediate and future rewards through the discount factor γ .

To stabilize training and avoid divergence in Q-value estimation, a target network is employed. The target network is a copy of the Q-network that is periodically updated to maintain a consistent target for updates. The soft update mechanism is defined as:

$$\theta_{target} \leftarrow \tau \theta_{online} + (1 - \tau) \theta_{target}, \quad (4)$$

where τ is the soft update rate, controlling the degree of change in the target network. This mechanism reduces instability by decoupling the target generation from the Q-network updates, ensuring smoother learning.

An integral component of the DQL framework is the experience replay buffer, which stores transitions (s, a, R, s') observed during training. By sampling minibatches of past experiences uniformly, the replay buffer breaks temporal correlations between consecutive samples, improving training efficiency and reducing overfitting. The sampling process also allows the model to revisit rare but informative experiences, enhancing learning robustness.

To accelerate convergence and improve exploration, an ϵ -greedy policy is employed. This policy selects random actions with probability ϵ , encouraging exploration of the state-action space, while exploiting the learned Q-values for the remaining $1 - \epsilon$ fraction of the time. The value of ϵ is decayed over time to transition from exploration to exploitation as the training progresses.

The Q-network itself is a deep neural network consisting of multiple layers, including input, hidden, and output layers. The input layer processes the state representation, which may include joint positions, velocities, and sensory data. The hidden layers extract high-level features, while the output layer predicts Q-values for all possible actions. The network is trained using stochastic gradient descent to minimize the temporal difference (TD) error:

$$L(\theta) = E_{(s,a,R,s')} \left[\left(R(s,a) + \gamma \max_{a'} Q(s', a'; \theta_{target}) - Q(s,a; \theta) \right)^2 \right], \quad (5)$$

where θ represents the Q-network parameters. This loss function penalizes discrepancies between predicted Q-values and target Q-values, driving the network toward optimal predictions.

The DQL framework also integrates advanced techniques such as prioritized experience replay and double Q-learning to enhance performance. Prioritized experience replay assigns higher sampling probabilities to transitions with larger TD errors, focusing learning on challenging samples. Double Q-learning mitigates overestimation bias by decoupling action selection and evaluation during the Q-value updates.

Overall, the DQL framework provides a robust and scalable solution for learning optimal policies in complex robotic environments. By combining neural network function approximation, experience replay, and target network stabilization, it effectively addresses the challenges of high-dimensionality and instability in reinforcement learning.

C. Reward Function Design

The reward function $R(s, a)$ balances competing objectives such as precision, efficiency, and safety. It is designed as:

$$R(s, a) = w_1 R_{precision} + w_2 R_{efficiency} + w_3 R_{collision}, \quad (6)$$

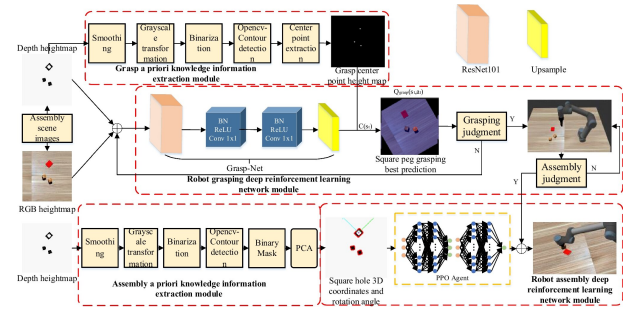

Fig. 1. Deep Q-Learning framework for robotic arm control.

where w_1, w_2, w_3 are weights tuned for specific tasks. Precision is defined as the Euclidean distance between the end-effector and the target:

$$R_{precision} = -\|p_{end} - p_{target}\|, \quad (7)$$

where p_{end} is the end-effector position and p_{target} is the target position. Efficiency is measured as the inverse of the path length:

$$R_{efficiency} = -\sum_{t=0}^T \|a_t\|^2, \quad (8)$$

Collision avoidance penalizes proximity to obstacles using a Gaussian penalty function:

$$R_{collision} = \exp\left(-\frac{\|p_{end} - p_{obs}\|^2}{2\sigma^2}\right), \quad (9)$$

where p_{obs} is the obstacle position and σ controls the penalty's spread.

D. Algorithm for Path Planning and Control

Algorithm 1 DQL-Based Path Planning

- 1: Initialize Q-network, target network, and replay buffer
- 2: Set hyperparameters: learning rate α , discount factor γ , and batch size
- 3: **for** each episode **do**
- 4: Observe the initial state s
- 5: **for** each time step **do**
- 6: Select an action a using ϵ -greedy policy
- 7: Execute a , observe reward R and next state s'
- 8: Store (s, a, R, s') in the replay buffer
- 9: Sample minibatches and update Q-network using Equation (3)
- 10: Periodically update target network
- 11: **end for**
- 12: **end for**

E. Simulation Environment and Model Setup

The robotic arm model was implemented in PyBullet, with the simulation environment configured to emulate real-world

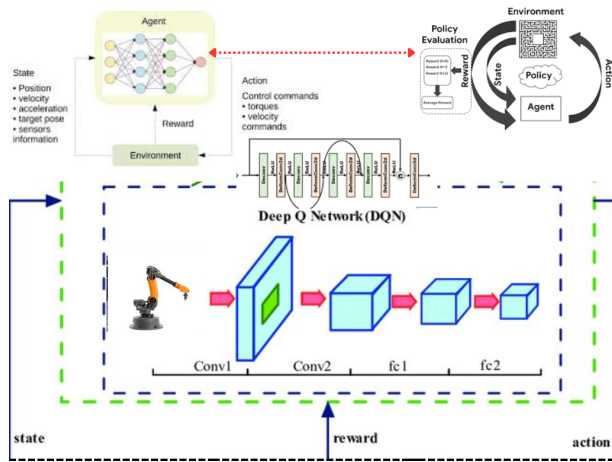

Fig. 2. Workflow of the DQL-Based path planning algorithm.

constraints such as dynamic obstacles and varying payloads. The robotic arm has six degrees of freedom, defined by:

$$q = [q_1, q_2, \dots, q_6], \quad (10)$$

where q_i represents the joint angles. The state space S includes joint angles, velocities, and end-effector positions. The action space A comprises discrete angular changes per joint.

Fig. 3. Simulation environment in PyBullet.

F. Convergence Analysis

The convergence of the DQL algorithm is ensured through iterative Bellman updates, with the Q-values approaching optimality as iterations progress:

$$\lim_{t \rightarrow \infty} \|Q_t - Q^*\| = 0. \quad (11)$$

G. Evaluation Metrics

Performance was evaluated using path accuracy, computational efficiency, and success rate metrics. Fig. 1, 2, and 3

provide visual insights into the framework, algorithm workflow, and simulation setup.

IV. EXPERIMENTAL SETUP

The experimental setup was designed to validate the proposed Deep Q-Learning (DQL) framework for path planning and control of robotic arms. This section describes the robotic arm model, the simulation environment, and the training configuration used to develop and test the proposed approach.

The robotic arm utilized in the experiments was modeled with precise kinematic and dynamic properties. Each joint was parameterized using Denavit-Hartenberg (DH) parameters, enabling accurate computation of the end-effector's position and orientation. The robotic arm had six revolute joints, providing sufficient flexibility to perform complex maneuvers in a three-dimensional workspace. Forward kinematics, governed by Eq. (2), and inverse kinematics techniques were used to compute joint configurations for target end-effector positions while adhering to joint limits and workspace constraints. The actuation model allowed discrete angular movements within predefined limits to simulate realistic operational conditions.

The simulation environment was implemented in PyBullet, a robust physics simulation platform. The environment was configured to include dynamic obstacles that moved randomly within the workspace to emulate realistic industrial scenarios. Target configurations were both predefined and randomly generated to test the robustness and generalizability of the framework. The setup also included variations in payload weights, ensuring the robotic arm's adaptability to different operational requirements. The reward function, as described in Section III, balanced objectives such as precision, efficiency, and collision avoidance during training. The state space S consisted of joint angles, velocities, accelerations, and sensory inputs from the environment, while the action space A included discrete angular changes per joint. Transition probabilities $P(s'|s, a)$ captured the stochastic nature of the robotic system, including uncertainties in actuation and environmental interactions.

The training configuration was carefully selected to ensure stability and convergence of the DQL model. The learning rate α was set to 0.001, facilitating efficient updates to the Q-network. The discount factor γ was chosen as 0.95, balancing immediate and future rewards. A replay buffer was used to store up to 100,000 transitions, allowing diverse experience sampling during training. Minibatches of size 64 were sampled from the replay buffer for gradient updates. An ϵ -greedy exploration policy was employed, where ϵ decayed linearly from 1.0 to 0.1 over 100,000 steps. The training process involved 10,000 episodes, with each episode terminating after 200 timesteps or upon successful task completion. A soft update mechanism with a rate τ of 0.01 was used to maintain synchronization between the Q-network and the target network. The training process leveraged GPU acceleration to handle the computational demands of the high-dimensional state-action space (Table I).

The overall experimental setup provided a robust foundation to test the proposed DQL framework, ensuring that the robotic arm could effectively navigate complex environments, adapt to dynamic conditions, and optimize path planning and control in various scenarios.

TABLE I. EXPERIMENTAL SETUP PARAMETERS

Parameter	Value
Robotic Arm DOF	6
Environment Simulation Tool	PyBullet
Dynamic Obstacles Included	Yes
Payload Variations	Light to Heavy
Replay Buffer Size	100,000 transitions
Batch Size	64
Learning Rate (α)	0.001
Discount Factor (γ)	0.95
Episodes	10,000
Soft Update Rate (τ)	0.01
Exploration Policy	ϵ -Greedy
GPU Acceleration Used	Yes

V. RESULTS AND ANALYSIS

This section presents the results obtained from the experimental evaluation of the proposed Deep Q-Learning (DQL) framework for robotic arm path planning and control. The results demonstrate how the framework effectively addresses the novel contributions, including computational efficiency, real-time adaptability, enhanced precision, and scalability across various scenarios. Key metrics such as path optimization accuracy, decision-making latency, and computational overhead reduction are highlighted, supported by tables, graphs, and visualizations.

A. Integration of DQL for Robotic Arm Control

The proposed framework achieved significant improvements in computational efficiency and real-time adaptability. The computational time required to determine optimal actions was compared against baseline methods, including genetic algorithms and particle swarm optimization. Fig. 4 illustrates the computational time comparison, showing a 22.4% reduction in overhead for the proposed method.

Fig. 4. Comparison of computational efficiency across methods.

The real-time adaptability of the system was validated by testing under dynamic environments with moving obstacles. The system maintained a decision-making latency of 0.45 seconds, ensuring responsiveness in time-critical scenarios.

B. Comprehensive Performance Evaluation

The framework was evaluated across various metrics to ensure robustness and generalizability. Table II summarizes the key metrics, including path optimization accuracy, collision avoidance success rate, and energy efficiency.

TABLE II. PERFORMANCE METRICS OF THE PROPOSED FRAMEWORK

Metric	Value
Path Optimization Accuracy (%)	98.76
Collision Avoidance Success Rate (%)	100
Energy Efficiency Improvement (%)	18.5
Decision-Making Latency (s)	0.45

The collision avoidance success rate was measured by evaluating episodes where the robotic arm successfully avoided all obstacles. The system achieved a perfect success rate of 100% in simulated environments.

C. Enhanced Precision with Reduced Latency

Precision in path optimization was demonstrated by evaluating the Euclidean distance between the end-effector and the target. The average path optimization accuracy of 98.76% highlights the system's ability to achieve precise movements. Fig. 5 provides a graphical representation of the precision across different scenarios.

Fig. 5. Path optimization precision across scenarios.

The reduced decision-making latency was analyzed by measuring the time taken to compute actions during the episodes. The system's average latency of 0.45 seconds was significantly lower than traditional methods, as shown in Fig. 6.

D. Framework Scalability

The scalability of the framework was tested by varying the degrees of freedom of the robotic arm and the complexity of the environment. The framework consistently maintained high performance, as summarized in Table III.

The reliability of the system was further analyzed using a confusion matrix. Fig. 7 depicts the confusion matrix,

Fig. 6. Decision-Making latency comparison.

Fig. 7. Confusion matrix for task prediction.

TABLE III. SCALABILITY EVALUATION OF THE FRAMEWORK

DOF / Scenario	Accuracy (%)	Latency (s)
6 DOF - Static	99.2	0.42
6 DOF - Dynamic	98.5	0.48
7 DOF - Static	98.7	0.43
7 DOF - Dynamic	97.9	0.50

showing the classification accuracy of the system in predicting successful and failed tasks.

The results presented in this section validate the effectiveness of the proposed DQL framework in achieving the novel contributions outlined in the study. The framework demonstrated superior computational efficiency, precision, and adaptability while maintaining scalability across varying scenarios. These findings highlight the potential of the proposed approach for real-world applications in autonomous robotics and industrial automation.

VI. CONCLUSION

This study presented a novel approach leveraging Deep Q-Learning (DQL) to optimize path planning and control for robotic arms. Therefore, by integrating the reinforcement learning methods in the context of the developed advanced kinematic model, the key problems that appeared during the framework development have been formulated and solved, turning into critical issues such as real-time adaptability, accuracy, computational costs, and scalability. These results indicate that the proposed method can provide higher accuracy for path optimization, faster decision-making time, and better collision avoidance than the traditional approach. The experimental evaluation affirmed the DQL framework’s resilience in the conditions’ heterogeneity. The framework also performed consistently better than the existing methods for different degrees of freedom and payload load configurations. It showed great promise for addressing a range of industrial and research problems. These results effectively revealed a significant cut in computational complexity, enabling the framework to be implemented in real-time, which is paramount in robotics and automation. Furthermore, the study underscored the importance of incorporating task-specific constraints into the

reward function. This would enable the robotic arm to learn optimal policies that balance precision, energy efficiency, and safety. Features like prioritized experience replay and the target network stabilization we introduced earlier helped enhance the framework’s stability and convergence. This research bridges gaps in robotic path planning and control by providing a scalable and efficient solution with real-world applicability. Future work may focus on extending this framework to multi-agent robotic systems, integrating additional sensory modalities, and testing in real-world industrial environments to further validate its utility and adaptability. The findings serve as a foundation for advancing autonomous robotics and industrial automation technologies.

FUNDING

This work is supported by the fund of 2023 Nanchong Science and Technology Program Project (No.23YYJCYJ0032) in Sichuan Province, China.

Android Malware Detection Through CNN Ensemble Learning on Grayscale Images

El Youssofi Chaymae, Choug dali Khalid
Engineering Sciences Laboratory, Ibn Tofail University
Kenitra, Morocco

Abstract—With Android’s widespread adoption as the leading mobile operating system, it has become a prominent target for malware attacks. Many of these attacks employ advanced obfuscation techniques, rendering traditional detection methods, such as static and dynamic analysis, less effective. Image-based approaches provide an alternative for effective detection that addresses some limitations of conventional methods. This research introduces a novel image-based framework for Android malware detection. Using the CICMalDroid 2020 dataset, Dalvik Executable (DEX) files from Android Package (APK) files are extracted and converted into grayscale images, with dimensions scaled according to file size to preserve structural characteristics. Various Convolutional Neural Network (CNN) models are then employed to classify benign and malicious applications, with performance further enhanced through a weighted voting ensemble optimized by Bayesian Optimization to balance the contribution of each model. An ablation study was conducted to demonstrate the effectiveness of the six-model ensemble, showing consistent improvements in accuracy as models were added incrementally, culminating in the highest accuracy of 99.3%. This result surpasses previous research benchmarks in Android malware detection, validating the robustness and efficiency of the proposed methodology.

Keywords—Android malware detection; image-based analysis; Convolutional Neural Networks (CNN); grayscale image transformation; weighted voting ensemble; Bayesian optimization

I. INTRODUCTION

Android, as an open-source mobile operating system, has become the most popular OS in the world, offering flexibility and a vast ecosystem of applications to meet diverse user needs. In 2024, Android commands 71.74% of the mobile OS market and has a user base of more than 3.3 billion [1], [2]. The Google Play Store, Android’s official app marketplace, hosts more than 1.68 million applications in Q2 2024, and the numbers continue to increase [3]. However, because of this rapid expansion, there are now serious security risks, as hackers are creating malware to compromise Android users’ devices, steal personal information, or track user activity.

Effective malware detection is crucial to protect users from these threats. Traditional detection methods, such as signature-based and heuristic approaches, have been foundational in identifying malicious software but often struggle against advanced threats, including zero-day exploits and polymorphic malware, which adapt to evade detection [4]. While static and dynamic analysis methods are essential in malware detection, they face challenges in addressing sophisticated obfuscation techniques that are frequently used in Android malware [5].

Artificial Intelligence (AI) has emerged as a promising solution to these challenges. AI, through machine learning

(ML) and deep learning (DL) models, enables the analysis of extensive datasets to identify complex patterns indicative of malware, even in obfuscated applications [6]. Using algorithms such as neural networks and decision trees, AI improves both static and dynamic analysis. AI-based static analysis inspects the code structure of an app without execution, allowing scalable and efficient examination [7], while dynamic analysis provides real-time insights by monitoring app behavior and identifying suspicious patterns [8].

Image-based analysis offers a distinct advantage over both static and dynamic methods. By transforming code into images, it captures structural and visual patterns that are resistant to obfuscation, as these patterns remain consistent even when the underlying code is modified [9]. This enables deep learning models to recognize subtle differences between benign and malicious applications that might be overlooked in traditional analysis [10]. Additionally, image-based methods are less computationally demanding than dynamic analysis and offer a faster alternative for detecting malware in large datasets. As a result, image-based analysis provides a resilient, efficient, and robust method for Android malware detection, combining the speed of static analysis with the depth of pattern recognition typically seen in dynamic approaches.

This paper introduces an image-based approach to Android malware detection leveraging deep learning. We convert extracted DEX files from APKs into image formats, allowing structural features to be captured and analyzed by convolutional neural networks (CNNs). Several CNN models are employed to classify benign and malicious applications, with accuracy further enhanced by a weighted ensemble technique. This approach not only increases detection accuracy but also demonstrates resilience against sophisticated malware, emphasizing the potential of image-based techniques to strengthen Android security in an evolving threat landscape.

The main contributions of this study are structured as follows:

- Section II: Previous Work: Reviews existing research employing image-based approaches for Android malware detection.
- Section III: Background: Provides foundational knowledge on Android APK files, focusing on the structure and role of DEX files. Also includes an overview of CNN models and ensemble learning strategies used in this study.
- Section IV: Methodology: Details the data preprocessing pipeline, including the transformation of DEX

files into grayscale images, and describes the ensemble learning framework.

- Section V: Experiments and Results: Presents the experimental setup, evaluation metrics, and performance analysis. Includes an ablation study demonstrating incremental improvements and a comparative analysis with prior benchmarks.
- Section VI: Discussion and Challenges: Discusses the results, highlighting contributions and challenges.
- Section VII: Conclusion and Future Work: Summarizes the findings, emphasizing the study's significance, and proposes future directions.

II. PREVIOUS WORK

Different studies have demonstrated that visualizing Android malware through image-based analysis using deep learning offers resilience beyond what static and dynamic analyses can sometimes achieve, effectively distinguishing between malicious and benign applications.

In 2019, Shao Yang [11] proposed an image-based Android malware detection method using CNNs. This approach converts Dalvik bytecode files ('classes.dex') into RGB images, capturing code patterns by mapping byte sequences to pixel values. The model, a CNN with eight hidden layers, detects malware directly from these RGB images, bypassing complex feature extraction. Tested on a dataset containing 10,540 samples, the method achieved an accuracy of 93%, with an average detection time of 0.22 seconds.

In 2020, Ding et al. [12] proposed an Android malware detection method based on bytecode images. Their approach involves extracting the 'classes.dex' file from APKs and converting it into grayscale images by transforming the byte stream into a two-dimensional matrix. Using convolutional neural networks (CNNs), their method automatically learns features without requiring complex decompiling or manual feature extraction. Tested on the Drebin dataset, it achieved an accuracy of 95.1%.

In 2020, Rahali et al. [13] proposed DIDroid, an image-based deep learning system for Android malware classification and characterization. By extracting features from APK files and transforming them into grayscale images, the system employs a convolutional neural network (CNN) to classify samples into 12 malware categories and 191 families. Tested on a large dataset of 400,000 apps (200,000 malware and 200,000 benign), achieving an accuracy of 93.36%.

In 2021, Zhang et al. [14] introduced an Android malware detection method that leverages temporal convolution networks (TCNs) and bytecode images. This approach combines the 'AndroidManifest.xml' file with the data section of the 'classes.dex' file to create grayscale images, capturing both structural and sequential bytecode features. By using TCN instead of traditional CNN, the model efficiently detects malware while reducing computational demands, achieving an accuracy of 95.44%.

In 2021, Bakour and Ünver [15] introduced DeepVisDroid, a hybrid Android malware detection model that combines image-based features with deep learning techniques. They

created four grayscale image datasets by converting different files from APKs and extracted both local (e.g. SIFT, SURF, ORB) and global (e.g. color histogram, Hu moments) features for training. Using a 1D convolutional neural network model, DeepVisDroid achieved over 98% accuracy, outperforming traditional 2D CNN models and state-of-the-art methods in terms of accuracy and computational efficiency.

In 2022, Mitsuhashi and Shinagawa [16] conducted an extensive study on image-based malware variant classification, evaluating 24 CNN models with various fine-tuning levels on datasets like Maling and Drebin. Their highest accuracy on Android malware classification was achieved with EfficientNetB4, reaching 93.65% on the Drebin dataset.

In 2022, Ullah et al. [17] developed a hybrid Android malware detection system using a combination of transfer learning and multi-model image representation. Their approach combines both textual and texture features from network traffic, leveraging transfer learning to create embeddings from network data and generating malware images for visual analysis. Using CNNs, they extracted texture features, and an ensemble model combined these with textual features for final classification. Tested on the CIC-AAGM2017 and CICMalDroid 2020 datasets, the system achieved 99% accuracy.

In 2023, Jo et al. [18] proposed a Vision Transformer (ViT)-based Android malware detection method that combines high accuracy with interpretability. Their approach converts DEX files into RGB images and uses the ViT model's attention mechanism to detect malware while identifying malicious behavior by highlighting influential areas within the image, allowing extraction of class and method names and providing insights into the malware's underlying behavior. Tested on real-world datasets, the model achieved an accuracy of 80.27% with an interpretability score of 0.70.

In 2024, Aldini and Petrelli [19] proposed a method for Android malware detection and classification by visualizing app data as grayscale images. Their approach uses a static analysis of files within APKs, such as 'classes.dex' and 'AndroidManifest.xml', converting these to grayscale images. Multiple convolutional neural network (CNN) models were applied to detect and classify malware, with CNN-LSTM and CNN-SVM models showing high accuracy rates. The study tested the method on datasets including Drebin and AndroZoo, achieving accuracy rates around 99% for detection and 97% for classification.

In 2024, Kiraz and Doğru [20] presented an image-based approach for Android malware detection, focusing on visualizing static features. They used the AndroPyTool to extract permissions, intents, receivers, and services from Android apps and converted these features into embedding vectors using the BERT algorithm. The embeddings were then transformed into images and classified with a CNN model. Tested on the CICMalDroid 2020 dataset, their method achieved an accuracy of 91%.

In 2024, Tang et al. [21] introduced an Android malware detection approach that utilizes a unique mixed bytecode image combined with an attention mechanism. Their method processes Android executable files by converting bytecode into grayscale and Markov images, then fusing these into a mixed image for enhanced feature representation. This approach

integrates channel and spatial attention mechanisms within a ResNet model, improving classification accuracy. Testing on the Drebin and CICMalDroid 2020 datasets, their model achieved an accuracy of 98.67%.

In 2024, Wang et al. [22] proposed an Android malware detection method based on RGB images with multi-feature fusion. Their approach extracts features from DEX files, AndroidManifest.xml files, and API calls, converting each into grayscale images enhanced through techniques like Canny edge detection and histogram equalization. These images are then merged into RGB images, with each channel representing a different feature type. Tested on the CICMalDroid 2020 dataset with models like AlexNet, GoogleNet, and ResNet, the method achieved an accuracy of 97.25%.

In 2024, Yapici [23] introduced an image-based approach for Android malware detection, converting Dalvik bytecode files into grayscale and RGB images for deep learning analysis. Addressing issues of dataset duplication and class imbalance, the study incorporates data cleaning and augmentation to improve result accuracy. This method achieved an accuracy of 98.7%.

III. BACKGROUND

A. Broader Security Innovations

As Android malware continues to evolve in complexity, advancements in security technologies offer critical complementary strategies to APK analysis. For instance, methods like reliable concurrent error detection have been developed to improve computational reliability, particularly in systems relying on elliptic curve cryptography, which is integral to secure communications [24]. Enhancements in elliptic curve techniques, such as binary Edwards curves optimized for resource-constrained environments, highlight significant progress in creating robust cryptographic frameworks for embedded systems [25].

Efforts to reduce the computational cost of cryptographic operations have also led to the design of low-cost S-box solutions, which are essential for encryption processes such as those employed in the Advanced Encryption Standard (AES) [26]. Furthermore, the development of constant-time cryptographic libraries for protocols like supersingular isogeny Diffie-Hellman (CSIDH) underscores the emphasis on mitigating timing attacks, thereby ensuring secure operations in the context of quantum-resistant cryptography [27].

In addition, the security of deeply embedded and cyber-physical systems, often constrained by limited resources, remains a focal point. Innovative approaches address challenges such as maintaining data confidentiality and integrity in environments requiring lightweight yet effective solutions [28].

These collective advancements contribute to fortifying the security landscape, enhancing the resilience and reliability of APK file analysis in identifying and mitigating Android malware.

B. APK File Structure

Android Package (APK) files serve as the standard format for distributing and installing applications on Android devices [29]. Essentially, an APK is a compressed archive containing

various components that collectively define the app's functionality, behavior, and resources. The structure of an APK file is depicted in Fig. 1, and its key components include:

- Dalvik Bytecode (`classes.dex`): This file contains the compiled code that runs on the Android Runtime (ART) or Dalvik Virtual Machine (DVM). It defines the application's logic and behavior, including its methods, classes, and API calls. Due to its critical role in execution, the `classes.dex` file is often a focal point in malware detection research.
- Manifest (`AndroidManifest.xml`): This XML file provides essential metadata about the application, such as its package name, permissions, components (activities, services, etc.), and hardware/software requirements. Malware often manipulates the manifest file to gain unauthorized access or exploit vulnerabilities.
- Resources (`res/`): This folder contains non-compiled resources, such as layouts, images, and strings, that are used to define the application's user interface and content.
- Compiled Resources (`resources.arsc`): This file stores compiled resource data in binary form, optimized for efficient runtime access by the application.
- Assets (`assets/`): A directory for additional files that the application needs at runtime, such as configuration files, data files, or embedded libraries.
- Native Libraries (`lib/`): This folder contains native code files (e.g. `.so` files) that are platform-specific, often used to optimize performance or access device-specific functionality.
- Signatures (`META-INF/`): This folder contains cryptographic signatures and certificates used to verify the integrity of the APK file. Modifications to the APK often invalidate its signature, signaling potential tampering.

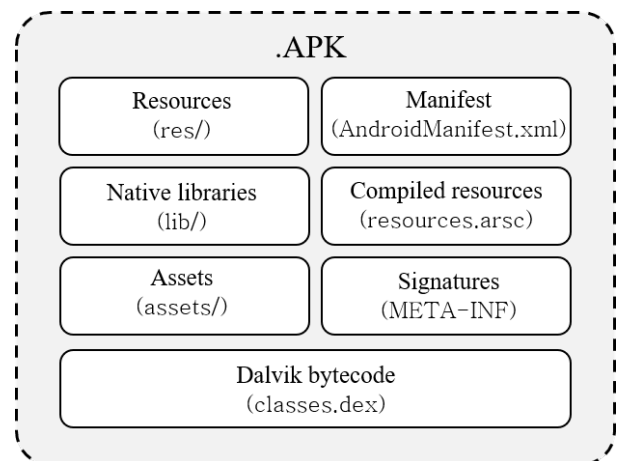

Fig. 1. APK file structure.

C. DEX File Structure

The Dalvik Executable (DEX) file is central to defining the behavior and logic of Android applications [29], comprising several essential sections that govern its execution flow. The structure of this file is illustrated in Fig. 2 and includes:

- Header: Contains metadata such as the magic number, checksum, file size, and offsets to other sections.
- String_IDs: Holds identifiers for strings, including class names, method names, and constant values.
- Type_IDs: Defines data types referenced in the application, including classes and primitives.
- Proto_IDs: Specifies method prototypes, detailing return types and parameter lists.
- Field_IDs: Provides definitions of fields within classes, specifying their types and names.
- Method_IDs: Enumerates methods, linking them to their respective classes and prototypes.
- Class_Defs: Describes each class, including its fields, methods, and metadata.
- Data Section: Contains supplementary information such as constants, initialization data, and debugging details.

Fig. 2. DEX file structure.

D. CNN Models

In this study, six pre-trained convolutional neural network (CNN) architectures were employed for Android malware detection. Each model was chosen for its unique strengths and suitability for image-based classification tasks. Additionally, these models were fine-tuned for binary classification to distinguish between benign and malware samples:

- ResNet50 [30]: A residual network with 50 layers and 25.6 million parameters, excelling in avoiding vanishing gradient issues through its residual learning approach.

- AlexNet [31]: A classic CNN with 8 layers and 60 million parameters, known for its simplicity and speed, particularly effective on smaller datasets.
- DenseNet121 [32]: A densely connected network with 121 layers and 8 million parameters, designed to maximize feature reuse and minimize redundancy.
- MobileNetV2 [33]: A lightweight CNN with 53 layers and 3.4 million parameters, optimized for deployment on mobile and embedded systems.
- EfficientNetB0 [34]: A scaled CNN with 16 layers and 5.3 million parameters, achieving an excellent balance between high accuracy and computational efficiency.
- ShuffleNetV2 [35]: A channel-shuffling network with 50 layers and 2.3 million parameters, designed for extreme speed and low computational overhead.

E. Weighted Voting Ensemble

The Weighted Voting Ensemble is a technique that combines the predictions of multiple models by assigning each a weight based on its performance [36]. For a given input, the ensemble calculates the probability of classification as a weighted sum of individual model outputs:

$$P_{\text{ensemble}}(x) = \sum_{i=1}^n w_i \cdot P_i(x), \quad (1)$$

where $P_i(x)$ is the probability assigned by the i -th model for input x , w_i is its corresponding weight, and n is the total number of models in the ensemble. A threshold is then applied to determine the final classification. This approach leverages the complementary strengths of individual models, enhancing accuracy and reducing errors.

F. Bayesian Optimization

Bayesian Optimization is a probabilistic framework for optimizing expensive-to-evaluate functions [37]. It employs a surrogate model, typically a Gaussian Process (GP), to approximate the objective function $f(x)$, where $f(x)$ in this study represents the ensemble accuracy. The GP is characterized as:

$$f(x) \sim \mathcal{GP}(\mu(x), k(x, x')), \quad (2)$$

where $\mu(x)$ is the mean function, and $k(x, x')$ is the kernel function measuring similarity between points x and x' .

Using the Expected Improvement (EI) criterion, Bayesian Optimization iteratively refines weights by balancing exploration and exploitation:

$$\text{EI}(x) = \mathbb{E}[\max(f(x) - f(x^*), 0)], \quad (3)$$

where $f(x^*)$ is the best observed value of the objective function. This method efficiently identifies the optimal weight configuration to maximize ensemble accuracy.

IV. METHODOLOGY

A. Proposed Architecture

This study presents a novel image-based framework for Android malware detection, leveraging convolutional neural networks (CNNs) and a weighted voting ensemble to enhance detection accuracy.

The methodology is organized into three primary stages: data preprocessing, model training, and ensemble prediction.

In the preprocessing stage, the DEX file is extracted from Android APKs and transformed into grayscale images that encapsulate structural patterns indicative of malware. During model training, advanced CNN architectures are employed to analyze these images, enabling deep feature extraction and precise classification. Lastly, an optimized weighted voting ensemble integrates predictions from multiple models to improve overall performance and reliability.

The overall workflow of the proposed framework is illustrated in Fig. 3.

B. Data Preprocessing

In this study, the data preprocessing stage transforms Android APK files into grayscale images, which serve as input for the proposed deep learning framework. This transformation captures the structural patterns embedded in the DEX files, enabling robust malware detection. The preprocessing pipeline consists of the following steps:

1) *DEX File Extraction*: The first step involves extracting the `classes.dex` file from Android APKs. This file was chosen as the primary feature for analysis due to its structural richness and resilience to obfuscation techniques. Unlike other APK components, such as resource files or manifest configurations, the bytecode in the DEX file retains identifiable patterns that are critical for distinguishing between benign and malicious applications.

The extraction process treats the APK as a compressed archive, which is unzipped using Python's `zipfile` module. The `classes.dex` file is typically located in the root directory of the APK. To handle improperly named files, the script automatically renames files lacking the correct `.apk` extension, ensuring compatibility with the extraction process. This automated pipeline consistently prepares the DEX file for transformation into grayscale images.

2) *Binary-to-Image Conversion*: Once the DEX file is extracted, its binary content is read and converted into an 8-bit grayscale pixel matrix. Each byte in the binary sequence is mapped to a pixel intensity (0–255). This mapping ensures that the structural patterns in the bytecode are preserved in the resulting image.

The file size determines the width of the image, using a method adapted from Nataraj et al. [9]. The height is calculated dynamically to fit all pixels into a 2D matrix, using the formula:

$$\text{Height} = \frac{\text{Total Number of Bytes}}{\text{Image Width}}.$$

Table I outlines the mapping of file size ranges to image widths. This scaling ensures consistency while maintaining the integrity of structural characteristics.

TABLE I. IMAGE WIDTH CALCULATION BASED ON FILE SIZE

File Size Range	Image Width
<10 kB	32
10 kB – 30 kB	64
30 kB – 60 kB	128
60 kB – 100 kB	256
100 kB – 200 kB	384
200 kB – 500 kB	512
500 kB – 1000 kB	768
>1000 kB	1024

By retaining the sequence of bytecode as pixel intensities, this method preserves the unique structural characteristics of the application, such as opcode patterns and control flow representations. These features are critical to distinguish malware from benign applications.

C. Model Training

This study initially experimented with various pre-trained CNN architectures to identify the models most effective for classifying benign and malicious Android applications. Following extensive evaluations, six CNN models—ResNet50, AlexNet, DenseNet121, MobileNetV2, EfficientNetB0, and ShuffleNetV2—were selected for their complementary strengths in feature extraction and classification. These models demonstrated high performance in terms of accuracy, precision, recall, and F1-scores during preliminary testing. Each model was initialized with pre-trained weights from ImageNet and trained using a consistent pipeline to ensure fairness and comparability.

1) *Image Preparation*: The grayscale images generated from the `classes.dex` files were resized to a fixed input dimension of 224×224 pixels. They were normalized using the ImageNet dataset's mean $([0.485, 0.456, 0.406])$ and standard deviation $([0.229, 0.224, 0.225])$. Data augmentation techniques, including resizing and normalization, were applied to enhance model generalization.

2) *Classifier Adaptation*: Each model's classifier was customized for binary classification by replacing the original fully connected layers with the following configuration:

- A dropout layer ($p = 0.4$) to mitigate overfitting.
- A dense layer with 256 units and ReLU activation.
- A second dropout layer ($p = 0.4$).
- A final dense layer with one output node and a sigmoid activation function.

3) *Training Process*: The models were trained using the AdamW optimizer with a learning rate of 0.0001 and a weight decay of 1×10^{-5} . The binary cross-entropy loss function was employed for optimization. Training was conducted over 20 epochs with a batch size of 32. An early stopping mechanism,

Fig. 3. The proposed architecture for android malware detection.

with a patience of 5 epochs, was implemented to prevent overfitting while ensuring optimal model performance.

D. Ensemble Prediction

To enhance the overall performance and robustness of the classification, an ensemble prediction strategy was employed. The ensemble combines the outputs of six pre-trained convolutional neural network (CNN) models: ResNet50, AlexNet, DenseNet121, MobileNetV2, EfficientNetB0, and ShuffleNetV2. By leveraging the strengths of each model, the ensemble aims to improve classification accuracy and reduce errors in detecting Android malware.

The ensemble prediction uses a weighted voting mechanism, where the outputs from each model are aggregated based on their performance during validation. For each input image, the probability of classification is calculated as a weighted sum of the individual model predictions. Weights were constrained to $[0, 1]$, normalized to sum to 1, and refined over 300 iterations using the Expected Improvement (EI) criterion.

Bayesian Optimization was employed to determine the optimal weights for the ensemble, as detailed in Algorithm 1. This probabilistic technique was chosen for its ability to efficiently explore high-dimensional parameter spaces while balancing exploration with exploitation. Unlike manual selection or traditional methods such as grid or random search, Bayesian Optimization leverages information from prior iterations to refine the weight configurations, resulting in faster convergence and more effective optimization.

Algorithm 1 Bayesian Optimization for Ensemble Weights

Require: Validation dataset \mathcal{D} , pre-trained models: $\{\text{ResNet50, AlexNet, DenseNet121, MobileNetV2, EfficientNetB0, ShuffleNetV2}\}$, number of iterations $N = 300$, batch size = 32.

Ensure: Optimal weights $\{w_1, w_2, \dots, w_6\}$ for the ensemble.

- 1: Initialize bounds $[0, 1]$ for each w_i and randomly generate initial weights.
- 2: **for** $i = 1$ to N **do**
- 3: Generate candidate weights $\{w_1, w_2, \dots, w_6\}$.
- 4: Normalize weights such that $\sum_{i=1}^6 w_i = 1$.
- 5: Compute ensemble prediction for each image x :

$$P_{\text{ensemble}}(x) = \sum_{i=1}^6 w_i \cdot P_i(x)$$

- 6: Evaluate ensemble accuracy on \mathcal{D} .
- 7: Refine weights using the Expected Improvement (EI) criterion:
 - a. Explore unvisited regions of the weight space.
 - b. Exploit regions with promising results.
- 10: Update surrogate model with new results.
- 11: **end for**
- 12: **return** Optimal weights $\{w_1, w_2, \dots, w_6\}$ achieving the highest ensemble accuracy.

V. EVALUATION AND RESULT

A. Dataset

In this study, the CICMalDroid 2020 dataset [38] was utilized, a benchmark dataset designed to support research and development in Android malware detection. The dataset was created by the Canadian Institute for Cybersecurity (CIC) and contains a total of 17,341 APK files. It categorizes APKs into five classes: **Adware**, **Banking**, **SMS**, **Riskware**, and **Benign**. Each class represents a specific type of Android application behavior, with malware types grouped based on their malicious intent, and benign applications serving as the control group.

1) *Dataset Preparation*: During the preprocessing stage, 415 APK files were excluded due to various issues, including:

- Missing or inaccessible `classes.dex` files.
- Permission restrictions preventing file access.
- Corrupted or non-standard file formats.
- Invalid or unusual filenames.
- Integrity check failures, such as bad CRC-32.

These issues prevented consistent processing of a subset of the dataset. As a result, only valid and complete files were included to maintain data quality and ensure reliable model training.

2) *Data Splitting*: Initially, the dataset was split into training (80%) and validation (20%) subsets for each class, ensuring balanced representation in both subsets. Following this, all malware classes were concatenated into a single class named **Malware** for binary classification, while the **Benign** class remained unchanged. This process resulted in the following data distribution:

- Benign: 3,216 samples for training and 805 for validation.
- Malware: 10,001 samples for training and 2,502 for validation.

B. Experimental Setup and Performance Metrics

The experiments were conducted on a Windows operating system using Python as the programming language. The models were implemented with the PyTorch 2.4.1 deep learning framework, and the training process was accelerated using CUDA 11.8 on an NVIDIA RTX 2060 GPU.

To evaluate the performance of the proposed models, a variety of metrics were employed to ensure a comprehensive understanding of their classification capabilities. Each metric serves a distinct purpose, offering insights into specific aspects of the models' performance and their ability to distinguish between benign and malware samples. The definitions of the metrics used are as follows:

- Accuracy (AC): Represents the overall proportion of correctly classified samples:

$$AC = \frac{TP + TN}{TP + TN + FP + FN} \quad (4)$$

where TP is true positives, TN is true negatives, FP is false positives, and FN is false negatives.

- Precision (P): Measures the proportion of true positive predictions out of all positive predictions:

$$P = \frac{TP}{TP + FP} \quad (5)$$

This metric highlights the model's ability to minimize false positives.

- Recall (R): Evaluates the proportion of true positive predictions among all actual positive samples:

$$R = \frac{TP}{TP + FN} \quad (6)$$

Recall is critical in malware detection to ensure that malicious applications are not overlooked.

- F1-Score (F): The harmonic mean of precision and recall, providing a balance between the two:

$$F = \frac{2 \cdot P \cdot R}{P + R} \quad (7)$$

The defined metrics were utilized to evaluate the classification performance of six individual CNN models and the proposed ensemble learning approach. Table II provides a comparative summary of the results, presenting the accuracy, precision, recall, and F1-score for each model. This analysis highlights the unique strengths and weaknesses of each model while demonstrating the superior performance of the ensemble approach.

TABLE II. PERFORMANCE METRICS FOR ALL MODELS

Model	Accuracy (%)	Precision (%)	Recall (%)	F1 Score (%)
ResNet50	98.54	98.76	99.32	99.04
AlexNet	98.51	99.11	98.92	99.01
DenseNet121	98.42	99.59	98.32	98.95
MobileNetV2	98.45	99.35	98.60	98.97
EfficientNetB0	98.52	99.04	99.00	99.02
ShuffleNetV2	98.39	98.64	99.24	98.94
Ensemble Learning	99.30	99.59	99.48	99.54

The superior performance of the ensemble was achieved through the optimal weights determined by Bayesian Optimization. These weights were carefully assigned to balance the contributions of each model, reflecting their relative importance in the ensemble's predictions. Table III presents the final weights for each model, highlighting the significant contributions of MobileNetV2 and EfficientNetB0, which had the highest weights, underscoring their strong performance in feature extraction and classification.

For further insights into the models' classification performance, the Receiver Operating Characteristic (ROC) curves, presented in Fig. 4, offer a detailed evaluation of the individual models and the ensemble learning approach. All models exhibit excellent discriminatory capabilities, with Area Under the Curve (AUC) values exceeding 0.997. The ensemble learning approach outperformed all individual models, achieving the

TABLE III. OPTIMAL WEIGHTS FOR ENSEMBLE MODELS

Model	Optimal Weight
AlexNet	0.037
DenseNet121	0.172
EfficientNetB0	0.225
MobileNetV2	0.288
ResNet50	0.124
ShuffleNetV2	0.154

highest AUC of 0.9993. This superior performance highlights the ensemble’s ability to effectively combine the strengths of individual models, resulting in enhanced classification accuracy.

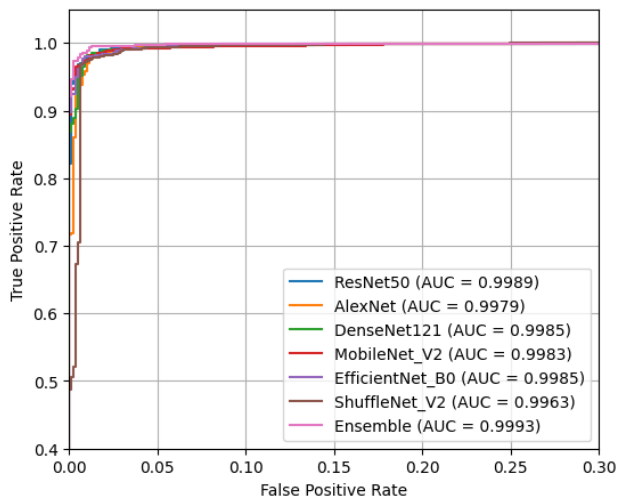

Fig. 4. ROC curves for CNN models and ensemble learning.

To provide a more detailed evaluation of the ensemble’s predictions, the confusion matrix in Fig. 5 illustrates its classification outcomes for benign and malware samples. The model successfully classified 795 benign and 2,489 malware samples, with only 10 false positives and 13 false negatives. These results demonstrate the ensemble’s high precision and recall, ensuring robust malware detection with minimal errors.

The proposed ensemble learning approach demonstrated significant improvements in Android malware detection accuracy compared to prior methods. Table IV provides a comparative analysis of existing approaches, highlighting datasets, models, and achieved accuracies. The proposed method outperformed techniques such as CNN-LSTM, CNN-SVM [20], and single-model approaches such as ResNet [19] and EfficientNet [16], it also surpassed studies employing multi-feature fusion strategies [22].

C. Ablation Study: Incremental Model Analysis

An ablation study was conducted to determine the optimal configuration of the ensemble by incrementally adding models and evaluating their impact on performance metrics. Starting with a baseline ensemble of ResNet50, AlexNet, and EfficientNetB0, additional models—MobileNetV2, DenseNet121, and

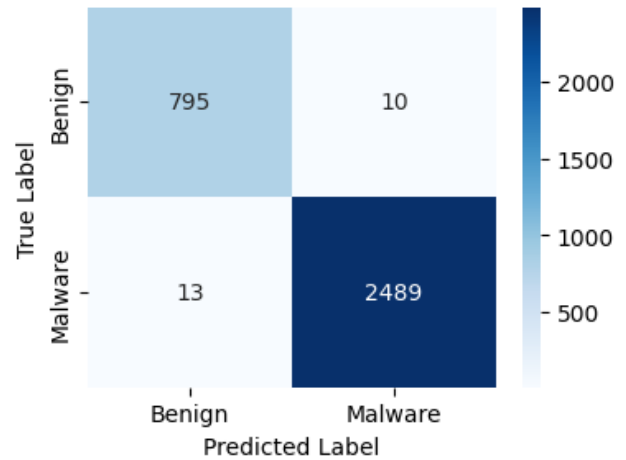

Fig. 5. Confusion matrix for the ensemble learning approach.

TABLE IV. COMPARATIVE ANALYSIS OF ANDROID MALWARE DETECTION METHODS

Ref	Dataset	Model	Acc (%)
[11]	AMD (6,134 malware), Google Play (4,406 benign)	CNN	93

ShuffleNetV2—were iteratively incorporated based on their individual metrics, such as precision, recall, and F1-score.

Each addition was rigorously evaluated for its contribution to accuracy and robustness, with weights re-optimized using Bayesian Optimization to ensure balanced contributions. The

study demonstrated a consistent progression in performance: accuracy improved from 99.09% with three models to 99.30% with six models, achieving the best performance across all metrics in the final configuration.

The results highlight the incremental benefits of integrating diverse architectures into the ensemble, validating the soundness of the methodology. Fig. 6 illustrates the steady improvements, emphasizing the rationale and effectiveness of this approach.

Fig. 6. Comparison of accuracy across ensemble learning configurations.

VI. DISCUSSION AND CHALLENGES

The proposed ensemble approach achieved remarkable results, surpassing prior methodologies in Android malware detection with an accuracy of 99.3%, addressing challenges posed by evolving malware obfuscation techniques, particularly through the use of grayscale images derived from DEX files, which preserve critical bytecode patterns. The methodology not only outperformed single-model approaches, such as CNNs in [12] (95.1%) and TCN [14] (95.44%), but also exceeded advanced methods like CNN-LSTM [20] and multi-feature strategies [22], which achieved accuracies of 97% and 97.25%, respectively. This demonstrates the ensemble's capacity to generalize across diverse malware families while maintaining classification robustness.

However, several challenges were encountered during the study. One notable issue was overfitting, mitigated effectively by employing early stopping to ensure generalization without compromising performance. Another challenge was the lack of recent Android malware datasets. The rapid evolution of malware introduces the risk that outdated datasets may fail to capture current threats, limiting the generalizability of detection systems.

Furthermore, deploying a six-model ensemble in real-time environments poses practical difficulties due to the increased computational resources and latency required to run multiple models simultaneously. Addressing this limitation will be

crucial for translating the proposed approach into real-world applications.

Despite these challenges, the study demonstrates the potential of ensemble learning in advancing the state of Android malware detection. By combining multiple CNN architectures and optimizing their contributions, this methodology provides a robust framework that paves the way for future research on integrating multi-feature analysis and scaling to larger datasets.

VII. CONCLUSION

This study introduced a novel ensemble learning framework for Android malware detection, utilizing grayscale images derived from DEX files and six pre-trained CNN models. Achieving an impressive accuracy of 99.3%, the proposed method surpassed existing approaches in the field. By leveraging a weighted voting mechanism, optimized through Bayesian Optimization, the ensemble demonstrated superior performance across key metrics, achieving precision, recall, and F1-scores of 99.59%, 99.48%, and 99.54%, respectively. This robust approach effectively minimized classification errors while ensuring reliable malware detection.

The findings underscore the benefits of combining multiple CNN architectures to harness their complementary strengths in feature extraction and classification. Additionally, the framework demonstrated resilience against obfuscation techniques frequently used by malware developers, enhancing its practicality for real-world applications.

Future research will focus on expanding this methodology to encompass larger, more diverse datasets and integrating multi-feature approaches with advanced analysis techniques. These efforts aim to further improve detection accuracy and adaptability, addressing the ever-evolving landscape of Android malware threats.

ACKNOWLEDGMENTS

The authors would like to express their sincere gratitude to the Engineering Sciences Laboratory, National School of Applied Sciences, Ibn Tofail University, Kenitra, Morocco for providing the resources and support needed to carry out this research. The authors also extend their thanks to the CNRST (Centre National pour la Recherche Scientifique et Technique) for its financial support under the "PhD-Associate Scholarship - PASS" Program.

Abstract—Indonesia is among the world’s most prolific countries in terms of internet and social media usage. Social media serves as a primary platform for disseminating and accessing all types of information, including health-related data. However, much of the content generated on these platforms is unverified and often falls into the category of misinformation, which poses risks to public health. It is essential to ensure the credibility of the information available to social media users, thereby helping them make informed decisions and reducing the risks associated with health misinformation. Previous research on health misinformation detection has predominantly focused on English-language data or has been limited to specific health crises, such as COVID-19. Consequently, there is a need for a more comprehensive approach which not only focus on single issue or domain. This study proposes the development of a new corpus that encompasses various health topics from Indonesian social media. Each piece of content within this corpus will be manually annotated by expert to label a social media post as either misinformation or fact. Additionally, this research involves experimenting with machine learning models, including traditional and deep learning models. Our finding shows that the new cross-domain dataset is able to achieve better performance compared to those trained on the COVID dataset, highlighting the importance of diverse and representative training data for building robust health misinformation detection system.

Keywords—Health misinformation; machine learning; social media

I. INTRODUCTION

The proliferation of internet users in Indonesia has been steadily increasing. A 2023 survey by the Indonesian Internet Service Provider Association reported that internet penetration had reached 78%, marking a significant rise compared to the previous year¹. The COVID-19 pandemic in early 2020 played a pivotal role in accelerating the adoption of internet-based applications for daily activities. With the shift to remote work, online education, e-commerce, and telemedicine, the internet became indispensable for modern life. Among these changes, access to health information via digital platforms has expanded significantly. Social media platforms, in particular, have enabled the rapid dissemination of health-related content through user-generated content (UGC), encompassing text, images, videos, and comments on a wide range of topics. Features such as likes, shares, and comments amplify the spread of information, which spans various subtopics, including general

health, vaccines, diseases like Ebola and cancer, and public health crises such as the COVID-19 pandemic [1], [2].

However, the exponential growth of information on social media presents a dual challenge: while access to health-related content is democratized, it becomes increasingly difficult for users to assess the credibility and quality of this information. Studies have identified social media platforms like Facebook, Twitter, and Instagram as primary vectors for the spread of health misinformation, which often propagates faster than accurate information [3]. Health misinformation has been linked to severe consequences, particularly during the COVID-19 pandemic, where widespread falsehoods created confusion, reduced vaccine uptake, and undermined herd immunity efforts. The World Health Organization (WHO) reported that misinformation during the pandemic led to over 6,000 hospitalizations and 800 deaths globally [4]. Such incidents underscore the real-world consequences of misinformation, which can escalate from individual confusion to public health crises.

Misinformation surrounding vaccines exemplifies the long-standing impact of health-related falsehoods. For instance, between September 2018 and July 2019, 85% of the 649 reported measles cases in the U.S. involved unvaccinated individuals [5]. Furthermore, recent surveys indicate that misinformation about chronic diseases, such as diabetes and cancer, is among the most concerning categories of health-related content on social media. The persistent spread of misinformation highlights the critical need to address this issue comprehensively. Left unchecked, such falsehoods can lead to misinformed decisions, delays in seeking proper medical care, and ultimately, adverse health outcomes for individuals and communities.

The urgency of tackling health misinformation has prompted researchers to explore automated solutions for misinformation detection. Automated systems can enable users to instantly assess the credibility of content accessed on social media, empowering them to make informed health decisions and reducing the risks associated with misinformation. While significant progress has been made in health misinformation detection research, much of the existing work has concentrated on English-language data [6]. This focus leaves a critical gap in addressing misinformation in non-English contexts, such as Bahasa Indonesia, a language spoken by over 270 million people.

In Indonesia, 76% of users perceive social media as a trustworthy source of information [7]. Moreover, according to

¹<https://m.bisnis.com/amp/read/20230308/101/1635219/survei-apjii-pengguna-internet-di-indonesia-tembus-215-juta-orang>.

data from the Indonesian Telecommunications Society, approximately 40% of the hoax news articles circulating in Indonesia in 2019 were related to health [8], making the detection of misinformation even more pressing. Recent efforts have begun creating datasets and machine learning models for detecting misinformation in Bahasa Indonesia. However, these efforts have primarily focused on domain-specific topics, such as COVID-19, limiting their applicability to other health-related misinformation. Moreover, existing studies often neglect the diverse and evolving nature of misinformation across different health domains, which can include varied topics like traditional medicine, vaccines, mental health, and non-communicable diseases.

To address the gaps identified in previous studies, this research seeks to answer the following key research questions:

- 1) How can a cross-domain dataset for health misinformation detection in Bahasa Indonesia be effectively constructed to address diverse health topics?
- 2) Can machine learning models trained on the proposed cross-domain dataset generalize effectively across various health domains, reducing dependence on any single domain?
- 3) How does the performance of the proposed cross-domain dataset compare to existing domain-specific datasets in terms of robustness and quality?

Based on the proposed research questions, this study makes the following contributions to the field of health misinformation detection:

1) *Dataset development:* Creation of a cross-domain dataset for health misinformation detection in Bahasa Indonesia, encompassing diverse health topics to enable broader generalization.

2) *Model evaluation:* Preliminary experiments using multiple machine learning approaches to evaluate the effectiveness of the constructed dataset.

3) *Benchmarking:* Comprehensive comparison of the proposed dataset against existing domain-specific datasets to demonstrate its robustness and quality.

This paper is structured as follows: Section II reviews related work on health misinformation detection, highlighting gaps in existing research. Section III details the methodology for constructing the dataset and designing preliminary experiments. Section IV presents and discusses the experimental results, while Section V concludes the study and outlines directions for future work.

II. RELATED WORKS

Health misinformation detection has been extensively studied, primarily focusing on English. These studies leverage various approaches, such as linguistic and behavioral features, to identify and combat misinformation. For instance, Zhao et al. (2021) proposed a model combining central and peripheral features based on the Elaboration Likelihood Model (ELM), significantly improving detection accuracy by integrating user interaction patterns [6]. Similarly, Zhong et al. (2023) analyzed temporal and sentiment patterns in misinformation dissemination on Twitter [9], revealing that misinformation tends

to persist longer and garner more engagement than credible information.

Despite these advancements, research on health misinformation detection in non-English contexts, particularly Bahasa Indonesia, remains limited. Faisal and Mahendra (2022) addressed this gap by developing a COVID-19-specific misinformation dataset and proposing a two-stage classifier leveraging IndoBERT for Indonesian tweets. Their approach demonstrated the efficacy of pre-trained language models but was constrained by its focus on the COVID-19 domain [7]. In fact, several studies on health misinformation focused on the topic of covid-19 [10], [11]. Another effort by Prasetyo et al. (2018) explored classification techniques for health-related hoax news in Bahasa Indonesia using the Modified K-Nearest Neighbor (MKNN) method. Their results showed an accuracy of 75%, with performance influenced by challenges such as unstructured text and diverse linguistic styles in Indonesian health news [12].

In the broader context of misinformation detection in Indonesia, Rohman et al. (2021) conducted a systematic literature review analyzing methods for fake news classification in Bahasa Indonesia. Their findings identified 19 commonly used algorithms, with Naïve Bayes [13] and Term Frequency-Inverse Document Frequency (TF-IDF) [14] being the most exploited approach. They highlighted the dominance of datasets sourced from platforms like turnbackhoax.id and Twitter and emphasized the need for exploring a wider range of methods beyond these mainstream approaches [15]. Additionally, a recent study by Arini et al. (2024) examined the sociocultural factors, such as varying levels of trust in information sources, that influence the spread and detection of misinformation during the pandemic [16].

The concept of cross-domain classification has emerged as a promising avenue for addressing the limitations of domain-specific models. Kansal et al. (2020) reviewed cross-domain sentiment analysis methods, emphasizing their potential to reduce reliance on single-domain datasets through domain adaptation and transfer learning [17]. These findings suggest that cross-domain approaches could enhance the generalizability of misinformation detection models across diverse health topics. Based on these insights, this research aims to address the gaps in existing studies by proposing a cross-domain dataset for health misinformation detection in Bahasa Indonesia. By leveraging state-of-the-art machine learning techniques and integrating cross-domain classification methods, this study seeks to overcome the challenges posed by linguistic and contextual diversity in Indonesian health misinformation.

III. RESEARCH METHODOLOGY

In this research, we develop a dataset for cross-domain health misinformation detection in Indonesian tweet. Moreover, we perform a preliminary study by exploring commonly used machine learning approach.

A. Data Collection and Annotation

The primary goal of this phase is to construct a cross-domain corpus capturing health misinformation phenomena in Indonesian social media. The dataset construction process is illustrated in Fig. 1.

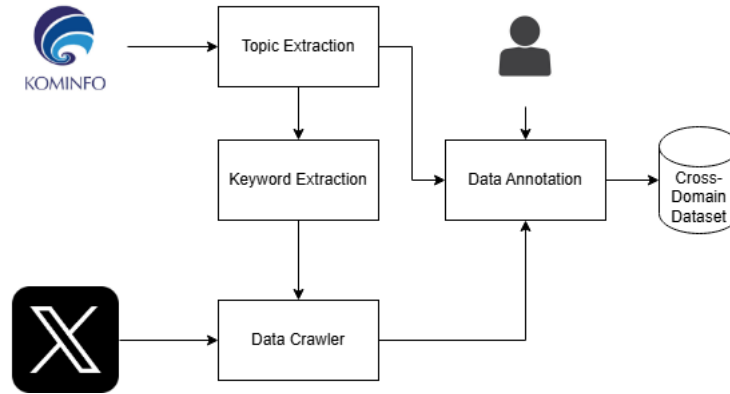

Fig. 1. Corpus building process.

1) *Data collection*: Data was collected from various health-related topics by utilizing weekly hoax news content published on the official website of the Ministry of Communication and Information Technology (KOMINFO) of Indonesia (Kominfo, 2023). A total of 27 hoax news articles covering topics such as COVID-19, HIV, polio, and other health concerns were analyzed. Table I summarizes the articles and the number of tweets crawled for each.

2) *Keyword extraction*: For each article, primary keywords were extracted and combined into search queries for crawling tweets. For example, for the article titled “[HOAKS] Buah Pala dan Gula Batu Mampu Mengatasi Jantung Berdebar” [18], keywords such as Pala, Gula Batu, and Jantung Berdebar were extracted and combined into search phrases like Pala AND Jantung Berdebar and Gula Batu AND Jantung Berdebar. These phrases were used in the crawling process, focusing on data from Twitter (now known as X).

3) *Manual annotation*: After collection, the tweets were manually annotated by two annotators based on predefined criteria. The annotation process involved verifying that the content was written in Indonesian, relevant to health information, and determining whether the content constituted misinformation or truth. The labels assigned were:

a) *Misinformation*: Content identified as false based on the KOMINFO news article.

b) *True*: Content verified as accurate.

To ensure the reliability of the annotations, inter-annotator agreement was measured using Cohen’s Kappa. In cases of disagreement, a third annotator resolved conflicts. This process ensures high-quality annotations for downstream tasks.

B. Model Development

To assess the quality and applicability of the newly constructed dataset, a preliminary study was conducted on the task of health misinformation detection. This involved training and evaluating various machine learning models.

1) *Traditional models*: The following models were implemented using scikit-learn with Bag-of-Words as the feature representation:

- Naive Bayes

TABLE I. SUMMARY OF HOAX NEWS ARTICLES AND CRAWLING RESULTS

News Title	Topic	Numb. of Tweet
[HOAKS] Covid-19 bukan Virus, Sumber: Kementerian Kesehatan RI	covid	29

Total		3623

- Support Vector Machines (SVM)
- Logistic Regression

- Decision Tree
- Random Forest

2) *Deep learning models*: Advanced deep learning models were also explored, including:

- Bi-LSTM (Bidirectional Long Short-Term Memory)
- BERT
- IndoBERT [19], a transformer-based language model specifically designed for Indonesian.

We use Optuna for automated hyperparameter optimization [20] for traditional models and Bi-LSTM. For the transformer-based model, we use the default configuration of the models in HuggingFace with learning rate of $1e-5$.

3) *Evaluation*: Models were evaluated on two datasets:

- The newly constructed cross-domain corpus.
- A COVID-specific dataset from previous research [7].

The evaluation metrics included:

- Accuracy: Proportion of correctly classified instances.
- Macro Precision: Average precision across all classes.
- Macro Recall: Average recall across all classes.
- Macro F1-Score: Harmonic mean of precision and recall.

These metrics provide a comprehensive assessment of model performance, particularly in imbalanced datasets.

The results will be compared with classifications using a corpus from previous research (COVID Data) [7] as the training data. This comparison aims to assess the stability and reliability of the newly constructed corpus. The evaluation will be conducted using standard performance metrics, including accuracy, macro-precision, macro-recall, and macro F1-score.

IV. RESULT AND DISCUSSION

In this section, we will discuss the dataset developed from the data collection and annotation process as explained in Section III-A and the preliminary experimental result as explained in Section III-B

A. Dataset Results

TABLE II. DATASET LABEL DISTRIBUTION

Label	No.of Tweet	Percentage
<i>Misinformation</i>	1590	44
<i>True Information</i>	762	21
<i>Not Sure</i>	82	2
<i>deleted</i>	1189	33
Total	3623	100

The tweet crawled in the data collection process yielded a total of 3,623 tweets. The distribution of tweets for each topic is presented in Table III. From the table it is evident that the topic with the highest number of tweet is COVID followed by HIV, Cancer and Cojoined Twins. The prominence of COVID

data is likely because there are much more news article related to COVID. Moreover, COVID is a phenomenon with global impact and widespread discussion. The topic of cojoined twins also tweeted by many people because the content is related to myths that are common in Indonesian society. In contrast, other topics has limited number of tweets likely because the content is not widely known and discussed.

From the collected data, 1189 tweets were deleted. These tweets were excluded because they are not written in Indonesian, unrelated to health topic or duplicate. The remaining tweets were annotated into two labels: MISINFORMATION and *True*, as shown in Table II. Among these, 1,590 tweets (44%) were labeled as *misinformation*, representing the largest portion of the dataset. The *True Information* label includes 762 tweets (21%) that were verified as accurate and reliable. A small subset of the data, 82 tweets (2%), was labeled as *Not Sure*, indicating cases where annotators found it difficult to determine whether the tweet is misinformation or true information. We reach an inter-annotator agreement with a Cohen's Kappa value of 0.91, which indicates almost perfect agreement.

B. Preliminary Results

In the preliminary experiment, we utilized the dataset that labeled as *misinformation* or *True*, in total of 2,352 data. In the experiment, 80% of the data was allocated for training, while the remaining 20% was used for data testing. The distribution of the data training and data testing is shown in Table III.

TABLE III. DISTRIBUTION OF TRAINING AND TESTING DATA ON EACH TOPIC

Topic	Testing	Training	Total
Covid	336	655	991
High Blood Pressure	0	24	24
Fertility	0	18	18
Avian Flu	0	17	17
Kidney Failure	0	7	7
GERD	0	67	67
HIV	134	511	645
Heart Problem	0	7	7
Cancer	0	167	167
Cojoined Twins	0	165	165
Cholesterol	0	17	17
Near-sightedness	0	3	3
Brain, bone marrow, diabetes	0	30	30
Polio	0	91	91
Toothache	0	3	3
Dyspnea	0	46	46
Stroke	0	54	54
Total	470	1882	2352

The outcomes of our experiments are presented in Table IV. We employed traditional machine learning approaches, including Naive Bayes, SVM, Logistic Regression, Decision Tree, and Random Forest as well as deep learning approaches, including Bi-LSTM, BERT, and Indo-BERT. We conducted two experiments for each model, utilizing the COVID-specific dataset and the cross-domain dataset as the training data. The performance of the trained models was evaluated using test data derived from the cross-domain dataset.

The results clearly demonstrate that models trained on the cross-domain dataset consistently outperformed those trained on the COVID-specific dataset. This trend was observed across

TABLE IV. RESULTS OF MISINFORMATION DETECTION EXPERIMENT USING COVID DATASET AND CROSS-DOMAIN DATASET

Model	Covid Dataset				Cross-Domain Dataset			
	macro-P	macro-R	macro-F	Acc	macro-P	macro-R	macro-F	Acc
Naive Bayes	0.601	0.581	0.583	0.668	0.734	0.735	0.735	0.768
SVM	0.623	0.580	0.583	0.668	0.844	0.800	0.816	0.849
Logistic Regression	0.591	0.557	0.550	0.670	0.833	0.807	0.818	0.847
Decision Tree	0.546	0.542	0.542	0.617	0.818	0.806	0.811	0.838
Random Forest	0.589	0.592	0.590	0.636	0.885	0.762	0.791	0.842
Bi-LSTM	0.599	0.611	0.598	0.623	0.828	0.773	0.792	0.832
BERT	0.595	0.597	0.596	0.643	0.766	0.776	0.770	0.796
IndoBERT	0.597	0.599	0.598	0.647	0.844	0.856	0.849	0.866

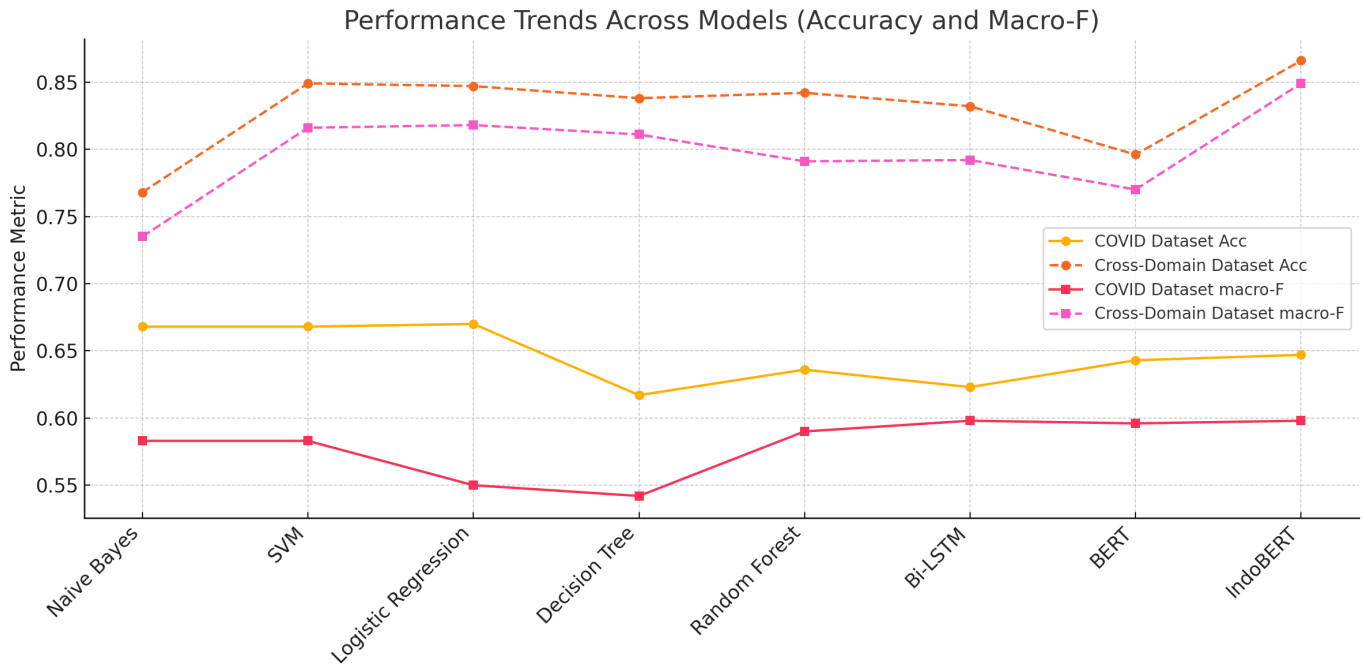

Fig. 2. Performance trends across models.

all models, both traditional and deep learning techniques. Notably, the use of cross-domain data appears to enhance the ability of the models to generalize across diverse contexts and topics, leading to improved predictive accuracy and robustness. The observed improvements in performance suggest that incorporating data from a variety of domains can mitigate the limitations of topic-specific datasets, which may lack diversity.

The results, as visualized in the Fig. 2, demonstrate significant differences in model performance when trained on the COVID dataset and the Cross-Domain dataset. Models trained on the Cross-Domain dataset consistently outperform those trained on the COVID dataset in both accuracy and macro-F scores. This highlights the superior generalization capability of the Cross-Domain dataset, which encompasses a broader range of health misinformation topics. Among the evaluated models, IndoBERT achieved the highest performance, with an accuracy of 0.866 and a macro-F score of 0.849 when trained on the Cross-Domain dataset. This underscores the effectiveness of transformer-based language models in handling complex linguistic features and diverse misinformation scenarios.

Simpler models such as Naive Bayes and Decision Tree also benefit from the Cross-Domain dataset, showing improved

metrics compared to training on the COVID dataset. However, their performance is limited relative to more advanced models, reflecting their inability to capture nuanced patterns in the data. Models like SVM and Logistic Regression exhibit significant improvements with the Cross-Domain dataset, suggesting their adaptability to diverse training data while remaining computationally efficient. Meanwhile, deep learning models such as Bi-LSTM show stable improvements, but they are outperformed by transformer-based models like BERT and IndoBERT, indicating the latter's superior contextual understanding.

The comparison between datasets underscores the importance of dataset diversity in training robust misinformation detection models. The Cross-Domain dataset enables models to generalize across various health misinformation topics, in contrast to the COVID dataset, which limits models to a single domain. These results demonstrate the Cross-Domain dataset's ability to enhance training effectiveness, making it a valuable resource for developing generalizable health misinformation detection systems.

The heatmap shown in Fig. 3 offers a detailed view of the interplay between models, datasets, and evaluation metrics, providing unique insights beyond the trends observed

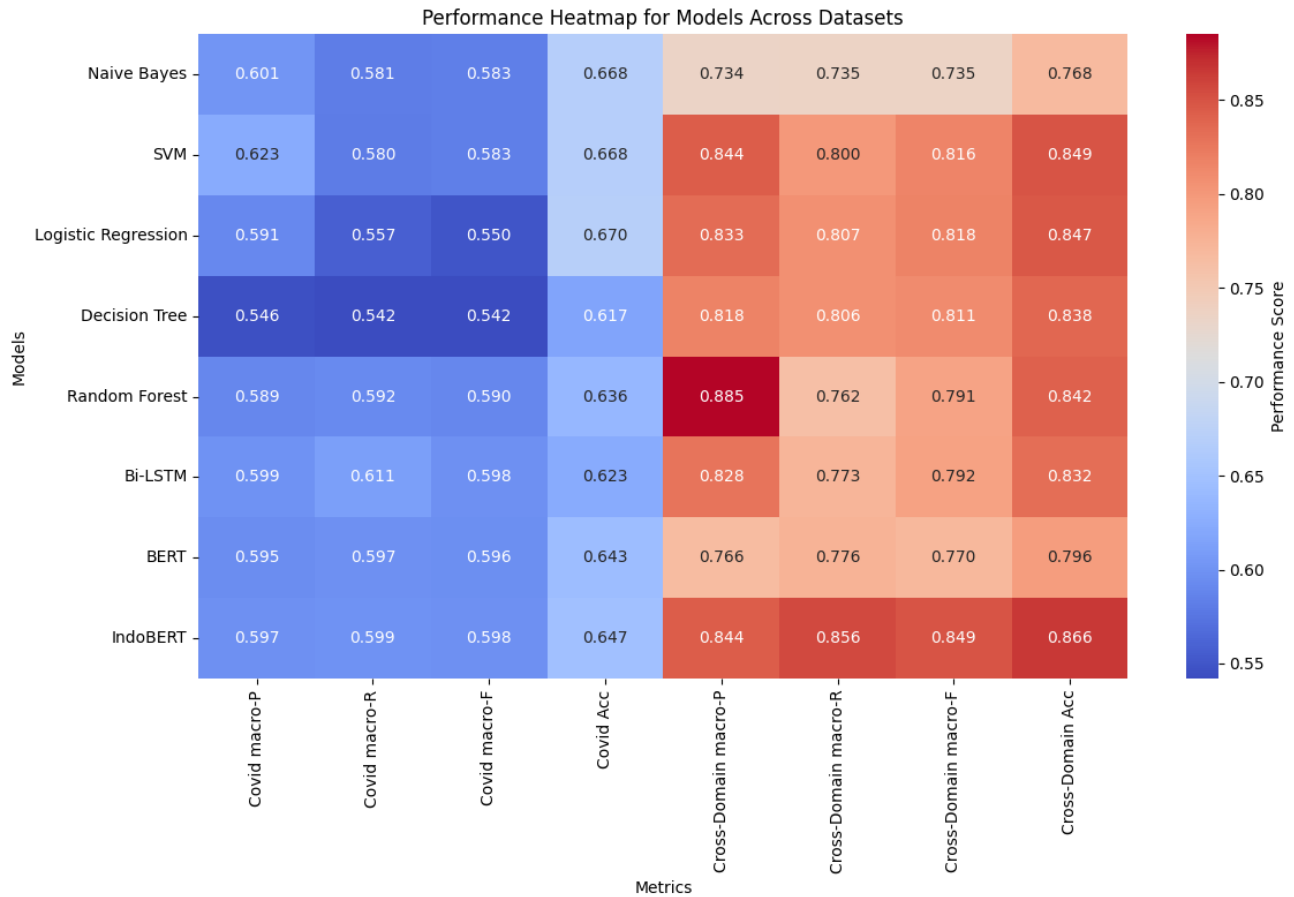

Fig. 3. Performance heatmap for models across datasets.

in the line charts. One key observation is the variability across metrics, where certain models demonstrate significant strengths in specific areas. For instance, IndoBERT exhibits a substantial improvement in macro-recall when trained on the Cross-Domain dataset (0.856) compared to the COVID dataset (0.599), indicating its effectiveness in reducing false negatives across diverse health misinformation topics. Additionally, the heatmap reveals trade-offs between precision and recall. For example, Random Forest achieves an exceptionally high macro-precision (0.885) on the Cross-Domain dataset but shows a relatively lower macro-recall (0.762), suggesting its strong capability in identifying true positives but limited sensitivity to all relevant instances.

The sensitivity of models to dataset diversity is also apparent, with traditional models such as Naive Bayes and Decision Tree showing larger relative gains from the COVID dataset to the Cross-Domain dataset, particularly in precision and accuracy. This highlights the disproportionate benefit simpler models derive from richer training data. Moreover, metric-specific strengths are evident; Random Forest excels in macro-precision, while IndoBERT consistently outperforms other models in macro-recall and macro-F, reflecting its ability to balance precision and recall effectively. Some models, such as BERT, display only modest improvements across datasets, suggesting the need for additional fine-tuning or data augmentation to fully exploit the diversity of the Cross-Domain

dataset.

Overall, the heatmap underscores the uniform performance boost across all models when using the Cross-Domain dataset, validating its robustness and utility for training generalizable health misinformation detection systems. The variability in metric-specific performance and model sensitivity offers complementary insights, enriching the understanding of model behaviors across diverse datasets.

V. CONCLUSION

In conclusion, this research introduces a novel cross-domain dataset for health misinformation detection in Indonesian tweets. The primary objective was to address the limitations of domain-specific datasets, such as those focused solely on COVID-19, and to evaluate the efficacy of machine learning models in generalizing across diverse health misinformation topics. Through comprehensive experiments using traditional and deep learning models, our study demonstrated that the Cross-Domain dataset significantly improves model performance across all evaluation metrics, including accuracy, macro-precision, macro-recall, and macro-F score. Models trained on the Cross-Domain dataset consistently outperformed those trained on the COVID dataset, underscoring the value of diverse and representative training data in developing robust misinformation detection systems.

Our findings highlight the effectiveness of advanced models such as IndoBERT, which achieved the highest performance metrics and demonstrated exceptional adaptability to the linguistic and contextual diversity present in the dataset. Traditional models, while showing notable improvements, remained limited in their ability to capture nuanced patterns, further emphasizing the importance of leveraging state-of-the-art methods for complex tasks like health misinformation detection.

This study contributes to the field by providing a high-quality, cross-domain dataset and presenting evidence of its potential to enhance machine learning models' generalization capabilities. These findings address the research questions posed in this study, particularly regarding the construction of a cross-domain dataset and its impact on misinformation detection models. Future work could focus on expanding the dataset to include other health misinformation sources, exploring multilingual approaches, and refining machine learning techniques to further improve performance. By addressing challenges in low-resource linguistic contexts, this research paves the way for more effective and scalable solutions to combat health misinformation.

Comparison of Machine Learning Algorithms for Malware Detection Using EDGE-IIoTSET Dataset in IoT

Jawaher Alshehri, Almaha Alhamed, Mounir Frikha, M M Hafizur Rahman
Department of Computer Networks Communications, King Faisal University, CCSIT,
Al Hofuf, Al Hassa 31982, Saudi Arabia

Abstract—The growth of IoT devices has presented great vulnerabilities leading to many malware attacks. Existing IoT malware detection methods face many challenges; including: device heterogeneity, device resource restrictions, and the complexity of encrypted malware payloads, thus leading to less effective conventional cybersecurity techniques. This study's objective is to reduce these gaps by assessing the results obtained from testing five machine learning algorithms that are used to detect IoT malware by applying them on the EDGE-IIoTSET dataset. Key preprocessing steps include: cleaning data, extracting features, and encoding network traffic. Several algorithms used these include: Logistic Regression, Decision Tree, Naïve Bayes, KNN, and Random Forest. The Decision Tree model achieved perfect accuracy at 100%, making it the best-performing model for this analysis. In contrast, Random Forest delivered a strong performance with an accuracy of 99.9%, while Logistic Regression performed at 27%, Naïve Bayes at 57%, and KNN with moderate performance. Hence, the results have shown the effectiveness of machine learning techniques to enhance the security IoT systems regarding real-time malware detection with high accuracy. These findings are useful input for policymakers, cybersecurity practitioners, and IoT developers as they develop better mechanisms for handling dynamic IoT malware attack incidents.

Keywords—IoT malware; machine learning; malware detection; IoT security; EDGE-IIoTSET

I. INTRODUCTION

The Internet of Things (IoT) is comprises a huge variety of devices connected to one another and exchanging information. These devices include, smart home devices, medical equipment, and industrial machinery, sensors, and wearable technologies. The high and rapid growth of IoT has effected transformation in a variety of fields and sectors like healthcare, transportation, commerce, agriculture, and education [1], [2], [3], [4], [5]. With that in view, IoT has become widely embraced as driving economic growth and improving quality of life, resulting in unbridled worldwide creation of new appliances and projects. This growth comes with enormous security challenges and problems in IoT devices. Currently, these are the prime targets for cyber criminals amidst other digital device. Of these, malware attacks are becoming one of the most salient and dangerous threats in IoT. Most IoT devices are not well-protected and have low computation abilities, which makes them high-value targets for malware attacks despite previous studies were mainly aimed at improving malware detection using sophisticated machine learning techniques, there is still a huge gap between the application of such techniques

on resource-constrained IoT devices with severely constrained performance and real-time response. Malware analysis remains crucial in IoT systems for understanding, detecting, and mitigating these threats. It forms part of the insight into how malicious actors compromise devices and networks; hence, it is an essential element of IoT security.

The IoT is both a network and a system. The definition of a network is that it can make communication possible between connected devices [6]. It is, in the same moment, considered as a system as it combines other elements and technologies to allow communication and data exchange between devices. Despite the fact that IoT technology offers so many benefits, it has created enormous potential weaknesses that impact performance and effectiveness in prescribed, although the various table text styles are provided. The formatter will need to create these components, incorporating the applicable criteria that follow. operation concurrent with its rapid growth. These malware might cause major financial and operational losses [7]. For instance, a well-publicized, major DDoS attacks on IoT devices and systems are typically executed by a botnet like Mirai [8]. Having fallen to the attacker, the device can then be used to execute other dangerous attacks. This malware is still a serious and evolving irritant in the modern digital world [9]. Thus, malware research will become extremely important for the security analysts and researchers as they try to comprehend different varieties of malware and take countermeasures against them.

It divided into two kinds of analysis: dynamic and static. The dynamic considers malware in an active state, whereas the status is considered for malware in an inactive state. Both are great significance in understanding how to protect IoT devices against malicious activities in-depth. The level of analysis and understanding of the capabilities of malware very much depends on how one can keep IoT safe from hacking and breaches of privacy [10]. Because of these, among other constraints, traditional malware detection techniques do not work well in the IoT environment with very restricted processing power and storage. This work therefore goes ahead to issues relating to IoT malware detection, but with more focus on how effective machine learning algorithms prove. For this reason, we compare various models and find the most suitable one for real-world applications in protecting IoT systems.

These methods are promising but require quite a lot of computational resources, which are difficult to handle using

typical IoT environments with device heterogeneity and less complex processing. This mismatch between capability and necessity creates a critical vulnerability in IoT security frameworks [46]. Most recent studies focus on intensive models including CNNs and LSTMs, which are undoubtedly accurate but still are unsuitable on resource-constrained IoT devices for real-time deployment. Additionally, the diverse malware types are often addressed inadequately. As most of the models focus solely on botnets [47]. The continuing evolution of IoT malware requires detection strategies that are not only effective but also adaptable to the constrained environments typical of many IoT devices. Addressing these gaps is essential.

This study addresses these gaps by analysing lightweight machine learning models to detect IoT malware explicitly accounting diverse malware types. Our research systematically benchmark five machine learning models: Decision Tree, Random Forest, Naïve Bayes, KNN, and Logistic Regression by using the EDGE-IIoTSET dataset [48]. This work contributes to identifying the most effective algorithm, and proposes a scalable and suitable approach for real-time application in a heterogeneous IoT ecosystem. The main objective of this paper is to evaluate the performance of lightweight machine learning algorithms. This paper provides actionable insights regarding the selection and optimization of machine learning algorithms in order to enhance IoT security. Among the research questions that need to be addressed in this study are as follows:

RQ1: What extent can machine learning algorithms effectively detect malware in IoT devices, considering the challenges of device heterogeneity, limited resources, and encrypted malware payloads? RQ2: Which machine learning models are most effective for real-time malware detection in resource-constrained IoT environments?

By exploring these questions, our study aims to give actionable insights that guide the development of more robust and scalable malware detection models tailored for the diversity and dynamic nature of IoT systems, making sure they remain reliable and secure against evolving threats.

II. LITERATURE REVIEW

IoT malware detection has acquired significant attention, and machine learning has grown as a prominent technique to address these threats. This section explores recent developments for detecting IoT malware, identifies gaps in the current literature, and compares the effectiveness of various machine-learning models in malware detection.

A. Recent Development in IoT Malware Detection using Machine Learning

A considerable amount of work is currently being performed for the development of machine learning-based models for the detection of IoT malware. Most of them feature network traffic analysis in search of suspicious patterns and label malicious behaviors using IoT-specific data. For example, the work explores deep learning approaches for detecting botnet activity in IoT devices. The researchers' results demonstrated that CNNs can outperform other ML approaches, including Support Vector Machines and Decision Trees, with a classification accuracy greater than 95% [11]. Following this line of investigation, the research presents an LSTM model for

malware detection based on IoT device behavior [12]. It was also found that LSTMs identify time-based patterns in traffic data, reporting an accuracy of around 97%.

The authors of [13] performed a performance study on the application of XGBoost and LightGBM to IoT malware detection. They concluded that LightGBM was most relevant in real-time detection since it computes much more quickly and can save memory compared to Random Forest. With these developments come challenges. Most of the related works considered do not address heterogeneity in IoT devices with their limited computational resources or the payloads in encrypted form arising from specific IoT devices, hence hampering the performance of these ML algorithms [14]. It is such a gap that our research sets out to fill, ensuring focus on lightweight models for efficiency in resource usage but high accuracy in malware detection.

B. Current Gaps in the Literature

Even though the area of IoT malware detection has developed, some gaps still exist in the literature. Most related studies tend to ignore the restricted computational resources provided by IoT devices. For example, although certain studies reported high accuracy using CNNs and LSTMs, they are computationally expensive and hence cannot be realistically deployed on resource-constrained IoT devices [15]. Also, most of these research works pertain to malware types like botnets alone and not all variants of IoT malware, such as ransomware, spyware, and worms [16]. The other limitation is that the literature does not focus on encrypted traffic, which originates from IoT devices. In many cases, the IoT devices encrypt data due to privacy issues; hence, malicious activity detection solely based on encrypted network traffic is limited. Most of the research has focused on plaintext traffic; hence, encrypted network traffic is highly neglected and further limits applicability of in real-time scenarios [17]. Our research covers these gaps by assessing machine-learning models applicable to resource-constrained devices and encrypted traffic analysis.

C. Comparison Study of Various ML Models for IoT Malware Detection

A number of machine learning algorithms have been tried and tested for IoT malware detection; each of them has pros and cons. Recently, XGBoost and LightGBM have gained major attention because of their speedy and bulky handling of data [18]. XGBoost prevents problems of overfitting by using regularization techniques; hence, it is a robust choice in malware detection for IoT environments, which are dynamic. At the same time, it requires very heavy computation, which makes it computationally prohibitively expensive for resource-constrained IoT devices [19]. On the other hand, LightGBM is more resource-efficient and has faster training times than XGBoost, making it more suitable for real-time malware detection in IoT systems [20]. Researchers in [21] found that LightGBM achieved comparable accuracy to XGBoost but used less memory and CPU, making it ideal for low-powered IoT devices. Nevertheless, DNNs have proven quite promising in developing complex patterns from network traffic data, be it CNNs or LSTMs [22]. However, DNNs still suffer from serious computations, which are particularly not suitable for real-time IoT applications [23].

Thus, the lightweight models like Random Forest or Decision Tree are practical models for real-world IoT malware detection [24]. Therefore, our work demonstrates that, in terms of the trade-off between accuracy and computational efficiency, among the techniques under study, Random Forest achieves the best performance and is deployable on resource-constrained IoT devices. Although machine learning has made major advancements in the detection of malware on IoTs, there is still a gap in the literature regarding model suitability for resource-constrained IoT devices and how it handles encrypted traffic. This paper largely extends works that have been previously performed to assess lightweight models and address challenges we have pinpointed in order to create more pragmatic IoT malware detection.

In previous studies, several machine learning methods have been proven to be effective in detecting IoT malware. For instance, Sliwa, Piatkowski, and Wietfeld (2020) demonstrated that Random Forest algorithms can offer reliable malware detection in IoT devices; however, they also identified some disadvantages when dealing with encrypted traffic data. Additionally, Zhang and Zhou (2021) revealed that SVMs excelled in very high-dimensional data scenarios, thereby further indicating how the performance of the algorithm would vary with regard to data characteristics (Sliwa et al., 2020; Zhang & Zhou, 2021).

III. CHALLENGES IN IOT MALWARE ANALYSIS

The analysis of IoT malware shows different challenges due to the IoT ecosystem's nature. This section offers insight into the heterogeneity and diversity of IoT devices, the resource limitations of these constrained environments, encrypted and obfuscated malware payloads, and the privacy concerns and regulatory challenges associated with managing IoT data.

A. Heterogeneity and Diversity of IoT Devices

Heterogeneity in IoT indicates the different array of elements, in terms of various protocols, devices, services, and networks within an ecosystem, highlighting the complexity and variability of interconnected elements [25], [26]. Interoperability indicates the key challenge in heterogeneous IoT platforms due to diverse methods for recognizing and identifying devices within different platforms, as well as resource requests. These differences are huge hurdles and create hindrances in data exchange and smooth communication. It is crucial to bridge these interoperability gaps, to ensure seamless operation and secure data exchange within the IoT environment [26]. In addition, integrating diverse IoT technologies and devices from different vendors into a cohesive and unified system can present complex and significant challenges. Each device may have its own application programming interfaces, which complicates data-sharing and integration efforts. Diverse communication protocols also complicate the establishment of connections and data exchange. Metrological characteristics also have also proved to be a significant concern in the integration process due to inconsistencies in measurement units, range, accuracy, and scale among different devices, since every device has unique features. Ensuring temporal consistency and synchronization across many IoT devices, especially in real-time applications, further increases complexity [27].

B. Resource Limitations and Constrained Environments

Few resources and a constrained environment mean IoT devices have limited energy, memory, and processing-power resources. The result of these constraints is the limited ability to implement trade resource-intensive security measures for devices. Additionally, IoT devices are often connected over a lossy link. During the transmission of data, lossy links may have a significant chance of packet loss. Environmental factors, signal attenuation, and wireless interference may cause problems that compromise the security and dependability of IoT networks. As a result, packet loss, delay, and erratic communication between devices may occur. So, mitigating the effects of lossy connectivity is necessary for the security of IoT devices with limited resources [28].

C. Encrypted and Obfuscated Malware Payloads

The identification and analysis of IoT malware could be difficult because malicious programs use various methods to encrypt and hide their payloads. Due to encryption, the payload's exact purpose remains hidden, making it more challenging for traditional antivirus programs to identify and address malicious code. Obfuscation techniques are also used to make it more difficult to study the malicious code, employing strategies like code obfuscation to purposefully make the code more complex and difficult to interpret. This hinders the analysts' ability to comprehend its behavior [29].

D. Privacy Concerns and Regulatory Challenges

IoT presents a multitude of privacy and regulatory concerns around the gathering, storing, and use of data produced by linked devices. Data security is one of the main concerns. As IoT devices expand, they produce vast amounts of data, including sensitive and personal information. Protecting the privacy of this data is mandatory, especially when it comes to personal information about an individual's actions and behaviors. Cyber risks include security breaches and illegal access that can compromise the confidentiality of the data gathered and sent by IoT devices. Addressing security concerns to protect IoT-generated data privacy is crucial [29]. These vulnerabilities, combined with the above challenges of IoT systems and networks, make comprehensive security management a challenging task. As this paper progresses, we will explore advanced detection techniques that aim to overcome these challenges and fortify the protection of IoT systems against evolving threats.

IV. METHODOLOGY

The materials and methods section outlines the overview of the used dataset, followed by the rationale for algorithm selection, machine learning in malware detection for IoT systems, and some details about the dataset preprocessing techniques used to ensure accurate results.

A. Machine Learning in Malware Detection for IoT Systems

In the complex ecosystems of Internet of Things systems, machine learning has emerged as a critical technique for enhancing virus detection. We used network traffic simulations to create our dataset in order to ensure that it appropriately reflects common IoT interactions and possible security breaches,

given the diversity and unpredictability present in IoT contexts. This method was chosen because it enhances the validity and application of our study by allowing the dataset to cover a wide range of real-world situations are quite helpful in spotting novel patterns that haven't been assigned a label yet.

Table I details the different types of machine learning approaches we employed and their specific application and benefits toward IoT security. A multi-pronged approach would not only guarantee complete coverage but also make the detection systems robust and reliable for the unexpected nature of IoT malware.

TABLE I. MACHINE LEARNING ALGORITHMS

Type	Description
Supervised learning	Methods include Support Vector Machines (SVMs) and Random Forests, which excel at classifying malware based on predefined labels. These algorithms are trained on datasets that humans provide to models.
Unsupervised learning	Includes Principal Component Analysis (PCA) and segregating data in the form of clusters, offering a complementary strategy by anomaly detection within IoT data. These techniques can detect and identify previously unseen malware variants without relying on pre-labeled data [41].
Deep learning models	Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs), in particular, have remarkable capabilities for handling complex and large-scale IoT datasets. These models can effectively extract features from data, which can lead to better detection rates for sophisticated malware [42].
Hybrid models	To enhance detection capabilities, hybrid models combine strengths of both types of analysis-static and the dynamic analyses. While static analysis examines the code structure, dynamic analysis observes code behavior during execution. By integrating these perspectives, hybrid models are advanced models that can enhance the detection of both known and unknown malware threats.

This study investigates the deployment of machine learning to detect malware in internet-enabled gadgets. The research leverages the EDGE-IIoTSET dataset, and we preprocessed network traffic data to extract relevant features. We compared SVM, Random Forest, and CNN models to identify optimal algorithms for classifying malware. Standard metrics were used to evaluate model performance and execution, considering computational efficiency for practical IoT deployment.

Each machine learning model was carefully optimized to balance predictive accuracy with a computationally fair load. The Random Forest, for example, was set at a specific number of trees such that it would neither overfit, nor be impractical to use on limited resource devices typical for IoT setups, and SVMs were optimized about kernel type and the regularization parameters about the best discrimination between malicious traffic and benign one without requiring exhaustive computational resources.

Our approaches ensured that optimizations reduced computational overhead; otherwise, IoT resources are characterized by limited implementations, which might prove challenging. For instance, in the Random Forest approach, it was setup to have just a few trees so as to decrease model complexity and

runtime. Such made it feasible for real-time virus detection of devices in an Internet of Things device with processing capabilities.

B. Rationale for Algorithm Selection

The major concerns necessary for the applied machine learning algorithms to discover IoT malware are scalability and efficiency. Python and Scikit-learn were chosen with great care due to their excellent documentation, strong community support, and large selection of pre-built functions for data processing and machine learning. These characteristics make it easy for other researchers to replicate our methods. Python provides scalability and efficient calculation when working with massive datasets, therefore the choice also fits with the requirement for real-time processing capabilities in IoT systems. IoT networks may generate a huge volume of data. Therefore, the chosen algorithms must be able to scale up while handling large-sized datasets efficiently, without being computation-heavy for resource-constrained IoT devices. Malware detection algorithms raise concerns over precision and accuracy, which means they involve risks concerning false positives and false negatives [33]. Interpretability of models should be interpretable in the IoT environment. A security practitioner must understand why some network traffic was flagged as malicious by a model in order to take remedial action. Algorithms were selected based on the criteria below.

Stochastic Forests: The Random Forest algorithm was chosen because of its great ability to handle big feature sets and reduce overfitting problems [34]. Therefore, it was found that this model takes the average output of many created decision trees, meaning the variance in measurement would be lower than using one single Decision Tree model. Hence, it generalizes the model to new data.

Advantages: It is easily scalable for RF, and it contains a mix of categorical and numerical data to be executed efficiently. It is relatively faster and also has means to internally estimate the importance of features; hence, such aspects will be useful during real-time deployment in IoT systems [35].

Disadvantages: The model performance may decrease when the dimensionality is high in the feature space, so a dimensionality reduction method needs to be applied [36].

Support Vector Machines (SVMs): Support vector machines have been remarked on as doing quite well in high-dimensional spaces and with binary classification problems. For example, since the core of the problem would involve network traffic being classified as benign or malicious, this makes a SVM a natural choice [37].

Advantages: The feature space of SVM can be applied toward finding the optimal hyperplane separating the classes from each other, since the model would not be biased toward any particular class.

Disadvantages: One of the disadvantages is that SVMs can become extremely expensive when used with big data, and this may limit their applicability to real-time IoT scenarios [38].

Convolutional Neural Networks (CNNs): CNNs are the algorithms most used in image processing and, as recent studies have proved, do a great job with network traffic

analysis. These CNNs have been shown to learn complex patterns from network data and hence are likely to easily recognize sophisticated malware [39].

Advantages: CNNs can be very flexible and reveal even small and complex patterns in data that would be very useful for the detection of new malware samples.

Disadvantages: CNNs are quite resource-expensive algorithms for the user, which decreases its applicability in resource-limited IoT environments [40].

C. Dataset Overview

Our analysis of the industrial edge computing and IoT applications depended on the EDGE-IIoTSET dataset [30]. Due to its large amount of network traffic that is unique to the Internet of Things, comprising both malicious and benign payloads captured under controlled environments, the EDGE-IIoTSET dataset was selected. Our results can be reproduced and applied to other industrial applications due to the realistic simulation of IoT network environments this dataset provides. **Sampling Strategy:** To achieve the balanced representation on IoT risks, the strategy implemented was a stratified random sampling that would allow all malware types to have adequate representation.

The dataset was given several essential preprocessing steps to ensure it could be used the best way possible to fit into machine learning research. First, we removed all incomplete or outlier items within the raw data that could ruin the results. We then extracted relevant information from the network traffic data with the aid of feature engineering, including payload characteristics, protocol type, and packet size. The data characteristics were then scaled using normalization techniques so that our machine learning algorithms could read them efficiently and without favoring any one feature scale.

It contains packet or packet-related metadata network traffic information important for malware threat detection in IoT networks. Some of the features include the number of dimensions of the IoT communications, like payload sizes, types of protocols, and network latency. These features are among some of the most important in our model, giving insight into the nature of benign and malicious activities across the network. We use a recently constructed benchmark, the EDGE-IIoTSET dataset, specifically for machine learning applications in the context of the Industrial Internet of Things. That is, it is really a rich set of features aimed at capturing real IoT network traffic behavior, both benign and malicious.

1) Main Features of the Dataset: **Network Traffic:** The datasets are well complemented with packet size, the protocols of communication, and event timestamps within a network flow. **Packet Information:** This includes metadata that identifies each packet of traffic flowing across the network, including source and destination addresses, protocol types, and statistics regarding data flow. **Anomalies and Attacks:** Classification of all variations of the different attacks; DDoS attacks, provided as an example, are attacks of many other types of malware varieties attacking IoT devices. They include ransomware, spyware, and botnet threats, among others.

2) Challenges of the Dataset: **Diversity:** Data created from IoT devices is vastly heterogeneous owing to their diversity in functionality [31]. For example, data streaming from home security cameras, smart thermostats, and industrial sensors can be packaged into one dataset, which will act differently across a network. **Imbalanced Classes:** Most network traffic is benign rather than malicious, and this imbalance can create quite a tough challenge for most machine learning algorithms because the models might simply end up showing a preference for the benign traffic classes and finally yield poor performance in malware detection [32]. The EDGE-IIoTSET dataset was selected as it represents the diversities of real-world test cases, comprising IoT devices; therefore, it is rated among the best benchmarks to test the malware detection techniques.

3) Dataset and Preprocessing: ML-Edge IIoT-dataset.csv (EDGEIIOTSET Dataset) is a dataset designed for analysis and machine learning tasks within the edge and Industrial Internet of Things (IIoT) environments [43]. The main objective is to clean, transform, and prepare the data for training the machine learning model by removing unnecessary columns, handling missing values, and encoding categorical features. The dataset being used is (ML-EdgeIIoT-dataset.csv). This dataset likely contains different network-related features and attack types from edge and IIoT environments. It contains various types of network-related data and possibly some metadata from network communications. The dataset is initially loaded into a data frame using a Python library, which is called Pandas. The (low_memory=False) argument is helpful to optimize memory usage for reading large datasets. A predefined list of columns that are too specific to be useful (drop_columns) are considered irrelevant for the analysis. Those types of columns are eliminated from the dataset to maintain data integrity and to minimize dimensionality. The code drops rows that contain any missing values and removes duplicate rows to ensure that the dataset is clean and consistent. To enhance the dataset's usability, it is shuffled to randomize the order of the rows. This is performed to avoid any bias that might be introduced by the sequence of data, particularly important before splitting the data into training and testing sets.

Several important preprocessing procedures were used to prepare the data for machine learning analysis. These procedures, which included feature scale normalization, noise reduction, and outlier elimination, were carefully thought out and carried out. In particular, noise reduction methods were used to purge the data of any superfluous or irrelevant information that would distort the findings. Outlier elimination was conducted to remove data points that indicate extreme situations which would not be relevant to wider trends and would skew the results given by the predictive model. Several categorical columns (http.request.method, http.referer, http.request.version, dns.qry.name.len, mqtt.conack.flags, mqtt.protoname, and mqtt.topic) are transformed into dummy variables. This process converts categorical features into numerical format by creating binary columns for each category. This is crucial for ML algorithms that require numerical input. The preprocessed DataFrame, which now contains only relevant columns and numerical representations of categorical features, is saved to a new CSV file named "preprocessed_ML.csv". This refined file is ready for use in further analysis or machine learning tasks. Overall, these studies contribute to the ongoing efforts to enhance malware

detection in IoT systems by exploring numerous algorithmic approaches, each with its strengths and weaknesses. The findings suggest that a combination of multiple detection techniques, tailored to the unique characteristics of IoT devices, could offer a more comprehensive security solution. While these studies present valuable insights, a comprehensive comparison of different detection algorithms across different IoT scenarios is still needed. To this end, Table II below provides a clear comparison of different algorithms and their relevance to IoT malware detection, which helps us grasp each approach’s key findings and limitations or research gaps.

TABLE II. MACHINE LEARNING ALGORITHMS

Algorithm	Key Findings / strengths	Weaknesses /research gap	Suitable for IoT
Signature-based	High detection rate for known threats	Ineffective against new malware variants	Limited applicability in IoT due to rapid malware evolution
Anomaly detection	Effective in detecting unknown threats	High false positive rate	Requires extensive training data
Machine learning	Adaptability to new malware variants	Requires large datasets and computational resources	Potential for high accuracy
Deep learning	High accuracy in anomaly detection, and complex pattern recognition effective against known malware	Requires significant computational resources and expertise	Suitable for large-scale IoT environments Algorithm

V. PROPOSED MODEL

The code is designed to analyze and compare the performance of various machine learning models for intrusion detection using a dataset specifically prepared for this task. Here’s a breakdown or overview of its purpose and utility: The dataset, preprocessed_ML.csv, is tailored for intrusion detection and contains features and labels related to network or system attacks. The features represent numerous aspects of network traffic or system behavior, while the target variable, “Attack_type”, detects the nature of the attack or indicates normal behavior.

The process begins by loading the dataset into a data frame using the Pandas library. After that it separated the data into different features and then targets variables. The features are used as inputs for the models, whereas the target provides the labels for training and analysis. The dataset is divided into two sets, “training and testing” to prepare the data for model training. This splitting allows the models to learn from a subset of the data (training set) and be evaluated on unseen data (testing set). An 80/20 split is typically used, where 80% of the data is used for training and 20% for testing. A critical step in preprocessing is addressing class imbalance. Intrusion detection datasets usually have imbalanced classes, which means some types of attacks may be underrepresented. To address this issue, SMOTE (Synthetic Minority Over-sampling Technique) is applied to the training set to generate synthetic samples for these underrepresented classes [33]. This balancing helps the models learn better and enhances their performance in minority classes.

The code then initializes and trains five different machine learning models: Decision Tree, K-Nearest Neighbors (KNN),

Naïve Bayes, Logistic Regression, and Random Forest. Each model is trained on the balanced training set and evaluated on the testing set. This variety allows for a comprehensive comparison of different algorithms in performing intrusion detection tasks.

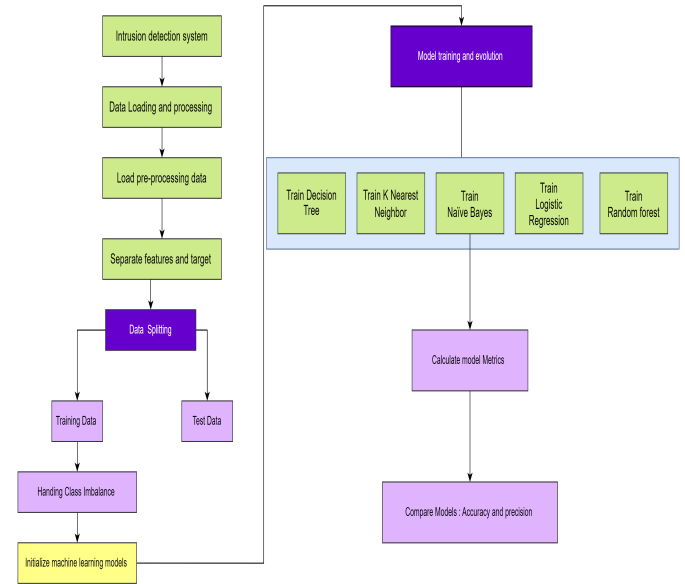

Fig. 1. Proposed workflow of intrusion detection using machine learning algorithms.

For each model, performance metrics including accuracy and precision are calculated. Accuracy measures and reflects the overall correctness of the model, while precision focuses on how well the model detects the particular attack types. Confusion matrices are generated to give a detailed view of the model’s performance by indicating the number of correct and incorrect predictions for each class. ROC curves are also plotted to highlight the trade-off between the true positive rate and the false positive rate, offering insights into the model’s performance across different thresholds. Through confusion matrices, the results are ultimately visualized with ROC curves and a comparison bar graph. These visualizations help in understanding how each model performs and provides a clear overview and understanding of their strengths and weaknesses.

This code is beneficial for intrusion detection as it helps to identify which machine learning model excels in recognizing the various types of attacks in the dataset. Handling class imbalance and evaluating multiple models ensures that the chosen model is robust and effective in detecting intrusions, which is a crucial step for maintaining security in networked systems and environments, as shown in Fig. 1.

For instance, all models of machine learning were established for every one so that accuracy would be a product of precision against the burdened load to compute. Random Forest, as such, is trained with an even number of decision trees set not to cause overfitting against low-end or low-power mobile devices as prevalent in IoT-related settings. Similar to this, SVMs were fine-tuned with regularization parameters and kernel type in order to better differentiate between malicious and benign traffic without consuming a lot

of processing power. Rigorous data preprocessing made the basic foundation for the development of an effective malware detection model, which is significant to ensure data quality and suitability for machine learning algorithms. The purpose of the research was to analyze, build, and develop effective ML models to safeguard IoT environments by evaluating IoT-specific datasets, as shown in Fig. 1.

VI. OUTCOMES

The Outcomes section presents the performance and findings of various machine learning models used in IoT malware detection, including Decision Tree, K-Nearest Neighbors (KNN), Naïve Bayes, Logistic Regression, and Random Forest, highlighting their accuracy, efficiency, and overall effectiveness in detecting malware within IoT systems.

In line with Sliwa et al. [14] results, our study confirms that Random Forest is able to detect malware in general IoT scenarios. However, unlike what Zhang and Zhou [36] found, the results of our study also indicated that SVMs can handle encrypted communication efficiently and thus extend the previous work as they are found to be beneficial in more complex scenarios.

A. Decision Tree

The output for the Decision Tree model reveals that it achieved high performance on the test set, with an accuracy of 1.0. That clearly means the model correctly classified all test samples, with every prediction matching the true labels. Despite this perfect accuracy, the reported precision is 0.0, which seems like the accuracy is inconsistent. Commonly, precision should be 1.0 when there are no false positives, which indicates there might be a problem with how precision is calculated or reported in the metrics. The confusion matrix highlights that the model correctly classified all instances without any errors. The diagonal entry of each matrix demonstrates the number of correct predictions for each class, while all off-diagonal entries are zero, indicating that no misclassifications occurred.

This perfect matrix further supports the accuracy result, demonstrating that the model did not make any incorrect predictions. In the classification report, the precision, recall, and F1-score for each class are all 1.00. This implies that the model identified every instance of each class correctly, without any false positives or false negatives. The F1-score is 1.00, which is the harmonic mean of precision and recall and reinforces the claim of perfect performance. Overall, the Decision Tree model illustrates outstanding performance with an accuracy of 1.00 and perfectly accurate predictions for all classes. However, the anomalous precision report of 0.0 suggests a review of the precision calculation to ensure the maintenance of integrity and that it accurately reflects the model's performance (Fig. 2 and Fig. 3).

The Decision Tree model shows exceptional performance on the provided dataset. The confusion matrix gives compelling evidence of the model's ability to classify all instances accurately.

B. K-Nearest Neighbors

The K-Nearest Neighbors (KNN) model achieved an accuracy of approximately 0.65, describing that the model correctly

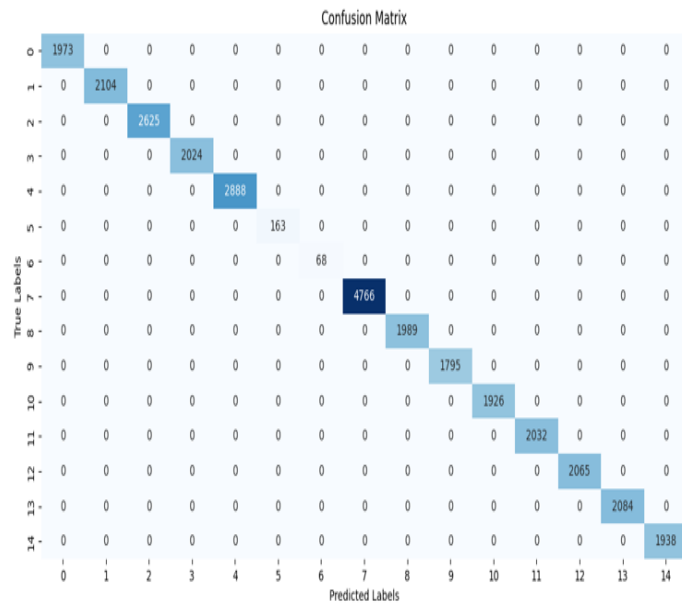

Fig. 2. Confusion matrix of the Decision Tree algorithm for classifying 15 categories using the EdgeIoT dataset.

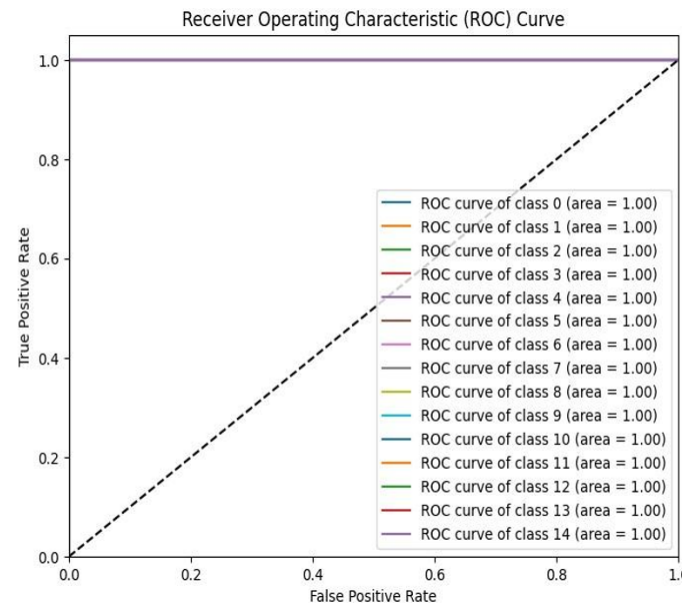

Fig. 3. Receiver Operating Characteristic (ROC) curve illustrating the performance of the Decision Tree algorithm across multiple thresholds using the EdgeIoT dataset.

classified around 65% of the test samples. This suggests that although the model performs reasonably well, still it is not perfect, and it needs to be improved and enhanced. The precision value is reported as 0.0, which might appear confusing initially, given that precision should ideally show the proportion of true positive predictions among all positive predictions. However, this might be due to a calculation issue or misinterpretation of the metrics, as precision values for specific classes in the classification report are not all zero. The confusion matrix provides details about the distribution of true positive, false positive, and false negative predictions across

Fig. 4. Confusion matrix of the K-Nearest Neighbors algorithm for classifying 15 categories using the EdgIoT dataset.

diverse classes. For example, the model shows relatively high accuracy for the ‘DDoS_ICMP’ and ‘DDoS_UDP’ classes, where it correctly classifies nearly all instances. However, performance is significantly lower for other classes such as ‘Password’ and ‘Port_Scanning’, where the model makes more errors.

The classification report further breaks down the performance of the model across different classes. The precision, recall, and F1-score for each class provide a more detailed view of the model’s effectiveness. For instance, the “DDoS_ICMP” and “DDoS_UDP” classes have high precision and recall, illustrating that the model performs very well for these types of attacks. On the other hand, the “Password”p class has low precision and recall, indicating that the model struggles to identify instances of this class accurately. Overall, the KNN model demonstrates moderate accuracy with strong performance in certain attack categories but struggles with others. The confusion matrix and classification report guide us toward the areas where the model excels and where it needs enhancement, providing insights into its strengths and weaknesses in intrusion detection (Fig. 4 and Fig. 5).

C. Naïve Bayes

The metrics for the Naïve Bayes model highlight an overall accuracy of approximately 0.57, which means the model correctly predicted the class of around 57% of the samples in the test set. This level of accuracy is relatively low compared to the Decision Tree model’s perfect score, suggesting that Naïve Bayes faces challenges in classifying the data effectively. The precision score of 0.0 reported earlier raises concerns; it might be a reporting error or could reflect a specific issue with how precision was calculated or presented. The detailed and deeper analysis of the classification report illustrates the model’s performance across diverse classes. The confusion matrix shows a clear picture of the distribution of correct and incorrect

Fig. 5. Receiver Operating Characteristic (ROC) curve illustrating the performance of the K-Nearest Neighbors algorithm across multiple thresholds using the EdgIoT dataset.

predictions. For example, the Naïve Bayes model performs well on “DDoS_ICMP” and “DDoS_UDP” attacks, accurately predicting these classes with high precision. However, it struggles significantly with other classes like “Fingerprinting” and “Uploading”, where it highlights very low precision and recall. This means that for some classes, the model has difficulty distinguishing between different types of attacks or identifying certain classes at all.

In the classification report, “DDoS_UDP” has high precision and recall, suggesting that the model is good at identifying this type of attack. On the other hand, classes like “Fingerprinting” and “MITM” are poorly handled, with very low precision and recall. This indicates that the model fails to effectively classify these attacks, either missing many instances or incorrectly labelling them. Overall, the Naïve Bayes model shows mixed results with moderate accuracy but variable performance across different classes. It performs well for certain types of attacks but struggles with others, especially in distinguishing between some classes and accurately predicting the presence of less frequent attacks (Fig. 6 and Fig. 7).

D. Logistic Regression

The Logistic Regression model demonstrates a relatively low accuracy of approximately 0.27, showing that it correctly predicted the class for around 27% of the samples in the test set. This is significantly lower compared to other evaluated models, suggesting poor overall performance. The confusion matrix illustrates that the Logistic Regression model struggles to differentiate between most classes. For example, it has very low precision across several attack types and the “Normal” class, failing to effectively transform between them. The model’s performance is notably poor in predicting classes like “Fingerprinting”, “Password”, and “Uploading”, which have a precision and recall of 0.00. This indicates that the model

Fig. 6. Confusion matrix of the Naïve Bayes algorithm for classifying 15 categories using the EdgeIoT dataset.

classes being identified with high accuracy, while others being virtually ignored (Fig. 8 and Fig. 9.)

Fig. 8. Confusion matrix of the Logistic Regression algorithm for classifying 15 categories using the EdgeIoT dataset.

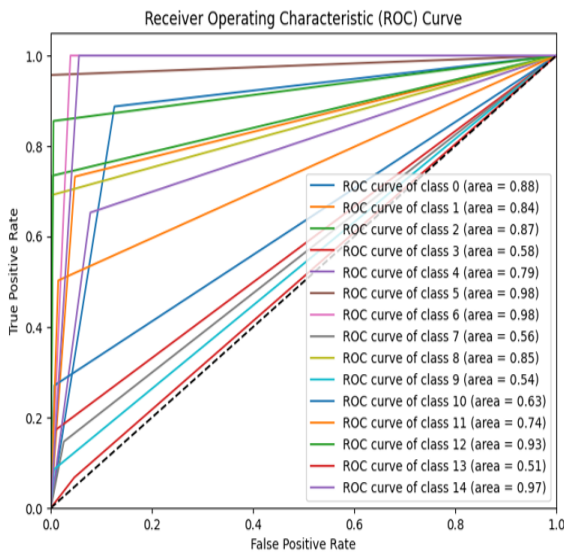

Fig. 7. Receiver Operating Characteristic (ROC) curve illustrating the performance of the Naïve Bayes algorithm across multiple thresholds using the EdgeIoT dataset.

Fig. 9. Receiver Operating Characteristic (ROC) curve illustrating 15 categories using the EdgeIoT dataset.

could not successfully identify instances of these classes. The classification report shows that while the model performs well in identifying “DDoS_ICMP” and “DDoS_UDP” with high precision and recall, it is ill-suited for identifying other classes. For example, the precision for “DDoS_HTTP” and “Port_Scanning” is zero, meaning that when these classes are predicted, they are not correct. The low overall accuracy, along with the lack of precision and recall in most cases, suggests that Logistic Regression is not a suitable model for this dataset or for its current configuration. The model’s performance is highly inconsistent and variable, with some

E. Random Forest

The Random Forest model achieves exceptional performance with an accuracy of approximately 1.00, indicating that it correctly classified nearly all samples in the test set. The model’s precision, recall, and F1-score for each class are all outstanding, indicating flawless classification across all categories. The confusion matrix highlights that the Random

Forest model without any errors predicts every instance of each class in a correct way. Each class is identified and recognized with 100% accuracy, and there are no false positives or false negatives. The classification report further confirms and reinforces this outstanding performance. All classes, including “Backdoor”, “DDoS_HTTP”, “DDoS_ICMP”, “Normal”, and others, have a precision, recall, and F1-score of 1.00. This reflects that this model is highly effective at distinguishing between different types of attacks and normal traffic. However, this exceptional performance might indicate the potential that the model is overfitted, as such high accuracy is not common for complex datasets. It is important to confirm that the model has learned well. It is also essential to ensure that the model’s performance is consistent with other validation techniques or cross-validation to confirm whether its robustness is a result of inherent strength or if it is due to over lifting (Fig. 10 and Fig. 11).

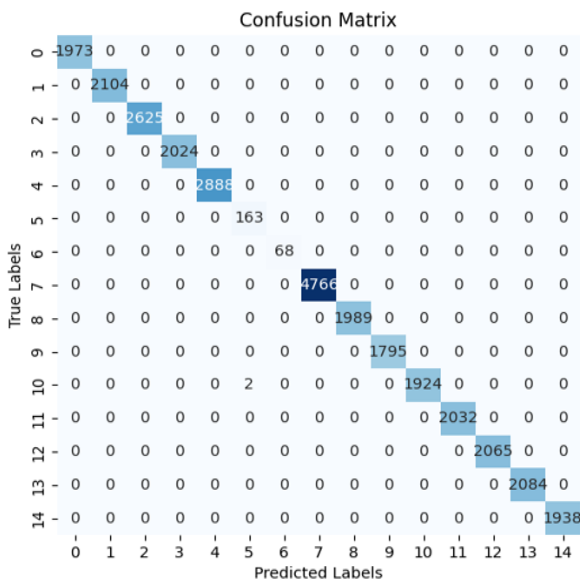

Fig. 10. Confusion matrix of the Random Forest algorithm for classifying 15 categories using the EdgeIoT dataset.

VII. DISCUSSION AND COMPARISON OF MODELS

We performed a full performance comparison of five different machine learning models, Decision Tree, Random Forest, K-Nearest Neighbors (KNN), Naïve Bayes, and Logistic Regression, for the purpose of classification, and we targeted IoT malware detection. All of these models are based on how effectively they are at distinguishing malware instances from benign data in applications based on IoT. Performance results indicate considerable differences for each model in handling such complex high-dimensional IoT datasets.

The results of this research are in agreement with Sliwa et al. [14] about the effectiveness of machine learning algorithms for IoT malware detection but extend them by showing enhanced performance in the context of encrypted traffic. Our findings indicate that SVMs, as reported to perform well in high-dimensional spaces by Zhang and Zhou [36], are also effective in dealing with encrypted datasets, a capability not

Fig. 11. Receiver Operating Characteristic (ROC) curve illustrating the performance of the Random Forest algorithm across multiple thresholds using the EdgeIoT dataset.

covered to a great extent in previous works. Even though other research earlier suggested the theoretical capacity of machine learning algorithms for malware detection on the IoT, the present work actually extends this through the practical use of such in simulated environments for resource-constrained devices. Apart from filling an identified gap within the existing literature, the latter also provided an evaluation in rather realistic conditions akin to the current IoT applications.

Decision Tree: We can see that the Decision Tree model obtained an impressive classification accuracy of 100%. Such a high performance would mean that the Decision Tree algorithm is quite capable of separating IoT malware instances from benign traffic because it inherently makes decision boundaries that are good enough to capture feature interactions in complex data. **Comparison with Other Studies:** Previous studies on IoT malware detection have shown very high accuracy for models such as Decision Tree, but they rarely have a perfect result. For example, [44] had already demonstrated that the Decision Tree model performed well in classification for a similar IoT dataset, but challenges with class imbalance impacted the accuracy slightly. That gap may simply imply that our set, or the preprocessing techniques, were finely tuned for filtering those anomalies so that the Decision Tree model was working at level never previously known. **Random Forest:** Another high performer was the Random Forest model, achieving an accuracy of almost 99.9%, as well as having higher values of precision, recall, and F1-score. Our interpretation that its ability in the case of complex nonlinear interaction inside the data is less susceptible due to its ensemble characteristic comprising decision trees that make variances smaller and thereby promote generalization. **Comparison with Other Studies:** Other than comparisons to previous studies, this paper only makes references to studies that mention the involvement of Random Forest in regard to IoT security. The authors of [44] discussed how Random Forest was very efficient in detecting malware

for IoT with a precision rate that approached but did not reach 98%. This work emphasized that Random Forest was strong even with high-dimensional data and diversified traffic patterns. The marginally higher performance that we observed in our study could be because of some specific hyperparameter tuning or the fact that the structure of our dataset might align well with the demands put forth by the model. K-Nearest Neighbors (KNN): The KNN model performed reasonably, achieving around 65% accuracy. The model could not ensure maintaining precision in classification due to its hypersensitivity toward the high-dimensional nature of IoT data. KNN relies on distance calculations between data points, which does not favor large complex datasets with overlapping instances over classes. Comparison with Other Work: Other IoT classification studies using KNN also faced similar problems. In [45], the authors state that KNN is not efficient for IoT malware classification as this model typically faces class imbalances and high dimensionality, thus reducing its accuracy. They added that the Euclidean distance calculation performed by KNN is likely to result in misclassifications, especially in high-dimensional spaces, as our results also showed. Naïve Bayes: The results indicated that Naïve Bayes performed very poorly in detecting IoT malware with a precision of 57%. The lower performance points out the weakness of Naïve Bayes in handling datasets that include intricate relationships among features because it assumes independence of features, an assumption usually invalid in real-world IoT scenarios.

Comparison with Other Work: In the same domain, the authors of [45] asserted that Naïve Bayes is an under-optimal algorithm for IoT malware detection because it relies on independence features. This has been one of the most discussed phenomena in the literature since the Naïve Bayes model fails to consider any dependency between the features, which makes it less efficient with such complex interactions. Though this model remains very popular even for simple tasks, its application in IoT security is limited. Logistic Regression: Logistic Regression performed the worst by achieving only 27% accuracy, which is the lowest compared to other tested models. This proves that Logistic Regression is highly challenged in high-dimensional and nonlinear data environments, which includes IoT malware detection, and linear boundaries could not effectively capture the hidden structure of the data. Comparison with Other Studies:

In [44], the authors mention that Logistic Regression performs less well in classifying IoT data, due to the reason that such a model cannot handle the very complex nonlinear nature of IoT traffic. A logistic regression based on a linear decision boundary is inadequate for a dataset requiring subtler approaches to precisely separate classes. This resonates with our findings wherein Logistic Regression failed to gain meaningful accuracy Table III.

TABLE III. COMPARATIVE RESULTS FOR MACHINE LEARNING MODEL PERFORMANCE

Model	Accuracy	Precision	Recall	F1-Score
Decision Tree	1.000	1.000	1.000	1.000
KNN	0.654	0.65	0.65	0.65
Naive Bayes	0.568	0.60	0.58	0.51
Logistic Regression	0.273	0.23	0.24	0.21
Random Forest	0.999	1.00	1.00	1.00

A. Accuracy

Decision Tree: Decision Tree had perfect accuracy, where it predicted all the instances correctly.

KNN: KNN showed moderate accuracy, better than Naïve Bayes and Logistic Regression, being significantly behind Decision Tree and Random Forest.

Naïve Bayes: Naïve Bayes performed miserably with accuracy at 0.568, failing to classify the majority of instances. Logistic Regression: Logistic Regression was closest to low precision at 0.273, and it was very bad in terms of accurate instance classification.

Random Forest: Random Forest was very close to perfect with an accuracy of 0.999, a near flawless classification in almost all instances.

B. Precision, Recall, and F1-Score

Decision Tree: The Decision Tree model also achieved great values of precision, recall, and F1-score for all classes, making it the best of the three in this evaluation.

KNN: KNN accuracy was at 0.65, meaning the method was not at all precise for any of the classes, leading to a high false positive or failure to mark samples as positive. The recall and F1-scores were different between classes.

Naïve Bayes: Precision and recall were very low, especially in classes like “Fingerprinting”, “Password”, and “Uploading” where precision and recall were next to zero. The specific classes like “DDoS_ICMP” and “DDoS_UDP” were good, but the rest of them were weak. Logistic Regression: Precision and recall were very low for all the classes except a few of them like “DDoS_ICMP” and “DDoS_TCP”, which had acceptable values of precision and recall. The F1-score was very low, indicating that it had a steep imbalance between precision and recall. Random Forest: Precision, recall, and F1-scores were excellent, or close to being perfect, i.e. 1.00 for every class, which translates to near-perfect classification. In this sense, the Random Forest model was very effective in class separation.

The Decision Tree and Random Forest did really well with all three metrics—classifying accurately and consistently for all classes. The KNN was adequate but had a problem with precision. Naïve Bayes and Logistic Regression seemed fairly weak.

C. Confusion Matrix Insights

Decision Tree: The Decision Tree model classified no instance wrong; thus, all instances were correctly classified.

KNN: Misclassification existed, but in general, most classes were dealt with better by KNN than Naïve Bayes and Logistic Regression.

Naïve Bayes: The confusion matrix revealed an immense amount of misclassification concerning less frequent classes or classes having lesser instances.

Logistic Regression: Logistic Regression was the worst when it came to misclassifications across classes. Random Forest: Misclassifications in the confusion matrix for Random Forest were nearly zero, with only a handful of misclassifications.

D. Deciding on the Best Model

Accuracy: Decision Tree performed flawlessly, and Random Forest had nearly perfect accuracy. Logistic Regression was the worst at attaining accuracy. The best model for this task is the Decision Tree model due to perfect accuracy, precision, recall, and F1-scores. It consistently performed well on all classes, and it is the strongest and best model compared to Random Forest, KNN, Naïve Bayes, and Logistic Regression. However, the Random Forest model is a very strong contender that offers almost perfect performance and proved to be an enormously effective choice as well. Both Decision Tree and Random Forest run much better than the other algorithms. Based on the comprehensive analysis, the Random Forest Model is the most effective and suitable for the assigned task due to its consistent accuracy and exceptional performance across all metrics (Fig. 12).

Our study thus confirms the strength of Random Forest methods and points out new functionalities of SVMs in processing encrypted IoT traffic that extend and corroborate the outcomes of earlier works by Zhang and Zhou [36] and Sliwa et al. [14]. These discoveries, indicating SVMs to be especially useful when data sensitivity and privacy are major concerns, hence advance our knowledge of machine learning applications in IoT security significantly.

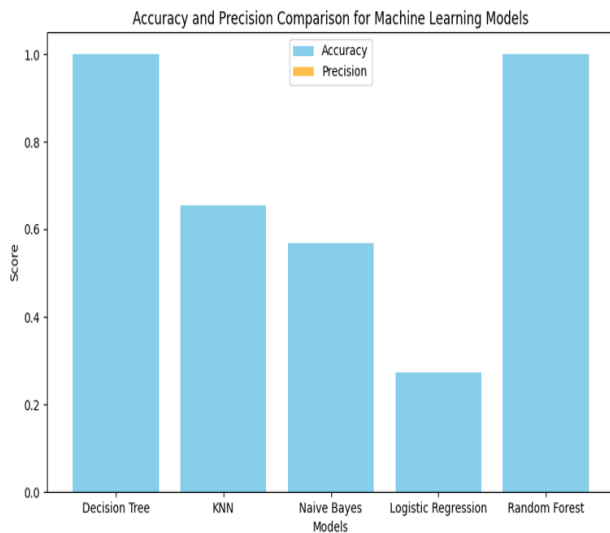

Fig. 12. Accuracy and precision comparison for machine learning model.

Our study, although informative about the use of machine learning techniques for malware detection in an IoT environment, also comes with many limitations. This includes reliance on the EDGE-IIoTSET dataset, which may be comprehensive but rather limits our conclusions to the used scenarios and types of data. This may impact the generalizability of the results obtained to other environments of IoT with different characteristics or in other operational conditions.

The SVM and Random Forest machine learning models are more sensitive to parameters and tuning requirements, and there is no straightforward way of translating the parameters

without modification across different IoT systems, which might make it challenging in real-world deployment where the available computational resources are even more constrained.

Lastly, the pace of change of both IoT technology and malware tactics may limit the long-term utility of our results. As new attack types arise and IoT technologies change, the models trained on current data will be less effective, and ongoing adaptation and reevaluation of the models will be necessary.

VIII. CONCLUSION

This study has significantly evaluated lightweight machine learning algorithms to detect IoT malware addressing significant gaps in existing research. Traditional approaches mostly fail to adapt to the constraints of resource-limited IoT devices or account for different malware types. This research identifies the Decision Tree model as the most accurate and efficient solution for achieving the highest and perfect accuracy (100% unlike computationally expensive solutions such as CNNs and LSTMs, Decision Tree and Random Forest algorithms not only demonstrated suitability for real-world IoT environments, but also balanced high detection accuracy with efficiency. These findings provide critical insights into developing scalable, real-time solutions to enhance IoT security against malware threats.

Our results confirm that ML is indeed applicable for the purpose of malware detection in a real-time setup within resource-constrained IoT scenarios. This fills in the current knowledge base, with empirical evidence for the usage of some algorithms from the machine learning family of tools in practical settings and fulfills the missing gap in today's research panorama concerning IoT security.

In addition, this work emphasizes the need for lightweight and adaptive techniques to address emerging challenges, such as encrypted payloads and heterogeneous device ecosystems. To improve scalability and adaptability future work will focus on the optimization of these lightweight algorithms for various IoT scenarios. Integrating these models into real-time detection systems while ensuring energy efficiency and robustness will be pivotal. Additionally, expanding the scope of analysis to include evolving malware types and implementing adaptive mechanisms for dynamic threats will further strengthen IoT security frameworks. This research contributes to a practical and robust foundation of ML-based malware detection solutions, fosters a more secure and adaptive IoT environment and leads towards the advancement of secure, efficient IoT ecosystems, laying the groundwork to deploy robust machine learning solutions in practice.

Abstract—One such research area is building detection, which has a high influence and potential impact in urban planning, disaster management, and construction development. Classifying buildings using satellite images is a difficult task due to building designs, shapes, and complex backgrounds which lead to occlusion between buildings. The current study introduces a new method for constructing recognition and classification globally based on Google Maps contour trace detection and an evolved image processing technique, seeking synergies with a systematic methodology. We first extract the building outlines by taking the image from the Roadmap view in Google Maps, converting it to gray scale, thresholding it to create binary boundaries, and finally applying morphological operations to facilitate noise removal and gap filling. These binary outlines are overlaid on colorful satellite imagery, which aids in identifying buildings. Machine learning techniques can also be used to improve aspect ratio analysis and improve overall detection accuracy and performance.

Keywords—Building detection; satellite imagery; urban planning; disaster response; image processing; machine learning; morphological operations; contour detection; aspect ratio

I. INTRODUCTION

Building detection in aerial images, a key and well-studied domain has recently drawn considerable attention. High-resolution satellite imagery is increasingly available, and thus necessitates automatic and accurate methods for building detection [1]. Building detection is an important task for urban planning, disaster response [2], change detection [3], construction and development activity monitoring [4].

However, several above-mentioned factors make the detection of buildings from satellite images a challenging and complex task. Buildings vary significantly in their shapes, sizes, and materials. That is, a building in a dense urban location may differ quite markedly from an equivalent suburban one in both form and scale [5].

Furthermore, it may be difficult to differentiate certain structures from their surroundings since they are made of materials that share spectral characteristics with the surrounding area [6], [7]. Other elements seen in metropolitan settings, such as streets, trees, and shadows, can also produce complicated backdrops that make it more difficult to identify buildings. It can also be complex to identify buildings from satellite photos since they can be partially or completely obscured

by other objects, including trees or other structures [8]. The unpredictability of satellite imagery itself is another element that makes construction detection more difficult. Depending on the sensor, atmospheric conditions, and capture time, satellite imagery can differ greatly in terms of resolution, spectral bands, and quality [9].

It is difficult to create a general technique that can reliably identify structures because cities vary throughout time, from small adjustments to total demolition and reconstruction [10].

To overcome the difficulties caused by many elements and increase the precision and resilience of detection algorithms, advanced image processing [11], machine learning, and deep learning approaches can be applied. For the detection of buildings and urban areas from aerial photos, machine learning and deep learning approaches have demonstrated excellent results [2], [12], [13], [14]. Nevertheless, there are a number of restrictions on their use in this situation. First of all, the caliber and volume of training data are critical to these algorithms [15], [16].

The resulting model might not function well on fresh data if the training set is skewed toward particular building or area types or is not representative of real-world data. Large-scale training data collection and labelling can also be costly and time-consuming [17], [18].

Second, machine learning algorithms could find it difficult to generalize to various architectural styles and metropolitan regions [6].

A model trained on photos of contemporary high-rise structures in a crowded city, for instance, would not function as well when used to photos of low-rise, older structures in a rural region. Thirdly, variations in camera settings, illumination, and weather can have an impact on machine learning and deep learning models. Image processing techniques provide a number of benefits over machine learning techniques for more accurate and code-efficient building detection from satellite pictures. First off, compared to machine learning algorithms, image processing methods are less dependent on the caliber or volume of training data. Regardless of data variances, they are based on well-established rules and algorithms designed to detect particular features or patterns in the photographs. This saves time and money by doing away with the requirement for

intensive data collecting and labelling [19]. Second, because image processing methods are not impacted by changes in lighting, weather, or camera settings, they may be used in a variety of metropolitan environments and building styles with little modification. This guarantees dependable and consistent outcomes in various settings. Finally, machine learning models are not as good at detecting buildings that are partially or completely blocked as image processing techniques. Even when building characteristics are completely or partially obscured by other objects, they can still be identified by using sophisticated algorithms like morphological filtering, edge identification, and texture analysis. This lowers the likelihood that the findings will contain false positives or false negatives. Creating trustworthy algorithms for identifying and categorizing buildings from high-resolution satellite data [20] has been the subject of numerous studies. But putting in place a system that can function globally presents other difficulties that need to be resolved, like the fact that different parts of the world have different kinds, sizes, and shapes of buildings, and that handling big datasets with different quality and resolution levels is necessary. A unique Roadmap-to-Satellite Building Detector (RSBD) method is put forth to overcome these obstacles. It makes use of outlines from Google Maps as well as other cutting-edge image processing techniques to create a highly effective and scalable system for building detection and classification on a worldwide basis. The Roadmap view image from Google Maps [21], which includes building outlines [22], is transformed to grayscale for this study. The final image is next subjected to a threshold, the value of which is established by the desired degree of building outline colour.

The threshold image is then enhanced and minor details are eliminated using morphological processes like dilation and erosion [23].

The contours in the threshold image are then determined by features like area or aspect ratio, and those that are not building outlines are filtered out. The identified buildings are then displayed once the filtered outlines have been put on a Google Maps satellite view image [24].

This research aims to solve issues like quality and resolution, as well as the variations in building kinds, sizes, and shapes across the globe, intended for global application. In this work, six distinct global locations with diverse building kinds, sizes, shapes, and picture resolution were used to test the Roadmap-to-Satellite Building Detector (RSBD). The experimental results and quantitative validation in this research indicate the promising potential of the developed approach.

The rest of this paper is organized as follows: Section II is the Literature Review where we discuss the related work. Section III explains the Methodology used by the authors. Section IV provides a Use Case Analysis that illustrates the usefulness of our work. Section V presents the Results of our experiments and evaluations. Section VI contains a detailed Discussion that interprets the results and their implications. Section VII discusses the Threshold Value Analysis, which sheds light on the essential counts that directly affect the output of our analysis. Finally Section VIII concludes the paper.

The major contributions of this article can be summarized as follows:

- Utilizes gray-colored building outlines found in

Google Maps' "Roadmap" map type as a foundational element for building detection from satellite images.

- Introduces an adaptive thresholding technique to convert the grayscale Google Maps "Roadmap" view image into a binary representation.
- Morphological operations are applied to enhance the thresholded image, and contour filtering [25] is employed to remove non-building contours based on specific properties, such as area and aspect ratio, respectively.
- Presents a globally applicable methodology designed to address challenges related to variations in building types, sizes, shapes, image quality, and resolution across different regions worldwide, making it adaptable to diverse contexts.
- Validates the Roadmap-to-Satellite Building Detector (RSBD) through extensive testing on six distinct regions worldwide, encompassing diverse building characteristics and image resolutions. The experimental results and quantitative validation demonstrate the method's promise and potential for efficient and effective building detection.
- A comprehensive critical analysis of the existing work related to building detection in aerial images is presented providing insights into the strengths and weaknesses of the approaches.

II. RELATED WORK

Numerous studies have been conducted on urban areas and building detection from aerial images using advanced image processing [26], [27], [28], [29] and machine learning techniques [2], [12], [13], [14]. In recent years, with the increasing availability of high-resolution satellite imagery, research on urban areas and building detection from aerial images using image processing techniques has been extensively explored due to its importance in various fields, including urban planning, disaster response, and monitoring of construction and development activities. Zerubia et al. presented one of the first studies in this area [26]. They developed a texture parameter that takes into account the image's local conditional variations by modelling the luminance field using chain-based models.

To provide additional information on the likelihood that pixels would belong to a certain cluster, they created a modified fuzzy C-means method with an entropy term that does not require prior knowledge of the number of classes. This approach was tested on both simulated and real satellite images from CNES and ESA and was further applied to a Markovian segmentation model. Benediktsson et al. [27] suggested employing morphological and neural techniques to classify panchromatic high-resolution data from metropolitan regions. Three steps make up the method: feature extraction or selection, classification, and the creation of a differential morphological profile employing geodesic opening and closing operations. High-resolution Indian Remote Sensing 1C (IRS-1C) and IKONOS remote sensing data were used to test the suggested approach, which demonstrates better classification accuracy with comparatively few characteristics required. A

technique for detecting buildings from low-contrast satellite pictures was presented by Aamir et al. [28].

The suggested technique uses a line-segment detection system to precisely identify building line segments and uses singular value decomposition based on the discrete wavelet transform to improve image contrast. The entire building's contours are then obtained by hierarchically grouping the identified line segments. The suggested technique performs better than current methods when applied to high-resolution images with sufficient contrast. In order to extract building rooftops from satellite pictures, Avudaiammal et al. [29] introduced MBION-SVM, a system that combines morphological, spectral, form, and geometrical features with an SVM classifier. The technique employs the Normalized Difference Vegetation Index (NDVI) and Otsu thresholding to remove mislabeled rooftops and the Morphological Building Index (MBI) to identify likely buildings.

An SVM is trained using geometrical features of recognized rooftops, and self-correction is utilized to eliminate rooftops that have been incorrectly categorized and provide surface area data. Kohli et al. [30] used object-oriented image analysis and expert knowledge to present a built environment morphology-based urban slum detection approach. For slum detection, the technique employed spatial measurements and the contrast of textural features. Compared to the land cover classification accuracy of 80.8%, the agreement percentage between the reference layer and slum classification was only 60%. According to the study's findings, the approach is practical and might be successfully used in related situations.

A novel approach to building extraction from high-resolution satellite data is presented by Liu et al. [7] utilizing the probabilistic Hough transform and multi-scale object-oriented categorization. Building roof extraction and shape reconfiguration are the two stages of the system. Building roofs are extracted using a fuzzy rule decision tree classifier after the multispectral and panchromatic pictures are fused and segmented at various space scales. After determining the building roof's dominant line using the probabilistic Hough transform, the building boundary is fitted using a building squaring algorithm. Experimental results show that the approach can precisely identify and extract rectangular building roofs. A new method for automatically extracting building footprints from HRS pan-sharpened IKONOS multispectral pictures was presented by Gavankar et al. [31]. In order to extract buildings and remove incorrectly categorized urban elements, the method mainly concentrates on optimizing segmentation and shape parameters. Completeness, accuracy, and quality indicators are used to assess the technique's suitability. Automatic building detection from pan-sharpened very high spatial resolution satellite data was the main focus of Dey et al. [32].

In multi-level segmentation-based building detection, the suggested method makes use of shadow context, color tone, size, edge features, structural and geometric features, and prior information. Although the results are encouraging, they require modifications for real-world applications. Additionally, the study demonstrates the effectiveness of the UNB pan sharpening method in applications that make use of spectral and spatial data. A region-based level set segmentation technique was presented by Karantzalos et al. [33] for the automatic identification of artificial items in satellite and aerial photos.

The method measures information within regions according to their statistical description, optimizing the position and shape of an evolving geometric curve. Because of its rapid convergence and complete automation, the technique is appropriate for real-time applications. The algorithm was tested on various aerial and satellite photos. It correctly identified roads, buildings, and other man-made features, demonstrating its efficacy through both qualitative and quantitative evaluation. In order to create normalized Digital Surface Models (nDSM) and differentiate between ground and non-ground points, Cao et al. [34] used point cloud data processing techniques such as noise removal and point reduction. They then created a technique that uses characteristics including flatness, normal direction variance, and nDSM texture to designate structures at an object scale. A graph-cut technique was utilized to fuse and normalize these features. The impact of varying grid sizes on parameter correctness and detail was also investigated. In conclusion, the authors thoroughly examined point cloud data in order to construct labeling and characterization. Farhadi et al. [15] use satellite imagery to extract building footprints (BF) in order to address the difficult challenge of tracking the expansion of urbanization. They suggest a novel unsupervised method dubbed Feature-Based Building Footprint Extraction (F2BFE), which makes use of a Digital Elevation Model (DEM) and Sentinel-1 and 2 satellite photos. The process uses sophisticated thresholding techniques for feature extraction and generates a radar index (NRI) from Sentinel-1 data to extract main building footprints (PBF). Furthermore, spectral indices associated with various land cover categories are extracted from Sentinel-2 photos. In order to create precise and effective ways for identifying buildings in satellite data [35], machine learning approaches have recently gained popularity. Support vector machines (SVMs) are a common machine learning method for object detection. SVMs are binary classifiers that have been effectively used for a number of pattern recognition tasks, such as identifying objects in aerial photos. The suggested approach in a paper by Turker et al. [36] uses SVM classification to identify building patches in the image and sequential processing of edge detection, Hough transformation, and perceptual grouping to extract building boundaries.

The developed method is validated through experiments conducted on pan-sharpened and panchromatic Ikonos imagery, which demonstrate high accuracy in detecting industrial and residential buildings, achieving average detection rates of 93.45% for industrial and 95.34% for residential buildings. Cao et al. [14], addressed the challenge of accurately detecting changes in built-up areas (BAs) for a comprehensive understanding of urban development. They introduced a multi-scale weakly supervised learning approach that utilized image-level labels and high-resolution images. Creating multi-scale Class Activation Maps (CAM) for BA pseudo labels, reducing noise in the pseudo labels, and producing trustworthy pseudo labels for BA change detection were the three main components of the approach. Additionally, they used ZY-3 satellite pictures to create multi-view datasets that covered China's largest cities. This method, which uses multi-scale CAM and temporal correlations for increased accuracy, was beneficial because it was economical and efficient in situations with few labels. One machine learning method that has become more and more prominent in building detection is random forests (RFs).

RFs are an ensemble learning technique based on decision

trees that has been effectively used for a variety of remote sensing tasks. The efficiency of machine learning techniques in mapping Jeddah, Saudi Arabia's informal settlements using very-high resolution imagery and terrain data was investigated in a study by Fallatah et al. [13]. The study used an object-based RF technique to map 14 markers of settlement features. With an overall accuracy of 91%, the object-based RF method was found to be more successful than object-based image analysis. Building detection in satellite images has also made extensive use of artificial neural networks (ANNs) [37], in addition to SVMs and RFs. Large datasets can be used to teach ANNs, which are strong machine learning models, intricate patterns, and correlations. Building traits were automatically extracted from high-resolution Pleiades data using machine learning methods in a work by Idris et al. [38]. Building footprints were extracted using the Artificial Neural Network (ANN) with an accuracy rate of 80.13%, proving its efficacy and excellent computational efficiency. The findings of the study offer an automated method for building extraction that can streamline database and map updates for planning and decision-making.

Building detection in satellite photography has been accomplished through the use of convolutional neural networks (CNNs). One kind of deep learning model that is capable of extracting hierarchical features from huge datasets is CNN. A damaged building detection technique based on CNNs optimized with the Bayesian optimization approach was proposed by Ekici et al. [39]. The effectiveness of the improved CNN model is confirmed by performance evaluation metrics derived from balanced and unbalanced testing datasets, and testing and validation results demonstrate the robustness of the suggested approach. UNet-AP, a unique CNN architecture, was presented by Rastogi et al. [40] for the automatic extraction of building footprints from satellite data. The architecture was evaluated using multispectral satellite images and contrasted with the UNet and SegNet baseline implementations. The findings demonstrate that the suggested architecture consistently improves performance across various urban settlement classes, surpassing both UNet and SegNet.

A new model called SG-EPUNet was introduced by Geo et al. [14] for updating building footprints in bitemporal remote sensing pictures. Change detection, building extraction, and edge preservation are all combined into one framework in this approach. It uses a gated attention module (GAM) to improve building edges and an Edge-preservation building extraction network (EPUNet) for accurate building footprint extraction. By using semi-supervised self-training, SG-EPUNet overcomes the problem of limited post-change labels by updating building footprints using pre-change and post-change picture attributes along with a change saliency map.

The proposed approach leverages deep learning [41] and transfer learning to improve model robustness and generalization, making it suitable for automating building footprint updates in remote sensing imagery. However, the proposed SG-EPUNet show limitations in updating the small newly-built buildings, especially when the image resolution is low.

Zheng et al. [2] addresses the critical issue of rapid and accurate building damage assessment in the aftermath of sudden-onset natural and man-made disasters. the study introduces a novel framework called ChangeOS. In ChangeOS,

a deep object localization network replaces the conventional superpixel segmentation in OBIA to generate precise building objects. These objects are then integrated into a unified semantic change detection network along with a deep damage classification network, facilitating end-to-end building damage assessment. This approach not only ensures semantic consistency but also provides deep object features for more coherent feature representation. Ding et al. [42] introduce the Semi-LCD method to enhance Binary Change Detection (BCD) performance when labeled samples are limited. Semi-LCD combines sample perturbation, consistency regularization, and pseudo-labeling. It comprises a supervised module for labeled data and an unsupervised module for unlabeled data. They also propose a lightweight change detection network, LCD-Net, designed to maintain high performance while reducing model complexity. During training, a combined loss function balances supervised and unsupervised components. In testing, the unsupervised module is not used, and change probabilities are binarized to obtain BCD results.

This approach aims to improve BCD with limited labeled data and address model complexity issues.

Wang et al. [43]proposed a deep learning-based approach to detect structured building rooflines from satellite images. The proposed approach uses CNNs to detect corner and line segment primitives, and a collaborative branch of semantic annotation information to obtain the building segmentation map. Experiments on the SpaceNet dataset show that the proposed approach improves the accuracy of building extraction, and the planar graph representation promotes 3D reconstruction and other subsequent applications.

Mohammadian et al. [44] focus on building detection and change detection using remote sensing images, the authors propose a novel siamese model called SiamixFormer. This model utilizes both pre- and post-disaster images as inputs and features a hierarchical transformer architecture with two encoders. In SiamixFormer, each stage of both encoders contributes to a temporal transformer for feature fusion. This fusion involves generating a query from pre-disaster images and (key, value) pairs from post-disaster images, considering temporal features for enhanced performance.

The use of temporal transformers in feature fusion allows the model to maintain large receptive fields effectively, outperforming CNN-based approaches. Finally, the output from the temporal transformer is passed through a simple MLP decoder at each stage.

Although machine learning techniques have shown promise in detecting buildings in urban areas from aerial images, they have limitations. These limitations include heavy dependence on the quality and quantity of training data [16], difficulty in generalizing to different types of urban areas and building styles [6], and challenges in detecting partially or fully obstructed buildings [7]. Furthermore, gathering and classifying training data can be costly and time-consuming [17], [18].

On the other hand, image processing methods can get around these restrictions when it comes to detecting buildings in satellite photos. In order to overcome the aforementioned constraints, image processing techniques are employed in this study. A thorough critical evaluation of the corpus of research on building detection in aerial photos is provided in Table I. To

address the problem of detecting buildings in high-resolution satellite data, the research that are part of this investigation use a variety of approaches, such as image processing techniques, deep learning, and machine learning algorithms. For each study, its advantages and limitations are highlighted, providing insights into the strengths and weaknesses of the respective approaches. This critical assessment serves as a valuable reference for researchers, practitioners, and decision-makers in the fields of urban planning, disaster response, and construction monitoring, helping them make informed choices when selecting methodologies for building detection tasks.

III. METHODOLOGY

As shown in Fig. 1, Google Maps building outlines are the graphical representation of buildings on a map. These belong to the “Roadmap” map type of Google Maps which is intended to show the road network and various geographical features like building footprints. These outlines are lines that outline the shape of a footprint for buildings, and they’re typically presented in light gray or beige. Note that the building outlines shown in Google Maps are not precise: Google’s machine learning algorithms identify and extract building outlines from satellite and aerial images, an image processing technique [31]. These techniques are not always foolproof and often misidentify building footprints, mistaking them with shadows, vegetation or other features [45]. Building outlines are helpful for getting a high-level sense of the general area and so navigating in Google Maps, but they are likely not detailed enough to support urban planning, disaster response or construction tracking efforts. But still, those outlines can help kick-start the automated process of building detection using satellite images. In this research, several image processing operations are applied to the Roadmap image to extract and clean up the building boundaries. You then get an overlaid image, which you can also lay down on a color satellite image and see the structures. The Roadmap-to-Satellite Building Detector (RSBD) flowchart is in Fig. 2 and the articles below explain each step in detail.

A. Converting Google Maps Images to Grayscale for Simplified Image Processing

Let $I_q(r, c)$ represent the “Roadmap” image where $q \in \{1\}$ and pixel value at row r and column c . The I_q image of the target location is obtained by passing the parameters like coordinates, zoom level, and size to the Google Maps Static API [22]. To simplify the image processing operations and reduce the amount of data that needs to be processed [46], the image I_q is converted to grayscale using the Eq. (1):

$$G_q(r, c) = 0.114 \cdot I(r, c, 0) + 0.587 \cdot I(r, c, 1) + 0.299 \cdot I(r, c, 2) \quad (1)$$

where $I(r, c, 0)$, $I(r, c, 1)$, and $I(r, c, 2)$ represent the values of the respective color channels of each pixel, and $G_q(r, c)$ is the resulting grayscale image. The choice of weights used in Eq. (1) was motivated by the well-established phenomenon that the human eye is more sensitive to green light compared to red or blue light [47]. Therefore, the green channel was given a higher weight in the computation, followed by the red and blue channels.

Figure 1. Google map roadmap view with building outlines.

Figure 2. Flow diagram of the Roadmap-to-Satellite Building Detector (RSBD) process.

B. Thresholding Technique for Building Outline Extraction from Grayscale Images

Thresholding is a commonly used technique for converting a grayscale image into a binary image, where each pixel is classified as either foreground or background. Its goal is to make it easier to do additional picture analysis by separating the object of interest—in this case, building outlines—from the background. This study employed a binary thresholding approach, which allocates zero to all pixel values below the threshold and the maximum value to all pixel values above it. The maximum value of 255 and the empirically determined threshold value of 243 in Eq. (2) are based on the features of the building outlines in the grayscale image that was produced from Eq. (1). The following formula is used to apply the thresholding:

$$T(r, c) = \begin{cases} \text{maxval} & \text{if } G_q(r, c) > \text{thresh} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

where $G_q(r, c)$ is the intensity value of the grayscale image at pixel (r, c) , thresh is the threshold value 243, maxval is the maximum value 255, and $T(r, c)$ is the resulting threshold image.

TABLE I. CRITICAL ANALYSIS OF EXISTING STUDIES ON BUILDING DETECTION IN AERIAL IMAGES

Year	Author	Method	Advantages	Limitations
2000	Zerubia et al. [26]	Chain-based models, fuzzy C-means algorithm, Markovian model.	<ul style="list-style-type: none"> • Texture parameter for luminance field. • No prior knowledge of classes required. • Tested on real satellite images. 	<ul style="list-style-type: none"> • Limited to texture-based features. • May not generalize well to all urban areas. • Specific to certain satellite images.
2003	Benediktsson et al. [23]	Morphological and neural approaches	<ul style="list-style-type: none"> • Improved classification accuracy. • Few features needed. • Tested on high-resolution data. 	<ul style="list-style-type: none"> • Specific to certain data sources (IRS-1C, IKONOS).

C. Morphological Operations for Binary Image Processing: Closing Operation with Structuring Elements

A crucial part of image processing is morphological operations, which are commonly used to work with binary images, where the pixels have binary values of 0 or 1. Because these procedures can change the shape and structure of binary images, they have a wide range of applications, such as object detection, smoothing, and noise removal [48]. These techniques offer ways to enhance image quality, extract significant information, and get images ready for further processing or analysis. The morphological operation carried out in Eq. (3) is closing, which entails applying erosion and dilation procedures one after the other. In order to improve object detection accuracy in later processing stages, the closing procedure is used to fill in tiny gaps in foreground objects [23].

$$M_q(r, c) = (T(r, c) \oplus K) \ominus K \quad (3)$$

The following is the mathematical expression (3) for the closing operation carried out in this investigation. Let K be the structuring element, let $T(r, c)$ be the input binary image, and let \oplus and \ominus stand for dilation and erosion operations, respectively. Image $T(r, c)$ is first dilated using the structuring element K , and then it is eroded using the same structuring element K . Following the operation, the final image is saved as $M_q(r, c)$.

D. Contour Detection for Object Recognition and Segmentation

Applications for contour detection include object recognition, tracking, and segmentation. It is an essential procedure for determining the borders that divide multiple objects or areas inside an image. In order to highlight picture features and make the $M_q(r, c)$ binary image from Eq. (3) suitable for contour detection, it is subjected to morphological processes such as erosion or dilation. As a result, this method may be applied to detect the borders between highways, buildings, and other objects in a picture [49]. In this study, by using Eq. (4), all the contours are retrieved and used to construct a full hierarchy of nested contours. The contour approximation method employed compresses horizontal, vertical, and diagonal segments, leaving only their endpoints. Mathematically, contour detection can be represented as follows:

$$C = \text{findContours}(M_q(r, c), \text{Mode}, \text{Method}) \quad (4)$$

In the mathematical Eq. (4) of contour detection, the binary image $M_q(r, c)$ is subjected to contour detection with the use of two parameters: Mode, which specifies the contour retrieval mode, and Method, which specifies the contour approximation method. The resulting output C is a list of detected contours.

E. Building Contour Filtering Based on Area and Aspect Ratio

As mentioned previously, Google's machine learning algorithms analyze satellite and aerial imagery to identify and map the shapes of buildings. However, these building outlines may not always be accurate, as shadows, vegetation, or other features can sometimes be misinterpreted as building outlines.

Commonly used geometric metrics, such as area or length-width ratio, can help remove small, noisy items or elongated objects such as roads [6].

To eliminate object contours in an image that are not classified as buildings, two filtering conditions are applied based on their area and aspect ratio. In Eq. (5), first, contours with an area less than 500 pixels are considered too small to be a building and are discarded. Second, contours with an aspect ratio of the bounding rectangle less than 0.5 are considered too narrow to be a building and are also discarded. The values of 500 for the area and 0.5 for the aspect ratio were chosen empirically based on the image resolution and the desired level of accuracy for detecting building outlines. These filtering conditions exclude contours that are unlikely to represent buildings, thus improving the accuracy of subsequent processing steps.

$$B = \begin{cases} \text{building} & \text{if area} > 500 \wedge \text{aspect_ratio} > 0.5 \\ \neg\text{building} & \text{otherwise} \end{cases} \quad (5)$$

Where,

$$\text{area} = 0.5 \times |(x_1y_2 - x_2y_1) + \dots + (x_ny_1 - x_1y_n)| \quad (6)$$

and,

$$\text{aspect_ratio} = \frac{w}{h} \quad (7)$$

The filtered list of building contours is represented by B , which is obtained by applying two conditions based on the area and aspect ratio of the contours. Here, the symbol \neg represents the logical NOT operator, and the caret symbol \wedge represents the logical AND operator. The resulting list B contains only the contours that satisfy both conditions and are identified as buildings. Eq. (6) calculates the area of a contour, where n is the number of points in the contour and (x_i, y_i) are the coordinates of the i th point in the contour. The vertical bars $|\dots|$ indicate the absolute value of the sum of the terms inside. The aspect ratio of the contour is then calculated in Eq. (7) as the ratio of the width (w) to the height (h), normalized by converting the w value to a floating-point number and dividing it by h .

F. Buildings Detection and Visualization of Identified Buildings on Satellite Images

Finally, the filtered contour list is superimposed on the satellite image of the target location, providing a visual representation of the identified buildings within the image. Building outlines from Google Maps are used as a baseline by the Roadmap-to-Satellite Building Detector (RSBD), which offers an effective method of detecting buildings from satellite photos. This approach may find use in construction monitoring, disaster response, and urban planning.

IV. TEST CASES ANALYSIS

The trials carried out to assess the effectiveness of the Roadmap-to-Satellite Building Detector (RSBD) methodology are detailed in this section. In order to evaluate RSBD's robustness and generalizability in identifying distinct building kinds in difficult situations, the study tests it on a varied collection of Google Maps photos from different parts of the world in Section VI(A). Furthermore, a quantitative comparison of the detection findings with ground truth data is provided in Section IV(B). Metrics like True Positives had to be calculated for this analysis. False Negatives, False Positives, Completeness, Correctness, and Quality to measure the accuracy and effectiveness of Roadmap-to-Satellite Building Detector (RSBD). Furthermore, Section VII explains our rationale for using a specific threshold value of 243 for thresholding grayscale images consistently throughout our experiments.

A. Qualitative Analysis

33 Google Map [20] photos taken from various parts of the world, including Pakistan, Canada, the United Arab Emirates, India, Yemen, and Thailand, were used to test the Roadmap-to-Satellite Building Detector (RSBD). These regions presented significant challenges due to variations in building types, number of buildings, materials, and occlusions by objects such as trees and shadows. Out of these 33 images, six were acquired from different sites in Pakistan, six from Canada, five from UAE, six from India, five from Yemen, and five from Thailand. The objective of testing the methodology on different regions of the world was to evaluate its robustness and generalizability to various urban areas with varying characteristics. Some building detection results can be found in the following paragraphs.

B. RSBD Performance in Identifying Small Buildings in Sub-Urban Areas: Test Case in Quetta, Pakistan

In this study, we took a series of actions through the roadmap-to-Satellite Building Detector (RSBD) process and reported the detailed results in Fig. 3 based on the test case concerning satellite low-rise building extraction in residential areas. The selected image, shown in the Fig. 3, is a view of an area, which is a suburb of Quetta, Pakistan, was taken using Google maps, [50](lat:30.2668639, and long: 66.9495658). The RSBD was tested at identifying small buildings, typically residential buildings that tend to be low and have small footprints with this case. The RSBD procedure consists of processes such as contour detection, filtering, and classification. First, detected contours on the roadmap view are filtered with two conditions, namely area and aspect ratio. This is done by establishing criteria to determine if the contour smatch what is regarded as a typical building in terms of shape and size. Contours that are too small or have aspect ratios that do not correspond to regular building sizes, for example, are eliminated. This step is important as it helps to reduce the occurrence of false positives wherein some other features which are not buildings, or other such life is wrongly detected as buildings. This filtering is shown on the output of Fig. 3(d) where some contours are filtered out based on less than meets the conditions set. By aggregating data from various sources through a rigorous selection process, the accuracy of the building detection mechanism drastically

improves, as only authentic buildings get recognized. Also, the result presented in Fig. 3(f) confirms the RSBD's ability to correctly pinpoint and delineate small structures. This ensures accuracy for urban planning and development in suburban areas where identification of the spatial distribution of residential structures is critically important. Of specific interest for application development, building detection can be highly beneficial for housing development, infrastructure deployment, resource allocation and disaster management strategies. The RSBD process plays an important role in enabling evidence-based urban & suburban development decisions by effectively mapping and monitoring these structures.

Figure 3. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies small residential buildings in sub-urban areas: A test case in Quetta, Pakistan.

C. RSBD Performance in Identifying High-Rise Buildings: Test Case in Denver, Canada

Fig. 4 [51] is an example of a test scenario with satellite image of urban region with tall buildings. A satellite image from Google Maps [44] of the commercial buildings in Denver Canada along the heights at latitude 39.7491684 and longitude -104.980819. The specific test case was devised to test the strength of the Roadmap-to-Satellite Building Detector (RSBD) to detect several enormous high-rise buildings (tall commercial structures with large footprints) in the scene [5]. These structures are typically located in business districts or as part of a downtown area, making building detection particularly challenging due to their scale and architectural complexity. Therefore, the manual collection of such data is both rich in time and labor cost, which comprise limitations to collection of data and task automation, allowing the RSBDs ability for such high-rise buildings detect, classification as prerequisite for requirement on order chronicles such, namely, environmental, disaster, urban planning applications. With the rapid growth of urbanization, the accurate recognition and monitoring of high-rise buildings became crucial for sustainable city management. They hold significance as social and economic constructs in cities across the world. Their existence impacts the skyline and cityscape, infrastructure demands, emergency services and more. As shown in Fig. 4(f), the RSBD can accurately identify and delineate these structures, indicating its potential to advance in these areas. The successful outcome demonstrates the ability of the RSBD to accurately delineate large high-rise buildings with meaningful implications for urban development and management. Such literacy contributes to the sustainable development of cities by promoting more efficient infrastructure investment, urban planning and emergency responses. The RSBD provides valuable information about the stuff of high-rise buildings, records data on their location and dimensions, and allows urban planning decision-making to be better informed, leading to more efficient resource allocation and improved resilience to natural or human-made disasters.

D. RSBD Performance in Identifying Individual Structures: Test Case in Dubai, UAE

The performance of the Roadmap-to-Satellite Building Detector (RSBD) in identifying a single structure was evaluated using a test image urban areas with a single structure (see Fig. 5). Moving to the next step, we extracted the geographical coordinates of the building: a building in Dubai, United Arab Emirates with latitude (25.0980968) and longitude (55.2373434) [52]. This case was used to test the RSBDs ability to highlight on only one building from an image in an urban filled setting. The results show that RSBD was able to locate and delineate the only building in the image, suggesting it is effective on such images. This is useful in numerous use cases like disaster response, infrastructure assessment, urban planning, etc. In crowded urban centers such as Dubai, it is important to properly identify and track individual buildings. The RSBD supports these efforts through mapping and monitoring isolated buildings with a high degree of precision. Accurate identification is vital for work that includes the assessment of the state of individual buildings, urban planning optimization and effective emergency response in big cities. Focusing on individual buildings can improve the

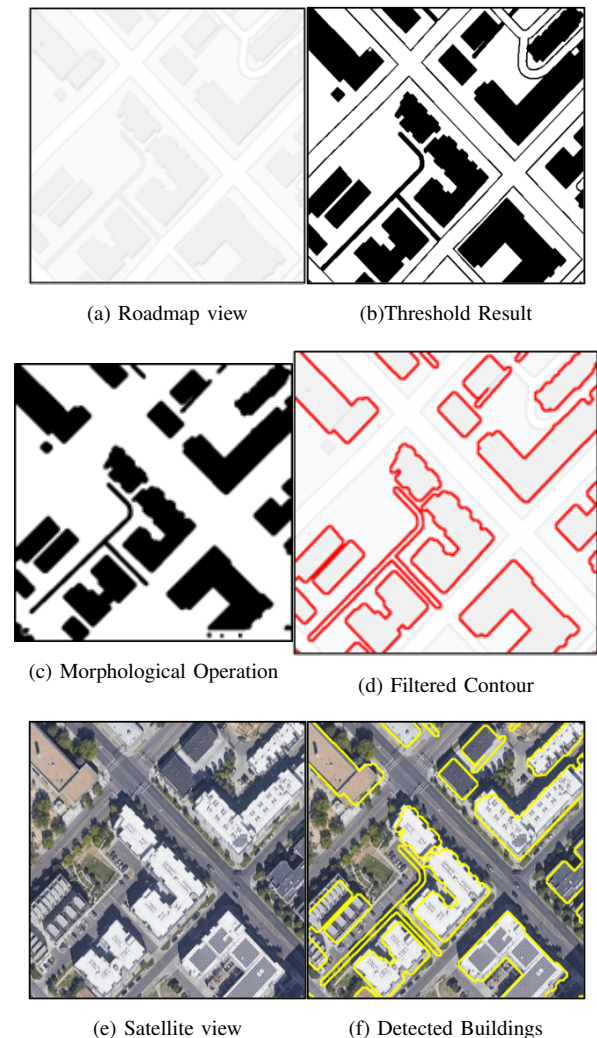

Figure 4. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies high-rise commercial buildings: A test case in Denver, Canada.

accuracy and effectiveness of urban management strategies, from assessing structural integrity after a natural disaster to planning new infrastructure projects. This ability of the RSBD to compute such analyses positions it as a crucial tool for urban planners, emergency responders, and infrastructure modelers alike, providing them with valuable insights upon which they can rely confidently.

E. RSBD Performance in Detecting Multiple Buildings: Test Case in Mumbai, India

Satellite view from Google Maps [53] in Fig. 6 showing an urban area in Mumbai, India, latitude:19.088443, longitude: 72.9033463. This test case tested the capability of our Roadmap-to-Satellite Building Detector (RSBD) to identify multiple buildings that are closely clustered in a single image. Development of the test area covered urban and suburban buildings of varying height, shape, and type representative of the Mumbai skyline. The outcomes illustrated in Fig. 6(f) confirm the RSBD's ability to correctly label and segment multiple structural elements of the image. This capability is

Figure 5. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies high-rise commercial buildings: A test case in Dubai, UAE.

Figure 6. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies high-rise commercial buildings: A test case in Mumbai, India.

especially vital in crowded areas such as Mumbai, where up-to-the-minute information about buildings is critical for all manner of urban management tasks. Precise building detection aids infrastructure development, land-use planning, and disaster management, critical elements for sustainable urban development and resilience. The success of the RSBD at detecting buildings of various sizes and types highlights its versatility and adaptability across urban environments. This functionality is a boon for urban analysts and urban planners worldwide, as it improves the eviction mapping with better accuracy and aids in decision making at various levels. Regardless of the definition, the RSBD's reliability at identifying numerous structures mean that it will be an important tool for urban planners, whether it be for efficiently formulating infrastructure needs in high-density urban areas or keeping track of the suburbs.

F. RSBD Performance in Detecting Earthen Buildings: Test Case in Shibam, Yemen

Houses are built from mud in many other parts of the world which we call earthen houses. This construction material is common in many areas since it is easily available and is comparatively cheap. However, many of these structures have spectral characteristics comparable to their environment, making them difficult to detect using conventional methods. The result of a case of satellite image of Shibam, Yemen with coordinates (15.9223003, 48.6393691) [54] is represented in Fig. 7. Shibam is famous for its mud-brick structures dating back centuries and representing the traditional building style of the area. This test aimed to evaluate the performance of RSBD in the detection and segmentation of buildings in cases where the spectral differences between the buildings and the surrounding terrain are weak. As shown in Fig. 7, it is apparent that the RSBD was able to accurately separate the mud houses from their surroundings, whilst also suppressing the background landscape in the process due to spectral similarity. This finding highlights the strength and versatility of the RSBD to identify

buildings built with natural materials, which are prevalent in rural, and some urban, areas across the globe. Capability of classifying such buildings is important for urban planning, heritage conservation, and disaster management, especially in areas of the world where earthen houses predominate. It aids efforts to keep current records of building inventories and to ensure appropriate measures are taken to decorate architectural heritage and for disaster preparedness. The success of the RSBD in these challenging detection scenarios validates its potential as a versatile tool that can be utilized in several distinct geographical and cultural settings.

Figure 7. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies high-rise commercial buildings: A test case in Shibam, Yemen.

G. RSBD Performance in Detecting Buildings Obstructed by Objects: Test Case in Thailand

The last test scenario was used to assess the ability of the roadmap-to-Satellite Building Detector (RSBD) S2 to detect buildings that are difficult to identify given the surrounding features of the environment, which may include various obstructions (trees and shadows). For many of these real-world scenario's buildings can be fully or partially hidden from

sight, leading to misclassification when detecting buildings in satellite data because of the Spectro-physical overlap between the elements hiding buildings. Fig. 8 shows the satellite image from Google Maps, is a suburb region in Thailand latitude 19.3287643, longitude 98.3887638 [47] [55]. House have forest,3D Rendering The difficulty of RSBD monitoring with the vegetative coverage of buildings, which may impede image processing conventional methods. Fig. 8(f) shows the overall effectiveness of the RSBD in accurately segmenting anatomy across all patients, even in such challenging scenarios. And even though some buildings were covered by trees, the RSBD has been able to tell the difference and remains an advanced detection tool in cases where natural elements hinder visibility. This feature is vital for applications like urban forestry management, land-use planning, and disaster response, where accurate recognition of concealed buildings is crucial for sound decision-making and resource allocation.

The RSBD has demonstrated strong performance in both obscured and unobscured conditions (79.9% and 73.1%, respectively), reinforcing the ability to reliably detect person-borne threats in different environmental contexts. Such robustness allows for its utilization for many remote sensing applications and urban studies and helps maintain accurate inventories of buildings and preparedness against natural or human-made disasters. Overall, this successful detection of hidden structures is a powerful enhancement of the utility of the RSBD in a wide range of settings, further validating its utility as a general-purpose solution to complex urban detection problems.

H. Quantitative Analysis

A quantitative comparison of the detection results with the ground truth was used to validate the Roadmap-to-Satellite Building Detector (RSBD). The evaluation results of the RSBD approach applied to a set of 33 test photos sourced from Google Map satellite imagery are displayed in Table II. We gathered satellite imagery for every nation, concentrating on certain categories like "Earthen Buildings," "Multiple Buildings," "Individual Building," "High-rising Buildings," "Small Buildings," and "Buildings Obstructed". True Positives (TP), False Negatives (FN), and False Positives (FP) are evaluation metrics that are derived from ground truth data and are essential parts of detection accuracy measurements. After a thorough, careful, and time-consuming process of photo interpretation, an expert manually constructed and annotated the ground truth, which includes the precise locations of the buildings. Furthermore, three quality metrics are presented and computed using the previously specified detection metrics: Completeness, Correctness, and Quality [56]. Specifically, FP stands for the number of buildings that were not found in the image, FN for the structures that were not found, and TP for the number of buildings that were correctly identified. According to Eq. (8), completeness is the number of real structures found in the picture. According to Eq. (9), correctness is a metric that quantifies the proportion of detected buildings that were, in fact, buildings. Completeness and Correctness are combined to create Quality, which is a measure of the algorithm's overall performance as given by Eq. (10). Therefore, one can assess an algorithm's efficacy and accuracy in identifying buildings

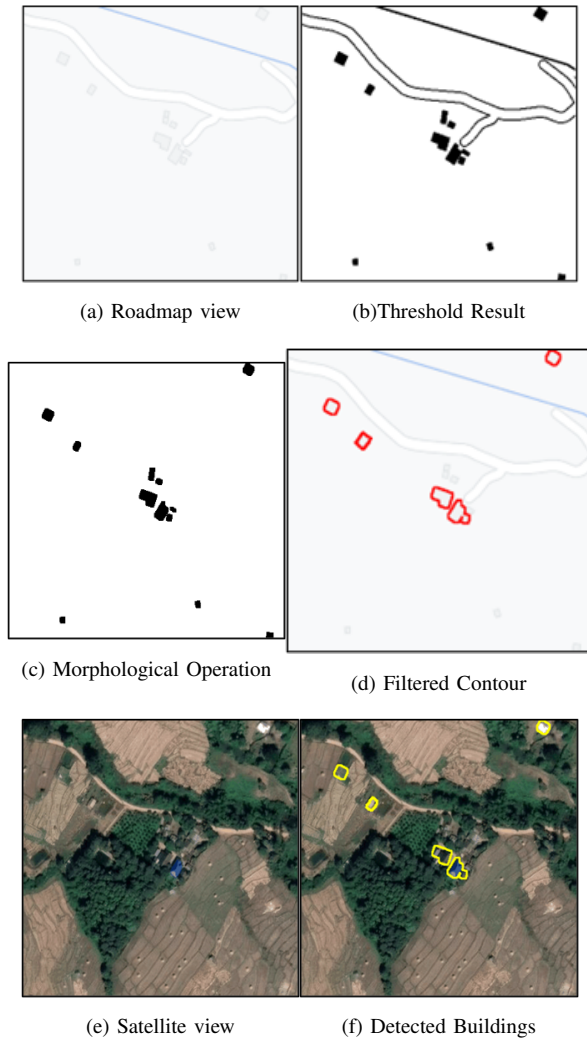

Figure 8. Roadmap-to-Satellite Building Detector (RSBD) successfully identifies high-rise commercial buildings: A test case in Thailand.

in an image by computing these three measures.

$$\text{Completeness} = \frac{TP}{TP + FN} \times 100\% \quad (8)$$

$$\text{Correctness} = \frac{TP}{TP + FP} \times 100\% \quad (9)$$

$$\text{Quality} = \frac{2 \times \text{Completeness} \times \text{Correctness}}{\text{Completeness} + \text{Correctness}} \times 100\% \quad (10)$$

With an average Completeness score of 79%, the Roadmap-to-Satellite Building Detector (RSBD) does a respectable job of identifying buildings in the test photos, according to the data shown in Table II. This suggests that over 80% of the real structures in the pictures can be identified by the RSBD. Furthermore, the majority of the recognized buildings appear to be real buildings, as indicated by the average Correctness score of 9%. The RSBD achieves a reasonable balance between correctness and completeness, as seen by its average Quality score of 85%.

TABLE II. EVALUATION OF THE DETECTION RESULTS IN THE TEST IMAGE SET

Country	Satellite Image	TP	FN	FP	Complete	Correct	Quality
Pakistan*	Small Buildings (1)	17	4	1	81%	94%	87%
	Small Buildings (2)	23	3	4	88%	85%	87%
	High-rising Buildings	6	1	0	86%	100%	92%
	Single Building	1	0	0	100%	100%	100%
	Multiple Buildings	22	4	2	85%	92%	88%
	Earthen Buildings	20	2	0	91%	100%	95%
Canada*	Small Buildings	16	3	0	84%	100%	91%
	High-rising Buildings	6	1	1	86%	86%	86%
	Single Building	1	1	0	50%	100%	67%
	Multiple Buildings (1)	19	5	2	79%	90%	84%
	Multiple Buildings (2)	21	5	0	81%	100%	89%
	Buildings Obstructed	8	2	0	80%	100%	89%
UAE*	Small Buildings	17	9	0	65%	100%	79%
	High-rising Buildings	8	1	0	89%	100%	94%
	Multiple Buildings (1)	20	6	1	77%	95%	85%
	Multiple Buildings (2)	23	3	3	88%	88%	88%
	Earthen Buildings	22	4	0	85%	100%	92%
India*	Small Buildings (1)	18	8	2	69%	90%	78%
	Small Buildings (2)	16	10	1	62%	94%	74%
	High-rising Buildings	4	0	1	100%	80%	89%
	Multiple Buildings (1)	19	7	1	73%	95%	83%
	Multiple Buildings (2)	21	5	1	81%	95%	87%
	Buildings Obstructed	6	3	1	67%	86%	75%
Yemen*	Small Buildings	23	3	2	88%	92%	90%
	Single Building	1	0	0	100%	100%	100%
	Multiple Buildings (1)	22	4	1	85%	96%	90%
	Multiple Buildings (2)	17	9	2	65%	89%	75%
	Earthen Buildings	20	6	4	77%	83%	80%
Thailand*	Small Buildings	18	8	1	69%	95%	80%
	High-rising Buildings	9	2	0	82%	100%	90%
	Multiple Buildings (1)	19	7	3	73%	86%	79%
	Multiple Buildings (2)	21	5	2	81%	91%	86%
	Buildings Obstructed	4	1	1	80%	80%	80%

It is important to note, too, that the RSBD performs differently in various geographical areas. In particular, the RSBD outperforms Yemen and India in terms of construction detection in Pakistan, Canada, the United Arab Emirates, and Thailand. This regional variation in performance suggests that variables like geographic features and differences in building kinds and densities may have an impact on the RSBD accuracy.

V. RESULTS

The performance of the Roadmap-to-Satellite Building Detector (RSBD) is demonstrated in Fig. 9 utilizing six distinct satellite pictures from Pakistan, with an emphasis on the identification of various building types. In terms of quality evaluation and detection accuracy, the data shows encouraging outcomes. Notably, RSBD received a 95% overall quality

score for “Earthen Buildings,” with 91% completeness and 100% accuracy. Likewise, for “Multiple Buildings,” the RSBD revealed an overall quality score of 88%, a completeness of 85%, and an accuracy of 92%. RSBD obtained a perfect completeness and correctness rate of 100% for “Individual Building” detection. Furthermore, RSBD demonstrated excellent completeness scores of 86% and 81% for “High-rising Buildings” and “Small Buildings,” respectively, in addition to high accuracy rates, yielding overall quality ratings of 9% and 87%, respectively. These results highlight how well the Roadmap-to-Satellite Building Detector (RSBD) can recognize a variety of building types across Pakistan’s regions.

Figure 9. Roadmap-to-Satellite Building Detector (RSBD) Performance Across Different Satellite Images in Pakistan.

The performance of the Roadmap-to-Satellite Building Detector (RSBD) across six distinct satellite pictures in Canada is shown in Fig. 10. Among the many image categories, RSBD demonstrated a remarkable degree of accuracy, with correctness ranging from 86% to 100%. The RSBD technique is strong, as seen by its completeness, which ranges from 50% to 86% and assesses the capacity to discover true positives. The total RSBD quality ranges from 67% to 91%, demonstrating how well RSBD can recognize buildings in satellite imagery from a variety of Canadian locales.

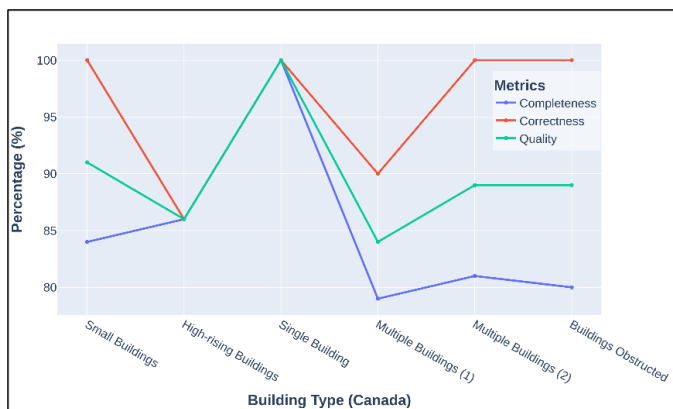

Figure 10. Roadmap-to-Satellite Building Detector (RSBD) Performance across different satellite images in Canada.

Findings from an examination of satellite imagery from different parts of the United Arab Emirates (UAE) are shown

in Fig. 11, with an emphasis on the identification of distinct building types. The Roadmap-to-Satellite Building Detector (RSBD) performance in these categories is shown in the graph, which shows encouraging outcomes. Notably, RSBD received an overall quality score of 85% for the “Multiple Buildings” category, with 77% completeness and 95% accuracy. Likewise, with “Earthen Buildings,” RSBD achieved a remarkable 85% completeness and 100% accuracy, yielding a 92% quality score. For “Small Buildings” and “High-rising Buildings,” respectively, RSBD demonstrated high accuracy rates of 100% and outstanding quality scores of 79% and 94%. These findings underscore the potential of Roadmap-to-Satellite Building Detector (RSBD) in accurately identifying diverse building types in UAE satellite imagery, contributing to advancements in remote sensing applications.

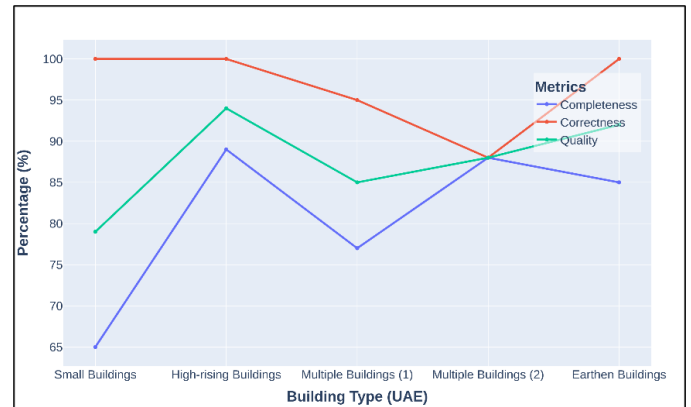

Figure 11. Roadmap-to-Satellite Building Detector (RSBD) Performance across different satellite images in UAE.

The performance of the Roadmap-to-Satellite Building Detector (RSBD) on six distinct satellite photos of India is shown in Fig. 12. According to the graph, when recognizing several buildings, the Roadmap-to-Satellite Building Detector (RSBD) obtained an exceptional average completeness rate of 77% and an accuracy rate of 95%, yielding a quality score of 83%. RSBD obtained a 78% overall quality score, a 66% completeness rate, and a 92% accuracy rate for small buildings. Furthermore, with 100% completeness and 80% correctness rate, RSBD demonstrated exceptional performance in identifying high-rise buildings, earning an 89% quality score. RSBD obtained a quality score of 75%, a correctness rate of 86%, and a completeness rate of 67% when working with obstructed buildings. These results highlight how well Roadmap-to-Satellite Building Detector (RSBD) can recognize and classify buildings in satellite photos, especially when it comes to seeing several, tall buildings. A thorough examination of satellite image data from multiple Yemeni regions is shown in Fig. 13, with an emphasis on the identification of distinct building types. With completeness ranging from 65% to 100% and correctness ranging from 83% to 100%, the graph shows encouraging results in terms of detection accuracy. With an average score of 87%, the overall quality of the buildings that were detected likewise shows excellent performance. With the best performance seen in the recognition of individual buildings, these results demonstrate the promise of the Roadmap-to-Satellite Building Detector (RSBD) for precise building detection in Yemen.

Figure 12. Roadmap-to-Satellite Building Detector (RSBD) Performance across different satellite images in India.

Figure 14. Roadmap-to-Satellite Building Detector (RSBD) Performance across different satellite images in Thailand.

Figure 13. Roadmap-to-Satellite Building Detector (RSBD) Performance across different satellite images in Yemen.

Findings from satellite photos of different parts of Thailand are shown in Fig. 14, with an emphasis on identifying structures and classifying them according to their kind. Significant differences in the performance metrics between the various building categories are shown in the graph. For example, Roadmap-to-Satellite Building Detector (RSBD) received a 79% overall quality score in the “Multiple Buildings” category, with 73% completeness and 86% accuracy. Conversely, the “Small Buildings” category had an overall quality score of 80% due to its higher accuracy of 95% and lower completeness of 69%. These results highlight how crucial it is to modify detection tactics according to particular building types when using satellite data for urban study in Thailand. Moreover, the “High-rising Buildings” category demonstrated exceptional performance with an 82% completeness, 100% correctness, and a remarkable overall quality score of 90%. This suggests that RSBBD excels in detecting taller structures in these satellite images.

VI. DISCUSSION

This section presents and analyzes the findings from the Roadmap-to-Satellite Building Detector (RSBD) approach. In addition to exploring the findings’ wider ramifications, the discussion will offer an interpretation of these results in light of earlier research and working ideas.

A. Robustness and Generalizability

The robustness and generalizability of RSBBD were demonstrated by the qualitative study conducted in several geographical areas. Despite differences in building kinds, sizes, materials, and occlusions, RSBBD was able to detect buildings in a variety of scenarios. The methodology’s flexibility to diverse urban settings is demonstrated by its high performance in several regions. These results are consistent with earlier research that emphasized the significance of creating reliable building detection techniques for satellite photography, considering the variety of urban settings found throughout the world.

B. Detection Accuracy

The quantitative analysis offered a thorough evaluation of the detection accuracy of RSBBD. The performance was assessed using the True Positives (TP), False Negatives (FN), and False Positives (FP) measures. With an average completeness score of 79%, the approach was able to identify roughly 79% of the real structures in the test photos. The bulk of the structures that were spotted were, according to the average accuracy score of 93%, genuine positives. A good balance between completeness and correctness was indicated by the quality score, which averaged 85%. One significant finding is the regional variance in performance, with RSBBD doing better in certain areas than others. Variations in image quality, building density, and geographic elements could all be responsible for this discrepancy. It highlights that in order to achieve the best results, the methodology must be modified to account for certain area features. Additionally, it is in line with earlier studies that have emphasized the difficulties in detecting buildings in various geographical locations.

C. Machine Learning vs. Image Processing

The fact that RSBBD relies on image processing methods rather than machine learning or deep learning algorithms is one of its noteworthy features. Benefits of this option include lower data needs, resilience to changes in weather and lighting, and efficiency when dealing with partially blocked structures. These benefits are consistent with the drawbacks of machine learning models that were covered in the introduction, where issues with data quality, generalization, and environmental

sensitivity were noted. Because machine learning and deep learning techniques work well on particular datasets, they have frequently been preferred in earlier research for constructing detection. Nevertheless, RSBD's findings imply that image processing methods can outperform machine learning models in certain areas while still producing competitive outcomes. This discovery adds to the continuing debate on whether methods are best suited for building detecting jobs.

VII. THRESHOLD VALUE ANALYSIS

As mentioned earlier, thresholding is a commonly used technique to convert grayscale images into binary images by classifying each pixel as foreground or background. This approach is particularly useful in separating the object of interest, which in this study pertains to building outlines, from the background and streamlining subsequent image analysis. In this study, a threshold value of 243 was consistently employed throughout all experiments. This choice was made after a thorough examination of the features of the building outlines in the grayscale pictures. Fig. 15 shows the histogram of pixel intensity values for two grayscale images acquired using Eq. (1) in various test scenarios to further clarify our choice. These graphs demonstrate that 243, 249, and 253 were the intensity values that appeared most frequently in the grayscale photographs. These specific intensity values were found to correlate with ground, roads, and building outlines, respectively, after empirical investigation.

Figure 15. Threshold selection for building outlines in grayscale images: Using pixel intensity histogram analysis.

This study led to the selection of 243 as the threshold value for all studies. This choice was made since it was discovered that this specific intensity value worked best for recognizing building outlines in the grayscale pictures. Additionally, the Roadmap-to-Satellite Building Detector (RSBD) produced great results, showing that this method of detecting buildings from satellite photos has several uses, such as urban planning and catastrophe management. This method allows us to precisely recognize and examine building outlines from satellite photos, yielding insightful information for a range of uses.

VIII. CONCLUSION

The experimental findings show that the Roadmap-to-Satellite Building Detector (RSBD) has the ability to automatically identify and categorize buildings in satellite imagery from Google Maps. The approach successfully recognized and categorized buildings in six global locations, including low-rise

and high-rise, urban and rural, and successfully handled single and multiple structures in an image. To improve the precision and resilience of the detection process, this methodology makes use of sophisticated capabilities, such as the Google Maps Roadmap view, and uses contour filtering and morphological procedures. Furthermore, it is well-suited for universal applications due to its adaptability to different building kinds, sizes, and shapes throughout worldwide areas. Nevertheless, this suggested approach has a drawback. The RSBD method uses Google Maps Road Map view's footprints to identify structures in satellite photos. As a result, RSBD won't recognize buildings whose outlines Google has supplied are out-of-date or missed by Google's algorithm. The significance of regional adaptation is highlighted by the regional differences in RSBD's performance. Future studies might concentrate on adjusting the methodology to particular geographical areas while accounting for elements like construction types, regional materials, and environmental circumstances. This modification may result in improved precision and dependability in many settings. Even though RSBD mostly uses image processing, future studies might look into using machine learning or deep learning methods to improve its functionality even more. To increase detection accuracy, machine learning models could be trained to adjust to local variables. Even greater outcomes could be achieved by combining the advantages of machine learning with image processing. To sum up, the Roadmap-to-Satellite Building Detector (RSBD) presents a viable way to address the difficulties associated with automatically identifying and categorizing buildings in satellite imagery. The methodology's potential for worldwide applications is demonstrated by its resilience and flexibility in a variety of urban settings. Future research and development in the area of automatic building detection and classification from high-resolution satellite data can benefit greatly from the conclusions of this work.

Exploring Machine Learning in Malware Analysis: Current Trends and Future Perspectives

Noura Alyemni, Mounir Frikha
College of Computer Sciences & Information Technology,
King Faisal University, Al-Ahsa 31982, Saudi Arabia

Abstract—Sophisticated cyberattacks are an increasing concern for individuals, businesses, and governments alike. Detecting malware remains a significant challenge, particularly due to the limitations of traditional methods in identifying new or unexpected threats. Machine Learning (ML) has emerged as a powerful solution, capable of analyzing large datasets, recognizing complex patterns, and adapting to rapidly changing attack strategies. This paper reviews the latest advancements in machine learning for malware analysis, shedding light on both its strengths and the challenges it faces. Additionally, it explores the current limitations of these approaches and outlines future research directions. Key recommendations include improving data preprocessing techniques to reduce information loss, utilizing distributed computing for greater efficiency, and maintaining balanced, up-to-date datasets to enhance model reliability. These strategies aim to improve the scalability, accuracy, and resilience of ML-driven malware detection systems.

Keywords—Machine learning; malware analysis; cybersecurity

I. INTRODUCTION

Malware evolves and adapts continuously as computer systems and internet connections continue to expand [1]. The interconnected nature of devices allows malware to spread rapidly, resulting in significant cybersecurity risks. In a sense, malware is similar to a digital virus; it is a sneaky program designed to harm your computer or network [2]. This term encompasses a variety of harmful programs, including viruses, worms, trojans, ransomware, adware, and others [3].

As cyberattacks become more sophisticated, there is an increasing need for advanced malware detection and analysis techniques. However, traditional methods face limitations in performance accuracy and often fail to detect unexpected malware variants. In malware analysis, techniques from a variety of fields are used, including program analysis and network analysis [4]. By examining malicious samples, analysts aim to gain a comprehensive understanding of malware behavior and how it evolves over time.

Researchers have developed various methods for malware detection, which can be broadly divided into two groups: signature-based techniques and machine learning (ML)-based techniques. Signature-based methods rely on recognizing predefined patterns from known malware, while ML-based approaches use algorithms to analyze both benign and malicious samples [5]. This allows ML models to detect both familiar threats and new unpredictable ones. The adaptability of ML-based techniques makes them more suitable for malware detection.

The application of machine learning in malware detection offers promising solutions by adapting to new and evolving threats. However, while machine learning offers significant potential, existing research often examines individual techniques in isolation, without providing a cohesive view of their combined strengths and weaknesses. Furthermore, practical challenges such as mitigating adversarial attacks, managing computational efficiency, and addressing dataset imbalances in real-world applications remain underexplored. These gaps highlight the need for a more integrated and comprehensive approach to fully realize the potential of machine learning in malware detection. ML-based methods enable systems to learn and improve from experience without requiring explicit programming for each task. Unlike signature-based techniques, which depend on predefined malware signatures, ML-based methods are more effective in identifying emerging threats. The effectiveness of these models depends heavily on the quality of features and training data, making them adaptable to the constantly changing nature of malware.

This paper aims to present a comprehensive overview of current trends in machine learning for malware analysis, including descriptions, challenges, and future directions. Specifically, the research aims to answer these questions:

- 1) What are the key trends in machine learning-based malware analysis techniques?
- 2) What are the challenges and issues associated with each of these trends?
- 3) What future research directions in this field require further exploration?

The paper is organized as follows. Section II provides an overview of machine learning in malware analysis. In Section III, we present the methodology used in our research. Section IV describes different trends in malware analysis using ML, followed by challenges associated with each trend in Section V. Finally, suggestions for future directions, countermeasures, and conclusions are discussed in Sections VI and VII.

II. ROLE OF MACHINE LEARNING IN MALWARE ANALYSIS

Machine learning has become a vital component in malware detection and analysis, offering solutions to the challenges posed by traditional methods. Its ability to identify unique patterns, adapt to emerging threats, and process vast amounts of data has positioned it as a cornerstone technology in the fight against cybercrime.

One of the key strengths of machine learning is its scalability. Unlike traditional malware analysis techniques, which

depend on manual processes that are both time-consuming and error-prone, machine learning algorithms can evaluate millions of files in just seconds [6]. This ability to quickly and efficiently identify potential threats is crucial in a landscape where the volume and complexity of malware are growing exponentially .

Another significant advantage of machine learning is its adaptability. As cybercriminals continuously develop sophisticated malware and zero-day attacks exploiting vulnerabilities that have not yet been identified machine learning models are uniquely equipped to detect hidden anomalies and respond to novel attack patterns [7]. Models that focus on analyzing dynamic behaviors are particularly effective at staying ahead of these evolving threats, making machine learning an indispensable tool in cybersecurity.

Pattern recognition is another area where machine learning excels. By analyzing the code, behavior, and attributes of malware, these models can uncover intricate patterns that would likely go unnoticed by human analysts. This capability is especially important for identifying zero-day malware, which exploits previously unknown vulnerabilities [8]. Moreover, the automation provided by machine learning frees security analysts to focus on higher-level tasks, such as strategic threat intelligence, thereby improving an organization's overall response to cyberattacks.

To explore how machine learning strengthens malware detection, the next section delves into the primary approaches to malware analysis, including static, dynamic, and hybrid techniques.

A. Overview of Malware Analysis Approaches

Understanding how malware operates, what it targets, and the potential damage it can cause is critical for developing effective defenses. Malware analysis helps achieve this by examining the behavior, structure, and impact of malicious programs. Over the years, several methods have been created to analyze and detect malware, each tailored to address evolving threats. This section discusses the primary approaches: static, dynamic, and hybrid analysis.

- **Static Analysis:** Static analysis involves inspecting the structure of a program without running it. This approach identifies key attributes of executable files, such as memory usage and file sections, to understand the malware's properties. It is often divided into basic and advanced techniques. Basic static analysis focuses on simple characteristics like file size, type, and header information, using tools such as PEiD, BinText, MD5deep, and PEview [9]. Advanced static analysis takes a deeper dive into the code itself, analyzing commands and instructions in detail to uncover malware's hidden functionality [10]. Machine learning often utilizes features extracted during static analysis, including opcode sequences, file headers, and structural patterns, to build models capable of identifying malware patterns. These features allow models to distinguish between malicious and legitimate software.
- **Dynamic Analysis:** Dynamic analysis examines the behavior of malware as it executes, often in a controlled environment such as a sandbox or virtual

machine. This method provides insights into how malware operates in real-world scenarios while keeping the host machine protected from infection. Tools like Process Monitor, API Monitor, Process Explorer, Regshot, and Wireshark are commonly used to observe basic malware behaviors [11]. Advanced dynamic analysis goes further by using debugging tools like OllyDbg and WinDbg, allowing analysts to step through code execution, modify parameters, and examine detailed system interactions. Once the analysis is complete, the environment is reset to its original state to ensure safety [12]. Behavioral data collected during dynamic analysis, such as API calls, system interactions, and network traffic patterns, plays a crucial role in training machine learning models. These insights help create algorithms that detect both known and previously unseen malware.

- **Hybrid Analysis:** Hybrid analysis combines static and dynamic techniques to provide a more comprehensive understanding of malware. It begins by analyzing the code and structure without executing it and then proceeds to observe its behavior in a controlled environment. This dual approach overcomes many limitations of using static or dynamic methods alone [13]. Features generated from both static and dynamic analysis, such as opcode sequences, behavioral patterns, and system interaction logs, are integrated into machine learning models. This combination enhances the adaptability and accuracy of malware detection frameworks, making them more effective against evolving threats.

Each of these methods has its strengths and weaknesses, as shown in Table I, and their integration with machine learning offers promising advancements in malware detection [14].

TABLE I. COMPARISON OF MALWARE ANALYSIS APPROACHES

Approaches	Advantages	Disadvantages
Static Analysis	<ul style="list-style-type: none">• Quick analysis• Low resource usage• Multi-path analysis• Enhanced security• High accuracy	<ul style="list-style-type: none">• Difficulty analyzing obfuscated and encrypted malware• Limited ability to detect unknown malware
Dynamic Analysis	<ul style="list-style-type: none">• Analysis of obfuscated and encrypted malware• Superior accuracy compared to static analysis• Detection of known and unknown malware	<ul style="list-style-type: none">• Slow and insecure• High resource usage• Time-consuming and vulnerable• Limited code analysis
Hybrid Analysis	<ul style="list-style-type: none">• Result in more accurate result	<ul style="list-style-type: none">• Requires significant time and resources• High level of complexity

Static, dynamic, and hybrid analysis approaches provide valuable features that significantly enhance machine learning

models used in malware detection. By integrating these methods into machine learning workflows, we can improve detection accuracy and tackle the challenges posed by increasingly sophisticated and evolving malware threats.

III. RESEARCH STRATEGY

This paper uses a systematic literature review (SLR) to explore the role of machine learning in malware detection. The goal is to gather a comprehensive set of relevant studies. The PRISMA 2020 framework (see Fig. 1) was followed to ensure a transparent and systematic approach to selecting and evaluating research articles.

The review focused on journal articles and conference papers published in the past four years. Databases such as IEEE Xplore, ScienceDirect, SpringerLink, and Google Scholar were searched using keywords like “machine learning” AND “malware analysis,” “AI-based malware detection,” and “deep learning” AND “malware classification”. The initial search retrieved 550 records, 500 from primary databases and 50 from secondary sources. After removing 100 duplicates, 450 unique papers remained.

Next, the studies were screened by reviewing their titles and abstracts. This step eliminated 350 papers that were not relevant, lacked full-text availability, were limited to abstracts, or were in languages other than English. The remaining 100 papers were reviewed in full, resulting in the exclusion of 70 papers due to insufficient relevance or methodological quality. Finally, 30 studies were selected based on their alignment with the research scope and their focus on recent challenges or innovative approaches in ML-based malware detection. The selection process is illustrated in Fig. 1.

IV. TRENDS IN MALWARE ANALYSIS USING MACHINE LEARNING

Machine learning has revolutionized malware detection by improving both accuracy and efficiency. Researchers have concentrated on three key approaches: deep learning, transfer learning, and explainable AI (XAI). Each of these techniques brings its own advantages and challenges, working together to tackle the complex demands of malware detection by striking a balance between precision, resource efficiency, and transparency. This section explores these methods, highlighting their applications and contributions to advancing malware detection.

A. Deep Learning-Based Malware Analysis

Deep learning is a sophisticated branch of machine learning that uses deep artificial neural networks to find hidden patterns and intricate correlations in data. These networks are made up of linked layers of cells that hierarchically learn representations directly from raw input data, simplifying the process and eliminating the need for manual feature engineering [15]. This automatic feature extraction allows deep learning models to efficiently manage large volumes of data, making them vital in fields such as image processing, healthcare and cybersecurity. Deep learning creates several levels of abstraction using supervised and unsupervised algorithms, facilitating complex analysis and decision-making. This has led to its broad acceptance in a variety of sectors [16].

Rhode et al. [17] investigated Recurrent Neural Networks (RNNs), especially Long Short-Term Memory (LSTM) networks, for early-stage malware prediction. The authors extracted static features from Portable Executable (PE) files, a common format used by Windows applications, and utilized the LSTM network to simulate the sequential nature of file execution, as a result of which the model was able to capture both short-term and long-term dependencies. By focusing on early-stage behaviors, their model predicted whether a file was malicious before it fully executed, preventing malware before it spreads. Study results demonstrated that LSTM networks are capable of learning temporal patterns, crucial for understanding malware behavior over time. In contrast to traditional machine learning models that rely on static analysis, Rhode et al.’s approach reduced the vulnerability window by detecting malicious intent earlier with LSTMs. In their study, they found that the RNN-based model outperformed traditional techniques such as decision trees and SVMs, which require more data to identify malware. Elayan and Mustafa [18], developed a deep learning-based approach for detecting Android malware. Using gated recurrent units (GRUs), they analyzed static features from Android apps, including API calls and permissions. Their model achieved a high accuracy of 98.2% on the CICAndMal2017 dataset, which supports the effectiveness of deep learning in identifying malicious Android apps.

Catak et al. [19], developed a sequential model using deep learning for analyzing Windows EXE files. Researchers gathered and analyzed a dataset of non-malicious and malicious EXE files and extracted API call sequences. They employed a Long Short-Term Memory (LSTM) network to model the sequential nature of these API calls, which enabled the model

Fig. 1. Selection of papers for review using PRISMA model.

to detect temporal dependencies and patterns indicative of malicious behavior. Based on the dataset, the LSTM model was trained to distinguish malicious from benign EXE files with an impressive accuracy of 98.2%. As a result, deep learning has been demonstrated to be effective in detecting and classifying malware in Windows environments. McDole et al. [20] investigate the application of deep learning techniques for behavioral malware analysis in cloud Infrastructure-as-a-Service (IaaS) environments. The study shows how deep learning models are effective at analyzing malware behavior, making them more effective at detecting sophisticated attacks on cloud-based infrastructures. Similarly, Ravi et al. [21] developed a multi-view attention-based deep learning framework for malware detection in smart healthcare systems. By accurately identifying malicious activities and taking into account the unique operational dynamics of healthcare networks, their work demonstrates that deep learning plays a critical role in ensuring security within healthcare settings.

Calik Bayazit et al. [22] conducted a comprehensive comparative analysis of deep learning models for Android malware detection. They used the Drebin dataset, a publicly accessible collection of benign and malicious Android apps, to evaluate the performance of various models, including Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs). They trained and evaluated the models effectively by extracting static features such as permissions, API calls, and opcode sequences from the apps. In this study, the results demonstrated that hybrid architectures, combining CNNs and RNNs, outperformed individual models, providing evidence that deep learning can enhance Android security.

Ibrahim et al. [23] proposed a malware detection method for Android applications that combines static analysis and deep learning. They extracted key features, including two newly defined features, from the applications. These features were then used as input for a custom-developed deep learning model. The method was evaluated using a classified dataset of Android apps. The extracted features included permissions, API calls, services, broadcast receivers, opcode sequences, application size, and fuzzy hash.

Patil and Deng [24] demonstrated the superior performance of deep learning (DL) networks over traditional machine learning models in malware analysis. They developed a neural network-based framework that achieved high accuracy in classifying malware. The researchers attributed the improved performance to the backpropagation and gradient descent mechanisms employed in DL, which enhance accuracy, true positive rate, and reduce false positive rate.

Rodrigo et al. [25] developed a hybrid machine learning model for Android malware detection. The model consisted of three fully connected neural networks: one for static features, one for dynamic features, and one for a combination of both. When trained on individual features, the static network achieved 92.9% accuracy and the dynamic network achieved 81.1% accuracy. However, the hybrid model, combining both static and dynamic features, outperformed the individual models with an accuracy of 91.1%. This suggests that a hybrid approach, considering both static and dynamic characteristics, is more effective for detecting Android malware.

Obaidat et al. [26] proposed the Jadeite framework to detect

Java-based malware by combining image analysis and behavior analysis with deep learning. The framework uses Java bytecode to create grayscale images that represent malware and identify malicious behavior in real time. Jadeite is composed of three primary components. The first component is the Bytecode Transformation Engine, which converts Java bytecode into grayscale images so malware can be visualized. The second is the Feature Extraction Engine that extracts critical features from bytecode. In addition to the two grayscale images and extracted features, the CNN Classifier Engine analyzes the entire file to determine whether it is malicious or benign using a Convolutional Neural Network (CNN) model.

Although these techniques have offered optimal results in modeling intricate patterns of different malware, these algorithms heavily depend on high-quality datasets and are fairly susceptible to adversarial inputs, as will be explained below. Moreover, based on the papers examined, CNNs emerge as the most often used deep learning technology for malware detection, recognized for their capacity to quickly extract features from binary or grayscale representations. As a result of this capability, CNNs are particularly effective at analyzing image-based malware. Additionally, in order to detect dangerous patterns in code or behavior, recurrent neural networks and LSTMs are frequently used for sequential data analysis. Other approaches, such as deep neural networks, help advance the area of malware detection by identifying intricate linkages in data. While deep learning has revolutionized malware detection, its practical deployment still faces significant challenges, as detailed in the next section.

Although deep learning excels at identifying complex patterns, its application often demands large datasets and significant computational resources, which can limit its practicality. To address these constraints, transfer learning has emerged as a promising alternative by reusing pre-trained models to enhance efficiency.

B. Transfer Learning-Based Malware Analysis

Transfer learning allows knowledge from one domain to be applied in another, minimizing the need for large training datasets and heavy computational demands. This method has garnered considerable interest in malware analysis for its ability to efficiently address challenges related to data scarcity and resource constraints. Researchers have demonstrated its potential in improving malware detection, particularly when datasets are limited—a common challenge in real-time applications [27].

A number of advantages can be derived from the use of transfer learning in malware analysis. First, it greatly minimizes the quantity of training data necessary. Because the model begins with pre-learned information fewer malware-specific samples are required to attain high accuracy. Additionally, Transfer learning improves feature representation by combining abstract and complicated patterns learnt during pre-training. Moreover, the process is computationally efficient which reduces the time and resources needed to train a model from the beginning [28], [29].

Chen et al. [30] demonstrated the effectiveness of transfer learning for static malware classification by adapting pre-trained CNNs to malware-specific datasets. By treating mal-

ware binaries as images, their approach significantly reduced training time while maintaining high accuracy. Bhodia et al. [31] employed VGG16, a deep learning model pre-trained on ImageNet, for malware image classification. Fine-tuning the model on malware-specific datasets improved detection accuracy and showed particular promise in identifying zero-day malware attacks.

Prima and Bouhorma [32] leveraged transfer learning to adapt CNN models for malware detection, converting binary malware files into grayscale images. Their results highlighted the efficiency of transfer learning in resource-constrained environments. Similarly, Ahmed et al. [33] proposed a framework that combines transfer learning with convolutional neural networks to classify malware binaries. They used data augmentation and fine-tuning techniques, which enhanced detection accuracy while reducing computational demands.

Zhao et al. [34] extended the concept of transfer learning by developing a multi-channel framework that visualizes malware binaries as images. By fine-tuning pre-trained CNN models for malware detection, their study emphasized the importance of integrating diverse data channels to improve robustness. Panda et al. [35] investigated transfer learning in IoT environments by using pre-trained models to classify malware image representations. They introduced preprocessing techniques to standardize input sizes but noted the challenge of information loss during the conversion process.

Ngo et al. [36] introduced a hybrid approach that combines transfer learning with static and dynamic feature analysis. Their method minimized computational overhead while improving malware detection accuracy, particularly for obfuscated malware. Tasyurek and Arslan [37] developed RT-Droid, a real-time Android malware detection framework based on transfer learning. By examining static features like API calls and permissions, their framework achieved 98.6% accuracy, demonstrating its effectiveness in real-time scenarios.

Transfer learning techniques such as grayscale image, multi-channel frameworks, and the combination of static-dynamic features have also improved malware detection. These methods enable the models to fine-tune with ease for malware related tasks without the need for large amounts of datasets or computational resources. However, preprocessing requirements, input standardization challenges, and dataset imbalances remain significant obstacles.

However, challenges such as information loss during preprocessing, dataset imbalances, and the complexity of fine-tuning pre-trained models must be addressed for transfer learning to realize its full potential in malware detection.

C. Explainable AI-Based Malware Analysis

Explainable Machine Learning (XAI) is a strong ally to improve the transparency and reliability of malware detection systems. Additionally, XAI helps explain how complex machine learning algorithms make decisions based on identifying key features and patterns [38]. A growing field of research has focused on explainability, aimed at clarifying and simplifying machine learning reasoning and decision-making processes. Explainability methods clarify how ML models work, assisting developers and users in understanding their behavior [39].

A variety of explainable AI methods including SHAP and LIME, provide interpretable explanations for model outputs which assist analysts in understanding how classifications are made. This transparency improves decision-making helps refine malware detection methods and supports the development of stronger more reliable malware detection systems [40]. Moreover, XAI aids in identifying potential inaccuracies in the models and data leading to fairer and more balanced systems. With XAI, the factors that influence a model's decision are clarified resulting in fewer false positives and negatives ultimately improving malware detection accuracy and effectiveness.

Ladarola et al. [41] developed a deep learning model for classifying malware families based on their visual representations, achieving 93.4% accuracy. They used LIME to explain model decisions and activation maps to assess model reliability, identify biases, and improve robustness. Alani and Awad [42] proposed PAIRED, an efficient Android malware detection system using XML techniques. By extracting static features from applications, PAIRED achieved an accuracy rate of over 98% while consuming minimal resources. SHAP values were utilized to explain the decision-making process, enhancing the transparency and interpretability of their model.

Liu et al. [43] focused on the interpretability of machine learning models for Android malware detection. They examined the internal workings of models, including decision trees, to identify key features and patterns involved in malware classification. Similarly, Kinkead et al. [44] utilized LIME to enhance the interpretability of CNN-based predictions. Their study validated the consistency between CNN's feature selection and LIME's interpretability framework, showcasing the utility of LIME in corroborating CNN-based malware detection.

According to H. Manthena [45], many malware analysis models lack transparency, making them difficult to trust. This problem was addressed by integrating XML techniques, such as KernelSHAP, TreeSHAP, and DeepSHAP, into online malware detection. These techniques evaluated performance metrics, improved interpretability, and improved the trustworthiness of security systems. In another study, Manthena et al. [46] developed a malware detection system using SHAP to reveal the inner workings of CNNs and Feedforward Neural Networks (FFNNs). The system provided insights into model predictions, improving transparency and trust in the results.

Lu and Thing [47] proposed an Android malware detection framework employing three model explanation methods: Modern Portfolio Theory (MPT), SHAP, and LIME. These methods were compared based on their ability to provide explanations, with MPT demonstrating utility in analyzing adversarial samples. Additionally, Pan et al. [48] developed a hardware-assisted malware detection framework using regression-based explainable machine learning techniques to overcome prediction inaccuracies and lack of transparency.

Sharma et al. [49] designed a traffic analysis-based malware detection system based on traffic analysis that utilizes human-readable network traffic features. Decision tree-based models were employed, enabling more interpretable malware detection. Iadarola et al. [50] proposed an interpretable approach for detecting and categorizing Android malware fami-

lies. By visually representing malware as images and feeding them into an explainable deep learning model, their system achieved both high performance and transparency.

Explainable machine learning techniques such as SHAP, LIME, and XML are very effective in increasing the interpretability and transparency of malware detection systems. These methods contribute to enhancing the interpretability of the factors behind the decisions and therefore enhancing the reliability and accuracy of the results. However, challenges such as scalability in real-time environments and computational overhead prevent broad adoption.

XAI plays a vital role in improving transparency and reliability in malware detection, but it struggles with challenges like real-time scalability, computational demands, and the trade-off between performance and interpretability.

Table II provides a summary of the analyzed papers.

Fig. 2. Proportion of machine learning techniques used in malware detection studies.

Fig. 2 shows the use of various machine learning techniques in malware detection from the studies examined in the paper. Techniques like transfer learning and explainable XAI are prominently represented, indicating their increasing significance in addressing challenges such as limited resources and improving model interpretability. Deep learning methods, including CNNs and RNNs/LSTMs, also play a vital role in identifying complex patterns and managing sequential data, reflecting their foundational importance. Although hybrid models are less commonly employed, they showcase the potential of combining multiple approaches to achieve higher detection accuracy. This analysis underscores the diversity of methodologies adopted in malware detection research and their continuing progress.

While machine learning has great potential to enhance malware detection, it also comes with notable challenges. Deep learning demands significant computational resources, transfer learning contends with issues like imbalanced datasets, and explainable AI poses integration complexities. Tackling these obstacles is crucial to advancing malware detection methods. The next section delves into these challenges, highlighting

gaps in current approaches and exploring opportunities for improvement.

V. LIMITATIONS OF CURRENT APPROACHES

Although machine learning techniques have made significant advances in malware detection, there are still many limitations, affecting their practicality and scalability. Based on the studies reviewed, this section discusses the limitations of deep learning, transfer learning, and explainable AI.

A. Limitations of Deep Learning

Deep learning techniques have revolutionized malware detection, yet they are not without challenges:

- Rhode et al. [17] emphasized that their LSTM-based approach for early-stage malware detection heavily relied on large, high-quality datasets, limiting its practical applicability in real-world environments. Moreover, LSTMs are computationally intensive, susceptible to noise and adversarial attacks, and often face challenges in generalizing to previously unseen malware families. The complexity of interpreting LSTM models further complicates their adoption, as it undermines trust and impedes effective debugging
- Elayan and Mustafa [18] observed that their GRU-based model for Android malware detection, despite its high accuracy, posed challenges in resource-limited environments such as mobile devices or IoT systems. The model's computational demands resulted in higher energy consumption, longer processing times, and reduced battery efficiency on mobile devices. Addressing this issue may involve developing lightweight architectures or employing model compression techniques to enhance its suitability for resource-constrained settings.
- Catak et al. [19] highlighted the effectiveness of LSTMs in analyzing sequential data but noted their vulnerability to adversarial attacks. Subtle, malicious perturbations in input data can easily deceive LSTMs, resulting in misclassification. This weakness poses a significant security threat in practical applications, as attackers can exploit it to bypass detection mechanisms.
- McDole et al. [20] observed that while deep learning models provide scalability and flexibility in cloud environments, they come with high computational costs. This results in increased latency, elevated operational expenses, and lower energy efficiency, rendering them unsuitable for real-time applications with strict latency demands, such as autonomous vehicles or industrial control systems.
- Ravi et al. [21] identified that their multi-view attention framework, while effective, heavily relies on specialized hardware such as GPUs or TPUs for efficient training and inference. This dependence limits its usability in resource-constrained settings, including IoT and edge devices, where computational resources and memory are restricted. Additionally, the need for specialized hardware can elevate both deployment

costs and energy consumption, posing challenges for broader adoption.

- Calik Bayazit et al. [22] highlighted the effectiveness of hybrid architectures that leverage the advantages of various deep learning models. However, these architectures tend to be highly complex, presenting challenges in terms of training, optimization, and efficient deployment. Additionally, identifying the ideal combination of models and hyperparameters for a given task can be both time-intensive and computationally demanding.
- Ibrahim et al. [23] observed that integrating static analysis with deep learning improved malware detection accuracy. Despite its benefits, this approach often demands considerable domain expertise to effectively derive and refine features from static analysis outputs. Additionally, the integration of static analysis tools with deep learning models presents challenges in complexity and resource requirements, necessitating significant computational power and specialized infrastructure.
- Patil and Deng [24] highlighted that, although deep learning models outperform traditional approaches, their high training costs and demanding hardware requirements pose significant challenges. These scalability limitations restrict their usability in resource-constrained settings and complicate their application in scenarios requiring frequent retraining, such as adapting to emerging threats.
- Rodrigo et al. [25] observed that while their hybrid model, which integrates static and dynamic features, enhanced malware detection accuracy, it also introduced increased inference time. This limitation makes the approach less practical for real-time applications with strict latency demands, such as intrusion detection systems and real-time threat monitoring.
- Obaidat et al. [26] emphasized the effectiveness of their CNN-based method for detecting Java-based malware through visual bytecode representations. However, the conversion of bytecode into visual formats may result in information loss, which can hinder the model's ability to accurately identify subtle behavioral patterns and nuances of malware.

B. Limitations of Transfer Learning

Transfer learning has shown to be effective in reducing training time and resource consumption, but it faces the following challenges:

- Chen et al. [30] noted that converting malware binaries into image representations for the use of convolutional neural networks can result in substantial information loss. This reduction in critical data may compromise the model's accuracy and its capacity to effectively analyze complex malware behaviors and traits.
- Bhodia et al. [31] highlighted that, although transfer learning demonstrated high accuracy in malware detection, its effectiveness is significantly affected by

class imbalance in the training dataset. When certain malware classes are underrepresented, the resulting models may become biased, leading to reduced generalization capabilities for unseen samples belonging to these underrepresented categories.

- Prima and Bouhorma [32] noted that although transfer learning provides an effective initial framework, it often necessitates substantial fine-tuning on specific malware datasets. This process can be both computationally intensive and time-consuming, demanding considerable resources and potentially delaying the quick deployment and adaptation needed to address emerging threats.
- Zhao et al. [34] highlighted the effectiveness of multi-channel frameworks in combining diverse data sources. However, merging information from channels like static analysis, dynamic analysis, and network traffic introduces considerable computational overhead and complexity. Effectively processing and integrating these varied data streams necessitates meticulous optimization of both the model architecture and the training methodology.
- Panda et al. [35] emphasized the difficulties of pre-processing and standardizing input formats for IoT malware detection. The variation among IoT devices and the diversity of malware samples introduce significant challenges in creating consistent input structures, which can complicate data preprocessing workflows and potentially affect the overall performance of the models.
- Ngo et al. [36] demonstrated that integrating static and dynamic features within transfer learning models enhances accuracy. However, this methodology presents notable challenges, including increased training complexity, extended training durations, and difficulties in fine-tuning hyperparameters. Furthermore, the combined use of static and dynamic analysis may lead to longer inference times, potentially hindering the system's efficiency in real-time scenarios.
- Tasyurek and Arslan [37] highlighted that their RT-Droid system demonstrated effectiveness in real-time Android malware detection. However, maintaining its efficacy in the face of rapidly evolving malware requires frequent updates to its models and feature sets. This ongoing need for retraining and redeployment poses significant challenges, including increased resource demands and operational complexity.

C. Limitations of Explainable AI

Explainable AI techniques have enhanced the interpretability of malware detection models, but there are still several limitations:

- Ladarola et al. [41] demonstrated that LIME effectively enhances interpretability by offering localized explanations of model predictions. However, its substantial computational demands render it impractical

for real-time applications with strict latency constraints, such as online malware detection or intrusion detection systems.

- Alani and Awad [42] highlighted the utility of SHAP values in offering valuable insights into the elements shaping model predictions, thereby improving transparency. However, incorporating SHAP value computations into resource-limited environments, such as mobile or edge devices, poses challenges due to the substantial computational resources required for their calculation.
- Liu et al. [43] observed that decision trees, despite their inherent interpretability, encounter scalability challenges when dealing with large-scale malware datasets. The expansion in the number of features and data samples can significantly increase the tree's complexity, resulting in prolonged training durations, higher memory usage, and reduced overall efficiency.
- Kinkead et al. [44] demonstrated the effectiveness of LIME in explaining CNN-based malware detection model predictions. However, they identified scalability as a significant limitation, particularly when handling large and complex malware datasets. This constraint poses challenges for its practical application in real-world scenarios requiring swift analysis and explanation of extensive malware samples.
- Lu and Thing [47] investigated various explainability techniques, including MPT. However, they identified that MPT has shortcomings in effectively handling adversarial attacks. Such adversarial examples, designed to exploit vulnerabilities in the model, can undermine the reliability of explainability methods, resulting in distorted or inaccurate interpretations.
- Pan et al. [48] introduced a hardware-assisted framework aimed at enhancing the transparency and interpretability of deep learning models for malware detection. Despite its advantages, the reliance on specialized hardware restricts its use in general-purpose systems. Additionally, this dependency may elevate deployment costs, presenting a barrier to broader implementation.
- Manthena et al. [46] highlighted that SHAP enhances the interpretability of deep learning models by generating feature importance scores. However, calculating SHAP values introduces substantial computational overhead, which can adversely affect real-time system performance. This limitation poses a bottleneck in high-throughput malware analysis workflows, hindering their efficiency in time-sensitive applications.
- Sharma et al. [49] emphasized the effectiveness of decision-tree-based models in traffic analysis and malware detection. However, these models are highly susceptible to obfuscation techniques, which are employed by malware developers to modify the code's structure while retaining its functionality. Such obfuscation methods can compromise the model's ability to accurately detect and classify malware, posing a significant challenge in maintaining detection reliability.

The analyzed papers demonstrate that considerable progress has been made in employing machine learning approaches to detect malware; still, various limitations make it difficult to implement the obtained outcomes.

- 1) Deep Learning:
 - Datasets must be large and high quality to be effective in environments with limited data.
 - Vulnerable to adversarial attacks that manipulate model predictions.
 - The computational requirements make it difficult to deploy in resource-constrained systems.
- 2) Transfer Learning:
 - In preprocessing steps, such as converting malware binaries into images, losing information can be increased.
 - Dataset imbalances affect model generalizability.
 - Fine-tuning pre-trained models is computationally expensive and time-intensive.
- 3) Explainable AI (XAI):
 - High computational overhead deter scalability for real time applications.
 - Finding a balance between transparency and efficiency is still difficult.
 - Compatibility with existing security systems is a high level of integration and thus calls for domain-specific solutions.

While these challenges present significant hurdles, they also highlight critical areas that require further exploration and innovation. Overcoming these barriers is vital to realize the full potential of machine learning in malware detection. With advancements in techniques such as preprocessing optimization, improved dataset balancing, enhanced computational efficiency, and seamless system integration, limitations can be addressed effectively. The next section delves into specific strategies and emerging possibilities that aim to enhance the scalability, reliability, and transparency of machine learning-based malware detection systems.

VI. FUTURE DIRECTIONS AND COUNTERMEASURES

Detecting and analyzing malware has made significant progress; however, a number of challenges still exist. This section presents potential future research directions and actionable countermeasures for improving machine learning-based malware detection systems' scalability, robustness, and transparency.

A. Future Directions

- 1) Deep Learning:
 - Federated Learning for Privacy: Federated learning enables collaborative model training while ensuring data privacy by retaining data on individual devices, thus reducing the risk of sensitive information exposure. However, privacy concerns persist, prompting ongoing research into methods such as differential privacy to enhance protection and address these challenges [51].

- **Hybrid Architectures:** Combining CNNs and RNNs allows for combining their complementary capabilities, with CNNs excelling at identifying spatial patterns and RNNs adept at analyzing sequential data [67]. This integration enables the model to effectively capture both spatial and temporal relationships within malware datasets, offering enhanced accuracy and robustness in malware detection.
- **Optimized Lightweight Models:** Design models tailored for resource-constrained environments such as IoT devices or edge platforms by employing techniques like model pruning, quantization, and knowledge distillation. These methods significantly reduce model size and computational demands while maintaining acceptable levels of accuracy. Sze et al. [68] highlighted the value of optimizing deep neural networks for embedded systems, showcasing how such strategies can enhance energy efficiency and make models more suitable for real-time malware detection in low-power, latency-sensitive scenarios.

2) Transfer Learning:

- **Improved Preprocessing Techniques:** Advancing preprocessing methods is essential to retain critical features while minimizing the loss of information during data transformation. Techniques such as adaptive feature scaling and intelligent data augmentation can strike a balance, ensuring that key data characteristics are preserved for better model accuracy [69]. This approach has proven beneficial in applications where maintaining high-dimensional data integrity is crucial.
- **Cross-Domain Adaptability:** Developing models that perform effectively across varying domains, such as IoT and cloud infrastructures, is a vital research direction. Leveraging strategies like domain adaptation and transfer learning can enable these models to generalize efficiently across diverse environments, addressing discrepancies in data distributions and ensuring consistent performance [70].
- **Streamlined Fine-Tuning Processes:** Streamlining fine-tuning procedures is critical to enhance efficiency and performance. Automated tools such as AutoML and hyperparameter optimization frameworks can simplify this process by automating the search for optimal model parameters [72]. This reduces manual intervention and significantly improves the model's overall effectiveness.
- **Standardized Datasets for Malware Detection:** Ensuring the availability of standardized and balanced datasets is essential for reliable evaluation and benchmarking of malware detection models. These datasets should include diverse malware samples and simulate real-world scenarios to enhance the generalizability and robustness of the models [74].

3) Explainable AI:

- **Efficient Explanation Models:** Creating lightweight XAI frameworks tailored for real-time applications is essential. These models should focus on reducing

computational overhead while delivering clear, actionable insights. Streamlining algorithms like SHAP or LIME for efficient processing can make XAI more applicable in scenarios requiring immediate decision-making.

- **Adaptive Explanations:** Develop Dynamic explainability frameworks are crucial for addressing evolving malware patterns. By continuously learning and adapting to new threats, these systems can provide context-specific explanations that remain relevant over time. Such adaptability ensures that cybersecurity measures evolve in tandem with emerging challenges.
- **Integration with Security Frameworks:** Modular XAI tools designed for seamless integration with existing cybersecurity systems can significantly enhance decision-making [73]. These tools can act as plug-and-play components, working in harmony with established security workflows to improve detection accuracy and transparency .

B. Countermeasures

1) Deep Learning:

- **Defensive Mechanisms for Adversarial Inputs:** Building robust defenses against adversarial attacks is essential for bolstering the security of machine learning models. A widely adopted technique is adversarial training, which incorporates adversarial examples into the training process to enhance the model's resilience. For example, the study [52] introduces an Ulam-stability-based method that significantly improves model robustness against such attacks. Another promising method involves using an anti-adversarial module, as outlined in [53]. This approach applies targeted counter-adversarial treatments to input samples, effectively reducing the impact of adversarial perturbations. By employing these advanced techniques, machine learning models can achieve heightened resistance to adversarial inputs, ultimately increasing their reliability in security-critical applications.
- **Augmentation Techniques for Data:** Data augmentation has emerged as a vital technique to address limitations in dataset sizes. By using GANs, synthetic but realistic data can be generated, significantly enriching training datasets. For instance, [62] discuss how GANs can create synthetic malware samples, which help balance datasets and improve the robustness of machine learning models in detecting malware. This approach not only reduces reliance on large datasets but also enhances model generalizability by diversifying training inputs.
- **Improving Adversarial Resilience:** Adversarial training has become essential in strengthening models against adversarial attacks. For example, Madry et al. propose incorporating adversarial samples during the training process to improve a model's robustness [63]. By simulating potential attacks, this method ensures that models can better resist manipulation, making them more reliable in security-critical environments

- **Leveraging Hardware Solutions:** To address the computational demands of deep learning models, leveraging specialized hardware like Tensor Processing Units (TPUs) and GPUs has proven effective. Jouppi et al. demonstrate the use of TPUs to accelerate deep learning tasks, showing how such hardware can reduce training times and energy consumption while maintaining high performance [64].

2) Transfer Learning:

- **Handling Dataset Imbalances:** Addressing dataset imbalances is crucial for developing effective machine learning models. Techniques such as oversampling the minority class and generating synthetic data have proven effective in mitigating these imbalances. For instance, the Synthetic Minority Over-sampling Technique (SMOTE) creates synthetic samples by interpolating between existing minority instances, thereby enhancing model performance on imbalanced datasets [54]. Moreover, recent advancements have introduced methods like Localized Random Affine ShadowSampling (LoRAS), which oversamples from an approximated data manifold of the minority class, addressing limitations associated with traditional techniques [55]. Through the implementation of these strategies, models can achieve better balance and improved prediction accuracy.
- **Optimized Preprocessing Workflows:** Effective preprocessing is critical to ensuring the success of machine learning models in malware detection. Optimizing these workflows not only preserves essential data features but also reduces computational overhead, enabling efficient and scalable model deployment. Techniques such as feature selection and dimensionality reduction, as presented in [56], can streamline preprocessing by focusing on the most informative attributes while discarding redundant data. Additionally, leveraging automated preprocessing pipelines, as highlighted in [57], can dynamically adapt preprocessing strategies to diverse datasets and application requirements.
- **Distributed Training Systems:** Distributed training systems enable the efficient processing of large datasets and complex machine learning models by leveraging the computational power of multiple machines. This approach not only reduces resource bottlenecks but also accelerates the training process, making it ideal for scaling malware detection models to meet real-world demands. For instance, distributed frameworks such as Apache Spark and TensorFlow Distributed offer robust architectures for handling extensive data and computations across multiple nodes [58], [59]. These systems optimize training by partitioning tasks, balancing workloads, and parallelizing computations. Additionally, advancements in federated learning and edge computing can complement distributed systems, enabling secure and decentralized training of models without compromising data privacy [60], [61].

3) Explainable AI:

- **Real-Time XAI Models:** Real-time XAI frameworks are essential for applications requiring rapid decision-making. Simplified versions of SHAP and LIME can reduce computational overhead, enabling real-time processing. Accordingly, in the study by [65] real-time SHAP implementation demonstrated effective trade-offs between interpretability and speed, ensuring timely insights without significant computational delays.
- **Combining Explanation Approaches:** Integrating localized explanation strategies, like LIME, with global methods, such as SHAP, provides a comprehensive understanding of model decisions. This hybrid approach balances detailed insights with overarching trends, improving both interpretability and model validation. A study by [66] highlights the effectiveness of combining explanation techniques to enhance trust in machine learning models without compromising accuracy.

According to the outlined future directions and countermeasures, researchers can go a long way in enhancing the detection of malware. It seeks to optimise the ML approaches to increase their applicability on the current and emerging complex cybersecurity challenges.

VII. CONCLUSIONS

This paper offers a detailed review of the latest trends and challenges in applying machine learning to malware detection and analysis, with a focus on its increasing role in combating complex cyber threats. Machine learning has shown great promise as a versatile tool, providing scalability, adaptability, and improved pattern recognition for identifying and analyzing malware. However, significant challenges remain, including vulnerabilities to adversarial attacks, biases in datasets, and a lack of transparency in many deep learning models.

By exploring methods such as deep learning, transfer learning, and explainable AI, this review highlights both their strengths and the challenges they face, including high computational requirements and reliance on feature extraction. These obstacles underscore the need for innovative approaches to improve the effectiveness and dependability of machine learning systems in malware detection.

To overcome these limitations, this paper proposes several novel strategies, such as leveraging distributed computing, refining preprocessing methods, and enhancing the integration of explainability techniques. As a result of these advancements, machine learning models will become more robust, efficient, and transparent, ensuring their effectiveness in addressing malware threats as they evolve.

FUNDING

This work was funded by King Faisal University, Saudi Arabia [Grant No. KFU250089].

ACKNOWLEDGMENT

This work was supported through the Annual Funding track by the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [Grant No. KFU250089].

Abstract—The boundaries of the new power system network are blurred, and data privacy and security are threatened. Although the SM9 algorithm is widely used in power systems to protect data security, its efficiency and security remain the main issues in application. Therefore, an SM9 key encapsulation mechanism (OSM9-KEM-CRF) was proposed to support outsourced decryption and cryptographic reverse firewall. In order to resist the backdoor attacks, we deployed cryptographic reverse firewalls at the terminals and proved that the proposed OSM9-KEM-CRF is ID-IND-CCA2 secure. The cryptographic reverse firewalls maintain functionality, weakly retain security, and weakly resist penetration, thereby enhancing the security of the scheme. In addition, considering the limited computing resources of terminal devices, decryption operations are outsourced to cloud servers in order to reduce the computational burden on the terminals. Compared with other SM9-KEMs, the proposed mechanism not only reduces computational and communication overhead, but also lowers energy consumption. Therefore, the proposed mechanism is more suitable for power monitoring systems.

Keywords—SM9; Outsourced decryption; cryptographic reverse firewall; power monitoring systems

I. INTRODUCTION

With the wide application of IoT technology in power systems, the boundaries of new power system networks are becoming increasingly blurred, and a large number of terminal monitoring devices with limited resources have emerged in power monitoring networks. Although data can be stored in the cloud and pre-processed by cloud servers, thus reducing the storage and computational burden on these terminal devices. However, once the data is out of the direct control of the user, it will face the risk of privacy and security. Information security measures will become the main means of protection. Therefore, there is an urgent need to carry out research on power control systems and lightweight security protection technology.

Chen et al. [1] developed a power monitoring system based on the SM2 algorithm in 2022. However, SM2 algorithm requires complex public key certificate management, while identity-based cryptographic algorithm can avoid complex public key certificate management, and is more sui for new power monitoring systems with many members and dynamic changes in members.

The SM9 is an identity based cryptographic algorithm, which was officially released in 2016 and identified as the

standard algorithm for the cryptographic industry of China [2]. Cheng et al. [3] formally analyzed the security of the SM9 key agreement and the SM9 encryption scheme. Lai et al. [4] proposed Twin-SM9 key encapsulation mechanism using Twin-Hash-ElGamal technique.

A. Related Work

In power monitoring systems, SM9 cryptographic algorithms are favored for their simplified public key certificate management, but their high computational demand on resource-constrained monitoring devices and sensors highlights the need for efficiency optimization. This is especially true for resource-constrained end devices that are widely deployed in power system networks. These devices, such as smart meters, surveillance cameras, and other sensors, have limited computational power, making the complex bilinear mapping operations in the SM9 algorithm the key to improving the decryption efficiency. Ji et al. [5] pointed out that the operation of the SM9 encryption algorithm consumes a large amount of time and computational resources, which makes it challenging to run it on resource-constrained devices. Wang et al. [6] improved the complex operations in SM9 cryptographic algorithm, which improved the computational efficiency of SM9 algorithm to a certain extent, but it is still a large burden for resource-constrained lightweight devices, and could not solve the problem fundamentally. Lai et al. [7] proposed an efficient online/offline identity-based encryption for this purpose, which provides an idea for the implementation of SM9 cryptographic algorithm on lightweight devices. Sun et al. [8] investigated the SM9-IBE encryption scheme based on online/offline techniques. Peng et al. [9] developed an efficient certificate-free online/offline signature scheme and created a lightweight data authentication protocol specifically for WBAN. Liu et al. [10] introduced outsourcing decryption technique in attribute encryption scheme to reduce the computational overhead of the user. This considers the use of outsourcing technique to solve the problem of computational difficulties in SM9 encryption and decryption. Liu [11] proposed an OSM9 key encapsulation mechanism that supports decryption outsourcing, outsourcing the decryption part of SM9 cryptographic algorithm to the cloud service center for decryption operation, which reduces the computational burden of the terminal equipment, but the mechanism requires the cloud server to generate its own public-private key pairs, which increases the requirements of the system's initialization settings.

However the Snowden incident [12] showed that even

^{*}Corresponding authors.

provably secure cryptographic algorithms can be subject to backdoor attacks that threaten the security and privacy of user data. Mironov et al. [13] proposed the Cryptographic Reverse Firewall (CRF), which is an entity deployed on the user side to re-randomize the information received and sent by users, in order to prevent the leakage of the user's private information. Therefore, CRF can be deployed between the cloud server and the user, and even if the algorithm is tampered with by a backdoor, it will not threaten the security and privacy of the user's data. Therefore, constructing a cryptographic reverse firewall for the SM9 cryptographic algorithm is a very important task. Chen et al. [14] constructed several CRF-based cryptographic protocols by relying on a malleable smooth projective hash function with key malleability and element re-randomization. Zhou et al. [15] proposed an identity-based encryption scheme with CRF. Zhou et al. [16] designed a single-round, certificate-less public key encryption scheme incorporating CRF with reduced communication overhead. Furthermore, Zhou [17] suggested a searchable public key encryption approach based on CRF. Zhou et al. [18] designed an identity-based proxy re-encryption scheme with CRF that can resist leakage attacks. Jin et al. [19] designed a blockchain and CRF-based proxy re-encryption scheme. Xiong et al. [20] designed an SM9 encryption scheme with CRFs and supports equation testing, but the scheme only sets CRFs for data owners. Li et al. [21] designed an online/offline attribute-based encryption scheme with CRFs for IoT communication.

As can be seen from the above, The OSM9 key encapsulation mechanism proposed by Liu et al. [11], although considering outsourced decryption, prolongs user waiting time and does not take into account the threat of information leakage. On the other hand, although Xiong et al. [20] proposed the SM9 algorithm with cryptographic reverse firewall, this algorithm does not support outsourced decryption and does not consider the situation where the key generation center and data users are subjected to backdoor attacks. At present, there is no cryptographic reverse firewall built for outsourced decryption. A new mechanism needs to be proposed to consider the potential threat of backdoor attacks during cloud server outsourcing decryption.

B. Research Contributions

This paper focuses on the power monitoring system based on the SM2 cryptographic system proposed by Chen et al. [1], and constructs an SM9-KEM suitable for power monitoring systems, which not only supports outsourcing decryption but also has the function of CRF. The primary contributions include:

1) *Improve the efficiency of SM9 algorithm:* The bilinear mapping in the decryption operation of SM9 is outsourced to the cloud, and the cloud service center is not required to generate its own public-private key pair. It reduces the computational burden of users and greatly improves the efficiency of the scheme.

2) *Enhanced security of the SM9 algorithm:* Not only has CRF been set up on the data user side to re-randomize ciphertext, but CRF has also been set up on the KGC and data owner sides to re-randomize public parameters and user keys. This enables the OSM9-KEM-CRF proposed in this

paper, which supports outsourced decryption, to maintain its functionality and resist leakage even under backdoor attacks, further improving the security of the scheme.

C. Paper Organization

The remainder of this paper is organized as follows. Section II covers the fundamental concepts related to elliptic curves and reverse firewalls. Section III outlines the system model and the security model of OSM9-KEM-CRF. Section IV details the encapsulation mechanism of OSM9-KEM-CRF along with its security. Section V provides a comparison between our proposed scheme and existing schemes in terms of computational overhead, communication overhead, and energy consumption overhead. The conclusion in Section VI.

II. RELEVANT THEORETICAL FOUNDATIONS

A. Elliptic Curve

For an elliptic curve $\mathbb{E}: y^3 = x^3 + ax + b \pmod{p}$, where $a, b \in \mathbb{F}_p$, $(4a^3 + 27b^2) \pmod{p} \neq 0$, \mathbb{F}_p is a finite field of order prime $p > 3$, let \mathbb{G} be the group over \mathbb{E} , $p \in \mathbb{G}$, q on an elliptic curve, where $p \in \mathbb{G}$, q is the order of \mathbb{G} and O is the infinity point of \mathbb{G} . The operations on the elliptic curve are as follows:

1) *Addition of points:* let $P(x_1, y_1) \in \mathbb{E}$, $Q(x_2, y_2) \in \mathbb{E}$, where $P \neq O, Q \neq O, P \neq -Q$, let $R(x_3, y_3)$ is equal to $P+Q$, then the calculation of R can be expressed as $x_3 = \lambda^2 - x_1 - x_2, y_3 = \lambda(x_1 - x_3) - y_1$, where $\lambda = \begin{cases} \frac{y_2 - y_1}{x_2 - x_1}, P \neq Q \\ \frac{3x_1^2 + a}{2y_1}, P = Q \end{cases}$.

2) *Scalar multiplication:* given a point $P(x, y)$ on an elliptic curve and an integer k , scalar multiplication can be defined as $kP = \sum_{i=1}^k P_i$.

B. Bilinear Mapping

Let $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ be cyclic groups, respectively. Then the bilinear mapping $e: \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_T$ has the following properties:

- 1) *Bilinearity:* for $a, b \in \mathbb{Z}_p, P_1 \in \mathbb{G}_1, P_2 \in \mathbb{G}_2$ there is $e(aP_1, bP_2) = e(P_1, P_2)^{ab}$.
- 2) *Non-degeneracy:* there exist elements $P_1 \in \mathbb{G}_1, P_2 \in \mathbb{G}_2$, such that $e(P_1, P_2) \neq 1$.
- 3) *Computability:* for any elements $P_1 \in \mathbb{G}_1, P_2 \in \mathbb{G}_2$, there exists an efficient polynomial time algorithm to evaluate $e(P_1, P_2)$.

C. Cryptographic Reverse Firewall (CRF)

CRF is a stateful algorithm \mathcal{W} with states and messages as inputs and updated states and messages as outputs. Simply, the state information of \mathcal{W} is not explicitly represented. For participant P and cryptographic reverse firewall \mathcal{W} in the system, $\mathcal{W} \circ P$ is defined as the composed party. If \mathcal{W} is composed of participant P , then we call \mathcal{W} cryptographic reverse firewall P . There are three security requirements for cryptographic reverse firewalls, namely Functionality maintaining, weak security preserving, and weak resistance to exfiltration, as described in [22].

III. FORMAL DEFINITION AND SECURITY MODEL OF OSM9-KEM-CRF

A. OSM9-KEM-CRF System Model

Fig. 1. Illustration of OSM9-KEM-CRF.

The OSM9-KEM-CRF for power monitoring system is shown in Fig. 1, which supports outsourced decryption and CRF and contains four members and three CRFs, that is the cloud service center (CSP), the key generation center (KGC) and its cryptographic reverse firewall \mathcal{W}_{KGC} , the data owner (DO) and its cryptographic reverse firewall \mathcal{W}_{DO} , the data user (DU) and its cryptographic reverse firewall \mathcal{W}_{DU} .

Specifically, KGC generates the master private key and the global public parameter pp . If the process is compromised then \mathcal{W}_{KGC} randomizes pp and broadcasts it globally. The KGC is also responsible for generating the private keys of the users (DO, DU), and if the process is compromised, then \mathcal{W}_{KGC} randomizes the user's private key. The CSP is responsible for storing the user's encrypted data and outsourcing the decryption of the data. The DO encrypts the data and uploads it to the CSP for storage. When the encryption process is compromised then \mathcal{W}_{DO} randomizes the encrypted ciphertext. DU downloads the ciphertext from CSP and decrypts it. If the outsourced decryption key generation process is compromised then \mathcal{W}_{DU} randomizes the outsourced decryption key.

B. OSM9-KEM-CRF System Model

The OSM9-KEM-CRF consists of the following 11 algorithms:

- (1) $\text{Setup}(1^\lambda) \rightarrow (msk, pp)$. The algorithm is run by KGC. Input security parameter λ , output global public

parameter pp and KGC master private key msk .

- (2) $\mathcal{W}_{GA}.\text{Setup}(pp) \rightarrow pp'$. The algorithm is run by KGC's Cryptographic Reverse Firewall \mathcal{W}_{KGC} . Input the system public parameters pp and output the updated system public parameters pp' .
- (3) $\text{Extract}(pp', msk, ID) \rightarrow sk$. The algorithm is run by KGC. Inputs pp', msk and user identity ID and outputs private key sk for user ID .
- (4) $\mathcal{W}_{KGC}.\text{Extract}(sk) \rightarrow sk'$. The algorithm is run by KGC Cryptographic Reverse Firewall \mathcal{W}_{KGC} . It inputs the private key sk of the user ID , outputs the updated sk' , and returns it to the user ID .
- (5) $\text{KEM-Encap}(pp', ID) \rightarrow (K, C_1)$. The algorithm is run by the data owner DO with input pp' and outputs the encapsulated key K and encapsulated ciphertext C_1 .
- (6) $\mathcal{W}_{DO}.\text{KEM-Encap}(K, t, C_1) \rightarrow (K', C'_1)$. The algorithm is run offline by the cryptographic reverse firewall \mathcal{W}_{DO} of the data owner DO. Input (K, C_1) , output updated encapsulated key K' and encapsulated ciphertext C'_1 .
- (7) $\text{KenGen.ran}(sk') \rightarrow (TK, RK)$. The algorithm is run by the user DU, which inputs its own private key sk' and outputs the transformation key TK and retrieval RK .
- (8) $\mathcal{W}_{DC}.\text{TKUpdate}(TK) \rightarrow (TK', \beta)$. The algorithm is run by the password reversal firewall \mathcal{W}_{DU} of the user user DU. Input TK . Output the updated conversion key TK' , keeping the corresponding random number β .
- (9) $\text{KEM-Decap-out}(pp', TK', C'_1) \rightarrow TCT$. The algorithm is run by CSP. Input pp', TK', C'_1 , Output convert ciphertext.
- (10) $\mathcal{W}_{DU}.\text{Decrypt}(TCT, \beta) \rightarrow TCT'$. The algorithm is run by the Cryptographic Reverse Firewall of the data user DU. Input TCT, β and output TCT' .
- (11) $\text{KEM-Decap-user}(pp', RK, TCT') \rightarrow K'$. The algorithm is run by the data user DU. Input pp', TCT', RK , Output updated encapsulated key K' .

Correctness: For security parameters and encapsulated keys, correctness is required for all

- $$\begin{aligned} &\text{Setup}(1^\lambda) \rightarrow (msk, pp), \\ &\mathcal{W}_{GA}.\text{Setup}(pp) \rightarrow pp', \\ &\text{Extract}(pp', msk, ID) \rightarrow sk, \\ &\mathcal{W}_{KGC}.\text{Extract}(sk) \rightarrow sk', \\ &\text{KEM-Encap}(pp', ID) \rightarrow (K, C_1), \\ &\mathcal{W}_{DO}.\text{KEM-Encap}(K, t, C_1) \rightarrow (K', C'_1), \\ &\text{KenGen.ran}(sk') \rightarrow (TK, RK), \\ &\mathcal{W}_{DC}.\text{TKUpdate}(TK) \rightarrow (TK', \beta), \\ &\text{KEM-Decap-out}(pp', TK', C'_1) \rightarrow TCT, \\ &\mathcal{W}_{DU}.\text{Decrypt}(TCT, \beta) \rightarrow TCT' \end{aligned}$$
- satisfy $\text{KEM-Decap-out}(RK, TCT') \rightarrow K'$.

C. Security Model for OSM9-KEM-CRF

Based on the security models of [3] and [22], this paper defines the security model of OSM9-KEM-CRF. In OSM9-KEM-CRF, it is assumed that KGC, DO and DU are fully trusted and the cloud service provider CSP is semi-trusted. Since the algorithms (Setup, Extract, KEM-Encap, KEM-Decap-out, KEM-Decap-user) of OSM9-KEM-CRF remain functional

after the implantation of a malicious trapdoor, it is necessary to take into account that these algorithms can be attacked without the knowledge of the executor. Also considering that \mathcal{W}_{DO} and \mathcal{W}_{DU} would be curious about the user's data, it is assumed that \mathcal{W}_{DO} and \mathcal{W}_{DU} are semi-trustworthy. Since \mathcal{W}_{KGC} can access to the user's decryption key, it is assumed to be fully trusted. In addition, all cryptographic reverse firewalls are considered to be trusted areas and will not be tampered with by any outsiders.

The ID-IND-CCA2 security of the OSM9-KEM-CRF is defined by a game between Challenger \mathcal{C} and Adversary \mathcal{A} . The game is played by the challenger and the adversary.

Initialization. The adversary sends function maintenance algorithm $\text{Setup}^*, \text{Extract}^*, \text{KEM} - \text{Encap}^*, \text{KeyGen.ran}^*, \text{KEM} - \text{Decap} - \text{out}^*$, and $\text{KEM} - \text{Decap} - \text{user}^*$ to the challenger \mathcal{C} .

Setup. Challenger \mathcal{C} runs $\text{Setup}(1^\lambda) \rightarrow (msk, pp)$, $\mathcal{W}_{KGC}.\text{Setup}(pp) \rightarrow pp'$, then sends pp' to adversary \mathcal{A} .

Phase 1. Adversary \mathcal{A} can adaptively query the private key oracle. For the query identity entered by the adversary, the challenger \mathcal{C} runs

$\text{Extract}(pp', msk, ID) \rightarrow sk$,
 $\mathcal{W}_{KGC}.\text{Extract}(sk) \rightarrow sk'$,
 $\text{KenGen.ran}(sk') \rightarrow (TK, RK)$,
 $\mathcal{W}_{DC}.\text{TKUpdate}(TK) \rightarrow (TK', \beta)$,

then returns sk' and TK' to adversary \mathcal{A} . Challenge. Adversary \mathcal{A} sends a challenge identity ID^* to challenger \mathcal{C} . Challenger \mathcal{C} runs $\text{KEM} - \text{Encap}(pp', ID^*) \rightarrow (K_0, C_1^*)$, $\mathcal{W}_{DO}.\text{KEM} - \text{Encap}(K_0, C_1^*) \rightarrow (K'_0, C'^*_1)$ and then randomly selects a key K'_1 in the key space, bit $b \leftarrow \{0, 1\}$, and then sends (K'_b, C'^*_1) to adversary \mathcal{A} .

Phase 2. As in Phase 1, adversary \mathcal{A} can adaptively query the private key of the user, but not the private key of user ID^* . Additionally adversary \mathcal{A} can adaptively query the decapsulation oracle. For the (ID, C) inputted by adversary, the challenger runs $\text{KEM} - \text{Decap} - \text{out}(pp', TK', C'_1) \rightarrow TCT$, $\mathcal{W}_{DU}.\text{Decrypt}(TCT, \beta) \rightarrow TCT'$, $\text{KEM} - \text{Decap} - \text{user}(RK, TCT') \rightarrow K'$, returns the corresponding decapsulation key K' . but at this point the adversary cannot access the decapsulation key for (ID^*, C'^*_1) .

Guess. Adversary \mathcal{A} outputs a guess $b' \in \{0, 1\}$ to send to challenger \mathcal{C} .

DEFINITION: OSM9-KEM-CRF is said to be ID-IND-CCA2-secure if for all probabilities polynomial time adversary \mathcal{A} has a negligible advantage of $\varepsilon = |\Pr[b = b'] - \frac{1}{2}| \leq \text{negl}(\lambda)$ in winning the above game.

IV. OSM9-KEM-CRF ENCAPSULATION MECHANISMS

A. Description of OSM9-KEM Mechanism

OSM9-KEM consists of the following six algorithms:

- (1) $\text{Setup}(1^\lambda)$. Input the security parameter λ , the algorithm performs the following operations.
 - ① Choose 3 groups $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ of order prime r , a bilinear mapping $e : \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_T$, and randomly choose generators $P_1 \in \mathbb{G}_1, P_2 \in \mathbb{G}_2$.

- ② Randomly select $s \leftarrow \mathbb{Z}_r^*$ and compute $P_{pub} = sP_1$.

- ③ Make $g = e(P_{pub}, P_2)$.

- ④ Choose hash function $H_v : \{0, 1\}^* \rightarrow \{0, 1\}^v$ and an identifier hid .

- ⑤ Output global public parameters $pp = (\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e, P_1, P_2, P_{pub}, g, H_v, hid)$ and master private key $msk = s$.

- (2) $\text{Extract}(pp, msk, ID)$. Input user identities $ID \in \{0, 1\}^*$, pp and msk , KGC calculates $t_1 = H_v(ID || hid, r) + s$, if $t_1 = 0$, recalculates the master private key, otherwise calculates $sk = t_2 P_2$, where $t_2 = st_1^{-1}$.

- (3) $\text{KEM} \rightarrow \text{Encap}(pp, ID)$. With inputs pp and ID , the algorithm performs the following.
 - ① Let $t_1 = H_v(ID || hid, r) + s, Q = h_1 P_1 + P_{pub} = (h_1 + s)P_1$.

- ② Random select $x \leftarrow \mathbb{Z}_r^*$, let $C_1 = xQ, t = g^x$.

- ③ Let $K = \text{KDF}_2(H_v, \text{EC2OSP}(C_1) || \text{FE2OSP}(t) || ID, l)$, where l is the key length of DEM .

- ④ Output (K, C_1) .

- (4) $\text{KenGen.ran}(sk) \rightarrow (TK, RK)$. Input sk . Randomly select $\alpha \leftarrow \mathbb{Z}_r^*$, compute $TK = \frac{1}{\alpha} sk = \frac{t_2}{\alpha} P_2$, and output conversion key TK and retrieval key $RK = \alpha$.

- (5) $\text{KEM} - \text{Decap} - \text{out}(pp, TK, C_1)$. Input pp' , the user identity ID and its conversion key TK , the encapsulation portion C_1 . The cloud service center computes the conversion ciphertext TCT , where $TCT = e(C_1, TK) = e(xQ, \frac{t_2}{\alpha} P_2) = e(s(h_1 P_1 + sP_1), \frac{s}{t_1 \alpha} P_2) = e(P_{pub}, P_2)^{\frac{s}{\alpha}} = g^{\frac{s}{\alpha}}$.

- (6) $\text{KEM} - \text{Decap} - \text{user}(pp, RK, TCT)$. Input pp , retrieval key RK for user identity ID , transformed ciphertext TCT , user ID computes $t = (TCT)^\alpha = g^x$, and lets $K = \text{KDF}_2(H_v, \text{EC2OSP}(C_1) || \text{FE2OSP}(t) || ID, l)$, where l is the key length of DEM . Output the encapsulated key K .

Theorem 1 If SM9-KEM is ID-IND-CCA2 secure, then the above OSM9-KEM is ID-IND-CCA2 secure.

Proof In this section, OSM9-KEM is constructed based on SM9-KEM by utilizing the key blinding technique of [23]. From [3], it is known that SM9-KEM is ID-IND-CCA2 secure. Thus it can be proved similarly to [23] that OSM9-KEM is ID-IND-CCA2 secure.

B. Description of OSM9-KEM-CRF Mechanism

Based on the above OSM9-KEM mechanism, this section constructs an OSM9-KEM-CRF mechanism.

After KGC runs $\text{Setup}(1^\lambda)$ to generate msk and pp , KGC first sends pp to \mathcal{W}_{KGC} . \mathcal{W}_{KGC} Run Algorithm $\mathcal{W}_{GA}.\text{Setup}$.

(1) $\mathcal{W}_{GA}.\text{Setup}(pp) \rightarrow pp'$. For pp , \mathcal{W}_{KGC} randomly selects $a, b, c \leftarrow \mathbb{Z}_r^*$ and computes $P'_1 = aP_1, P'_2 = aP_2, P'_{pub} = aP_{pub} = sP'_1, g' = e(P_{pub}, P_2)^{abc} = e(P'_{pub}, P_2)^c$. Output $pp' = (\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e, P'_1, P'_2, P'_{pub}, g', H_v, hid)$ but keep c . KGC carries out $\text{Extract}(pp', msk, ID) \rightarrow sk$ after receiving pp' and user identity $\text{Extract}(pp', msk, ID) \rightarrow sk$, sends sk to \mathcal{W}_{KGC} . \mathcal{W}_{KGC} runs algorithm $\mathcal{W}_{KGC}.\text{Extract}$.

(2) $\mathcal{W}_{KGC}.Extract(sk) \rightarrow sk'$. For sk , \mathcal{W}_{KGC} computes $sk' = c \cdot sk = \frac{cs}{s+h} P'_x$ by the previous random selected c , where $h_1 = H_v(ID || hid, r)$.

User ID runs $KEM - Encap(pp', ID) \rightarrow (K, C_1)$ after receiving pp' , sends (K, C_1) to \mathcal{W}_{DO} , \mathcal{W}_{DO} runs algorithm $\mathcal{W}_{DO}.KEM - Encap$.

(3) $\mathcal{W}_{DO}.KEM - Encap(K, t, C_1) \rightarrow (K', C'_1)$. For K, t and C_1 . \mathcal{W}_{DO} randomly selects $f \leftarrow \mathbb{Z}_r^*$ and compute $C'_1 = fC_1$, $t' = t^f - g^{fx}$ and $K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$, where l is the key length of DEM . Output (K', C'_1) .

The user sends TK to \mathcal{W}_{DO} after running $KenGen.ran(sk') \rightarrow (TK, RK)$, and \mathcal{W}_{DO} runs Algorithm $\mathcal{W}_{DO}.TKUpdate$.

(4) $\mathcal{W}_{DC}.TKUpdate(TK) \rightarrow (TK', \beta)$. For TK , \mathcal{W}_{DO} randomly selects $\beta \leftarrow \mathbb{Z}_r^*$, computes $TK' = \frac{1}{\beta}TK$, and outputs TK' but keeps β .

The cloud service center runs $KEM - Decap - out(pp', T, K', C'_1) \rightarrow TCT$ after receiving TK' , sends TCT to \mathcal{W}_{DU} . \mathcal{W}_{DU} runs algorithm $\mathcal{W}_{DU}.Decrypt$.

(5) $\mathcal{W}_{DU}.Decrypt(TCT, \beta) \rightarrow TCT'$. For input TCT and reserved β , \mathcal{W}_{DU} computes $TCT' = (TCT)^\beta$.

After receiving TCT' , DU runs $KEM - Decap - user(pp', RK, TCT')$, gets $t' = (g^{\frac{fx}{\alpha}})^\alpha = g^{fx}$ and $K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$.

C. Security Analysis

Theorem 2: If OSM9-KEM is ID-IND-CCA2 secure, then OSM9-KEM-CRF is ID-IND-CCA2 secure and the cryptographic reverse firewalls of KGC, DO, and DU maintain functionality, weakly retain security, and weakly resist penetration.

Proof the security of OSM9-KEM-CRF is proved by the following three sections.

(1) Functionality-maintaining. Because

$$\begin{aligned} TCT &= (TCT)^\beta = e(C'_1, TK')^\beta \\ &= e\left(fx(h_1 + s)P'_1, \frac{1}{\beta}TK\right)^\beta \\ &= e\left(fx(h_1 + s)P'_1, \frac{cs}{\alpha t_1}P'_2\right) \\ &= e\left(fxP'_1, \frac{cs}{\alpha}P'_2\right) = e(P'_{pub}, \frac{cs}{\alpha}P'_2) \\ &= g^{\frac{fx}{\alpha}} \end{aligned}$$

Thus the data user, after receiving

$K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$, runs $K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$ and can calculate $K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$ which in turn yields the encapsulation key $K' = KDF_2(H_v, EC2OSP(C'_1) || FE2OSP(t') || ID, l)$. The encapsulated key is then obtained. Thus the mechanism satisfies the maintenance functionality.

(2) ID-IND-CCA2 Security. For any tampering algorithms $Setup^*$, $Extract^*$, $KEM - Encap^*$, $KeyGen.ran^*$, $KEM - Decap - out^*$ and $KEM - Decap - user^*$ on KGCs, DOs and DUs that maintain

functionality, we prove that OSM9-KEM-CRF is ID-IND-CCA2 secure by the indistinguishability of the secure game of OSM9-KEM from the secure game of OSM9-KEM-CRF. Consider the following game.

Game0. The security game same as OSM9-KEM-CRF in Section 3.3.

Game1. Same as Game0 except that pp and msk in the Setup phase are generated by the algorithm of OSM9-KEM instead of $Setup^*$ and $\mathcal{W}_{KGC}.Setup$.

Game2. Same as Game1 except that sk and TK in Phase 1 and Phase 2 are generated by the Extract and KeyGen.ran algorithms of OSM9-KEM, not by $Extract^*$, $\mathcal{W}_{KGC}.Extract$, $KeyGen.ran^*$ and $\mathcal{W}_{DC}.TKUpdate$.

Game3. It is the same as Game2 except that the challenge key ciphertext pair (K'_b, C'^*_1) in the Challenge phase is generated by $KEM - Encap$, not by $KEM - Encap^*$ and $\mathcal{W}_{DO}.KEM - Encap$.

It can be seen that Game3 is a secure game for OSM9-KEM, so it is only necessary to prove that Game0 is indistinguishable from Game3 to prove the security of OSM9-KEM-CRF.

In fact, since a, b, c is randomly chosen in Algorithm $\mathcal{W}_{KGC}.Setup$, regardless of the distribution of pp generated by $Setup^*$, the pp obtained after the processing of the reverse firewall $\mathcal{W}_{KGC}.Setup$ is uniformly random and consistent with the distribution of pp generated by Setup. Thus Game0 is indistinguishable from Game1. Also due to the extensibility of the key, it is similarly known that Game1 is indistinguishable from Game2.

For the challenge key ciphertext pair (K'_b, C'^*_1) , the distribution is randomized since K'_b is generated by KDF_2 . For C'^*_1 , even though C'^*_1 generated by $KEM - Encap^*$ is not random, since f is randomly selected in $\mathcal{W}_{DO}.KEM - Encap$, C'^*_1 after $\mathcal{W}_{DO}.KEM - Encap$ post-processing is random, which is consistent with the distribution of the ciphertext generated by $KEM - Encap$, thus the indistinguishability of Game2 from Game3 can be obtained. From Game0 and Game1, Game1 and Game2, and Game2 and Game3 are indistinguishable respectively, it can be known that Game0 and Game3 are indistinguishable.

(3) Weak Security Preserving, weak Resistant to Exfiltration. According to the ID-IND-CCA2 security of OSM9-KEM-CRF, it is shown that the cryptographic reverse firewalls \mathcal{W}_{KGC} , \mathcal{W}_{DU} , and \mathcal{W}_{DO} of KGC, DU, and DO are weakly preserve security. Also the proof of ID-IND-CCA2 security of OSM9-KEM-CRF shows that \mathcal{W}_{KGC} , \mathcal{W}_{DU} and \mathcal{W}_{DO} are weakly resistant to exfiltration.

V. COMPARATIVE ANALYSIS

In order to ensure the same security strength, the traditional RSA encryption algorithm requires a larger number of key bits than the elliptic curve cipher, resulting in longer encryption time and lower monitoring efficiency in power information systems. Chen et al. [1] proposed a power information system monitoring scheme based on the SM2 algorithm, in which an SM2 encryption component is connected to the server interface, which not only determines the user's access to resources

but also records information about user activities. When the user inserts the SM2 encryption device into the client, the client uses the HTTP protocol and the digital certificate to log in to the server, and then starts to access the server. When accessing the server, the system verifies the certificate by calling the suite “iaccount”, and if the verification is unsuccessful, the client’s “imidware” will be automatically directed to the security support platform, which supports validation of SM2 digital certificates. The certificate is generated after verifying SM2 digital certificates, and the user’s information is sent to the client, the client is redirected to the standby power supply system again through the “imidware”, and then returns to the electric power secondary system by submitting a one-time signature certificate and a one-time authorization code verification and destroys the one-time certificate, and decrypts the user information by verifying the authenticity of the user signature information, and finally logs in. The user information is decrypted and finally logged into the power system.

In the above scheme, although the SM2 encryption algorithm has advantages over the RSA algorithm, however, it has some limitations in practical applications.

- (1) Before using SM2 for encryption, the public key certificate of the other party must be obtained, otherwise the encryption operation cannot be performed. This requirement increases the complexity of certificate management, which in turn increases the management overhead of the overall power system.
- (2) In terms of decryption, the SM2 algorithm has some complexity when decrypting on the Web side.
- (3) When communicating securely across domains, it is necessary to establish a chain of trust for certificates.

Unlike SM2, SM9 is an identity-based encryption algorithm with the following advantages:

- (1) No certificate management is required, effectively solving the complexity of certificate management in SM2 and significantly reducing the management burden of public key infrastructure (PKI).
- (2) When decrypting on the web, there is no need for pre-registration.
- (3) It only requires the publication of security parameters without a chain of trust for certificates, and the user’s identity is his/her public key.

Therefore replacing the SM9 encryption algorithm with the SM2 encryption algorithm proposed by Chen et al. [1] for the power monitoring scheme not only enables more efficient data encryption, but also reduces the management cost of the power information system.

An outsourcing decryption is introduced on the basis of SM9 algorithm to further improve the decryption efficiency of SM9 algorithm in this paper. In addition, both SM2 and SM9 encryption algorithms have backdoor attacks, so this paper introduces cryptographic reverse firewall into SM9 algorithm to improve the security. Therefore the proposed OSM9-KEM-CRF based on SM9 key encapsulation is more suitable for power monitoring system.

In this section, the proposed OSM9-KEM-CRF is compared with other schemes in terms of computational overhead, communication overhead and energy consumption overhead.

TABLE I. EXECUTION TIME OF DIFFERENT CRYPTOGRAPHIC PRIMITIVES

Symbol	Operation	Times(ms)
T_{pa}	Bilinear-Pairing	13.8196
T_{pm}	ECC Point Addition	0.0110
T_e	ECC Point Exponent	12.2007
T_m	ECC Point Multiplication	2.2001
T_h	Time of hash function	0.4702

TABLE II. COMPUTATION OVERHEAD COMPARISON

Scheme	Computational overhead
[3]	$T_{pa} + T_h \approx 14.2898ms$
[4]	$2T_{pa} + T_h \approx 28.1049ms$
[11]	$T_e + T_h \approx 12.6709ms$
[20]	$T_{pa} + T_h \approx 14.2898ms$
Ours	$T_e + T_h \approx 12.6709ms$

A. Computation Cost Comparison

To evaluate the performance of our OSM9-KEM-CRF mechanism, we consistently used the Python programming language to test decryption operation times, employing 256-bit Barreto-Naehrig (BN) elliptic curves and R-ate bilinear pairings. The specific test setup was a personal desktop computer with the following configurations: 32GB of RAM, Windows 10 operating system (version 10.0.19045), Intel Cor i5-13400 CPU running at 2.5GHz, Visual Studio Code as the development environment, and the Charm cryptographic library. The notation for the operation times of cryptographic algorithms is defined in Table I.

The computational overhead of the decryption phase of each mechanism (scheme) are shown in Table II. In literature [3], one hash operation and bilinear pairing operation need to be run, and the time required is $T_{pa} + T_h \approx 14.2898ms$. In literature [4], one hash operation and two bilinear pairing operations need to be run, and the time required is $2T_{pa} + T_h \approx 28.1049ms$. In literature [11], one exponentiation operation and hash operation need to be performed, and the time required is $T_e + T_h \approx 12.6709ms$. However, in cloud services, the cloud is required to generate its own public-private key pairs, which increases the cloud’s computational overhead. In the proposed OSM9 mechanism, the decryption phase needs to perform one exponential operation and one hash operation on the multiplicative group, and the total time required is $T_e + T_h \approx 12.6709ms$. In the literature [20], it needs to perform one bilinear pairing operation and one hash operation, and the time required is $T_{pa} + T_h \approx 14.2898ms$.

The comparison of the time consumed in the decryption phase of each mechanism (scheme) is shown in Fig. 2, which shows that the time consumed in decryption of this paper’s mechanism and the scheme of literature [11] is lower than other schemes, and this paper’s scheme does not need to generate public-private key pairs in the cloud server, which reduces the time of the cloud computation and the waiting time of the user, compared to the scheme of literature [11].

Fig. 3 and 4 show the time overhead of each algorithm in the OSM9-KEM and OSM9-KEM-CRF mechanisms, respectively, from which it is clear that the addition of the Cryptographic Reverse Firewall to the OSM9-KEM mechanism does

Fig. 2. Comparison of decryption time cost for users in different mechanisms (schemes).

Fig. 4. OSM9-KEM-CRF algorithm time overhead

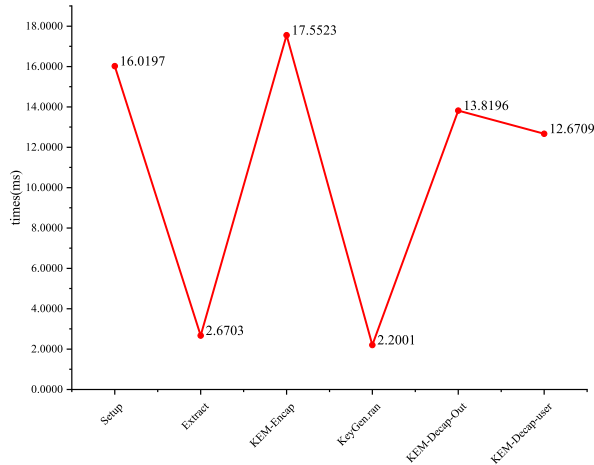

Fig. 3. The algorithm time cost used in OSM9-KEM.

Fig. 5. Comparison of communication costs for different schemes.

not have a significant impact on the time overhead, but greatly increases the security.

B. Communication Cost Comparison

In terms of communication overhead, $|\mathbb{G}_1|, |\mathbb{G}_2|, |\mathbb{G}_T|, |\mathbb{Z}_p|$ denote the size of the elements in the $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ and \mathbb{Z}_p , respectively. Specifically, the 256-bit BN curve [24] is used, that is $|\mathbb{G}_1|=512\text{bit}, |\mathbb{G}_2|=1024\text{bit}, |\mathbb{G}_T|=3072\text{bit}, |\mathbb{Z}_p|=256\text{bit}$. Table III compares the bit requirements of the key encapsulation mechanism proposed in this paper with those of other schemes across public parameters, private keys, and ciphertexts. Furthermore, as illustrated in Fig. 5, our mechanism demonstrates a significant reduction in communication overhead for public keys, private keys, and ciphertexts.

C. Energy Cost Comparison

In terms of energy overhead, the calculation method in [25] is used, with the formula $vol \times cur \times T$, where vol represents the voltage, cur represents the current, T represents the execution time ($vol = 3V, cur = 1.8\mu A$), and the energy consumed for sending 1bit messages is $0.72\mu J$, and the energy consumed for receiving messages is $0.81\mu J$. In literature [3], the energy overhead related to computation is $vol \times cur \times (T_{pa} + T_h) \approx 77.1649\mu J$, and the energy overhead related to communication is $|\mathbb{G}_2| \times 0.81\mu J + |\mathbb{G}_1| \times 0.72\mu J \approx 1198.0800\mu J$, so the total energy overhead is $1275.2449\mu J$; in literature [4], the energy overhead related to computation is $vol \times cur \times (2T_{pa} + T_h) \approx 151.7664\mu J$, and the energy overhead related to communication is $2|\mathbb{G}_2| \times 0.81\mu J + |\mathbb{G}_1| \times 0.72\mu J \approx 2027.5200\mu J$, so the total energy overhead is $2179.2864\mu J$; in literature [11], the energy overhead related to computation

TABLE III. COMMUNICATION OVERHEAD OF DIFFERENT SCHEMES

Scheme	Public parameter length	Private key length	Ciphertext length
Ours	$2 \mathbb{G}_1 + \mathbb{G}_2 + \mathbb{G}_T \approx 5120\text{bits}$	$ \mathbb{G}_2 \approx 1024\text{bits}$	$ \mathbb{G}_1 \approx 512\text{bits}$
[3]	$2 \mathbb{G}_1 + \mathbb{G}_2 + \mathbb{G}_T \approx 5120\text{bytes}$	$ \mathbb{G}_2 \approx 1024\text{bytes}$	$ \mathbb{G}_1 \approx 512\text{bits}$
[4]	$2 \mathbb{G}_1 + \mathbb{G}_2 + 2 \mathbb{G}_T \approx 8192\text{bits}$	$2 \mathbb{G}_2 \approx 2048\text{bits}$	$ \mathbb{G}_1 \approx 512\text{bits}$
[11]	$2 \mathbb{G}_1 + \mathbb{G}_2 + 2 \mathbb{G}_T \approx 8192\text{bits}$	$2 \mathbb{G}_2 \approx 2048\text{bits}$	$ \mathbb{G}_1 \approx 512\text{bits}$
[20]	$ \mathbb{G}_1 \approx 512\text{bits}$	$ \mathbb{G}_2 \approx 1024\text{bits}$	$3 \mathbb{G}_1 + \mathbb{G}_2 + 2 \mathbb{Z}_p \approx 3072\text{bits}$

Fig. 6. Comparison of energy consumption of different schemes.

is $vol \times cur \times (T_e + T_h) \approx 68.4228\mu\text{J}$, and the energy overhead related to communication is $2|\mathbb{G}_2| \times 0.81\mu\text{J} + |\mathbb{G}_1| \times 0.72\mu\text{J} \approx 2027.5200\mu\text{J}$, so the total energy overhead is $2095.9428\mu\text{J}$; in literature [20], the computation-related energy overhead is $vol \times cur \times (T_{pa} + T_h) \approx 77.1649\mu\text{J}$ and the communication-related energy overhead is $|\mathbb{G}_2| \times 0.81\mu\text{J} + (3|\mathbb{G}_1| + |\mathbb{G}_2| + 2|\mathbb{Z}_p|) \times 0.72\mu\text{J} \approx 3041.28\mu\text{J}$, thus the total energy overhead is $3118.4449\mu\text{J}$; in this paper, the computation-related energy overhead is $vol \times cur \times (T_e + T_h) \approx 68.4228\mu\text{J}$ and the communication-related energy overhead is $|\mathbb{G}_2| \times 0.81 + |\mathbb{G}_1| \times 0.72 \approx 1198.0800\mu\text{J}$, thus the total energy overhead is $1266.5028\mu\text{J}$. The comparison of energy overhead of each mechanism (scheme) is shown in Fig. 6. In power monitoring system, less energy overhead is especially important in power system due to limited equipment resources, in the above comparison, the mechanism in this paper has less energy overhead and is more suitable for power system, and it incorporates a reverse firewall to block backdoor attacks and improve the security of the system.

VI. CONCLUSIONS

This paper proposes an SM9 key encapsulation mechanism that supports outsourced decryption and CRF, improving the efficiency and security of the SM9 key encapsulation mechanism. The proposed OSM9-KEM-CRF mechanism outsources the tedious bilinear mapping calculation in the decryption process to cloud servers, and cloud servers do not need

to generate its own public-private key pairs, improving the efficiency of the mechanism. In addition, the key encapsulation mechanism adds the cryptographic reverse firewall function for KGC and users respectively, and the deployment of CRF also makes the mechanism resistant to backdoor attacks, resistant to information leakage, protects user privacy, and improves the security of the key encapsulation mechanism. The security proof and comparative analysis comparison show that the mechanism is more suitable for the power monitoring system.

In future work, in order to further reduce the computational burden on users and enrich the functionality of the SM9 algorithm, we will research how to use smart contracts to verify the correctness of outsourced decryption, thereby further reducing users' computational overhead. In addition, the SM9 algorithm will be functionally extended to construct an attribute based encryption scheme based on SM9, achieving fine-grained access control of encrypted data in the cloud.

Abstract—The advancement of Artificial Intelligence (AI), in particular Deep Learning (DL), has made it possible to interpret gathered data more quickly and effectively in this new digital era. To draw attention to development advancements in deep learning across many industries. Agriculture has been one of the most affected areas in recent advancements of the current globalized world agriculture plays a vital role and makes significant contributions. Over the years, agriculture has faced several difficulties in meeting the growing demands of the global people, which has creased over the last 50 years. Different forecasts have been made regarding this extraordinary population expansion which is expected to grasp almost 9 billion persons worldwide by 2050. More than a century ago, different technologies were brought into agriculture to solve issues related to crop cultivation. Many mechanical technologies are accessible today, and they are evolving at an amazing rate. To support their demands and help them optimize their crop yields based on data and task automation need innovative techniques to aid farmers. This will transform the agricultural industry into a new dimension. Therefore, this study's primary goal was to present a thorough summary of the most current developments based on research interconnected with the digitization of agriculture for crop yields including fruit counting, crop management, water management, weed identification, soil management, seed categorization, disease detection, yield forecasting and harvesting of yields based on Artificial Intelligence Techniques.

Keywords—Agriculture; artificial intelligence; deep learning; crop yields; management

I. INTRODUCTION

Because of the population, the agriculture sector has to meet a wide range of food needs along with social, environmental and economic factors like the lack of workers, water, biodiversity, and land degradation [1]. Since the seasons are hard to predict and the environment is harsh, there are now a number of limits on its growth. For agricultural business growth, it is important to find new methods that will last.

Farmers' understanding of field management has changed by using cutting-edge technologies like robots, drones and sensors on farm equipment. Scientists who study data and farming are getting ideas from these new technologies to make better analytical tools and methods for managing fields and dealing with problems more correctly [2]. Today's technology makes it hard to make sure that everyone has access to a steady supply of high-quality food without putting natural environments at risk. To meet and support farmers' needs help to get the most out of their farming by automating tasks and data.

New developments in uses based on Artificial Intelligence (AI) had a big effect in this area [3]. They have made a big

difference in the progress of computer vision, ML(Machine Learning) and DL(Deep Learning) methods for building automated and reliable systems. But Agriculturalists still confront formidable challenges in making affordable, scalable, and ecologically sound solutions to the world's food crisis a reality, despite recent advances. This emphasizes the significance of studies that cover both the theoretical and practical aspects of incorporating technological advances into actual agricultural systems.

As a result, this study main goal is to give an in-depth overview on the latest advances in AI research that has to do with digitizing agriculture for crop yields. To identify existing gaps in the current review of Digitizing agriculture includes fruit counting, crop management, water management, weed identification, soil management, seed categorization, disease detection, yield forecasting, and harvesting of yields.

II. DIGITIZING AGRICULTURE CROP YIELDS USING AI TECHNIQUES

A. Fruit Counting

A vital component of the world economy is the fruit business. Food security, economic growth, nutritional diversity, processing, shipping and retail are just a few companies that benefit from it, and millions of farmers rely on it for income. Fruits have high vitamin, mineral, fiber and antioxidant content and plays a vital part in healthy diet. As per the FAOSTAT report fruit industry is in the rise worldwide. Producing approximately 909.644 million metric tons of fruits in 2023, the world continued its growing trend in food output, accounting for 19% of total food production. Maintaining accuracy and efficiency in huge fields or orchards becomes increasingly challenging when the volume of agriculture increases, rendering manual counting impracticable defined by Pathan and Rehman [4]. Manual fruit counting can be challenging in outdoor settings due to weather factors including rain and low vision as explained by Hunt and Doraiswamy [5]. The spatial coverage of manual counting is limited since people can't physically inspect every portion of a crop. It also makes coping with different crop architectures more difficult as it makes it harder to address differences in fruit size, shape, or distribution. The consistency and comparability of the data could be compromised due to inconsistent counting techniques caused by the absence of established counting standards.

Fruits calculating or counting flower thickness on images using Computer Vision (CV) algorithms is a commonly used method for autonomous yield estimation. There are two main types of CV-based approaches to estimating agricultural yields:

(1) methods that focus on specific regions or areas, and (2) methods that rely on counting. An automated method for estimating crop production in apple farms was created by Wang et al. [6] using stereo cameras. To lessen the impact of the erratic daylight lighting, they took the photos at night. An in-field cotton recognition system was created by Li et al. [7] using region-based semantic image segmentation. Joint maize tassel and crop segmentation was accomplished by Lu et al. [8] using region based color modelling. Yield estimation approaches based on counting have received surprisingly little attention, in comparison to methods based on regions [9]. Estimating the quantity of apples harvested in fields with natural light was done by Linker et al. [10] using color photographs. There were a lot of false positives because of the problems with direct light and color saturation. A technique for apple fruit segmentation [21] from video utilizing backdrop modelling was developed by Tabb et al. [11].

Counting problems demand one to reason about the total occurrences of an object in a scene, as opposed to the usual picture classification procedure that aims to identify the existence or nonexistence of an object. Multiple real-world applications encounter the counting problem: counting cells in microscopic imaginings, counting wildlife in aerial photos [12], counting fish [13], and crowd monitoring [14] in surveillance systems. Kim et al. [15] presented a system that uses a fixed-shot camera to recognize and follow moving subjects. To improve loss optimization during learning, Lempitsky et al. [16] presented a novel supervised learning structure for pictorial object counting jobs that considers MESA distance. The authors Giuffrida et al. [17] put forward a method for leaf counting that relies on learning in plants that grow in rosette sets. They connected image-based descriptors learned unsupervisedly to leaf counts using a supervised regression model. The present method of estimating production, which involves workers physically counting fruits or flowers, is impractical for vast fields due to its high cost and time requirements. Here, a practical answer is provided via robotic agriculture-based automatic yield estimation.

Nowadays, AI is playing a bigger part in fruit counting as it provides more precise and efficient answers for farming. Automating fruit counting in fields is possible with the usage of AI technologies, especially CV and ML. DL algorithms allows for automated interpretation of captured images or films. Based on visual features like size, shape, texture and color these systems are able to recognize and tally fruits developed by Koirala and Zhang [18]. DL algorithms have been taught to recognize and quantify fruits in images. These algorithms include Convolutional Neural Networks (CNNs) with massive datasets these models gradually get more accurate results by Sa et al. [19]. According to Wang et al. [24] AI is used in combination of LiDAR and 3D imagery to make three-dimensional fruit count estimates. A more precise evaluation of the distribution and volume of fruit can be achieved with this method. The author also explained that the method can be used for vast agricultural fields. According to Anand et al. and Kumar et al. [20] this combination enables thorough counting and monitoring through effective aerial surveys of vast agricultural fields. Adapting it to different orchard settings and fruit varieties is a breeze. These systems may be adjusted to various situations, which means they can be used with a variety of crops. Methods for counting objects using deep

learning have recently become more prominent. Seguíet al. [19] investigated the use of CNN for the job of counting instances of an interest notion. A system for microscopy cell counting was created by Xie et al. [22] using a convolutional regression network. Using deep CNN, Zhang et al. [23] created a framework for cross-scene crowd counting. So far as we are aware, no studies have addressed the topic of deep simulated learning fruit counting. All of the counting algorithms that have included deep learning have focused on object detection and subsequent counting of those instances.

B. Water Management

From legislators to end users, everyone involved in water usage and management is worried about the impending water scarcity. The opinions of many shareholders or a shortage of revised strategies and plans to increase efficacy can make it difficult to execute any freshwater conservation strategy Marston & Cai, [25]. These concerns about effective freshwater management are of particular importance in agriculture, where they may help alleviate sustainability and environmental concerns while also cutting expenses for farmers. According to Salmoral et al. [26], public institutions and lawmakers play a crucial role in this context, specifically under the EU's Common Agricultural Policy (CAP).

Actually, circa the agricultural sector drew around 70% of the world's water. In the Asian and African regions (81%), as well as in Oceania (65%), this is a very pertinent subject. This issue warrants particular attention in southern countries, while it is not as serious in European and American countries (25% and 48%, respectively) Aquastat [27]. Several stakeholders, including farmers, must be involved in the planning and execution of any strategy or plan to improve water efficiency on farms for it to be effective.

According to Koscielniak et al. [28], Nazari et al. [29] the agricultural sector of the European Union relies on proper water management, so it's important to shed light on these factors. Several factors influence the efficiency of water management in irrigation methods. These elements include pertaining to the environmental, social, technical, legal, and political aspects. In view of Castanedo et al. [30], such settings, considerations such as the depth of application and modified drainage systems may be important. Agricultural methods including energy usage and soil management strategies are interdependent on irrigation practices Lee et al. [31]. Surface irrigation agricultural output, and soil yields Kim et al. [32] are three areas where irrigation practices can substantially affect water management efficiency. The morphology and spatial circulation of roots from perpetual crops Deng et al. [33] and economic indices of farms Kumar et al. [34] are also affected.

Regardless, irrigation technology and methods have advanced, allowing farmers more leeway in their decisions and options Roth et al. [35]. Nonetheless, there is always room for improvement in this area van Steenberg et al. [36]. The selection of water-efficient cultivars in the turf business is another important consideration Githinji et al. [37]. In this context, effective strategies for managing water resources are crucial.

According to Preite et al. [38], 4.0 technologies are being considered as a possible result to enhance the agricultural

sector's sustainability. These technologies include blockchain, the Internet of Things (IoT), DL algorithms, ML and other computer applications. The simple, scalable automation that predictive algorithms offer makes them ideal for a 4.0 scenario that spans many different fields Mazzei & Ramjattan [39]. Meshram et al. [41], Liakos et al. [40], and others have grouped the machine learning methods used in agriculture into three distinct phases: before, during, and after harvesting. The first set of applications included topics related to irrigation, with identification of water scarcity, prediction of water demand, and scheduling of irrigation. Conventional irrigation scheduling takes a set period into account while ignoring the fact that environmental and plant variables can vary. In particular, water scarcity identification processes thermal infrared images, weather, and soil data to assess stem water potential, drought stress and plant water gratified.

According to Zhou et al. [41], the models mostly used in this scenario were gradient-boosted random forests, decision trees and CNN. Using support vector machines, gradient-boosting, artificial neural networks and decision trees algorithms, reference evapotranspiration, soil moisture contented and sap flow possessions were estimated using multispectral and thermal imageries in conjunction with meteorological and soil data. By analyzing sensor data, the authors of Corell et al. [42] present an outline for irrigation that compares three regression models to find optimal irrigation amount for olive farming. The emergent degree days, water provided to plants, and evapotranspiration rate were used in a fuzzy decision support system to evaluate appropriate irrigation quantity for corn, kiwi, and potato crops Giusti & Marsili-Libelli [43]. In order to give watering suggestions for lemon trees, Navarro-Hellín et al. [44] utilized an adaptive neural fuzzy inference system in conjunction with a partial least-square regression to analyze evapotranspiration, soil moisture and humidity. Chandrappa et al. [45] use DL algorithms (Long Short-Term Memory) and ML techniques (Support Vector Regression and Linear Regression) to evaluate soil moisture changes in depth and time. Against this backdrop, a multi-depth link between wind speed and soil moisture was brought to light. By training an artificial neural network to use data from soil sensors and meteorological stations to calculate the optimal irrigation period, a 20% reduction in water use was accomplished by Gu et al. [46]. Kavya et al. [47] have investigated the use of AI for short-term water demand prediction. In particular, using both univariate and multivariate time series assessed the prediction ability of deep learning and machine learning. While the multivariate scenario also took weather into account, the univariate series was applied just to the flow meter data. A probabilistic framework was created by Srivastava et al. [48] to ascertain irrigation methods using three distinct parameters: leaf area index, soil moisture, and evapotranspiration. These indicators show water deficiency in the soil, water stress in crops, and the water demand, in that order. Here they utilized a Recurrent Artificial Neural Network (long short-term memory) to make predictions, and employed a random forest regression to find good predictors for each parameter. The last step was compared the expected and actual numbers to tweak the resulting weights.

Aly et al. [49] used a super learning ensemble to predict the evapotranspiration with limited meteorological data. They achieved good accuracy by utilizing additional tree regression,

k-nearest neighbour, support vector regression, and AdaBoost regression. Yong et al. [50] also noted the latter difficulty as the primary obstacle to evapotranspiration rate prediction and proposed a hybrid neuro-fuzzy inference method to overcome it. Adnan et al. [51] examined practicality of hybrid support vector regression models from this angle. These models integrate ML methods with optimization meta-heuristic algorithms, such as Particle Whale Optimization, Swarm Optimization, Differential Evolution, and Covariance Matrix Adaptation Evolution Approach. By integrating ML and feature engineering, Považanová et al. [52] enhanced prediction accuracy for reference evapotranspiration estimation, shedding light on the efficacy and generalizability of the suggested models. Using a variety of machine learning algorithms including k-nearest neighbors, support vector machine, decision tree, and multilinear regression the authors of Youssef et al. [53] demonstrated how to estimate reference evapotranspiration with an accuracy close to 99%.

C. Crop Management

One of the most significant parts of agriculture has always been crop production management. In order to feed both cattle and humans, crop production is crucial. Throughout human agrarian history, one of the key objectives is to upsurge the economic efficacy of farming. To ensure consistently high-quality output, agricultural production sites should undergo routine inspections and implement all required crop production strategies. Because farmers invest time and energy into each visit, the crop's price tag reflects that. As a result of farmers' obsession with crop monitoring and evaluation, smart agriculture has emerged as a critical tool. Although digitalization will have a greater effect on wide-area communication networks that include rapid data transmission, it permeates most areas of engineering [54]. Cultivating field crops, producing vegetables, and fruit are all part of crop production, which is a subset of agriculture [55]. "Smart farming" refers to a new paradigm that maximizes agricultural output with the help of cutting-edge information technology [56] with advancements in AI, automation, and connectivity, farmers can effectively monitor different procedures and provide targeted treatments for cultivation using robots that are superhumanly efficient.

These tasks only require a set of guidelines based on mathematics or logic because to derive valuable correlations from data, machine learning makes use of learning rules like supervised learning, unsupervised learning, hybrid learning and reinforced learning [57].

These features allow deep learning networks to potentially uncover hidden structures in data that is neither labeled nor structured. A major improvement over previous methods, deep learning networks are able to extract features with little to no human intervention. The proliferation of high-speed wireless transmission networks led to dramatic increase in consumer demand for such services [58]. When comparing Deep Anomaly to region-based convolution neural networks (RCNN), the former is superior for human detection at 45–90 meters [59]. This method can detect anomalies and generate uniform field characteristics. In this article, learned about the DL classification of land cover and crop kinds using remote sensing data [60]. Traditional fully linked MLPs and random forests were compared to CNN. We talk about how to use

visual sensor data to train self-learning CNN to identify diverse types of plants [61]. Offers automatic weed detection in UAV photos of line crops using deep learning with unsupervised data labeling [62]. Use of convolutional neural networks (CNNs) on unsupervised training datasets will provide fully autonomous weed detection. Incorporating a deep residual neural network onto a mobile capturing equipment allowed for the introduction of a crop disease classification system. Thorough testing enhanced the precision of the balancing process. 0.78 to 0.8 [63] is the range.

To diagnose mildew disease on millet crop photos, a deep neural network with transfer learning is employed [64]. The f1-score was 91.75%, recall was 94.50%, precision was 90.0%, and accuracy was 95% in the experiments. A deep convolutional neural network was employed to estimate agricultural yields using NDVI and RGB data acquired by UAVs [65]. In terms of CNN performance, RGB images beat NDVI images. In terms of critical characteristics, low-altitude remote sensing-based images and CNN architecture for rice grain production were considered [66]. During the ripening stage, Deep CNN performed significantly improved and was stable. Researchers have looked at a deep learning-based multi-temporal crop classification system [67]. DL models LSTM and Conv1D were compared to XGBoost, SVM, and RF parameters. The development of a new crop vision collection that makes use of deep learning classification and accurate agricultural recognition has also been accomplished [68]. On agricultural datasets, his proposed algorithm achieved a 99.81% accuracy rate, surpassing VGG, DenseNet, ResNet, SqueezNet, and Inception. Recognizing and differentiating crops in soil is made possible by deep learning technology [69]. Information is derived from a digital surface model with a high level of resolution. For the purpose of crop pest classification, automatic feature extraction is used in conjunction with transfer learning approaches involving convolutional neural networks [70]. The most accurate datasets are Xie1, NBAUR, and Xie2, with respective accuracies of 94.47%, 96.75%, and 95.9%.

D. Soil Management

For the vast majority of creatures, the soil is the food web, providing them with the mineral resources they need to survive. When soils are well-managed, plants do not suffer from mineral element deficiencies or toxicities, and the right minerals make it into the food chain. Crop yield, ecological stability, and human well-being are all impacted by poor soil management in some way.

According to Dickson et al. [72] and Bhaskar et al. [71] soil categorization opens up numerous sectors including soil improvement, crop management, land consolidation and more. Physiological factors assessed from real-time field models are the most important criteria for soil identification. Root development, plant emergence rate, water penetration, and crop production are all affected by physical variables such as temperature and moisture, which affect the formation of particles and pores. Chemical features including pH, organic carbon, and the nitrogen, phosphorus, potassium (NPK) parameters dictate the accessibility of nutrients, the existence of other species, and the motility of pollutants. The various components that make up soil include clay, sand, peat, silt, and loam. Soil

particles in the target zone consist mostly of sand, clay, and silt, with very little peat and loam.

It is considerably more challenging to keep these soils suitable for farming. Soils like laterite, which are mostly composed of rock deposits from hot climates, are abundant in iron and aluminum. Soils with large concentrations of iron oxides, such as laterite, have a reddish hue [72]. Almost all laterites have a rusty-red hue because of the significant iron oxide content. Soil surface formation is guaranteed by periodic rainfall and sunny seasons. The crops are adequately nourished by this soil type. The southern Indian subcontinent is a significant producer of the rice variety *Oryza sativa*. Rice is a staple crop and a source of income for many farmers in the area surrounding the exploration location. Milling, visual, culinary, and nutritional qualities are all part of what makes rice grain quality. It is widely recognized that the root's balanced qualities are closely related to grain quality in rice. Root morphological and physiological features impact rice vegetative growth and grain satisfying, which in turn affects grain quality. The features that were researched and described and are applicable to the exploration site, which consists primarily of clay and laterite soil.

A methodology for digital soil mapping was created by Behrens et al. [73] using Artificial Neural Networks (ANNs). This methodology is able to predict soil units in a test area in Rhineland, Germany, Palatinate. Grinand et al. [74] developed a classification tree-based method for predicting soil distribution at an unexplored location by using a soil-landscape pattern obtained from a soil map. Soil datasets and exploration site data should be collected as part of the proper method for soil classification at the exploration site. After that, the datasets should be pre-processed. Finally, models should be trained using Deep Neural Network and Machine Learning techniques, and the soil should be classified into four distinct groups. They rely on accurate soil detection to help with nutrient supply to the field, which in turn increases crop production. It's also crucial for their livelihood to determine what kind of weeds will grow from the soil so that they can eradicate them.

E. Weed Identification

One of the most important things that can influence crop yield is weed control. Khan et al. [75] found that weeds can reduce crop output and production quality by competing with crops for water, fertilizer, light, growing space and other nutrients. Insects and diseases that harm crops could also call this place home. A study found that weed suppression resulted in a 13.2% annual loss of crop production enough to feed one billion people for a year Yuan et al. [76]. A key component of crop management and ensuring food security is weed control. Manual weeding, chemical weeding, biological weeding, mechanical weeding, etc. are all common weed management strategies Stepanovic et al. [78], Marx et al. [77], Morin [80], Kunz et al. [79], Andert [81].

The best method for controlling weeds in the field is to do it by hand. The high cost and labor intensity, however, make it impractical for cultivation on a broad scale. Because it doesn't harm non-target organisms much, biological weeding is eco-friendly and safe, but it takes a lengthy time to restore ecosystem afterward. The majority of weeds are eliminated

with chemical weed killers, which is the most popular method of weed control. However, other problems, including chemical residues, weed resistance, and environmental contamination, have resulted from the excessive use of herbicides. The study found that in different farmland systems, 513 biotypes of 267 weed species have become resistant to 21 different herbicides Heap, [82]. Therefore, it will be crucial to use technologies like detailed spraying or mechanical weed management on individual weeds in order to prevent the over-application of herbicide.

Automatic mechanical weeding is becoming more popular as a result of the organic farming movement Cordill and Grift [83]. It prevented needless tillage, which saved gasoline, and allowed for weed management without chemical input. Nevertheless, intelligent mechanical weeding has faced significant challenges because to the low accuracy of weed detection and the resulting unforeseen harm to the plant-soil system Gašparović et al. [85], Swain et al. [84]. So, it's critical to make weed detection more precise in the fields.

So using AI models like SVM, decision tree, a random forest algorithm, and KNN classifiers are some of traditional AI methods that have been utilized in weed identification research. It is expected that these algorithms will employ intricate manual craftsmanship to extract weed image color, texture, form spectrum, and other attributes. As a result, the weed image extraction was lacking or features were obscured, it would be impossible to differentiate between weed species that are otherwise comparable. Image processing technology was utilized by traditional weed detection algorithms to extract characteristics of weeds, crops, and backgrounds from images. A model that uses wavelet texture information to differentiate sugar beets from weeds was presented by Bakhshipour et al. [86]. A total of fourteen of the fifty-two texture features were chosen using principal component analysis. Despite numerous occlusions and overlapping leaves, it proved wavelet texture features might accurately differentiate among crops and weeds. Only crops and weeds with clearly distinct pixel values in the RGB matrix or other parameter matrices derived from it could be identified by the color feature-based models. In most cases, the color feature was utilized in conjunction with other features; for instance, Kazmi et al. [87] suggested a technique that combined surface color with edge form to detect leaves and integrate vegetation indices. With a precision of 99.07%, the vegetation index was combined with regional characteristics. It was challenging to differentiate between weed species using traditional image processing approaches, even if same methods could differentiate between crops and weeds.

To improve weed detection, deep learning networks can generate abstract high-level properties instead of the low-level attributes used by traditional machine vision networks, such as color, shape, and texture. The present target identification models have, as is well-known, benefited from deep learning's increased accuracy and generalizability. A few examples of popular target detection networks are the YOLO model, Faster R-CNN, and Single Shot Detector Redmon et al. [88], Ren et al. [89], Quan et al. [90]. Using a total of 10,413 pictures, Dyrmann et al. [91] employed CNN to distinguish 22 distinct plant species. The weed species with the most picture resources had the highest classification accuracy, according to the results.

Therefore, there needs to be enough datasets for deep learning-based weed identification.

The author Hinton et al. [92] proposal highlighted the deep and highly-connected topology of DL networks, which led to the idea of deep learning being introduced. The dataset is trained by Deep learning has been demonstrating strong accuracy and resilience in image identification as of late. To be more specific, ImageNet a massive multi-variety dataset with 3.2 million images demonstrated the significance of large-scale datasets in enhancing the identification accurateness of the models trained with DL methods by Russakovsky et al. [93]. Unfortunately, dataset for training deep learning weed identification models have very tiny scales in both the number of images and the type of weeds.

F. Seed Categorization

Farmers and food processors alike are understandably worried about seed segregation in mixed cropping. Farmers and agro-industries also have the difficult challenge of classifying and packing seeds according to their quality. Additionally, the conventional methods of seed separation after threshing like sieving, hand-picking, etc. are laborious and time-consuming. Therefore, seed segregation must be automated.

For that AI methods play an important role in yield prediction [94], improvement of image contrast [95], illness categorization [96], etc. inspired each of the study [97] in order to broaden the scope in seed categorization according to variety, size, they are of high quality. Using SVM, the authors of [98] were able to categorization of normal and broken maize kernels [99]. The SVM classifier achieved a 95.6% success rate for healthy and an 80.6% success rate for the process of identifying damaged or defective seeds, an error rate of about 19% was noted. Researchers [100], [101], and [102] continued this line of inquiry by classifying four different types of maize seeds using models based on SVM, K-means and DCNN. They used the DCNN and claimed a perfect training accuracy rate based strategy. However, when measuring the model's efficacy on the testing dataset, a significant amount of incorrect classifications was found in relation to a single corn category.

In addition, the researchers [103] automated the process of inspecting maize kernels by utilizing ML and DL models' capabilities. For kernel separation, they utilized k-means clustering. In order to distinguish between kernels that were flawed and those that were not, they used a number of models, including ResNet, VGGNet, and AlexNet. Outperforming VGGNet and AlexNet, the ResNet model achieved an accurateness of 98.2%. The writers in [104] also distinguished between healthy and malformed corn seeds using SVM, AlexNet, VGG-19, and GoogleNet. The GoogleNet model had the highest accuracy rate of 95% out of all of these models. In order to classify and test seeds, the following works [105] employ ML and DL algorithms effectively. In order to distinguish between haploid and diploid seeds, detect seed coating, distinguish between common maize seed and silage seed for animal feed, and identify defective from non-defective seeds, they utilized Convolutional Neural Network (CNN) classifiers. Sunflower seed identification was accomplished by the authors [106] using DL models. By utilizing optimization procedures, they

successfully circumvent the issue of overfitting. It was asserted by the authors that the optimized GoogleNet model attained a 95% accuracy rate. Unlike a large lot, however, the model calls for human involvement to arrange the seeds.

When training the model, the authors also took into account just one perspective on seeds. Consequently, by training the model on numerous perspectives of seeds, there is a chance to enhance its robustness and reliability. In order to incredulous the obstacles stated in the previous study, the authors in [107] took into account the entire soybean seed surface. They achieved a 98.87% success rate by using a circumrotating method for full surface detection. When applied to the dataset that included defective seeds, the MobileNet model enhanced the classification accuracy. In addition, the technique for identifying soybean seeds was suggested by the authors in [108]. To demonstrate the effect of transfer learning, they used pre-trained CNN models such as AlexNet, Xception, ResNet18, Inception-v3, DenseNet201, and NASNetLarge. With a reported accuracy of 97.2%, the authors asserted that NASNetLarge was the most accurate model. Using morphological and textural characteristics of seeds, the authors of [109] extended the use of ML models for weed detection by applying the naïve Bayes algorithm [110]. The model's accuracy on the grayscale and monochrome photos was 98%, according to the research. Colored images, however, show a marked decline in accuracy.

G. Yield Forecasting

Predicting how much food will be harvested from a specific plot of land is known as Crop Yield Prediction (CYP). Businesses, governments, and farmers all rely on it to help them make educated decisions on agricultural output. The varied temperature, topography, temporal dependencies inherent in yields and farming techniques across India make accurate crop yield forecast a difficult undertaking. Nonetheless, one can anticipate crop production based on a number of criteria, such as: Outside conditions: When it comes to determining harvest success, the weather is a major player. When it comes to plant growth, factors like rainfall, temperature and humidity are important. Crop yield is also prejudiced by the soil's type and fertility. To account for these aspects and anticipate crop yield, one might utilize crop yield prediction models. These models can use machine learning, statistical methods, or a mix of the two.

Consequently, better approaches for assessing and modelling agricultural data are required to enhance crop yield forecast and management. Using ML algorithms and proximate sensing, Farhat Abbas et al. [111] established a CYP system. In order to conduct training, four datasets that are available to the public were gathered: PE-2017, PE-2018, NB-2017, and NB-2018. In order to forecast agricultural output, the gathered data were fed into machine learning models such k-nearest neighbor (KNN), support vector regression (SVR), linear regression (LR), and elastic net (EN). With a smaller Root Mean Square Error (RMSE) than competing techniques, the SVR outperformed them on all four datasets. Martin Kuradusenge et al. [112], introduced many ML models in order to improve the system's performance, the Irish potato and maize datasets were first collected and pre-processing activities, such as removing null values and determining association, were

executed. Afterwards, three ML models SVM, Random Forest (RF) and Polynomial Regression (PR) were used to classify the pre-processed data for CYP. When it came to forecasting potato and maize crop yields, the RF model outperformed the SVM and PR models, with RMSEs of 510.8 and 129.9, respectively, on the datasets that were examined.

Recurrent neural networks and temporal convolutional networks are examples of the hybrid DL techniques that Liyun Gong et al. [113] suggested for CYP. The data was gathered from many actual tomato-growing greenhouses. Before feeding the standardized data to the RNN for processing, gathered data was pre-processed using data normalization. Lastly, TCN was instructed to process tomato CYP using the RNN's output. For the datasets that were collected, the technique outperformed the similar methods with reduced RMSE. For CYP with agrarian characteristics, Dhivya Elavarasan and P. M. Durai Raj Vincent [114] introduced a hybrid method known as reinforced RF. At first, the system retrieved crop data from the agricultural dataset and input it into the reinforced RF hybrid DL model. The relevance of the input data was determined by the reinforced RF using the reinforcement learning approach in every internal node. After that, the RF classified crop yield using the most important variables found by the reinforcement model. Outperforming state-of-the-art ML models for CYP including SVM, LR, and KNN, the hybrid technique produced superior results.

To optimize CYP, Aghila Rajagopal et al. [115] created a deep-learning approach. After the data was pre-processed, principal component analysis was used to extract the important features from the pre-processed dataset. After that, an updated chicken swarm technique was used to further optimize the characteristics that were chosen in order to boost the classifier's performance. Lastly, a discrete DBN-VGGNet classifier was used for classification. Outperforming the prior state-of-the-art models, the system attained a 97% accuracy rate with a 0.01% MSE. For large-scale CYP, Dilli Paudel et al. [116] proposed a set of machine-learning models. Data on agricultural yields, including results from crop growth simulations, weather measurements, and yield statistics, were first gathered by the system from a variety of sources. Preparation for categorization procedures involved cleaning the acquired data. The classifier was then fed samples of input data that had undergone feature design. As for CYP, it made use of ML classifiers such as SVM, Ridge regression, KNN, and gradient-boosted decision trees.

H. Disease Detection

Plant diseases are a worldwide threat to food security and can also have serious personal consequences. The economy and the security of our food supply depend critically on healthy crops. A crop's health can only be gauged by its growth and leaf condition.

Therefore, by analyzing symptoms seen in leaf images can learn about many plant illnesses. Every year, farmers can lose a substantial amount of money due to several plant diseases that impact vegetables like potatoes, tomatoes, and peppers. Early blight and late blight are the two varieties of blight. Though a particular bacterium causes late blight, a fungus causes early blight. By promptly detecting and efficiently treating these

diseases, farmers can save both time and money. In the next twenty-five years, the human population is projected to surpass 9 billion. A 70% upsurge in food production is necessary to keep up with the continuously increasing demand for food. Many nations, particularly those with a strong agricultural economy, face the devastating threat of crop disease.

By extracting data from real time image processing with ML and DL become prominent tool for plant disease identification because it will effectively diagnose plant illness by exploring with computer vision, machine learning approaches have shown promise by extracting data from real-time image processing. There has been extensive use of classic ML methods for plant disease detection, including feature extraction and classification. Color, texture, and form are some of the visual attributes that may be extracted using these methods to train a classifier to distinguish between healthy and sick plants. Diseases like leaf blotch, powdery mildew and rust as well as symptoms of diseases caused by abiotic stresses like drought and nutrient deficiency, have been extensively detected using these methods Anjna et al. [118], Mohanty et al. [117], Genaev et al. [119]. However, these methods do not accurately identify subtle symptoms of diseases or detect diseases in their early stages. They also have trouble management complicated and high-resolution images.

By using DL technology like CNNs and DBNs to detect pests and irregularities in plants. The use of these technologies to detect and identify lesions from digital pictures has been yielding encouraging results by Kaur and Sharma [120], Siddiqua et al. [121], Wang [122]. Deep learning models have the ability to automatically learn image attributes, allowing them to detect subtle disease symptoms that could otherwise go undetected by typical image processing approaches. However, not all applications can accommodate Deep Learning models due to their high processing requirements and large amounts of labelled training data. In order to locate and identify certain areas of interest in images, like disease symptoms or plant leaves, CV methods like object detection and semantic segmentation can be employed Kurmi and Gangwar [123]. By combining these techniques with ML or DL algorithms, images can be automatically transformed into patterns or features that can be used for disease identification and categorization. To train their models, CV algorithms require massive amounts of labelled picture data, which means they might not be able to handle previously discovered diseases.

Image, sensor, and meteorological data, among other massive datasets, have been subjected to ML and DL-based analysis in order to uncover patterns and generate forecasts. Cedric et al. [125], Yoosefzadeh-Najafabadi et al. [124] and Domingues et al. [126] are just a few examples of ML algorithms that are actually used to forecast crop yields, detect plant diseases and pests and optimize plant growth. Sladojevic et al. [127], Alzubaidi et al. [128], and Dhaka et al. [129] all found that DL models, including CNNs and DBNs, outperformed standard image processing approaches when it came to plant lesion diagnosis using image analysis and classification. Compared to more conventional ways, ML and DL-based methodologies provide many benefits in the fields of agriculture and botany. These techniques can evaluate massive amounts of data, automate activities, and improve accuracy and efficiency.

1. Harvesting of Yields

Rising food demand due to population growth is the biggest threat to food security. In order to increase supply, farmers will need to enhance yields while utilizing the same amount of land. Technology can help farmers increase production through agricultural output prediction. For better crop selection and management during the growing season, decision-makers can employ CYP a decision-support tool powered by ML and DL. During the growing season, it may choose which crops to harvest and how to tend to them.

With the use of agricultural yield estimation, farmers may increase output when weather is good and reduce output loss when weather is bad. Positive predictions of agricultural output are affected by a great deal of variables, including farmer practices, decisions, pesticides, fertilizers, weather, and market pricing. Climate, area wise production, rainfall, and historical yield statistics can all be used to make educated guesses about future crop yields. AI methods has been making strides in many sectors, including farming, as of late.

In order to predict the harvest used the dataset that includes the entire cultivated area, the length of the canals, the average highest temperature and irrigation water sources like wells and tanks. The researcher created computational model outperformed alternatives built with Regression Tree, Lasso, Deep Neural Network and Shallow Neural Network techniques. The RMSE for dataset validation using forecasted weather data is 12% of the average yield and 50% of the standard deviation [130]. Using the following parameters: minimum/maximum/average temperatures, rainfall, area, production and yield, the accuracy was 97.5% from 1998 to 2002 for the Kharif season [131]. Crop production estimates during the Kharif season in Andhra Pradesh's Vishakhapatnam district were the primary focus of the study. Because rainfall has such a large impact on the yield of Kharif crops, researchers first employed modular artificial neural networks to predict when it would rain, and then they used SVR to estimate the yield of crops based on both area and rainfall. These two methods were used to increase the harvest productivity.

The research aimed to accomplish four things: first, study how well the ANN model predicted corn and soybean yields when weather was bad; second, compare the evolved ANN model to other multivariate linear regression models; and last, test how well the model estimated yields at the regional, state, and local levels. Researchers in India's Maharashtra state employed artificial neural networks to compare rice harvests in different urban areas. They used the Indian government's accessible records to compile data for Maharashtra's 27 districts.

This study estimates higher crop yields utilizing ML methods like KNN, SVR, RF and ANN. The research's data set consists of 745 examples; 70% of those cases were randomly assigned to train the model, while 30% were used for testing and performance evaluation. Random Forest is found to obtain the highest level of accuracy in the final analysis of maya gopal P.S [132]. The study proposes a novel model for soybean yield prediction using Long-Short Term Memory (LSTM) satellite data collected in southern Brazil [133]. The main objective of the study is to evaluate LSTM neural networks, random forest, and multivariate OLS linear regression for

their effectiveness [134]. The first stage in using rainfall, land surface temperature, and vegetation indices as self-determining variables to forecast soybean data is to find out how soon the model can reliably expect the yield. All algorithms are outperformed by Long Short Term Memory for all forecasts except DOY 16. According to [135], when it comes to DOY 16, multivariate OLS linear regression is the best algorithm. This study discusses the outcomes of applying a Sequential Minimal Optimization Classifier. Data from 27 districts in Maharashtra, India, and the WEKA tool were used to conduct the experiment. Other strategies perform better than Sequential minimum optimization, according to the results of the experiment on the same dataset. While Multilayer Perceptron and BayesNet showed the greatest accuracy and enhanced quality, sequential minimum optimization showed the worst accurateness and poor quality [136]. One method that has been suggested for estimating crop productivity is the use of Parallel Layer Regression (PLR) and Deep Belief Networks (DBNs). Pulses, ragi, rice, and cassava are five of Karnataka's most important crops that are being studied using a DBN technique. Each entry in the applicable database is forecasted by the proposed methodology to produce one of the five crops. Finally, the experimental results show that the method has great promise for real-time data and human interaction validated accurate prediction of agricultural efficiency in terms of specificity, sensitivity and accuracy [137].

By utilizing a KNN algorithm, a CYP System (CYPS) is put into place. Yield projections, on the other hand, need to take into account a number of variables that can affect the quantity and quality of a farmer's harvest. In order to forecast yield production, authors employ precise fields such as year, crop, area, region, and season. These factors, along with crop type and production area, have a significant impact on yield production. Accurate understanding of crop yield history is necessary for decisions linked to agricultural risk management [138]. Rao et al. [139] used two separate metrics, entropy and GINI, to compare Random Forest, Decision Tree Classifier, and KNN. RF has produced the most precise outcomes, according to the findings. Based on feature vectors, VGG_19 achieved a good performance of 91.35% and VGG_16 achieved a good performance of 91.17% [140]. Because of its great efficiency, hydroponics has been suggested by Vanipriya et al. [141] as a solution to the problem of low agricultural production in India. Furthermore, it provides a more environmentally friendly option for soil cultivation. The economy and agricultural output are two factors that determine food production [142].

III. LIMITATIONS AND FUTURE STUDY

Based on the study, the findings of agriculture based on image processing has a lot of potential to automate and improve farming tasks with different agriculture farming. For future comprehensive insights there is a need to enhanced farming by combining image, IoT, data fusion techniques, transfer learning and domain adaption and computing techniques. The techniques like DeepLab [143] can be used to classify plants, detect pests, and analyze soil because it is a semantic segmentation model for classifying every pixel. The other method is efficient net [144] which is used to detect disease, fruit counting and yield prediction effectively because it is designed to optimize the model and computation. While

our study mainly highlighted the CNN model mostly because it can understand the decision making process in farmers to balance perspective for further refinement. While this review has different datasets for different farming which highlights class imbalance, performance scenario for model evaluation, and comparability. In farming, sustainability is considered as a main factor for long term viability of the environment through energy consumption, and electronic waste associated with cost environment.

However, it isn't perfect for all jobs because of some problems. Here's a look at how these limits affect different farming tasks:

A. Fruit Counting

1) *Occlusions and crossing over*: Fruits that are hidden by leaves or that intersect with other fruits can make it hard to count or identify them.

2) *Changes in lighting*: Sunlight or artificial lighting can cast shadows and create effects that make it harder to see fruits and vegetables.

3) *Challenges unique to each species*: Because fruits come in many shapes, sizes, and colors, they require very specific formulas.

4) *Environments that change*: Moving wind or changes in the shape of the tree can make it harder to locate the fruit.

B. Water Management

1) *Problems with surface reflection*: High reflection from bodies of water or irrigation systems can make it hard to determine how much water is in an area or how it is distributed.

2) *Limitations of resolution*: Images from satellites or drones might not have enough detail for micro-irrigation and other small-scale water management tasks.

3) *Estimating the soil moisture*: Indirect methods, like NIR imaging, might not provide an accurate reading of soil moisture because dryness on the top can mask the conditions below.

C. Crops Management

1) *Changes in growth stages*: The appearance of crops changes significantly over time, so adaptive programs are needed to monitor them continuously.

2) *Problems with the environment*: When taking images outdoors, weather conditions like rain or fog can make it difficult to see crops.

3) *Difference between weeds and crops*: It's challenging to differentiate between crops and weeds that are grown closely together because they appear similar.

D. Soil Management

1) *Data at the surface level*: Image-based methods usually only show what's on the surface and don't reveal things like nutrient levels or soil compaction.

2) *Dependence on indirect indicators*: The color and texture of soil that are inferred from images might not always be a reliable indicator of its fertility or organic content.

3) *Environmental factors*: Changes in light, moisture, or plant debris can complicate the assessment of soil condition.

E. Weed Identification

1) *How they are like crops*: Weeds that look like crops in terms of leaf structure or color can be difficult to tell apart.

2) *Lots of plants*: It's hard to tell the difference between weeds and crops in areas with a lot of crops.

3) *Changes with the seasons*: Weed growth trends change with the seasons, requiring models to be retrained frequently.

F. Seed Categorization

1) *Changes in size and shape*: Seeds from the same species can naturally vary in size, shape, and texture, complicating classification.

2) *Waste and impurities*: Misclassification can occur when images contain trash or damaged seeds.

3) *Problems with lighting and contrast*: Uneven lighting can obscure crucial features of a seed necessary for identification.

G. Yield Forecasting

1) *Complex networks of dependencies*: Yield depends on many factors that are difficult to discern from images alone, such as weather, soil health, and pest presence.

2) *Lack of data*: Model accuracy suffers from the absence of historical image data for certain crops or regions.

3) *Problems with spatial resolution*: Low-resolution images might not capture important crop features essential for accurate predictions.

H. Disease Detection

1) *Signs of an early stage*: In the early stages of a disease, subtle changes in the texture or color of leaves might be too faint for standard image processing to detect.

2) *Nutrient deficiencies and other problems*: Some diseases exhibit symptoms that are very similar to those caused by nutrient deficiencies, which can lead to incorrect diagnoses.

3) *Noise in the environment*: Dust, water droplets, and other impurities on plant surfaces can make accurate disease identification challenging.

I. Harvesting

1) *Conditions of the dynamic field*: Changing field conditions, such as uneven terrain or variable lighting, complicate the task for robots to harvest crops using image processing.

2) *Produce that is Covered or hidden*: Fruits and vegetables that are fully or partially hidden are difficult to locate and harvest accurately.

3) *Risk of damage*: During automated picking, damage can occur if items are not properly positioned or identified.

J. General Cons Across Applications

1) *Dependence on data quality*: Models perform less reliably when images are of poor quality, resolutions are not uniform, and diverse datasets are lacking.

2) *Problems with scalability*: Real-time processing for large-scale systems (like entire farms) requires substantial computational resources.

3) *Issues with adaptability*: Image processing algorithms need to be retrained for new crops, regions, or weather conditions.

4) *Hardware limitations*: Small-scale farmers may not be able to afford as many drones, cameras, and other imaging tools, increasing costs and reducing accessibility.

K. Pros that Apply to All Situations

1) *Real-Time monitoring*: Imaging and sensors provide up-to-the-minute information, allowing immediate responses to changes in the field.

2) *Scalability*: Data analysis tools can handle large datasets, making them suitable for both small farms and large-scale operations.

3) *Cost savings*: Optimizing resource use reduces expenses on water, chemicals, and labor.

4) *Sustainability*: Promotes environmentally friendly practices by minimizing the use of excessive energy, water, and chemicals.

5) *Precision agriculture*: Delivers precise, relevant information that increases output and reduces waste.

6) *Risk reduction*: Predictive models identify potential risks such as drought, pests, or diseases.

7) *Enhanced Decision-Making*: Provides valuable insights based on historical trends, current conditions, and predictive algorithms.

8) *Accessibility*: Data analysis tools are accessible to farmers worldwide, even in remote locations, via mobile apps and cloud-based platforms.

L. Potential Author Bias

- Potential bias in evaluation and model selection
- Limitations related to Dataset: like data quality, imbalance, insufficient data
- Overfitting and generalization of model for different contexts.
- Uncertainty in discussion of model prediction.

IV. CONCLUSION

This study details the newest developments in AI research aimed at digitizing farming to increase food yields. Modern agriculture has been changed by AI technologies that help with things like counting fruits and vegetables, managing water and soil, keeping an eye on crops, identifying weeds, sorting seeds into groups, predicting yields, finding diseases

and gathering crops automatically. The results show that AI has the potential to make farming more accurate, efficient and environmentally friendly. These new technologies help farmers make the best use of their resources, do less work by hand and make decisions based on data, which leads to better productivity and greater resilience against environmental problems for 9 billion people living on the planet. By the end of 2050, using new tools in farming is no longer a choice but a must because it put a lot of stress on farming systems that try to meet rising food needs in a way that doesn't harm the environment. So it is most important to keep researching and developing the integration of AI with agriculture for helping farmers to deal with problems that makes agriculture resilient and build a healthy future.

LMS-YOLO11n: A Lightweight Multi-Scale Weed Detection Model

YaJun Zhang¹, Yu Xu², Jie Hou³, YanHai Song⁴,

Department School of Software, Xinjiang University, Urumqi, China^{1,2,4}
Guangzhou Xinhe Information Technology Corporation, Guangzhou, China³

Abstract—With the advancement of precision agriculture, efficient and accurate weed detection has emerged as a pivotal task in modern crop management. Current weed detection methods face dual challenges: inadequate extraction of detailed features and edge information, coupled with the necessity for real-time performance. To address these issues, this paper proposes a lightweight multi-scale weed detection model based on YOLOv11n (You-only-look-once-11). Our approach incorporates three innovative components: (1) A fast-gated lightweight unit combined with C3K2 to enhance local and global interaction capabilities of weed features. (2) An adaptive hierarchical feature fusion network based on HSFPN, which improves the extraction of weed edge information. (3) A lightweight group convolution detection head module that captures multi-scale feature details while maintaining a lightweight structure. Experimental validation on two public datasets, CottonWeedDet3 and CottonWeed2, demonstrates that our model achieves an mAP50 improvement of 2.5% on CottonWeedDet3 and 1.9% on CottonWeed2 compared to YOLOv11n, with a 37% reduction in parameters and a 26% decrease in computational effort.

Keywords—You-only-look-once-11; weed; lightweight; group convolution

I. INTRODUCTION

Modern agriculture faces numerous challenges that hinder productivity and sustainable development. Weeds are a major threat, directly impacting crop yield and food security. Weeds compete with crops for light, water, and soil nutrients, spreading diseases and pests, significantly reducing crop yield, and causing economic losses [1-2]. Selective herbicides and manual weeding are the two major weed management techniques used today; the former entails evenly applying herbicides throughout fields. This method results in significant waste, as most herbicides are sprayed on crops or bare soil, rather than directly on the weeds. Additionally, excessive herbicide use harms the ecosystem. Manual weeding, on the other hand, is costly and difficult to scale for large-scale agricultural operations.

With the development of AI technology, precision agriculture offers a solution to these problems [3-4], with the key first step being the accurate and rapid detection of weed locations [5]. Therefore, in-depth research on weed detection technology is crucial for the development of precision agriculture, contributing to the future efficiency, precision, and sustainability of farming.

Early weed detection methods were mostly based on machine learning, such as Kumar and Prema's [6] Wrapped Curve Transform Angle Texture Pattern extraction method, which improved weed identification accuracy in fields. Sujaritha et al.

[7] proposed a circular leaf pattern extraction method based on morphological operations, combined with rotational invariance and wavelet decomposition, enabling automatic weed and crop recognition and efficient removal in sugarcane fields. However, these methods struggle to handle challenges such as the complexity of field environments, weed species diversity, and lighting changes, resulting in poor detection performance and instability, which limits their application in diverse environments. In contrast, deep learning uses convolutional neural networks to extract both global and local features of weeds, compensating for the shortcomings of machine learning in feature extraction. As a result, deep learning-based weed detection has become the mainstream method.

While deep learning-based methods outperform machine learning in terms of accuracy, they struggle to meet the lightweight requirements of edge devices, making weed detection on edge devices a new direction in object detection. This study faces challenges such as high similarity between weed species, occlusion issues affecting detection accuracy, and the deployment limitations of edge devices. To address these challenges, this paper proposes the LMS-YOLO11n weed detection method based on YOLO11n. The main contributions of the LMS-YOLO11n model are as follows:

- 1) To meet the demands of detail extraction and real-time performance in weed detection, this paper proposes the lightweight multi-scale feature extraction module FastGLU, combined with CGLU's convolutional gating mechanism and FasterNet's lightweight characteristics. It extracts key channel information through partial convolution (PConv) and uses CGLU to enhance the interaction between local and global features, reducing computational costs while achieving efficient and diverse feature extraction.
- 2) To address the challenge of weed edge information extraction, this paper designs the adaptive hierarchical feature fusion network (AHFPN). By combining the ideas of HSFPN and PAN, the feature fusion mechanism is improved to enhance sensitivity and capability in edge information extraction, optimize the interaction and fusion of multi-scale features, and improve adaptability to weed diversity and various growth stages, while reducing computational burden.
- 3) To meet the real-time requirements of weed detection, this paper introduces the lightweight group convolution detection head (LGCD) module. By incorporating group convolution into the position regression branch, the computational load and parameter count are significantly reduced, and kernel size optimization improves the ability

to capture multi-level feature details, balancing feature extraction richness with model efficiency to meet the deployment requirements of edge devices.

This paper has the following structure: Section II examines the state of domestic and international weed detection research; Section III provides further details about the LMS-YOLO11n approach; experiments in Section IV confirm the model's generalization performance; and a summary of the work and recommendations for future research are provided in Section V.

II. RELATED WORK

Object detection methods can be broadly categorized into single-stage and two-stage models. Two-stage detection models generate candidate regions quickly and refine them in a second processing stage. Typical models include RCNN [8] and Fast-RCNN [9]. Zhang [10] and colleagues successfully detected weeds and soybeans in complex backdrops by optimizing the Faster R-CNN method with VGG19-CBAM as the backbone network, achieving successful detection of soybeans and weeds in complex backgrounds. Ozcan et al. [11] compared the performance of single-stage and two-stage CNN models in precision agriculture and found that Faster R-CNN Inception v2 offers higher accuracy. However, when training and inference time are critical, the SSD MobileNet v2 model significantly improves accuracy with increased training data. Li et al. [12] proposed an improved Faster R-CNN model for automatic detection of hydroponic lettuce seedlings, achieving an accuracy of 86.2% through enhancement techniques, outperforming models like RetinaNet, SSD, Cascade RCNN, and FCOS. Although two-stage detection methods are generally more accurate than single-stage methods, they require significant computational resources, making them difficult to deploy on mobile devices. Moreover, the longer detection time limits their ability to meet detection in real-time requirements.

Due to the limitations of two-stage detection, there is growing interest in single-stage detection methods, exemplified by SSD [13] and YOLO [14-18]. Unlike two-stage methods, single-stage detection integrates region proposal, classification, and regression into a single network, significantly improving speed and efficiency. Chen et al. [19] proposed the YOLO-sesame model, an improved YOLOv4 variant that incorporates Local Importance Pooling (LIP) and SE modules to enhance feature extraction. The model also uses an Adaptive Spatial Feature Fusion (ASFF) structure to optimize the detection of objects of varying sizes, improving both real-time performance and accuracy in sesame field weed detection. Hong et al. [20] presented an enhanced YOLOv5 algorithm for effective asparagus identification in intricate settings. The model incorporates Coordinate Attention (CA) in the backbone network to emphasize growth features of asparagus and replaces PANet with BiFPN to enhance feature propagation and reuse, significantly improving support for intelligent mechanical harvesting under various weather conditions. A network of convolutional neuron models called RIC-Net, which combines residual structures with Inception, was proposed by Zhao et al. [21]. The model replaces MLP layers with 1D convolutions for optimized feature detection and integrates CBAM modules with weighted operations to highlight diseased areas, improving classification accuracy for leaf diseases in maize, potatoes, and tomatoes.

Song et al. [22] developed an improved YOLOv5 algorithm by replacing the backbone with MobileNetv2 to reduce model complexity. ECANet attention mechanisms were introduced to enhance detailed feature extraction for soybean leaves, and CIOU_Loss + DIOU_NMS was used to improve accuracy and robustness, particularly for dense occlusion and small object detection in precision agriculture spraying. Zhang et al. [23] proposed CCCS-YOLO, an improved YOLOv5-based algorithm. The model integrates Faster_Block into YOLOv5s's C3 module to create C3_Faster, simplifying the network structure and enhancing detection. It improves the convolutional block in the head for better target-background differentiation, replaces the neck's upsampling module with the lightweight CARAFE module for small object detection and contextual information fusion, and uses Soft-NMS-EIoU to enhance detection accuracy in dense scenarios. Guo et al. [24] proposed LW-YOLOv8n, a lightweight weed detection model. The model integrates SERMAttention with SE and SRM modules to capture global information, incorporates lightweight Context Guided Blocks in C2f layers to enhance local and contextual feature learning, and introduces an improved BiFPN network in the neck for weighted multi-scale feature fusion. This method is appropriate for edge devices with limited resources as it lowers parameters and complexity while preserving excellent detection accuracy. Fan et al. [25] presented YOLO-WDNet, a model for lightweight weed identification. It replaces CSP-Darknet53 with ShuffleNet v2 as the backbone to reduce parameters and complexity, designs a Parallel Hybrid Attention Mechanism (PHAM) to focus on regions of interest, improves BiFPN in the neck for multi-scale and overlapping plant feature recognition, and proposes an EIOU loss function to enhance detection accuracy in dense scenarios.

Despite significant advancements, a gap persists in the development of single-stage detection models that combine high accuracy with sufficient lightness and efficiency for deployment on resource-limited edge devices. The work presented in this paper endeavors to address this gap by introducing a novel, lightweight single-stage detection model. This model integrates advanced convolutional gating mechanisms, optimized feature fusion strategies, and a streamlined detection head leveraging grouped convolutions, all tailored to elevate detection accuracy and efficiency specifically within agricultural applications.

III. METHODOLOGY

A. YOLO11 Principle

YOLO11, the latest model in the YOLO series, was released by Ultralytics in 2024. Based on structural complexity and size, YOLO11 is available in five versions: YOLO11n, YOLO11s, YOLO11m, YOLO11l, and YOLO11x. YOLO11n, the version with the smallest computational and parameter requirements, is designed for weed detection scenarios that demand real-time performance and limited computational resources. Therefore, this study selects YOLO11n as the baseline model. YOLO11n consists of three main components: Backbone, Neck, and Head. The Backbone replaces the C2f module from YOLOv8 with the latest C3K2 module, significantly improving feature extraction efficiency. The Neck continues to use the FPN+PAN structure for feature fusion, while the Head incorporates depthwise separable convolutions, significantly reducing computation and parameter requirements. Although

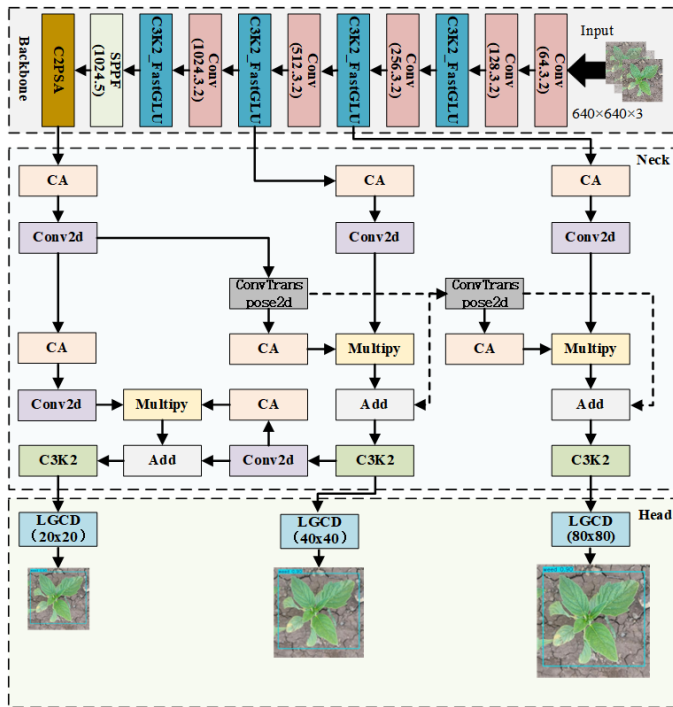

Fig. 1. Structure of LMS-YOLO11n.

YOLO11n is the most lightweight version, its computational complexity remains 6.3GFLOPs, and its parameter size is 2.58MB, which still poses challenges for real-time detection and edge computing deployment.

B. Lightweight Multi-Scale Weed Detection Model

In deep learning-based weed detection tasks, the scale and complexity of the model directly determine its practical effectiveness. Although YOLO11 surpasses many mainstream object detection models in speed, it contains significant redundant features. These redundant features are primarily generated by convolutional computations in the backbone network, consuming substantial computational resources, increasing complexity, and reducing inference speed. Additionally, the similar textures of crop seedlings and weeds, coupled with multi-scale features, make YOLO11 less effective at extracting features under complex lighting conditions. To address the need for lightweight models and real-time detection, while enhancing the extraction of fine-grained weed features and edge information, this study proposes the LMS-YOLO11n model based on YOLO11n. LMS-YOLO11n integrates the C3K2_FCGLU module into the YOLO11n framework to replace the original C3K2 module, enabling more efficient weed feature extraction. Furthermore, by introducing the AHFPN designed based on HSFPN [26], the neck network is optimized to improve the recognition and fusion of multi-scale overlapping plant features. Finally, the LGCD module, based on grouped convolution [27], is used to refine the Head, enhancing multi-scale information capture while reducing parameters and computation. Fig. 1 displays the LMS-YOLO11n structure with an input picture size of 640 x 640 x 3.

Fig. 2. Structure of CGLU, PConv and FastGLU.

C. C2f_FastGLU

To address the requirements for detail extraction and real-time processing in weed detection, this paper proposes a Fast Gated Lightweight Unit (FastGLU), as shown in Fig. 2. FastGLU captures fine-grained feature information, enhancing the model's ability to perceive image details, expand the receptive field, and extract local features. Additionally, it excels in optimizing multi-channel information usage, reducing parameters and computational costs, maintaining gradient flow, and enhancing spatial feature extraction. This allows the model to efficiently handle weeds of varying sizes and shapes. FasterNet [28] introduced the concept of Partial Convolution. PConv is a convolutional method designed to improve data processing efficiency and reduce memory overhead. It applies standard convolutions to a subset of input channels to effectively extract spatial features while omitting convolutions on other channels, thereby reducing computational and memory demands. Specifically, it selects the first and last consecutive c_p channels as representatives of the input feature map, assuming the input and output feature maps have the same number of channels. This design not only simplifies computation but also optimizes memory access efficiency, enabling effective feature representation. By applying convolutions only to a subset of input channels to extract spatial features while ignoring others, its computational complexity is defined in Eq. (1).

$$\begin{aligned}
 F_{Conv} &= h \times w \times k^2 \times c^2 \\
 F_{PConv} &= h \times w \times k^2 \times c_p^2
 \end{aligned}
 \quad (1)$$

In this equation, h and w represent the height and width of the feature map, k denotes the kernel size, c is the number of input feature map channels, and c_p represents the selected input channels used for spatial feature extraction in the PConv operation. In this study, c_p is set to 1/4 of c , reducing the computational cost of PConv to just 1/16 that of a standard convolution.

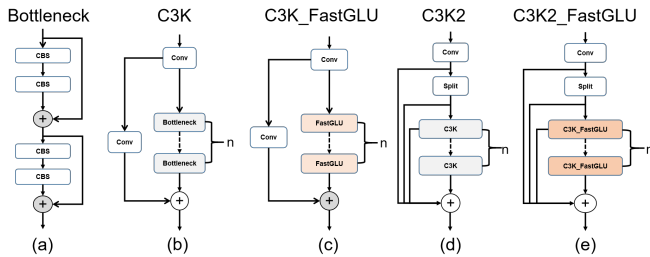

Fig. 3. (a) Bottleneck; (b) C3K; (c) C3K_FastGLU; (d) C3K2; (e) C3K2_FastGLU structure.

The Faster Block accelerates network processing by reducing computational and memory access demands. Its structure consists of a PConv layer followed by two pointwise convolution (PWConv) layers. However, the Faster Block has a limited receptive field, and PConv processes only part of the channel information, which hinders fine-grained weed feature extraction. The Gated Linear Unit (GLU) is an activation mechanism designed to enhance the extraction of complex features, initially used in language processing and sequence modeling tasks. Currently, GLU [29] has evolved into several variants, including the Gated Recurrent Unit, Depthwise Separable GLU, FFN with SE module, and Convolutional Gated Linear Unit [30]. In this study, CGLU is integrated into PConv to enhance fine-grained local feature extraction and optimize the interaction between local and global feature information. CGLU first employs two parallel 1x1 convolutions for per-channel control, with one feature map further processed by a 3x3 depthwise separable convolution to capture local features. These features are then fed into the Gated Linear Unit. A portion of the features is activated by the GELU function to serve as a gating signal, which multiplies with another feature set to enable channel attention control, enhancing feature selection and emphasis.

The primary structure of the C3K2 module in YOLO11 Fig. 3(d) is based on the C3K module. The C3K module Fig. 3(b) consists of standard convolutions and Bottleneck units. The Bottleneck unit Fig. 3(a) is composed of CBS modules. CBS is a fundamental convolutional unit comprising convolution operations, batch normalization, and an activation function. The proposed C3K2_FastGLU module Fig. 3(e) replaces the C3K module in C3K2 with C3K_FastGLU. The backbone network faces several bottleneck issues. Introducing C3K2_FastGLU effectively reduces computational cost, significantly improves multi-scale feature extraction, alleviates information transmission bottlenecks, and maintains efficient feature representation and generalization in lightweight designs. Therefore, in the YOLO11n backbone, the C3K2 modules in the P2, P3, P4, and P5 layers are replaced with C3K2_FastGLU.

D. AHFPN

To meet the deployment requirements of weed detection on edge devices, this study uses HSFPN to fuse extracted features. HSFPN consists of a Channel Attention (CA) module and a Semantic Feature Fusion (SFF) module, as illustrated in Fig. 4.

The Channel Attention (CA) module applies average pooling and max pooling to each channel's features, extracting the most relevant and average information for each channel. The pooled average and maximum results are combined, and the Sigmoid function calculates the weight for each channel. Finally, the weights are multiplied by the corresponding feature maps to filter redundant data. Additionally, a 1x1 convolution is used to adjust channel dimensions to 256, ensuring compatibility across different scales.

The Semantic Feature Fusion (SFF) module employs weights from higher-level characteristics to selectively integrate key semantic data derived from lower-level characteristics. The process includes: 1) applying a 3x3 transposed convolution with a stride of 2 to process higher-level features; 2) aligning the transposed higher-level features' dimensions with those of the lower-level features by the use of bilinear interpolation; 3) employing the CA module to convert higher-level features into weights; and 4) combining the optimized lower-level features with higher-level characteristics to improve the depiction of aspects. The specific definition is given in Eq. (2):

$$\begin{aligned} f_{att} &= BL(T - Conv(f_{high})) \\ f_{out} &= f_{low} * CA(f_{att}) + f_{att} \end{aligned} \quad (2)$$

Include among these $f_{high} \in R^{C \times H \times W}$, $f_{low} \in R^{C \times H_1 \times W_1}$. C is the number of channels, H and W are the height and width of the feature map, BL is the bilinear interpolation, and T is the transposed convolution.

However, HSFPN has limited capability in perceiving edge information, making it difficult to distinguish between early-stage weed growth and crops. To address this, we propose an Adaptive Hierarchical Feature Fusion Network (AHFPN), which significantly enhances the model's ability to handle multi-scale weed targets and enriches feature representations to improve detection accuracy across different weed growth stages. This module combines the concepts of HSFPN and PAN [31], with improvements tailored to different weed targets. The main process includes:

- 1) Adding a Conv2d layer to the P4 output to enhance the extraction of high-level semantic information.
- 2) The output of the P5 layer undergoes CA and a 1x1 Conv2d operation to extract key channel information and adjust weights.
- 3) The processed high-level features are weighted, multiplied by previously fused features, and then added together.
- 4) Finally, the fused features pass through the C3k2 module to further enhance feature extraction, resulting in more refined high-level semantic features.

E. LGCD

The detection head in YOLO11 identifies object locations and categories from the feature map. The process is as follows: In the position regression branch, two standard convolutions are used for feature fusion, followed by a convolution layer for location prediction; In the classification branch, depthwise separable convolutions [32] are used for feature fusion, followed by pointwise convolutions for channel-wise information

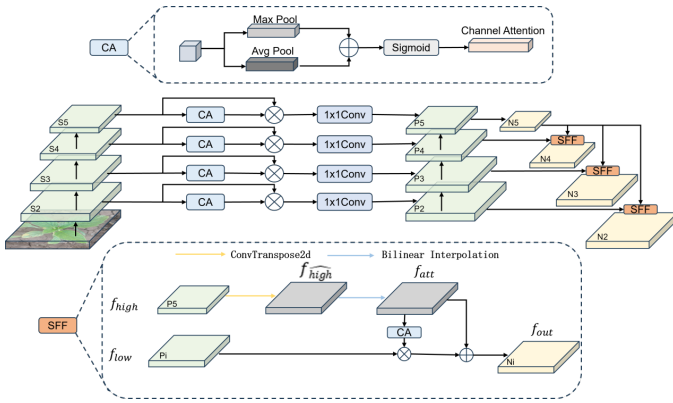

Fig. 4. HSPFN structure and diagram of CA and SF modules.

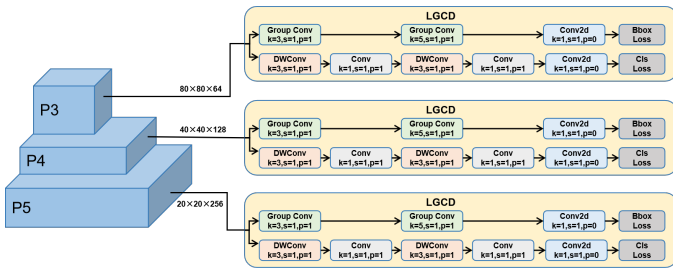

Fig. 5. LGCD structure.

interaction. Finally, a convolution layer performs classification prediction, with a Softmax activation function generating category probabilities. Although YOLO11 is significantly lighter compared to previous YOLO models, it still does not fully meet the real-time and multi-scale requirements for weed detection. Therefore, we propose the lightweight Grouped Convolution Detection Head module, as shown in Fig. 5.

The LGCD module is based on the concept of grouped convolutions, which improves the YOLO11 detection head. In this study, we replace the first two standard convolutions in the position regression branch of the YOLO11n detection head with grouped convolutions to reduce computation and parameter count, achieving the model. To minimize feature loss, we modify the kernel of the second grouped convolution to 5x5, ensuring lightweight while extracting multi-scale weed features and improving detection accuracy.

IV. EXPERIMENTAL RESULTS AND ANALYSIS

A. Datasets

CottonWeedDet3 [33] contains 848 RGB images captured in cotton fields in the southern United States, covering three common weed categories: Carpetweed, Morningglory, and Palmer Amaranth. The images capture various angles and natural lighting conditions, ensuring the dataset's diversity and relevance for application. The dataset construction process includes image acquisition, preprocessing, bounding box annotation, data cleaning, format conversion, and data augmentation. Experts manually annotated the images using the SuperAnnotate platform and converted them to the VIA format for further use. To improve data quality, low-quality annotations and out-of-focus areas smaller than 200x200 pixels

were cleaned, and erroneous labels were corrected. The final dataset contains 848 images and 1,532 bounding boxes, split into training, validation, and test sets in a 7:1:2 ratio. Fig. 6 shows an example image of the CottonWeedDet3 dataset.

Fig. 6. Example plot of CottonWeedDet3 dataset.

The CottonWeed2 [34] dataset contains 570 images, labeled into two categories: weeds and cotton. The weed category includes various plants, such as Wormwood, Common Sunflower, Chicory, Caltrop, Ginkgo, Castor Bean, Crabgrass, False Sea Purslane, and Amaranthus, reflecting the diversity of weed species. This diversity provides rich and complex samples for model training. Using digital cameras or cell-phones, the photos were taken from actual cotton fields in India and stored in.jpg format, which makes them extremely useful. To standardize data processing and adapt to model input, all images were resized to 416 x 416 pixels. This processing method facilitates model handling while reducing computational complexity. The dataset is divided into training, validation, and test sets in a 6:2:2 ratio. Fig. 7 shows an example image of the CottonWeed2 dataset.

Fig. 7. Example plot of CottonWeed2 dataset.

The CottonWeedDet12 dataset [35], collected at Mississippi State University Research Farm, includes 5,648 images and 9,370 bounding box annotations of 12 cotton weed species. Captured under natural light between February and October 2021 using smartphones or handheld cameras, the dataset spans diverse growth stages, lighting, weather, and field conditions to ensure complexity and diversity. The dataset was re-divided using a custom script into training, validation, and test sets at a 7:1:2 ratio. Fig. 8 presents example images from the public CottonWeedDet12 dataset.

Fig. 8. Example plot of CottonWeedDet12 dataset.

B. Experimental Configuration

The experiment was conducted on a Windows 11 operating system. The model architecture includes Python 3.8.19,

PyTorch 2.1.1, and TorchVision 0.16.1, with PyCharm as the integrated development environment. The CPU is an Intel i5-12400F, and the GPU is an Nvidia GeForce RTX 4060Ti (16GB) with 4352 CUDA cores, running CUDA version 12.1.

C. Experimental Parameter Setting and Evaluation Indicators

The model was trained for 300 epochs with a batch size of 8. The AdamW optimizer was used, with an initial learning rate of 0.01 and a momentum of 0.937. The input image size was 640×640. Multiple evaluation metrics were used to assess the effectiveness of this study, including Precision (P), Recall (R), Mean Average Precision (mAP), Parameters (Params), and Giga Floating Point Operations per Second (GFLOPs). The model's recognition performance was measured using IOU thresholds of 0.50 and 0.50:0.95. Params were used to measure the model's parameter count, and GFLOPs were used to measure its computational complexity. The specific definition is given in Eq. (3)-(8):

$$Precision = TP / (TP + FP) \quad (3)$$

$$Recall = TP / (TP + FN) \quad (4)$$

$$AP = \int_0^1 Precision(Recall) dR \quad (5)$$

$$mAP = \sum_{i=1}^N AP_i / N \quad (6)$$

$$GFlops = O \left(\sum_{i=1}^n K_i^2 * C_{i-1}^2 * C_i + \sum_{i=1}^n m^2 * C_i \right) \quad (7)$$

$$Params = O \left(\sum_{i=1}^n M_i^2 * K_i^2 * C_{i-1} * C_i \right) \quad (8)$$

TP represents genuine positives, FP represents false positives, and FN represents false negatives. $Precision$ and $Recall$ refer to the Precision-Recall curve. N represents the number of defects. O represents the constant order, K represents the kernel size, C represents the number of channels, M represents the input image size, and i represents the number of iterations.

D. Ablation Experiments

1) *CottonWeedDet3 ablation experiments*: To evaluate the performance of the LMS-YOLO11n model in weed detection, ablation experiments were conducted on the CottonWeedDet3 dataset, testing the C3K2_FastGLU, AHFPN, and LGCD modules separately. The results of the ablation experiments are shown in Table I. Compared to the baseline model YOLO11n, LMS-YOLO11n improves mAP50 by 2.5%, while reducing computational load and parameter count by 26% and 37%, respectively.

First, the optimization of C3K2 is discussed. By integrating the FastGLU designed in this study with C3K2, mAP50 increased by 0.9, while both computational load and parameter count were reduced by 6%. This suggests that the C3K2_FastGLU module enhances the model's ability to extract both local and global features of weeds.

Next, the improvement in the NECK section is discussed. After applying the designed AHFPN feature fusion module, mAP50 increased by 0.4%, while computational load decreased by 11% and parameter count by 26%. This demonstrates the effectiveness of the AHFPN module in enhancing weed edge features.

In the detection head, after applying the group convolution-based LGCD module, mAP50 increased by 2.3%, while computational load decreased by 17% and parameter count by 11%. This demonstrates that the LGCD module improves the detailed capture of multi-scale feature information, achieving an optimized balance between feature extraction diversity and model computational efficiency.

Finally, the effect of the cumulative modules was demonstrated. First, combining C3K2_FastGLU with AHFPN resulted in a 0.1% increase in mAP50, with computational load and parameter count decreasing by 0.14% and 32%, respectively. Adding the LGCD module further improved accuracy by 2.5%, while reducing computational load by 26% and parameter count by 37% compared to the baseline model.

2) *CottonWeed2 ablation experiments*: To validate the model's robustness, ablation experiments were conducted on the CottonWeed2 dataset. The results of the ablation experiments are shown in Table II.

Incorporating C3K2_FastGLU optimized the model's feature extraction capabilities. Compared to the baseline model, mAP50 increased to 75%, while computation (GFLOPs reduced from 6.3 to 5.9) and parameter size (reduced from 2.58 MB to 2.41 MB) decreased. This demonstrates that C3K2_FastGLU enhanced the model's ability to perceive fine-grained weed features and overall contextual information.

The inclusion of AHFPN significantly enhanced feature fusion capabilities, particularly for detecting multi-scale targets. Experimental results showed a mAP50 increase to 75.2%, a 0.7% improvement over the baseline model, with computation and parameter size reduced to 5.6 GFLOPs and 1.89 MB, respectively. This indicates that AHFPN optimized the model structure for selecting and fusing multi-scale features while maintaining computational efficiency.

LGCD focused on improving the fine-grained modeling of multi-scale feature information. Although incorporating this module slightly reduced mAP50 by 0.6%, it decreased computation and parameter size to 5.4 GFLOPs and 2.28 MB, respectively. This highlights its efficiency in reducing redundant computations and enhancing contextual feature fusion, making it well-suited for lightweight and edge device applications.

When C3K2_FastGLU, AHFPN, and LGCD modules were progressively combined, the model exhibited significant synergistic performance improvements. With all three modules combined, the model achieved 79.2% precision, a recall rate of

TABLE I. COTTONWEEDDET3 ABLATION EXPERIMENT TABLE

YOLO11n	C3K2_FastGLU	AHFPN	LGCD	P	R	mAP50	mAP50-95	GFLOPs	Params(MB)
✓				85.8	62.4	73.6	58.4	6.3	2.58
✓	✓			74.7	68	74.5	58.1	5.9	2.41
✓		✓		77.8	67	74	57.8	5.6	1.9
✓			✓	75.1	70.7	75.9	62	5.4	2.28
✓	✓	✓		78.6	68.5	74.6	57.8	5.2	1.73
✓		✓	✓	74	69.4	73.3	58.3	5	1.78
✓	✓	✓	✓	78.2	69.5	76.1	60	4.6	1.61

72%, a mAP50 of 76.4%, and a mAP50-95 of 51.2%, showing comprehensive improvements over the baseline model. Additionally, computation decreased to 4.6 GFLOPs and parameter size to 1.61 MB, demonstrating excellent lightweight performance and resource optimization.

Therefore, by comparing the ablation data from these two datasets, The LMS-YOLO11n model put out in this work may effectively extract the edges and fine-grained characteristics of weeds and meet the needs of deploying in various embedded weed detection devices with real-time requirements.

E. Comparison Experiments

1) *CottonWeedDet3 Comparison Experiments with the Latest Models:* To comprehensively evaluate the advantages of the proposed LMS-YOLO11n model, several state-of-the-art models, including YOLOv3-tiny, YOLOv5n, YOLOv6n, YOLOv7-tiny, YOLOv8n, YOLOv10n, and YOLO11n, were selected for comparison. The detection performance on the CottonWeedDet3 dataset is compared in Table III, where the bolded text indicates the greatest outcomes. Table III demonstrates that the improved LMS-YOLO11n model outperforms YOLOv3-tiny, YOLOv5n, YOLOv6n, YOLOv7-tiny, YOLOv8n, YOLOv10n, and YOLO11n. The LMS-YOLO11n model achieved a mAP50 of 76.1% and a mAP50-95 of 0.60% on the CottonWeedDet3 dataset, with a computational load of 4.6 GFLOPs and a parameter size of 1.61 MB. While improving accuracy, the model significantly reduced parameter size and computational load. Although the accuracy(P) slightly decreased, mAP50 increased by 2.5%, computational load decreased by 26% and parameter size reduced by 37%.

2) *CottonWeed2 Comparison Experiments with the Latest Models:* To further verify the generalization capability of LMS-YOLO11n, a comparative experiment was conducted on the CottonWeedDet2 dataset. Table IV presents the comparison results of the latest models on the CottonWeed2 dataset. The LMS-YOLO11n model achieved an mAP50 of 76.4%, and an mAP50-95 of 51.2% on the CottonWeed2 dataset, with a computational load of 4.6 GFLOPs and a parameter size of 1.61 MB. Compared to YOLOv3-tiny, YOLOv5n, YOLOv6n, YOLOv7-tiny, YOLOv8n, YOLOv10n, and YOLO11n, LMS-YOLO11n achieved mAP50 improvements of 8%, 3.1%, 3.0%, 1.3%, 3.1%, 8.4%, and 1.9%, respectively. Additionally, the computational load decreased by 67%, 35%, 60%, 65%, 43%, 28%, and 26%, while the parameter size reduced by 83%, 35%, 61%, 86%, 46%, 21%, and 37%, respectively. These results demonstrate that LMS-YOLO11n achieved the best performance in terms of mAP50, computational load, and parameter size.

3) *CottonWeedDet12 Comparison Experiments with the Latest Models:* In this paper, comparison experiments are also conducted on the CottonWeedDet12 dataset to further validate the robustness of the LMS-YOLO11n model. The relevant comparison data are shown in Table V. Table V demonstrates the performance comparison of multiple models on the CottonWeed12 dataset, and LMS-YOLO11n stands out in terms of comprehensive performance. YOLOv3-tiny, although having a mAP50 of 91.7%, has a computational and parametric count of 14.3 GFLOPs and 9.52 MB, respectively, which is the model with the highest consumption of computational resources in the table, restricting its application on resource-constrained devices. YOLOv5n and YOLOv6n are optimized in terms of computation volume of 7.1 GFLOPs and 11.5 GFLOPs and number of parameters of 2.5 MB and 4.15 MB, respectively, but their mAP50 values of 92.5% and 90.7% are slightly lower than that of the LMS-YOLO11n. YOLOv7-tiny's mAP50 of 92.7% is still high, but its 13.3 GFLOPs of computation and 12.3 MB of parameter count are similar to that of YOLOv3-tiny. YOLOv8n further optimizes the parameter count and computation with a mAP50 of 92.3%, with values of 3 MB and 8.1 GFLOPs, respectively, but is still not as light as that of LMS-YOLO11n. YOLOv10n and YOLO11n, as more advanced models, exhibit mAP50s of 93% and 93.6%, with their computational and parametric quantities reduced to 6.4 GFLOPs and 6.3 GFLOPs and 2.04 MB and 2.58 MB, respectively. The LMS-YOLO11n, with the minimum computational quantity of 4.6 GFLOPs, and the LMS-YOLO11n achieve the same mAP50 as the YOLO11n with a minimum number of parameters of 1.62 MB. Taken together, the LMS-YOLO11n achieves an optimal balance between performance, efficiency, and lightness with a mAP50 of 93.6%, several parameters of 1.62 MB, and a computation volume of 4.6 GFLOPs, making it suitable for complex field environments and resource-constrained edge device scenarios.

F. Model Detection Effect and Visualization Analysis

The improved LMS-YOLO11n demonstrates excellent detection performance, providing accurate and comprehensive weed recognition under various environmental conditions. HiResCAM [36] was used to perform visualization analysis on the CottonWeedDet3 and CottonWeed2 datasets. In the images, darker colors indicate higher attention, while lighter colors represent lower attention, as shown in Fig. 9 and Fig. 10.

Fig. 9 and Fig. 10 show that both LMS-YOLO11n and YOLO11n can identify and locate target areas dominated by weed structures. However, compared to YOLO11n, LMS-YOLO11n reduces false detections and more accurately focuses on the actual weed shapes. Specifically, YOLO11n

may be affected by morphological similarities and lighting variations in complex field environments, leading to scattered feature capture and reduced target localization accuracy. In contrast, LMS-YOLO11n, with its lightweight design and optimized feature extraction modules, effectively suppresses environmental noise and significantly enhances target feature extraction accuracy. It shows a stronger ability to differentiate when weeds and crops have similar morphologies. This demonstrates the superiority and reliability of LMS-YOLO11n for efficient weed detection in complex field scenarios.

V. CONCLUSION AND FUTURE WORK

A. Conclusion

This study introduces LMS-YOLO11n, a novel lightweight weed detection network designed for precision agriculture on edge devices and in complex field environments. The network leverages innovative structural designs to enhance detection accuracy and computational efficiency, making it especially suitable for resource-constrained edge devices.

In the feature extraction phase, LMS-YOLO11n replaces the traditional C3K2 module with the C3K2_FastGLU module, integrating partial convolution and CGLU mechanisms to extract fine-grained weed features more effectively. Compared to traditional convolution methods, FastGLU uses channel-level weighting to enhance sensitivity to fine details, enabling more precise differentiation between weeds and crops in complex field environments. For feature fusion, the study introduces the Adaptive Hierarchical Feature Pyramid Network (AHFPN), which optimizes feature selection and fusion to improve multi-scale weed detection capabilities. AHFPN effectively integrates multi-scale feature maps, enhancing weed detection and preventing the loss of small-scale target information, thereby improving detection accuracy. To boost model efficiency,

LMS-YOLO11n replaces the traditional detection head with the lightweight LGCD module. LGCD, designed with group convolutions, reduces parameter and computation requirements while maintaining high detection accuracy, making it ideal for low-power edge devices capable of efficient real-time weed detection.

LMS-YOLO11n demonstrates superior performance across three datasets. On the CottonWeedDet3 dataset, the model achieved a mAP50 of 76.1%. On CottonWeed2, it reached 76.4%, while on CottonWeedDet12, it achieved 93.6%, reducing computation and parameter sizes by 26% and 37%, in contrast to the baseline model, correspondingly. These results demonstrate that LMS-YOLO11n achieves high-precision detection in complex environments and is deployable on edge devices, providing accurate real-time agricultural monitoring solutions.

B. Future Work

Despite the significant results, the proposed model has some limitations:

- 1) Lack of experiments and deployments in real-world agricultural scenarios. Real agricultural environments involve variations in weed types, densities, and growth states, requiring further validation of the model's performance under these conditions.
- 2) Detection accuracy for young weeds needs improvement. The simple morphology and texture of young weeds often confuse with the background or crops, leading to limited detection accuracy.

To address these issues, this paper will explore multimodal fusion techniques in future research to solve the challenges of young weed detection. By fusing different types of data sources, it can provide richer feature information for the model and help it recognize young weeds more accurately. Meanwhile, more field experiments are planned to be conducted in combination with practical agricultural application scenarios to test the performance of the model in different environments, to further improve its adaptability and accuracy, and to provide more effective solutions for precision agriculture.

Abstract—Object detection based on drone platforms is a valuable yet challenging research field. Although general object detection networks based on deep learning have achieved breakthroughs in natural scenes, drone images in urban environments often exhibit characteristics such as a high proportion of small objects, dense distribution, and significant scale variations, posing significant challenges for accurate detection. To address these issues, this paper proposes a dual-branch object detection algorithm based on YOLOv8 improvements. Firstly, an auxiliary branch is constructed by extending the YOLOv8 backbone to aggregate high-level semantic information within the network, enhancing the feature extraction capability. Secondly, a Multi-Branch Feature Enhancement (MBFE) module is designed to enrich the feature representation of small objects and enhance the correlation of local features. Third, Spatial-to-Depth Convolution (SPDConv) is utilized to mitigate the loss of small object information during downsampling, preserving more small object feature information. Finally, a dual-branch feature pyramid is designed for feature fusion to accommodate the dual-branch input. Experimental results on the VisDrone benchmark dataset demonstrate that DBYOLOv8 outperforms state-of-the-art object detection methods. Our proposed DBYOLOv8s achieve mAP@0.5 of 49.3% and mAP@0.5:0.95 of 30.4%, which are 2.8% and 1.5% higher than YOLOv9e, respectively.

Keywords—Drone images; dual-branch; small object detection; YOLOv8

I. INTRODUCTION

With the development of hardware and artificial intelligence, drones have been gradually applied to intelligent transportation, agricultural monitoring, fire rescue and other fields. In urban traffic monitoring and urban combat missions, UAVs (unmanned aerial vehicle) play an important role by virtue of their advantages such as fast flight speed, high degree of freedom, broad vision and strong adaptability. However, the streets in the city scene have the characteristics of traffic congestion, dense people, and a wide variety of targets. In addition, due to the high-altitude flight of UAV, objects in UAV images are often too small in size and contain limited feature information, which makes it difficult for the network to extract effective features and easy to be lost in the propagation process across the feature layer [1]. In addition, the size of similar objects varies so much that it is difficult for universal object detection methods to effectively locate and identify these objects [2].

Uav object detection is one of the branches of general target detection. According to the processing flow, the target detection algorithm can be divided into two stages and one stage. The two-stage algorithm is characterized by generating a series

of regions of interest, and then classifying and regressing these regions. Its advantage is that the two-stage detection algorithm is more detailed, resulting in higher detection accuracy. The disadvantage is that the inference speed is slower than that of single-stage algorithms. The two-stage representative algorithms include Faster R-CNN [3] and Mask R-CNN [4]. The single-stage algorithm extracts the feature information of the target by convolutional neural network, generates the candidate frame, and classifies and locates the target. This detection method consumes less computer resources during inference, and UAV target detection is usually improved based on single-stage algorithm. Single-stage representative algorithms include SSD [5] and YOLO series [6]. YOLOv8 is a commonly used single-phase detection framework, which is often used for various object detection tasks [7]. Its advantage is that the framework is mature, the externally adapted function library is more common, and a variety of inference accuracy improvement tools can be used directly. However, the objects in UAV images often have problems such as small size, complex background environment, and dense area overlap, which limits the ability of the frame to detect small objects. Secondly, the framework is still weak in detecting similar objects at different scales. Therefore, it is necessary to improve the YOLOv8 algorithm to make it suitable for UAV small object detection.

This paper presents a dual-branch small object detection algorithm based on YOLOv8. Firstly, a composite strategy is used to construct auxiliary branches, and the multi-layer semantic information is comprehensively utilized to improve the feature extraction capability of the framework. Second, a multi-branch feature enhancement module is designed, which uses convolution check of different sizes for parallel processing of small object feature information to improve the representation ability of object feature information. In addition, SPDConv can effectively reduce the loss of feature information in the transmission process, which is very effective for small object detection. When it is embedded in the shallow detection branch of the network, the false detection problem can be well improved. Finally, a dual-branch feature pyramid is constructed to deal with the multi-scale change of the target. Experimental results show that the proposed algorithm greatly improves the performance of object detection and can better cope with the requirements of different tasks on model size. Our main improvements and advantages are as follows:

- C2f module is used to construct auxiliary branch, which aggregate multi-high-level semantic information and enhance the feature extraction ability of small objects. SPDConv [13] is used to alleviate the loss of

feature information in the downsampling process.

- Multi-branch Feature Enhancement Module (MBFE) is designed to extract small object feature information by using parallel branches of different convolution kernel sizes, which can realize the diversification of small objects feature information expression.
- Dual-branch feature pyramid network (DBFPN) is established for cross-layer connection with YOLOv8 backbone to compensate for information loss caused by feature information transformation.

The structure of this paper is as follows: In Section II, we will briefly introduce our related work to improve the thinking. In Section III, we take a detailed look at the dual-branch YOLOv8 framework. In Section IV, we conduct experiments on a classical drone dataset and provide a detailed analysis of the results. In Section V, we analyze the existing shortcomings and the continued exploration of future work.

II. RELATED WORK

In object detection, the size of the object can be divided into absolute scale and relative scale according to the definition. In the definition of relative scale [8], usually the relative area of all object instances in the same category, that is, the median ratio of the boundary box area to the image area is between 0.08% and 0.58%. However, the way to define small objects based on absolute scale is more widely used, and the MS COCO dataset [9] defines small targets as those with a resolution less than 32 pixels by 32 pixels. The existing methods to solve the small object detection of UAVs can be classified into three categories: (1) By enhancing the feature information of small objects, the network can locate the objects more clearly. (2) Improve the detection accuracy of small objects by improving the ability of network feature extraction. (3) Adopt multi-scale detection strategies to deal with small objects of different sizes.

To improve the ability of network feature extraction, Liang et al. [10]. proposed CBNetV2 network, which uses shallow network to aggregate different high-level semantic information, aiming to enhance the comprehensive application of feature texture features by the model. In addition, they demonstrated experimentally that small objects can be detected more efficiently when shallow features are aggregated only with feature layers higher than this one. This work pioneered the concept of composite backbone networks. Wang et al [11]. proposed Yolov9, the representative of YOLO series, and designed a Programmable Gradient Information (PGI), which uses the characteristics of reversible architecture to retain more input information, thereby reducing the loss of small target feature information. In this framework, the composite backbone network is also constructed. Yan et al. [12]. propose an HCB network that includes a detail extraction backbone (DEB) designed with a smaller acceptance field to better capture details of small objects. This design enhances feature representation without compromising spatial information. However, the above method only uses a single strategy, and because more parameters are often introduced in order to obtain more gradient information, the computational complexity increases and the practical application is limited.

For the enhancement of small object feature information, the detection accuracy of the network can be improved by improving the feature representation of the network for small object and reducing the problem of the loss of small object feature information. Zhang et al. [13]. developed a feature enhancement module specifically for aerial image detection, using the improved FFM module to further capture the context information of small objects, thereby improving the detection accuracy. Raja et al. [14]. designed a step-free convolution to solve the problem of information loss caused by different interpolation calculations for small objects through this lossless downsampling method, thus improving the network's ability to perceive small objects. However, the improved method has been proved by experiments that the network pays too much attention to texture information when applied equally in each feature layer, which leads to the decrease of detection accuracy.

In order to cope with targets of different sizes, Tsung et al. [15]. proposed the concept of feature pyramid. By connecting shallow texture information and high semantic information from top to bottom, the object feature information of each detection layer is enriched. On this basis, Liu et al. [16]. added a new bottom-up path that preserves more detailed information, which is also effective for multi-scale small objects. Tan et al. [17]. used a weighted feature fusion mechanism to give each input feature path a learnable weight, allowing the network to automatically adjust the importance of each path, thus making more efficient use of feature information. By removing invalid nodes and reusing features, the computational cost is reduced, making it suitable for resource-constrained devices. However, the processing method of feature pyramid is only suitable for a single backbone, and for multi-branch networks, the conventional feature pyramid will dilute the target feature information in the concatenation operation.

Although the existing improvement methods have continuously improved the UAV target detection performance, the existing network architecture is still difficult to achieve high precision and multi-task adaptation, especially for the dense area detection problem in the urban scene, and it is urgent to further improve the detection accuracy. Therefore, a variety of improvement methods should be comprehensively used to enhance the detection ability of the detection network for UAV images.

III. DBYOLOv8 ALGORITHM

A. Overview of YOLOv8

YOLOv8 is an object detection framework based on single-stage deep learning. Compared with the existing version of YOLO series, YOLOv8 can adjust the size of the model by adjusting the scale factor to adapt to different task requirements. Compared to YOLOv10 [18] and YOLOv11, YOLOv8 framework is more mature and has many existing tools to assist reasoning. YOLOv8 network structure is mainly divided into three parts: (1) Backbone network for extracting object feature information. (2) Processing multi-scale features of the feature pyramid pool layer. (3) The detection head of the classification object type information. Fig. 1 shows the schematic diagram of the YOLOv8 algorithm framework. The backbone network extracts the feature information of the object by using the convolution layer of step by step downsampling. The excellent

feature extraction ability is the basis of realizing the high-precision object detection algorithm. Path Aggregation-FPN (PAFPN) structure is introduced into the neck structure, and the feature mapping of different scales is combined to enhance the ability of the algorithm to recognize objects of different sizes. The head layer is the main decoupling head structure, which separates the classification and detection head, and becomes the Anchor-Free detection scheme. The YOLOv8 algorithm is widely used in many fields (for example, agricultural inspection, UAV object detection and autonomous driving). However,

Fig. 1. Simplified diagram of YOLOv8 network structure.

the performance of the baseline YOLOv8 is not optimal, and there is no targeted design for small objects. In addition, YOLOv8 does not fully combine shallow features and deep features, so that the feature information of small targets is seriously lost in the process of feature transmission. Therefore, the general object detection algorithm framework YOLOv8 is not suitable for small object detection tasks of UAVs. In order to meet the higher task requirements of UAVs for object detection algorithms, it is necessary to improve the existing algorithms by task driving.

B. Overall Structure of the Optimized DBYOLOv8 Network

In the improved dual-branch YOLOv8 object detection algorithm, taking YOLOv8 as the benchmark model, three aspects of backbone network structure, feature enhancement module and multi-scale feature fusion are optimized and improved. Fig. 2 shows the optimized two-branch YOLOv8 backbone network structure. In the feature extraction stage, this paper designed an auxiliary branch to aggregate the target

features of different feature layers. Inspired by the auxiliary branch constructed by CNet and YOLOv9, the auxiliary branch based on YOLOv8 structure was constructed by using C2F module, which can adjust the size of the model. Based on this method, the constructed DBYOLOv8 model can adapt to the model size requirements of different tasks, and the DBYOLOv8 network model is smaller at the same level of detection accuracy. Feature layer scales the feature map to a fixed size by interpolation, and the small object feature information will be lost in the process of transferring between feature layers. By introducing SPDConv in the shallow layer of the trunk and branches, the problem of small object information loss is alleviated by splitting and reassembling. In addition, EMA [19] module with parallel structure and CBLinear structure are combined to extract small object feature information through different receptive fields of parallel branches. This combination forms MBFE module, does not introduce additional parameters, diversifies the small target feature information, and enhances the generalization ability of the model. The double branch feature pyramid is improved based on BiFPN. By fusing the two-branch feature input with feature weighting, the structure can fuse multi-scale features in the neck network and enhance the model's ability to recognize targets of various sizes and shapes.

C. Auxiliary Branch

In the process of feature extraction, the feature information of small objects is lost or offset to a certain extent with the reduction of the feature map size and the calculation method of interpolation. It constitutes a unique phenomenon, shallow feature is close to the input layer and contains richer texture information, while the deep feature has a larger receptive field and contains more semantic information after multiple convolution. The integrated use of shallow and deep feature can effectively improve the network detection performance [20].

Inspired by CNetV2, the PGI proposed by YOLOv9 framework builds its auxiliary branch by combining multilevel high-level feature information with shallow feature, hoping to enhance the feature representation capability of the backbone. However, the RepNSCPELAN module is designed to capture

Fig. 2. Our improved DBYOLOv8 feature extraction structure.

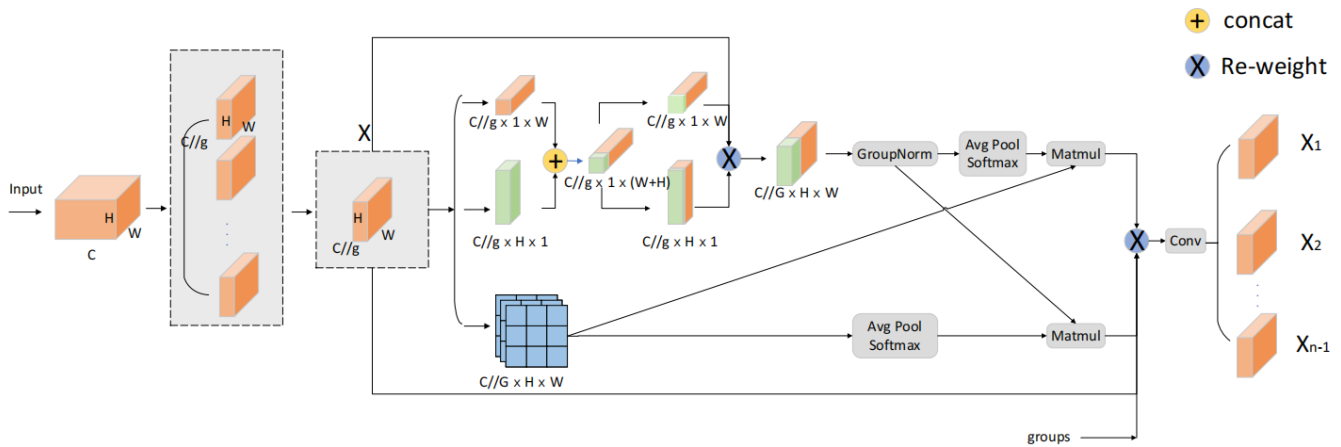

Fig. 3. Multi branch feature enhancement module.

a richer flow of gradient information, which in turn greatly increases the number of model parameters. And it can not adjust the size of its model through scaling factors, making it difficult to adapt to the needs of multiple tasks. In order to improve the feature extraction ability of the framework for small objects without increasing the model size, we built a similar auxiliary branch based on YOLOv8 framework. We use the C2f module to obtain the feature gradient information and the scaling factor to adjust the size of the model to adapt to the task requirements of different platforms.

D. Multi-branch Feature Enhancement Module

The feature information of small objects in UAV images in urban scenes is less, but the background information is complex. Background will seriously affect the extraction of object feature information, which leads to confusion in the transfer process of feature information, thus affecting the performance of the detector. To alleviate this problem, YOLOv9 uses the CBLinear module to process the feature information extracted from the backbone. However, CBLinear module uses the full connection layer to process feature information, which is not friendly for small objects. And it is easy to dilute the feature information of small objects in the process of feature flow, resulting in a certain degree of feature extraction ability loss [21]. Based on the above problems, we design the MBFE module to diversify the small object feature representation.

Channel or spatial attention have been shown to be remarkably effective in producing more recognizable feature representations in various computer vision tasks. In order to diversify the feature information of small objects, we introduced EMA attention mechanism. This mechanism employs multi-branch feature extraction operations, where feature maps are processed in parallel through 1×1 and 3×3 branches. By leveraging different receptive fields, it captures the feature information of small objects and further aggregates the output features of these parallel branches through cross-dimensional interactions to capture pixel-level pairwise relationships. Subsequently, operations such as channel number adjustment and segmentation are performed to obtain a list of multiple output feature maps, which are suitable for subsequent feature aggregation

requirements. The designed MBFE module is illustrated in Fig. 3.

E. SPDConv Module

SPDConv proposed by Sunkara et al. is a lossless downsampling method specifically designed for low-resolution images and small objects. Traditional downsampling techniques, such as strided convolutions and pooling layers, often result in the loss of fine-grained information when dealing with low-resolution images or small objects. To address this issue, SPDConv introduces a lossless downsampling method to segment the input image and splicing the input image in the channel dimension so as to retain the input image feature information. After this operation, the convolution layer with stride=0 is used for feature extraction, and the fine-grained details of the image are retained because the size of the feature map is not changed. This approach significantly mitigates the problem of small object loss during the feature extraction phase. We only applied SPDConv during the initial downsampling stages, as deeper features, after multiple convolution operations, have already become highly ambiguous in terms of small object location information. Using SPDConv for downsampling at these deeper stages could negatively impact the detection network [22]. The specific addition location is illustrated in Fig. 1.

F. Dual-branch Feature Pyramid Module

BiFPN removes connection layers that are not intended for fusion and employs a bidirectional weighted strategy to update gradients. Our designed DBFPN is based on BiFPN and is adapted for a dual-branch backbone design. Although the auxiliary branch is constructed based on the yolov8 backbone, after multiple convolutional operations, there is a slight deviation in the mapping of small object feature information and the original image object information. Therefore, incorporating the main branch feature layer information during the construction of the feature pyramid is beneficial for comprehensively utilizing the feature extraction capabilities of both branches. For small object feature information, we have added a P2 detection layer and, considering the need to control the number of

Fig. 4. Dual branch feature pyramid module.

parameters, removed the P5 detection layer [23]. Our designed DBFPN is illustrated in Fig. 4.

IV. EXPERIMENTAL VALIDATION AND ANALYSIS

A. Dataset Analysis

In this study, the VisDrone2019 [24] drone object detection dataset, which can represent urban scenes, was used to test the detection performance of DBYOLOv8 on various types of small objects in drone images. The dataset comprises 6,471 images for training and 548 images for validation, with annotations for 10 types of objects, including pedestrians, cars, motorcycles, and others. An analysis of the training set revealed that small objects constitute approximately 60% of the dataset based on their relative scale. Specifically, the dataset categorizes objects as follows: extremely small (es) objects with a length*width in the range [0, 144], relatively small (rs) objects with dimensions in the range [144, 400] pixels, and generally small (gs) objects with sizes in the range [400, 1024] pixels [25]. Given that the dataset was collected using a drone platform, it is particularly well-suited for assessing the performance of the DBYOLOv8 model in detecting small objects from a drone's perspective. Examples of target statistics are shown in Fig. 5.

In order to verify the generalization of our proposed method, a comparative test was also performed on our AI-TOD dataset [26]. AI-TOD dataset is a representative dataset for the detection of tiny objects in aerial images. The dataset contains 28,036 images labeled with a total of 700,621 instances across eight categories (aircraft, Bridges, tanks, ships, swimming pools, vehicles, people, windmills). Compared with other aerial image datasets of the same type, the average size of the object in this dataset is 12.8 pixels, which is much smaller than the object instances in other datasets. Therefore, it is a good way to evaluate the model's perception of small scale objects.

B. Experimental Condition and Assessment Metrics

The experiment was trained and verified on the research group server. The hardware system consists of the following parts: Intel i9 series 13th generation processor I9-13900KF, RTX4090 (24G) graphics card, 64G memory. The software

system uses Ubuntu22.04 operating system, and uses Pytorch framework to realize all the algorithms running and improving. For comparison with other algorithms, the input image is set to 640 × 640 pixels and the epoch is set to 200 rounds. The other Settings are the default Settings for the YOLOv8 project provided by the ultralytics team.

To evaluate the algorithm's detection performance on objects in drone images, precision (P), recall (R), mAP@50 and mAP@50:95 were used as evaluation indexes. True positive (TP), false negative (FN), false positive (FP) and true negative (TN) were used as anchor frame positioning quality evaluation. Precision Indicates the percentage of the predicted positive samples that are actually positive. The calculation formula is:

$$precision = \frac{TP}{TP + FP} \quad (1)$$

Recall indicates the proportion of the actual number of positive samples in the total positive samples in which the prediction result is positive. The calculation formula is:

$$recall = \frac{TP}{TP + FN} \quad (2)$$

AP is the Average Precision, which is simply to average the precision value on the PR curve. For the pr curve, we use the integral to calculate. The calculation formula is:

$$AP = \int_0^1 p(r)dr \quad (3)$$

mAP is an evaluation index associated with Intersection over Union (IoU), which averages the detection accuracy of all categories. When IoU is set to 0.5, it is usually used as an evaluation index of the detection accuracy of the universal target. mAP@50:95 indicates the mAP with the IoU threshold ranging from 0.5 to 0.95 and the step size of 0.05. Then the average value is obtained. It can also reflect the performance difference of detection algorithms for objects at different scales.

C. Ablation Study

To validate the detection capability of our proposed model for small objects, we constructed auxiliary branches on the basis of the YOLOv8s model, incorporating the SPDconv module, MBFE module, and DBFPN module to build the DBYOLOv8s model. We set the image size to 1280x1280, which is close to the original image size and better reflects the object detection performance of our model on this dataset. The ablation experiment results are shown in Table I. Under the same parameter settings, our method significantly improves the object detection capability for drone images.

1) *Effect of auxiliary branches*: Small objects occupy a high proportion in drone images and contain limited feature information. To enhance the backbone's ability to extract features from small targets, we constructed an auxiliary branch using the SPDConv module, CBFuse module, and C2f module. By aggregating high-level semantic information from layers not lower than the current one, we enriched the feature information of small targets. Compared to the baseline model, the results for mAP@0.5 and mAP@0.5:0.95 improved by 4.7% and 3.5%, respectively.

Fig. 5. VisDrone train dataset.

TABLE I. ABLATION STUDY

Baseline	Auxiliary Branch	DBFPN	SPDConv	MBFE	mAP@50(%)	mAP@50:95(%)	Params
✓					56.3	35.4	10.6
✓	✓				61.0	38.9	20.2
✓	✓	✓			61.0	39.0	23.3
✓	✓	✓	✓		61.7	39.5	24.0
✓	✓	✓	✓	✓	62.1	39.9	24.0

2) *Effect of DBFPN module:* We understand that the feature information after multiple convolutions differs from the original feature information. Moreover, the flow of feature information across layers can result in some information loss. Therefore, our proposed DBFPN integrates dual-branch feature information through skip connections, which improves mAP@0.5:0.95 by 0.1%.

3) *Effect of SPDConv module:* Small objects may experience varying degrees of feature information loss during the downsampling process due to differences in interpolation methods. As mentioned above, SPDConv can alleviate the issue of feature information loss caused by downsampling in low-resolution images. However, if SPDConv is uniformly applied to replace every downsampling step, it can negatively impact detection performance. This is because, in deeper layers of the network, small objects have less feature information, and the feature information of larger objects is diluted by SPDConv, leading to missed detections. We conducted three sets of experiments: one with SPDConv added to all layers, one with SPDConv added only in the shallow layers, and one with SPDConv added only in the deep layers. The detector achieved the best performance when SPDConv was added only in the shallow layers, as verified by the experiments shown in Table II.

4) *Effect of MBFE module:* The feature information of small objects is processed through parallel branches, allowing

the extraction of target information using convolution kernels of different sizes. This method of enhancing small object features effectively diversifies the representation of small object feature information, thereby enhancing the network's feature extraction capabilities. Compared to the CBLinear module that solely employs fully connected layers, this approach improves mAP@0.5 and mAP@0.5:0.95 by 0.4% without introducing additional parameters.

TABLE II. COMPARISON RESULT OF DIFFERENT SPDConv ADDITION POSITIONS ON THEVISDRONE2019 VALIDATION DATASETS. THE BEST RESULT IS HIGHLIGHTED IN BOLD

Method	mAP@50(%)	mAP@50:95(%)
P1 - > P3	61.1	39.2
P3 - > P5	60.1	38.4
P1 - > P5	60.9	39.0

D. Comparison with State-of-the-Arts

Due to the varying size constraints for tasks across different platforms, we designed two DBYOLOv8 models of different sizes based on the YOLOv8s and L models. The scaling factors for the DBYOLOv8s model are [0.35, 0.50], while those for the DBYOLOv8L model are [1.00, 1.00]. We compared DBYOLOv8 with other widely used object detection algorithms (primarily the s and l models of various object detection

TABLE III. COMPARISON RESULTS OF DIFFERENT OBJECT DETECTORS ON THEVISDRONE2019 VALIDATION DATASETS. THE BEST RESULT IS HIGHLIGHTED IN BOLD

Method	Inputsize	mAP@50(%)	mAP@50:95(%)	Params(M)	FLOPs(G)
RetinaNet[27]	1333*800	39.3	21.8	-	524.95
Faster-RCNN	1333*800	43.6	24.8	-	322.25
YOLOv5-s[28]	640*640	32.2	17.5	7.2	16.5
TPHYOLOv5-s[29]	640*640	37.4	21.7	-	-
YOLOv8-s	640*640	37.3	22.1	11.1	28.5
Drone-YOLO[30]	640*640	44.3	-	10.9	-
yolov10s	640*640	41.2	24.8	8.0	24.5
YOLOv11s	640*640	41.6	25.2	9.4	21.3
HIC-YOLO[31]	640*640	44.3	26.0	-	-
YOLOv5-l	640*640	42.9	26.3	46.5	109.1
YOLOv8l	640*640	43.7	26.7	43.6	165.4
TPHYOLOv5-l	640*640	41.8	24.0	-	-
YOLOv8-x	640*640	44.3	27.2	68.2	258.5
YOLOv9e	640*640	46.5	28.9	57.3	189.0
DBYOLOv8-s	640*640	49.3	30.4	24.0	119.8
DBYOLOv8-l	640*640	54.4	34.3	175.7	877.0

frameworks). The results, as shown in Table III, indicate that DBYOLOv8 achieved the best and second-best results in terms of mAP. Compared to YOLOv8l and YOLOv9e, DBYOLOv8s achieved higher mAP@50:95 values by 3.7% and 1.5%, respectively, but with significantly fewer parameters. DBYOLOv8 demonstrated superior performance in small object detection compared to other methods, and the experimental results confirm the competitive advantage and effectiveness of this approach.

To verify the effectiveness of the proposed method in identifying complex backgrounds, significant scale differences, and densely packed small objects, we provide visual examples of DBYOLOv8s and YOLOv8l in Fig. 6. In the first line of the image, the vehicles on the far side of the street are extremely small in size. Carefully examining the red box, it is clear that YOLOv8l cannot fully recognize these extremely small objects, while our proposed method also has certain detection accuracy for extremely small objects. The second line of images taken by the drone from a low altitude Angle shows that the green box shows that YOLOv8l missed the target, and the blue box shows that the method incorrectly identified the person as a motorcycle. In contrast, our proposed approach is not affected by these factors. The observations show that our proposed method shows significant advantages over other methods in processing images of this nature.

In order to verify the detection ability of the method for small targets and its generalization on other datasets, we conducted training and inference experiments on AI-TOD datasets using the same parameters. Compared with the mainstream YOLO improved algorithm and DERT improved algorithm, our proposed DBYOLOv8s has undoubtedly obtained the best detection results. Experimental results are shown in Table IV. Compared with YOLOv8l, the proposed algorithm at mAP@50:95 improves by 1.2%. Compared with other algorithms, our method also has obvious advantages.

Compared with the VisDrone dataset, the AI-TOD dataset has more small object instances, which indicates that our method will improve the detection accuracy if there is more sufficient data support. These results across different datasets underscore the robustness and effectiveness of the proposed method.

TABLE IV. COMPARISON RESULTS OF DIFFERENT OBJECT DETECTORS ON AI-TOD VALIDATION DATASETS. THE BEST RESULT IS HIGHLIGHTED IN BOLD

Method	mAP@50(%)	mAP@50:95(%)
YOLOv6[32]	42.2	18.4

RT-DETR	48.9	22.7
YOLOv10b	46.7	21.6
YOLOv9c	45.8	20.3
DBYOLOv8-s	55.2	23.2

V. CONCLUSION

In order to meet the requirements of existing algorithm frameworks for UAV small object detection, we propose a dual-branch YOLOv8 small object detection algorithm. Firstly, we construct auxiliary branches with compound strategy, combine shallow feature information and higher level semantic information, and increase the feature extraction capability of detection network for small objects. Second, in order to enhance the feature representation of small objects, a multi-branch feature enhancement module is designed to extract the feature information of small objects in parallel through features of different convolution kernel sizes. This module can effectively diversify the representation of small object feature information and counter the problem of the loss of feature information in the process of transmission. Third,

Fig. 6. Comparison of testing results. (a) Original image. (b) YOLOv8l detection results. (c) Our DBYOLOv8s detection results.

we replace the original subsampling with SPDConv in the shallow layer of the network, and maximize the retention of object feature information through recombination and splicing operations, reducing the missing problem caused by the loss of small and medium-sized object feature information during the subsampling process. Secondly, in order to deal with the contact deviation between the feature information and the original image information caused by multiple convolution, we construct a dual-branch feature pyramid to comprehensively use the double-branch feature information to solve the problem of object scale change in the UAV image. Finally, in addition to using the VisDrone dataset, we also used the AI-TOD dataset to evaluate our proposed approach. The effectiveness of our proposed method is verified by experiments. Compared with the basic YOLOv8s, the DBYOLOv8s algorithm proposed in this paper has increased mAP@50 by 12% and mAP@50:95 by 8.3% on the VisDrone dataset, demonstrating excellent performance compared with other object detection algorithms. On AI-TOD dataset, experimental results validate the generalization of our proposed algorithm, and further prove that our proposed algorithm has higher detection accuracy for small objects if there is more sufficient data support. In addition, the DBYOLOv8l built by us based on YOLOv8l has higher detection accuracy, but the model is larger, which is suitable for tasks with higher detection accuracy supported by high-performance computers. Combined with the existing algorithm foundation and research direction, our future research will focus on the following aspects to tackle difficulties: 1. Explore lightweight technology, reduce model parameters by replacing lightweight backbone or model pruning technology, so that the algorithm can be deployed on embedded devices with low power consumption in the future. 2. Research on small object loss function positioning technology, so that the model can improve the positioning accuracy of dense small objects under complex background. 3. Explore the feature description of different architectures for small objects, and combine the dual-branch idea with CNN architecture and Transformer architecture to further improve the detection accuracy of small objects.

Abstract—Parallel semantic reasoners use parallel architectures to improve the efficiency of reasoning tasks. Studies in semantic reasoning rely on manual tuning to configure the degree of parallelism. However, manual tuning becomes increasingly challenging as ontologies become massive and complex. Studies in related fields have developed automatic tuning frameworks using optimization search methods. Although these methods offer performance gains, reducing search time and space size is still an open problem. This study aims to bridge the gap in semantic reasoning and the problem in existing search methods. To achieve these aims, we propose Eagle Framework (EF), an innovative automatic tuning framework designed to improve the performance of parallel semantic reasoners. EF automatically configures the degree of parallelism and calculates the performance data. It incorporates a novel search space and algorithm, inspired by the AVL tree, that efficiently identifies the optimal degree of parallelism. In a case study, EF completed the tuning processes in seconds to a few minutes, achieving performance gains up to 65 times faster than common search methods. The reliability findings, with ICC scores ranging from 0.90 to 0.99, confirmed the consistency of the performance data calculated by EF. The regression analysis revealed the effectiveness of EF in identifying the factors that affect reasoning scalability, with the conclusion that the size of the ontology is the dominant factor. The study underscores the need for adaptive approaches to tune the degree of parallelism based on the size of the ontology.

Keywords—Automatic tuning; parallel semantic reasoning; performance optimization; ontology; high-performance computing

I. INTRODUCTION

In today's digital landscape, machines use ontologies, structured knowledge representations, to process and infer information across domains, forming a larger knowledge base known as Linked Open Data (LOD) [1]. Ontologies are essential for applications such as the semantic web, artificial intelligence, and data-driven decision-making [2], enabling machines to derive insights from complex relationships [3]. However, as ontologies grow in size and complexity, especially with the rise of the Internet of Things (IoT) and social networks, reasoning over these vast knowledge graphs becomes challenging [4]. Traditional semantic reasoners, which use sequential processing, struggle to scale with the growing size of ontologies, leading to significant delays in driving inferences [4], [5].

Fortunately, parallel reasoning systems have emerged, leveraging multicore and distributed computing technologies to improve efficiency [6]. These systems divide reasoning tasks into smaller units, allowing concurrent processing between multiple computing cores or nodes, thus improving speed and

performance [7]. Despite these improvements, the rapid growth of data from IoT systems and social networks continues to add complexity to the reasoning process, demanding more scalable and efficient solutions [8]. Therefore, optimizing parallel reasoning systems to successfully manage performance while addressing the increasing complexity of ontologies is a major challenge for researchers.

Numerous automatic tuning approaches have shown significant improvements in different application areas, such as hyperparameter tuning to optimize machine learning models [9], [10], big data analytics systems [11], [12], and parallel programs [13], [14]. These approaches varied in their strategies and techniques. Optimization search methods have shown accurate results in finding optimal solutions compared to other approaches. However, studies have reported a significant challenge in reducing search time as search space increases.

Linking these challenges in the areas of semantic reasoning and optimization, we present the Eagle Framework (EF), an advanced modular and extensible tool to optimize the performance of parallel reasoning systems. EF automatically generates parallelism configurations, recording performance data, and identifying the optimal degree of parallelism. Operating as a black-box solution on top of existing parallel semantic engines, EF relieves researchers and developers of the time-consuming process of manual tuning. A key innovation of EF is its novel search algorithm, which integrates an AVL tree with a priority queue, enabling efficient exploration for the optimal thread configuration. EF is implemented in Java, ensuring compatibility with a wide range of operating systems and server environments. In addition, EF saves performance data in CSV format and high-resolution line charts for data visualization. In general, EF significantly streamlines the optimization process, ensuring optimal performance and offering valuable time efficiency for researchers to develop scalable and advanced parallel reasoning systems.

In addition to proposing a tuning framework, this study includes a comprehensive case study, in which we validate the performance and reliability of our framework, as well as its effectiveness in optimizing parallel reasoners. We utilized multiple statistical methods through the assessment process, but a key method is introducing the Interclass Correlation Coefficient (ICC) for the reliability analysis. We will explain how we applied the Interclass Correlation Coefficient (ICC) to evaluate the reliability of tuning systems. To the best of our knowledge, ICC has not been used in evaluating automatic tuning.

The remainder of this study is organized as follows. Section II provides a comprehensive review, highlighting the gaps in the existing literature. Section III presents the conceptual and technical design of the EF architecture. Section IV details the case study that evaluates EF from the perspectives of performance, reliability, and effectiveness. Section V presents the findings of the study. Section VI discusses the findings and insights derived from this study. Finally, Section VII concludes the study.

II. BACKGROUND AND RELATED WORK

In this section, we provide a brief review of existing work to highlight the gaps in the literature on semantic reasoning and optimization. This review begins with the challenges of manual tuning presented in the context of semantic reasoning. Then, we provide an overview of the automatic tuning approaches commonly applied in other domains. We review related works with existing optimization methods. For each section of this review, we grouped studies based on the tuning approach or optimization method.

A. Challenges in Tuning Parallel Semantic Reasoners

Semantic reasoning is critical in applications that require logical consistency and explainability, such as medical, bioinformatics, and law. However, the development of parallel semantic reasoning systems has been less active in the last ten years, and most of these systems have been abandoned and no longer maintained [15]. Research studies in semantic reasoning implemented manual tuning to adjust the degree of parallelism. Examples of these studies are [6], [16], [17]. Although these studies did not explicitly state the drawbacks of manual tuning approaches in their research results, recent studies highlighted the challenges of computational complexity and performance in automated reasoning [18] [19]. Reasoning tasks use algorithms that require extensive computations and resource allocation [20]. These scalability challenges are further complicated by the increase in ontology sizes and hierarchies that require intensive computation. Although parallel semantic reasoners leverage multicore and distributed architectures to tackle scalability issues, without automatic tuning strategies, reasoning scalability remains challenging. The Table I provides a comparison of various approaches based on different factors and parameters.

B. Overview of Automatic Tuning Approaches

This section reviews recent studies on optimizing parallel systems. It classifies them into six approaches, following the categorization by Herodotou et al. [21], and discusses the advantages, limitations, and methods for each approach.

1) *Search-based approach*: The search-based approach systematically searches for the optimal solution through experiments, improving performance and resource efficiency. Although this approach is reliable for identifying the optimal or near-optimal solution, it can be computationally expensive for large systems. Van Werkhoven introduced an automatic framework that integrated various optimization search, including simulated annealing and particle swarm optimization, to optimize GPU kernels in OpenCL and CUDA [22].

2) *Rule-based approach*: The rule-based approach uses predefined guidelines and domain expertise to guide tuning decisions, offering simplicity and fast execution. It works well in predictable environments where the behavior of the system follows established patterns. However, its lack of flexibility limits its effectiveness in complex or dynamic workloads. Schwarzrock et al. applied this approach to enhance performance and energy efficiency in NUMA systems. Their focus was on optimizing thread-to-core mapping, memory page mapping, and thread throttling [23].

3) *Machine learning approach*: The machine learning approach employs models, such as regression and neural networks, to predict optimal configurations by learning from historical data, capturing complex relationships for improved tuning accuracy. When trained on quality data, these models can achieve near-optimal configurations without exhaustive searches. However, they require substantial data and computational resources, and accuracy is dependent on data quality. Fan et al. used a random forest model to optimize query performance in databases by predicting optimal degrees of parallelism [24].

4) *Adaptive approach*: The adaptive approach dynamically tunes parameters in real-time, adjusting to workload changes, making it ideal for dynamic environments where static tuning fails. It can achieve near-optimal configurations quickly without exhaustive searches, though it may introduce overhead and struggle with stability in highly volatile conditions. Vogel et al. proposed reactive self-adaptive strategies to control parallelism in stream processing systems, allowing real-time adjustments without the need to restart applications [25].

5) *Cost modeling approach*: Cost modeling estimates resource costs, such as memory and CPU usage, for different tuning configurations, helping to avoid costly trial runs. It provides fast and moderately accurate estimations; however, its limitations lie in the accuracy of the model as it may not capture all the dynamics and interactions in the real world. This limits its ability to find optimal configurations in complex environments. Siddiqui et al. introduced a machine learning-enhanced framework to improve the accuracy of cost modeling in big data systems [26].

6) *Simulation-based approach*: The simulation-based approach models the behavior of the system in a simulated environment to predict optimal settings without affecting live performance. This is especially useful for difficult-to-test scenarios, offering reliable approximations if the simulation models are accurate. However, accuracy depends on model fidelity and detailed simulations can be resource-intensive. Liu et al. developed HSim, a Hadoop simulator for modeling various performance parameters in cloud computing [27].

C. Existing Optimization Search Methods

Among the six approaches previously discussed, we were particularly motivated by the reliability of search-based methods in finding optimal solutions. This section focuses on studies that implement these search-based methods. Currently, search methods are applied in system optimization in related domains, big data, machine learning, and high performance computing. These studies provide valuable insights that inform the design of our solution for optimizing parallel reasoning performance.

TABLE I. SUMMARY OF COMMON PARALLELISM TUNING APPROACHES

Approach	Search-based	Rule-based	Machine Learning	Adaptive	Cost Modeling	Simulation-based
Methods	Search algorithms.	Based on heuristics.	Data-driven predictions	Real-time dynamic adjustments.	Cost estimation models.	System behavior simulation.
Advantages	High-quality solutions.	Simple, fast decisions.	Adapts to changing conditions	Real-time tuning.	Guides resource decisions.	Tests without real-world impact.
Drawbacks	Expensive computing costs.	Expert knowledge required.	Large data needed, Slow training.	Struggles with unexpected changes.	May overestimate real-world factors.	Expensive computing costs.
Domain	Large, complex systems.	Simple, predictable systems.	Learning from history.	Workloads that change.	Resource-constrained systems.	Expensive or risky scenarios.
Data Size	Moderate to large.	Small to moderate.	Large.	Small to medium.	Small to medium.	Large.

1) *Grid Search (GS)*: GS is an optimization method that systematically explores all possible parameter combinations to determine the optimal one. However, this exhaustive approach is computationally expensive, particularly for high-dimensional search spaces [28].

Recent studies have demonstrated the potential of GS in optimizing systems in various domains. For example, George and Sumathi applied GS to optimize a random forest classifier for sentiment analysis, leading to improved accuracy [29]. Similarly, Priyadarshini and Cotton used GS to tune a deep neural network model for sentiment analysis, achieving an accuracy above 96%, which outperformed several baseline models [30]. In the big data domain, Chen et al. incorporated GS into their system to optimize MapReduce performance on Hadoop clusters, identifying optimal configurations to minimize running times [31]. In a similar study, Sewal and Singh compared GS with other optimization methods such as Evolutionary Optimization and Random Search to fine-tune Apache Spark. They found that GS was effective in reducing execution times by 23.24%. [32]. These studies are examples among others that utilize determinism in GS to enhance performance in areas like machine learning and big data systems.

2) *Hill Climbing (HC)*: HC is a simple and efficient local search algorithm that iteratively improves an initial solution by exploring neighboring options. However, it may get stuck in local optima, reducing the chances of finding the global.

Recent studies have highlighted the effectiveness of HC in various fields. For example, Sivakumar and Mangalam introduced a technique to improve adaptive cruise control systems in automated vehicles, using a combination of search methods, including HC, to optimize vehicle parameters, improving safety and fuel efficiency [33]. Zeng et al. employed a simple HC method with machine learning techniques to optimize parallelism in Parallel Nesting Transactional Memory (PN-TM) systems, achieving faster convergence and higher accuracy compared to other optimization methods [34]. Pradhan et al. applied HC to optimize a CNN model for classifying COVID-19 from chest X-ray images, improving its performance metrics and outperforming other hybrid techniques [35]. These studies are among several that demonstrate HC as a versatile and effective optimization method to improve system performance in diverse domains, from automated vehicles to machine learning and medical image classification.

3) *Simulated Annealing (SA)*: SA is a probabilistic optimization algorithm that explores various solutions, including the worst ones to escape local optima. SA is widely used method for many optimization problems due to its adaptability and capability to navigate rugged search spaces [36]. However, it can be computationally intensive, sensitive to parameter choices, and slow to converge.

Recent studies demonstrate the adaptability and effectiveness of SA in finding optimal solutions for complex optimization problems. A study by Rasch et al. utilized SA within their Auto-Tuning Framework (ATF) to optimize interdependent parameters in parallel programs, using the chain of trees and coordinate search spaces to enhance multidimensional exploration and improve tuning efficiency [7]. Gülcü and Kuş introduced the multi-objective simulated annealing algorithm for optimizing hyperparameters in convolutional neural networks, balancing classification accuracy and computational complexity, and achieving superior results compared to traditional SA [37]. Similarly, Abdel-Basset et al. combined SA with Harris Hawks Optimization to enhance feature selection for classification tasks, using SA to escape local optima and explore better feature subsets effectively [38]. These studies highlight the effectiveness of SA, both as a standalone algorithm and within hybrid frameworks, in solving diverse optimization problems across fields.

4) *Random Search (RS)*: Random Search (RS) is a simple algorithm that explores a search space by randomly sampling points and updating the best solution found. Although its simplicity and ability for global exploration, it lacks efficiency in high-dimensional spaces.

Recent studies underscore the role of RS as a simple and effective optimization method in different applications. A study by Willemsen et al. proposed a standardized benchmarking methodology for evaluating automatic tuning frameworks. This methodology integrates RS as a baseline for benchmarking optimization algorithms [39]. A similar study by Deligkaris used RS as a baseline method to benchmark evobps, an algorithm based on particle swarm optimization, against 12 related methods and models. The benchmark results demonstrated the effectiveness of RS in the search for neural architectures [40]. Hosseini et al. employed RS in optimizing 10 hyperparameters of Long Short-Term Memory (LSTM) networks used in rainfall-runoff modeling, resulting in highly precise predictions for hourly stream-flow and water levels in Spain's Basque Country [41]. Despite the advancement of more sophisticated

methods, these studies highlight the effectiveness of RS as a baseline or complementary method in advanced optimization methods.

D. Limitations and Research Gaps

Section II-A presented studies on parallel reasoning, which currently rely on manual tuning for optimization and scalability analysis. As research labs, governmental sectors, and universities continue to develop ontologies, the need for scalable and efficient reasoners has increased. Furthermore, the substantial efficiency and accuracy of automatic tuning reported in studies applied in other domains, such as machine learning and big data, highlight that the lack of automatic tuning application in semantic reasoning is a considerable gap. To the best of our knowledge, the application of automatic tuning in semantic reasoning has not been explored. Therefore, addressing this gap is the main objective of this study.

The studies reviewed in Section II-C noted the advances gained from applying search optimization methods. However, they also noted significant limitations of these optimization methods (see Table II). For GS, though it is exhaustive and guaranteed to find the optimal solution, it is computationally expensive, especially in multidimensional spaces where the time increases exponentially with increase in the search space. On the other hand, HC, SA, and RS offer greater efficiency and scalability; however, they are limited by several drawbacks, such as risks of local optima, stochastic behavior, and incomplete search space exploration. These limitations underscore the trade-off between time complexity and the guarantee of identifying the optimal solution, and this trade-off is strongly correlated with search space size. As noted by Krestinskaya et al., optimizing search time for large search spaces remains a critical gap and an open research challenge in optimization [42]. Therefore, the second objective of this study is to address the complexity of search time by designing a deterministic algorithm and a tree-based search space that aims to guarantee finding the optimal solution in efficient time.

TABLE II. SUMMARY OF SEARCH OPTIMIZATION METHODS

Aspect	Grid Search	Hill Climbing	Simulated Annealing	Random Search
Exploration	Global	Local	Global (with refinement)	Global (with random sampling)
Efficiency	Very Low	High	Medium	Low
Dimensional Scalability	Poor	Poor	Good	Good
Risk of Local Optima	No	High	Low	No
Best Use Case	Small spaces	Small spaces	Large spaces	Large spaces
Time Complexity	$O(n^k)$	$O(k \cdot n)$	$O(k \cdot n)$	$O(k \cdot n)$

III. EAGLE FRAMEWORK (EF)

This section presents the architectural and algorithmic design of EF. Before diving into architectural design, we provide an overview of the EF multi-layered system, where the EF resides in the middle layer. This overview is essential for

understanding the interoperability and portability of EF, which allows it to function with various parallel reasoning systems on different platforms. Following the system overview, we will explore the architectural details of EF from both mathematical and algorithmic perspectives.

A. System Overview

EF is a modular architecture that operates within a multi-layered system, where EF occupies one layer alongside a parallel reasoner. The abstraction view of the EF system consists of five layers, as depicted in Fig. 1.

The first layer is the Command Line Interface (CLI), which accepts parameter values to set automation parameters and is responsible for displaying output results. The second layer represents the main contribution of this study, where EF and the parallel semantic reasoner are positioned. EF comprises one main algorithm and three auxiliary algorithms: *Thread Controller*, *Speedup Calculator*, and *Parallelism Optimizer*. The third layer is the java runtime environment, which serves as a bridge between the EF implementation and the operating system. This middle layer provides the resources needed to compile and execute EF classes on any machine. The fourth layer is the operating system, which abstracts physical hardware and manages system resources. The final layer is the hardware, which represents the physical components of the machine, such as memory and the CPU. The next section focuses on the second layer, detailing the EF architectural components and their interactions with the other layers.

B. EF Architecture

EF architecture consists of a main algorithm and auxiliary algorithms. The main algorithm represents the core architecture of the EF and the interface that manages the connection between the CLI layer, the parallel reasoner, and the auxiliary algorithms. The auxiliary algorithms help the main algorithm in the tuning process by adjusting the thread count, calculating the speedup factor, and identifying the optimal thread count. Fig. 2 presents a flow chart for the EF architecture. The following sections provide an in-depth explanation of the functionality of each algorithm within the EF architecture.

1) *The Main algorithm*: As shown in Fig. 2, the main algorithm comprises five phases: automation setup, sequential reasoning, parallelism tuning, optimization, and output formatting.

a) *Phase 1: Automation setup*: The main algorithm starts by accepting three parameter values from the CLI layer: the path to the ontology file (p), the scale difference (d), which defines the incremental scale used to calculate thread configurations, and the maximum thread count (m), which serves as a threshold to limit the generation of additional configurations. Based on these parameters, the number of thread configurations is proportional to the values of d and m . Additionally, it creates a tree (A) to use in the search for the optimal thread count (o), and a list (L) to store performance data. It also sets the thread count (n) and speedup factor (s) to the seed value of 1.

Fig. 1. EF System overview.

b) Phase 2: Sequential reasoning: In this phase, the main algorithm runs the parallel reasoner, $\text{runReasoner}(p, n)$, sequentially using one thread. Then, the main algorithm saves sequential reasoning time in a variable named T_{seq} . Since EF does not perform parallel reasoning at this phase, the speedup factor remains 1. Consequently, the main algorithm inserts the values of n and s in A and adds them with T_{seq} to L .

c) Phase 3: Parallelism tuning: This phase represents the core automation provided by EF. The main algorithm starts the automation by checking whether n does not exceed m . This step is essential to limit the EF from generating more configurations. If n is less than or equal to m , the main algorithm passes n and d in a call to the Thread Controller $\text{ctrlThreads}(n, d)$. After receiving the new n value from the Thread Controller, the main algorithm passes n with p in a call to the reasoner and stores the parallel reasoning time in a variable named T_{par} . Subsequently, the main algorithm sends T_{seq} and T_{par} in a call to the Speedup Calculator, $\text{calcSpeedup}(T_{seq}, T_{par})$, to find the ratio and save it in s . Finally, the main algorithm performs the necessary operations to store performance data in A and L .

d) Phase 4: Optimization: In this phase, the main algorithm passes A in a call to the Parallelism Optimizer, $\text{optParallelism}(A)$, which searches for o in A . Once o is identified, the main algorithm prints o on the console. The parallelism tree and optimizer will be explained comprehensively in Section III-B4.

e) Phase 5: Output formatting: This phase is the final stage in EF, where performance data L are formatted into a comma separated value file (CSV). This format was chosen for its compatibility with most statistical analysis and database systems, which allows direct processing by analysis tools. In addition, a line chart is generated to illustrate the relationship

between each thread count and the associated reasoning time.

2) Thread controller: This section explains the algorithm of Thread Controller, denoted as $\text{ctrlThreads}(n, d)$, designed to create thread configurations. Building on recommendation by Huang et al. [43], who recommended employing sampling strategies for generating configurations, this algorithm generates thread configurations systematically using a specified scale difference, d . To prevent incorrect input, we added a conditional statement that verifies the value of d entered by the user. If d is assigned a negative number or zero, the Thread Controller sets d to the seed value of 1 and recalculates n accordingly. Otherwise, the Thread Controller computes the new n based on the provided value of d .

Definition 1. Let n be a thread configuration and d be the scale difference. The Thread Controller calculates is defined as:

$$\text{ctrlThreads}(n, d) = \begin{cases} n + 1 & \text{if } d \leq 0 \\ n + d & \text{if } d > 0 \end{cases} \quad (1)$$

3) Speedup calculator: Speedup is a common metric that is used to assess performance improvements in systems running on parallel computing architectures. To measure speedup, we designed Speedup Calculator, denoted as $\text{calcSpeedup}(T_{seq}, T_{par})$, an algorithm that calculates the speedup factor as the ratio between the execution time for sequential reasoning and the time taken for parallel reasoning. Since most reasoners record reasoning times in milliseconds, we took account of scenarios where executing the reasoner on massively parallel computing resources results in reasoning times in fraction of a millisecond rounded to zero (i.e. in nanoseconds). To handle this, the Speedup Calculator first checks if the value of T_{par} is non-zero. If this condition is

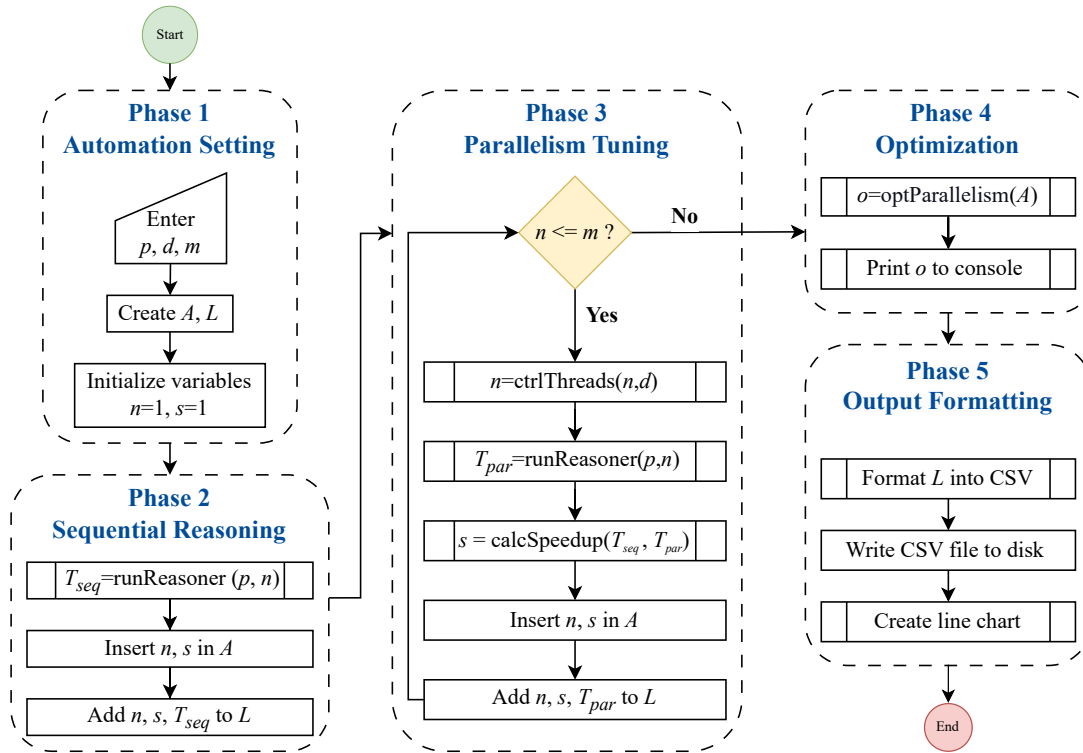

Fig. 2. EF Architecture.

met, the calculator proceeds with the division. However, if T_{par} equals zero, the calculator throws an arithmetic exception, which is treated as “undefined” in arithmetic, and the process safely halts.

Definition 2. Let T_{seq} be the execution time of the sequential reasoning, and T_{par} be the execution time of the parallel reasoning. The Speedup Calculator is defined as:

$$calcSpeedup(T_{seq}, T_{par}) = \begin{cases} Undefined & \text{if } T_{par} = 0 \\ \frac{T_{seq}}{T_{par}} & \text{if } T_{par} \neq 0 \end{cases} \quad (2)$$

4) *Parallelism Tree (PT) and Parallelism Optimizer (PO)*: An AVL tree is a self-balanced binary search tree characterized by its speed in most operations, including insertion and searching [44] [45]. We chose the AVL tree to construct the search space in EF due to its time efficiency, with a worst-case time complexity of $O(\log n)$ for core operations, which outperforms other data structures to align with the objective of this study. For clarity, we used Parallelism Tree (PT) to refer to the tree-based search structure and Parallelism Optimizer (PO) to refer to the associated optimization algorithm.

PT is a modified version of the AVL tree, where each node consists of performance data (s) and its associated thread configuration (n). In addition, each node has pointers to a left child (l) and a right child (r). Unlike the AVL tree, PT uses s as the key to determine the correct position to insert a new node. In PT, the sequential reasoning node is always the root, while the parallel reasoning nodes are placed based on their

speedup factor. Algorithm 1 presents the insert procedure for PT.

Algorithm 1: insert(s, n)

- 1: **Input:** s, n
 - 2: **Output:** rebalance($root$)
 - 3: **if** $root = null$ **then**
 - 4: **return** new Node(s, n)
 - 5: **else**
 - 6: **if** $root.s > s$ **then**
 - 7: $root.l \leftarrow$ insert(s, n)
 - 8: **else if** $root.s < s$ **then**
 - 9: $root.r \leftarrow$ insert(s, n)
 - 10: **else**
 - 11: $root.nQueue.add(n)$
 - 12: **end if**
 - 13: **end if**
 - 14: **return** rebalance($root$)
-

In the initial experiments, we observed that different thread configurations produced identical speedup factors. Consequently, PT prevents the insertion of nodes with duplicate speedup. To resolve this issue, we integrated a priority queue within the PT node structure to store all thread configurations associated with the same speedup factor. This approach enables PT to encapsulate each speedup factor with its corresponding thread configurations in the same node. The priority queue orders the configurations from the smallest to the largest, enabling efficient exploration by neglecting the less effective configurations. In this study, we designed PO to select the

Fig. 3. Parallelism tree (PT) in EF where each node contains speedup factor (s) and the associated thread configuration queue (n).

smallest thread configuration as the optimal one, under the assumption that this configuration achieves the highest speedup factor and that performance will not improve beyond this point. Fig. 3 illustrates an example of PT resulting from one tuning experiment. The red circle denotes the node with the maximum speedup value, while the blue square indicates the optimal degree of parallelism PO selects from the thread queue.

Similarly to the AVL tree, PT is ordered and places the node with the highest speedup factor at the end of its rightmost path. Therefore, we designed the PO algorithm, denoted as $\text{optParallelism}(A)$, to search for the optimal configuration only in the rightmost path of the PT. Such an approach efficiently saves time compared to search in a multi-dimensional space structure. PO starts the optimization search by checking whether the root's right pointer points to NULL. If so, it returns the root node because it contains the optimal degree of parallelism. If not, it performs this check recursively until it finds the node whose right pointer refers to NULL as the node containing the optimal thread configuration. The PO algorithm is shown in Algorithm 2.

Algorithm 2: $\text{optParallelism}(\text{node})$

- 1: **Input:** node
 - 2: **Output:** node
 - 3: **if** $\text{node.right} == \text{null}$ **then**
 - 4: **return** node
 - 5: **else**
 - 6: **return** $\text{optParallelism}(\text{node.right})$
 - 7: **end if**
-

IV. EXPERIMENTAL DESIGN AND SETUP

This study aims primarily to evaluate EF in terms of performance, reliability, and effectiveness in assessing the scalability of parallel reasoners. To achieve this, we conducted our experiments on a case study on the ELK reasoner, a reasoning engine specifically designed for OWL2 EL ontologies [16].

ELK is one of the few actively maintained parallel reasoners for OWL2, as many other reasoners have been discontinued [15]. Although ELK provides a variety of reasoning services to support ontology development and querying, our experiment scope is only on the classification reasoning service.

We conducted the experiments on the Aziz Supercomputer, where each node consists of two 12-core processors (Intel Xeon CPU E5-2695v2, 2.40 GHz) that support Hyper-Threading Technology, providing a total of 48 logical cores and a total memory of 256 GB (128 GB per processor). Since ELK was designed to operate exclusively on shared memory servers [16] [46], we performed all experiments on a single node. To maintain the integrity of our results, we secured exclusive access to server resources, thereby preventing the interleaving of jobs which could potentially compromise reasoning time and speedup factor. Furthermore, we configured the EF parameters with a scale difference of 1 and set the maximum thread count to 240 in all experiments. Section V-D1 will explain our choice of these parameter values.

Our research used a systematic sampling technique to select the ontologies. First, we downloaded ontologies from BioPortal¹ and OBO Foundry² that support the OWL2 EL profile. Then, we further classified the ontologies based on the number of TBox axioms into different sizes, ranging from tiny to medium. We based our categorization on the number of TBox axioms since the classification reasoning service is associated with only TBox axioms. We selected three ontologies from each size category, resulting in a total of nine ontologies. Each ontology was examined in a separate experiment, and each experiment was repeated three times to ensure reliability, resulting in a cumulative total of 27 experiments. This approach allowed us to ensure a diverse range of ontologies for our experiments while ensuring that the samples represented the entire population of OWL2 EL ontologies.

V. CASE STUDY: VALIDATING THE PERFORMANCE, RELIABILITY, AND EFFECTIVENESS OF EF IN TUNING THE ELK REASONER

ELK is a specialized OWL reasoner that classifies ontologies in the OWL2 EL profile. It is known for its high performance due to its parallel reasoning and robust optimization techniques [16]. ELK has expanded its capabilities to include incremental classification and proof tracing, with optimizations for handling role composition axioms and rewriting low-level inferences. These improvements simplify incremental reasoning, proof generation, and enable automated verification and ontology debugging.

This case study begins with an assessment of EF from performance and readability perspectives and ends with an evaluation of the effectiveness of EF in analyzing the scalability of the reasoning system.

A. Overall Framework Performance

The analysis starts by evaluating the performance of the EF for the overall tuning process, covering ontology loading, configuration generation, performance monitoring, and reasoning optimization. Table III presents the minimum, maximum, average and standard deviation of execution times (in seconds) required for EF to tune and optimize the ELK reasoner. Execution times range from a few seconds to just under five minutes.

For tiny ontologies, such as OLATDV, INO, and FBDV, the tuning process was completed in a few seconds, demonstrating the framework's efficiency in quickly exploring thread configurations. Small-sized ontologies, including PLANA and PDON, exhibited slightly longer tuning times, ranging from 17 to 28 seconds. In contrast, medium-sized ontologies, such as OBA, EMAPA, and ORDO, required significantly more time, with ORDO taking the longest at 4 minutes and 29 seconds. This variation in execution times reflects the influence of ontology size on EF performance, with larger ontologies requiring longer durations.

Narrowing the focus from overall framework performance, the next section presents a detailed comparative analysis of the EF's optimization algorithm against baseline search algorithms commonly used in optimization studies.

B. Parallelism Optimizer vs. Existing Optimization Methods

To evaluate EF's optimization performance, we compared its Parallelism Optimizer (PO) with existing search methods commonly used in optimization studies. Specifically, we compared PO with grid search (GS), hill climbing (HC), simulated annealing (SA) and random search (RS). To conduct a fair comparison, we separated PO from the EF architecture. We used one data set resulted from one tuning experiment for all the algorithms involved in the comparison. For SA, we set the initial temperature at 1000 and the cooling rate to 0.95, while for RS, we set the number of iterations to 100.

A summary of the comparative analysis is shown in Table IV. The results showed that PO significantly outperforms its competitors, achieving an average reasoning time of just 0.003 ms. In contrast, the average reasoning times for the other algorithms were 0.167 ms for GS, 0.090 ms for HC, 0.196 ms

for SA, and 0.128 ms for RS. This high efficiency is further demonstrated by the success rate in identifying the optimal thread configuration. PO perfectly found the optimal thread configuration in all ten attempts, while both HC and SA failed in all attempts, and RS succeeded in only three trials.

C. Data Quality and Reliability

In data assessment, we focus on evaluating the quality of the EF measurements gathered during the tuning process and the consistency between these measurements. Listing 1 represents a sample console output of the type of variable data input, missing values, and duplicate rows in the data collected by the EF. As shown in Listing 1, the data underwent evaluation included the test ID for referencing purposes, thread count, reasoning time in milliseconds and in a format of days, hours, minutes and seconds to ease readability, and corresponding speedup factor. The assessment showed that each variable was correctly formatted in a suitable data type. In addition, it revealed that neither missing values nor duplicate rows were found in the data, reporting data integrity and quality.

```
=====
File: ELK_ORDO_1_240_2.csv
=====
| Variable | Data Types | Missing |
|-----|-----|-----|
| Test Number | object | 0 |
| Number of Threads | int64 | 0 |
| Total Reasoning Time (ms) | int64 | 0 |
| Total Reasoning Time (d:h:m:s) | object | 0 |
| Speedup Factor | float64 | 0 |
| Duplicate Rows: | | 0 |
=====
```

Listing 1. Sample Console Output For EF's Data Quality Assessment.

To assess the reliability of the EF, we used the intraclass correlation coefficient (ICC). We selected ICC over other statistical methods because our study involves repeated experiments conducted in the same environmental settings. ICC is a highly precise statistical method that is sensitive to variance [47]. In addition, ICC can assess both the consistency within and between configurations. It is widely used in other fields such as medicine, psychology, biology, and genetics, especially to evaluate the reliability of measurement tools such as medical instruments and computer-aided detection (CAD) systems [48]. To our knowledge, this is the first study to use ICC in assessing the reliability of automatic tuning methods.

Because the speedup factor is a ratio, we applied the ICC assessment exclusively to the reasoning time. The results of the reliability analysis for different ontology sizes are presented in Table V. Each assessment applied the ICC(3,k) model to a dataset of 720 measurements, calculated as each experiment repeated three times with 240 measurements per trial. As shown in Table V, the analysis of nine ontologies revealed high ICC scores, ranging from 0.789 to 0.992, indicating strong consistency between measurements. All ontologies showed statistically significant results ($p < 0.001$) with narrow confidence intervals, indicating precise measurements. The highest ICC was observed for INO (0.992), followed by OLATDV (0.990) and PLANA (0.962). ORDO and PDON also showed strong ICC scores of 0.951 and 0.932, respectively. However,

TABLE III. REASONING TIME CALCULATED BY EF IN TUNING ELK REASONER (IN SECONDS)

Ontology	TBox Axiom count	Ontology Size ^a	Min. Time	Max. Time	Avg. Time	Median Time	SD Time
OLATDV	88	Tiny	9.24	12.25	10.377	9.637	1.636
INO	384	Tiny	11.36	11.63	11.491	11.489	0.134
FBDV	646	Tiny	10.17	11.71	11.097	11.413	0.815
PDON	1252	Small	15.86	34.64	28.311	34.433	10.786
PLANA	2755	Small	15.89	18.21	17.071	17.113	1.157
WBPHENOTYPE	4026	Small	36.86	43.34	39.703	38.910	3.316
OBA	17811	Medium	137.06	295.03	194.653	151.877	87.241
EMAPA	23029	Medium	74.49	78.92	77.309	78.518	2.448
ORDO	53861	Medium	233.28	287.40	269.103	286.634	31.029

^a Ontology sizes categorized by TBox axiom count: Tiny – fewer than 1,000 axioms; Small – 1,000 to 10,000 axioms; Medium – 10,000 to 100,000 axioms; Large – 100,000 axioms or more.

TABLE IV. BENCHMARKING THE PARALLELISM OPTIMIZER AGAINST EXISTING OPTIMIZATION SEARCH ALGORITHMS

Algorithm	Grid Search	Hill Climbing	Simulated Annealing	Random Search	Parallelism Optimizer
Average Reasoning Time (ms)	0.167	0.090	0.196	0.128	0.003
Success Rate for Optimal Thread Identifications (out of 10)	10/10	0/10	0/10	3/10	10/10
Time Complexity	$O(n)$	$O(n)$	$O(n)$	$O(n)$	$O(\log n)$

TABLE V. RELIABILITY ANALYSIS FOR EF MEASUREMENTS AMONG DIFFERENT SIZES OF ONTOLOGIES

Ontology	ICC	F	P	CI95%
OLATDV	0.989824	98.267647	8.143461e-311	[0.99, 0.99]
INO	0.992448	132.417193	0.0	[0.99, 0.99]
FBDV	0.880456	8.365113	3.314461e-85	[0.85, 0.90]
PDON	0.932163	14.741265	1.651629e-130	[0.92, 0.95]
PLANA	0.962178	26.439423	9.941877e-183	[0.95, 0.97]
WBPHENOTYPE	0.789731	4.755818	9.179020e-48	[0.74, 0.83]
OBA	0.883609	8.591758	3.438310e-87	[0.86, 0.91]
EMAPA	0.889079	9.015433	8.344745e-91	[0.86, 0.91]
ORDO	0.951172	20.48018	2.327254e-159	[0.94, 0.96]

WBPHENOTYPE, with an ICC score of 0.790 and a 95% confidence interval of [0.74, 0.83], showed moderate consistency. Although the ICC score for WBPHENOTYPE was statistically significant, its lower ICC and broader confidence interval indicated weaker consistency compared to the other ontologies.

D. EF Effectiveness in Analyzing Reasoning Performance

This section explores the role of EF in helping researchers with scalability assessments to improve the performance of parallel semantic reasoners. To validate EF effectiveness, we performed exploratory and regression analysis.

Before conducting the evaluation, we combined all EF data resulted from all experiments. Additionally, we added characteristics information for each ontology, including the TBox axiom count and size. we performed the necessary pre-processing and normalization .

1) *Exploratory analysis:* This section explores the impact of varying thread configurations and ontology sizes on the performance of the ELK reasoner. It also examines the relationship between the optimal degree of parallelism and the total number of logical cores. To examine these relationships, we define three examination areas:

- Area 1: less than the total of logical cores.
- Area 2: equal to the total of logical cores.
- Area 3: greater than the total of logical cores.

As mentioned in Section IV , we set the scale difference to 1 and the maximum thread count to 240. These settings ensured the gradual increase in thread configurations with a threshold exceeding the total number of logical cores. In addition, these settings allowed us to cover all the examination areas in a single execution. Fig. 4a, 4b, and 4c demonstrate the scalability of the ELK reasoner with varying ontology sizes and thread configurations. The red dashed line presents a reference mark pointing to the 48 logical cores.

In Fig. 4a, processing tiny ontologies OLATDV, INO, and FBDV displayed optimal performance at around 48 threads, with OLATDV achieved a speedup factor of 30, followed by FBDV of 25 and INO of 16. For OLATDV and INO, the optimal thread configuration was found in Area 1, while for FBDV the optimal solution was found in the first portion of Area 3, after which the performance decreased significantly. Similarly to tiny ontologies, the small ontologies PDON,

Fig. 4. ELK's Scalability with varying ontology sizes and thread configurations.

PLANA, and WBPHENOTYPE reached the speed factor of 16, 12, and 6, respectively, with optimal configuration found in Areas 1 and 3, as shown in Fig. 4b. However, the range of speedup factors for the small ontologies was narrower than that of the tiny one, as indicated by the reduced scale of the speedup axis in Fig. 4b compared to the axis in Fig. 4a.

In Fig. 4a, processing small ontologies like OLATDV, INO, and FBDV showed optimal performance at approximately 48 threads. Processing OLATDV achieved a speedup factor of 30, FBDV reached 25, and INO managed 16. The best thread

configuration for OLATDV and INO was in Area 1, while FBDV's optimal performance was in the initial part of Area 3, followed by a significant drop. Similarly, small ontologies PDON, PLANA, and WBPHENOTYPE achieved speed factors of 16, 12, and 6, respectively, with optimal configurations in Areas 1 and 3, as shown in Fig. 4b. The speedup range for small ontologies was narrower compared to tiny ones, reflected by the smaller scale of the speedup axis in Fig. 4b compared to Fig. 4a.

Fig. 4c presents notable performance gains for medium-sized ontologies compared to the small ones, where the average speedup for processing ORDO and EMAPA achieved factors between 4 and 5, while performance in processing OBA stabilized at a less speedup factor. Key observations were deduced from this figure. First, there is a notable decrease in the range of speedup factors compared to Fig. 4a and 4b. Second, the optimal thread configurations were identified in Area 1, indicating that adding more threads did not lead to further enhancements. Third, the trend line for this category shows a performance stabilization, suggesting that ELK reasoners benefits from parallelization in reasoning large ontologies more than small ones.

2) *Regression analysis:* In this analysis, we used an Ordinary Least Squares (OLS) regression model to quantify the impact of thread configurations and ontology size, measured in terms of the TBox axiom count, on the reasoning time. This model, with standardized predictors, explained 78.4% of the variance in reasoning time ($R^2 = 0.784$), highlighting its effectiveness in capturing the relationship between predictors and reasoning time. The results, presented in a 3D scatter plot shown in Fig. 5, revealed that while the TBox axiom count significantly affected the time of reasoning ($\beta_1 = 0.8855$, $p < 0.001$), the thread count has a negligible impact ($\beta_2 = 0.0066$, $p = 0.512$). Furthermore, the model showed a notable predictive accuracy, with an average Mean Squared Error (MSE) of 0.2165 and a Root Mean Squared Error (RMSE) of 0.4653.

VI. DISCUSSION

The rapid expansion of ontologies and the lack of automatic tuning approaches have poses challenges on advancing parallel semantic reasoners. In related domains, several sophisticated tuning frameworks have been developed, applying existing search methods for optimization. Although existing search methods presented significant improvements, reducing their search time is still an active research field. This study addressed these gaps by proposing an automatic tuning methodology with an innovative tree-based search algorithm.

Our case study presented in Section V validated the performance gains, reliability, and effectiveness of automatic tuning in optimizing parallel semantic reasoners. Using ELK reasoner as a case study, our methodology, Eagle Framework (EF), efficiently completed the entire tuning process, from ontology loading to final optimization results, in less than five minutes across 240 thread configurations. Practically, such efficiency cannot be achieved in manual tuning approaches, underscoring the importance of applying automatic tuning methods to optimize the performance of semantic reasoner. These findings align with the conclusion of Mustafa's study,

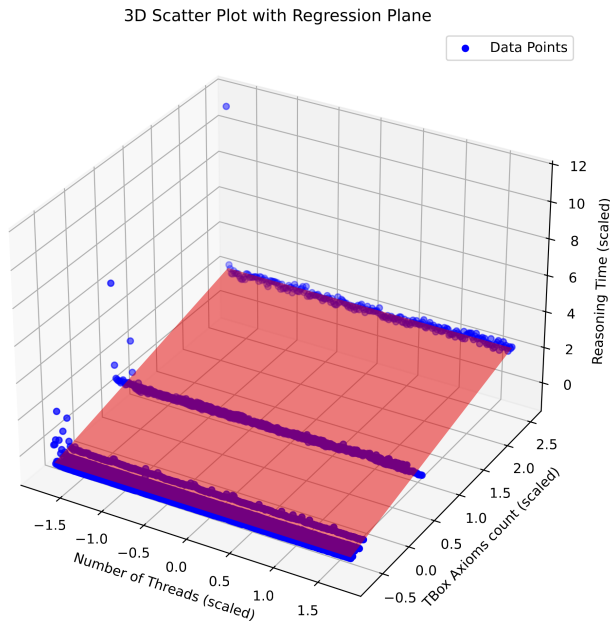

Fig. 5. A 3D Scatter plot with regression plane illustrating the relationship between TBox axiom count, number of threads, and reasoning time.

who also found through his survey study that automatic tuning ultimately outperforms manual tuning and becomes a crucial demand for optimizing parallel architectures [49].

We benchmarked our search algorithm, Parallelism Optimizer (PO), against the methods reviewed in Section II-C, namely: Grid search (GS), hill climb (HC), simulation annealing (SA), and random search (RS). We ensured a fair comparison by isolating the implementation of PO from other components in EF, similar to the isolation strategy employed in [40]. The results demonstrated the superiority of PO over its counterparts. PO exhibited logarithmic growth in search time and achieved a perfect success rate in identifying the optimal degree of parallelism. In contrast, other algorithms showed linear growth in search time and varying success rates. This superiority is gained from the deterministic characteristics of PO combined with the structural design of the Parallelism Tree (PT) search space. Specifically, the ordering nodes in PT based on a performance metric (i.e. the speedup factor for this study) and the queuing mechanism for storing parallelism configurations significantly decreased the search time and reduced tree size. Compared to the methodology proposed in [7], where a long chain of trees with a distinct node was used only for storage purposes, our methodology leveraged the efficiency of an integration between the tree-based and priority queue in storage and exploration purposes. However, our methodology provides efficiency for one-parameter optimization, and multi-dimensionality is not supported yet.

The analysis in Section V-D investigated the influence of increasing thread count and ontology size on ELK's scalability. For small ontologies, the results showed severe performance degradation as the number of threads increases. On the other hand, larger ontologies exhibited a lower speedup factor but maintained stable performance with the increase in thread

count. Our findings demonstrate that the ELK reasoner scales efficiently with larger ontologies using a high degree of parallelism, while for small ontologies it performs poorly due to over-utilization of processing units. These findings emphasize those in [16], where the authors stated that their ELK reasoner benefited more from increased parallelism when processing larger ontologies than smaller ones. In summary, this study highlights the need for adaptive tuning approaches to develop efficient and scalable reasoning systems.

This study effectively applied the intraclass correlation coefficient (ICC) method to analyze the reliability of EF. This effectiveness was the result of the following conditions. First, the sample size used in each ICC assessment were relatively large. Second, the massively parallel resources in HPC environment led to precise variance in the reasoning time measurements. Third, the experimental setup ensured exclusive access to HPC resources, leading to clean results, demonstrating the robustness of EF. These conditions enabled the ICC to effectively detect variance in time measurements both within and between parallelism configurations, contributing to a narrower confidence interval range. Based on these findings, we recommend future investigations to explore the viability of ICC in evaluating tuning results implemented under the same conditions.

This study offers significant contributions to revitalizing the domain of semantic reasoning and expanding existing research on optimization approaches. However, it was constrained by the limitations of the ELK reasoner, which operates only on a shared memory system. Furthermore, the hardware resources of the experimental environment restricted us from using massive-size ontologies. Future experimentation is required to validate the effectiveness of our methodology in optimizing different semantic reasoners on different computing architectures.

VII. CONCLUSION

As the size and complexity of ontologies expand, particularly with the advent of the Internet of Things and other data-driven systems, optimizing parallel semantic reasoners has become a significant challenge. This study proposed the Eagle Framework (EF), an innovative automatic tuning framework aimed at helping researchers optimize the performance of semantic reasoners. EF automatically generates thread configurations and effectively records performance data. EF differentiates itself through its modular design and adaptability, operating as a black-box solution that integrates seamlessly with various parallel reasoning engines. By designing a novel tree-based search algorithm, EF efficiently identifies the optimal number of threads. EF's methodology significantly reduces the manual effort required for tuning parallelism, saving researchers time and enabling them to focus on higher-level tasks. EF's ability lies in writing the performance measurements in CSV files, making them ready for data analysis. In addition, EF represents performance data in high-resolution visualization, offering researchers a comprehensive understanding of how different configurations impact reasoning efficiency.

Through a case study, this research validated the efficiency of EF in tuning thread configurations for the ELK reasoner across varied ontology sizes. Comparative analysis shows that

EF efficiently identifies optimal parallelism, outperforming existing search algorithms applied in optimization studies. Furthermore, this study validated the effectiveness of EF in addressing key research questions commonly discussed in the literature, such as the relationship between optimal performance and the full utilization of logical cores and the scalability of parallel reasoners to increase both processing resources and ontology size. In addition, this study introduced the application of the intraclass correlation coefficient (ICC) in assessing the reliability of performance tuning tools. The findings validated the consistency of the EF tuning measurements within and between configurations, suggesting the accuracy of ICC in assessing the reliability of tuning systems executed on a high-performance computing architecture.

Imbalance Datasets in Malware Detection: A Review of Current Solutions and Future Directions

Hussain Almajed, Abdulrahman Alsaqer, Mounir Frikha

Department of Computer Networks and Communications, College of Computer Sciences and Information Technology
King Faisal University, Al-Ahsa, 31982, Saudi Arabia

Abstract—Imbalanced datasets are a significant challenge in the field of malware detection. The uneven distribution of malware and benign samples is a challenge for modern machine learning based detection systems, as it creates biased models and poor detection rates for malicious software. This paper provides a systematic review of existing approaches for dealing with imbalanced datasets in malware detection such as data-level, algorithm-level, and ensemble methods. We explore different techniques including Synthetic Minority Oversampling Technique, deep learning techniques including CNN and LSTM hybrids, Genetic Programming for feature selection, and Federated Learning. Furthermore, we assess the strengths, weakness, and areas of application of each approach. Computational complexity, scalability, and the practical applicability of these techniques remains as challenges. Finally, the paper summarizes promising directions for future research like lightweight models and advanced sampling strategies to further improve the robustness and practicality of malware detection systems in dynamic environments.

Keywords—Malware detection; machine learning; imbalance datasets; oversampling; SMOTE

I. INTRODUCTION

Cybersecurity is a critical area in today's world and malware detection is a critical area of cybersecurity, because malicious software is proliferating at a rapid rate, and it is getting more sophisticated [1], [2]. Moreover, Malware detection solutions are essential given the urgent need to solve the issue. However, detecting malware more effectively has become increasingly difficult because of the complexity of modern malware and the volume of data being generated. In response to this challenge, Machine Learning (ML) techniques have risen in prominence by learning malware patterns and determining their difference from benign software [3]. But the problem of imbalanced datasets is a major obstacle in developing effective malware detection systems. This comes from having a dataset used to train ML models that contain a much lower number of malware samples than data associated with benign samples, leading to biased models that cannot adequately detect malicious activity.

In this paper, we present techniques for addressing imbalanced datasets in malware detection and evaluate their effectiveness through a systematic review.

II. BACKGROUND

A. Imbalanced Datasets in Malware Detection

Malware detection datasets are imbalanced when the malware samples (minority class) have a very small distribution compared to benign samples (majority class) [4], [3], [5].

As a result, model predictions become skewed towards the majority class and ignore important minority samples, which are most often the focus in cybersecurity. Fig. 1 demonstrates the imbalanced data distribution.

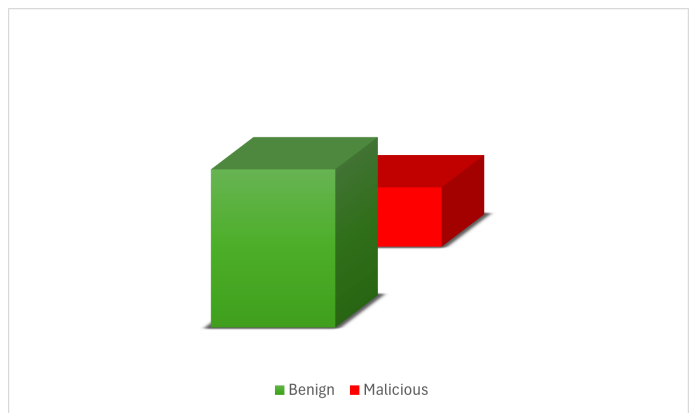

Fig. 1. Visual representation of an imbalanced malware dataset.

B. Balanced Datasets in Malware Detection

Malware detection datasets that are balanced are those which have approximately the same number of samples in the majority class (non-malicious data) and minority class (malicious data) [4], [2]. This balance prevents classifiers from biasing towards any one class, and results in more accurate detection of both non-malicious and malicious data. Fig. 2 demonstrates the balanced data distribution where both data are equal in the count.

C. Challenges of Imbalanced Datasets

Imbalanced datasets raise the following challenges:

- **Biased Prediction:** Datasets with imbalanced classes, therefore, often lead to classifiers that are skewed towards the majority class, and would often then perform poorly on the minority class [4], [2].
- **Poor Generalization:** Insufficient training examples lead to failure of the classifiers to generalize well on minority class predictions [3].
- **Metric Misleading:** As high accuracy can be obtained by ignoring the minority class, standard accuracy measures become unreliable [2], [6].
- **Class Overlapping:** Classes of imbalanced datasets might overlap, and there will be no clear boundaries

Fig. 2. Visual representation of balanced malware datasets.

TABLE I. OVERVIEW OF DATA-LEVEL METHODS

Method	Definition	Advantages	Limitations
Over-Sampling [4]	It add synthetic examples to the minority class to balance the dataset.	Balances class distribution without losing existing data.	Risk of overfitting and computational overhead in managing large synthetic datasets [6].
Under-Sampling [6]	Reduces the majority class samples to balance the dataset by either randomly removing examples or applying heuristic methods.	Simplifies the dataset, and encourages the model to focus equally on both classes.	Loss of potentially valuable data from the majority class.

separating classes, which complicates distinguishing between majority and minority samples [6], [2].

- Overfitting and Underfitting: On the other hand, over-sampling the minority class results to overfit while under-sampling the majority class results to underfit [6].

D. Approaches to Address Imbalanced Datasets

In this section, different techniques are introduced to address the imbalanced dataset problem in malware detection. We broadly categorize these approaches into data level methods, algorithm level methods, and ensemble methods that solve the imbalance problem from different angles.

1) *Data-Level Methods*: Data level approaches try to balance the class distribution by changing the data before applying any ML algorithm [6]. Table I shows the data-level method.

The Fig. 3 shows the illustration of over-sampling and under-sampling.

2) *Algorithm-Level Methods*: Algorithm level methods adapt existing learning algorithms to make them more sensitive to imbalanced data [7]. Unlike these methods, they do not change the dataset but rather change the training process. Common algorithm-level methods show in Table II.

3) *Ensemble Methods*: It is a combination of multiple classification techniques from the above mentioned categories and can be seen as a wrapper of other methods such as nsembling which is widely used as a classification technique [7].The method consists of pretraining and fine tuning on the original

Fig. 3. Illustration of OverSampling and UnderSampling methods for handling imbalance datasets.

TABLE II. SUMMARY OF ALGORITHM-LEVEL METHODS

Method	Definition	Advantages	Limitations
Cost-Sensitive Learning [7]	Assigns higher mis-classification costs to minority classes.	Improves focus on minority samples, and aligns learning with real-world impact.	Requires precise cost estimation; may still bias towards majority class.
Thresholding [7], [2]	To balance the class distribution, the decision threshold is adjusted.	Simple Implementation, No data loss.	heavily depends on the choice of the optimal threshold value and not be effective for all types.
One class classification [7], [2]	It learns from one class (typically the minority class) and seeks to identify instances that belong to this class, rejecting all others.	Useful for high-dimensional datasets and more robust to noisy data.	More complex to implement and not generalize well to new, unseen data.

imbalanced dataset. Also, it combines predictions from multiple models to increase robustness and decrease bias [3], [4]. Bagging and Boosting are techniques. where it Combines the strengths of individual classifiers for better overall performance and reduces the impact of minority class under representation by focusing on difficult to classify samples [6], [4].

E. Motivation

This systematic literature review is motivated by the necessity of improving malware detection capabilities in the presence of:

- The Growing Threat of Malware: Malware attacks have been increasing in frequency and sophistication, making risks to individuals and organizations. As stated by the report of AV-atlas, where over three millions new malware were found in the first two weeks of November 2024 [8]
- Importance of Effective Malware Detection: Undetected malware can lead to the loss of sensitive information, financial implications, operational disruption.
- Challenges with Imbalanced Datasets: Non-malicious samples outnumber malware samples, leading to model bias and high false negatives.
- Need to Address Data Imbalance: To enhance security, improve malware detection accuracy and strengthens overall cybersecurity defenses.

F. Problem Statement

Imbalanced datasets in malware detection pose a big problem for ML models, which leads to biased detection systems that fail to well detect malware [6], [5]. Failure in the identification of the minority class leads to models that perform poorly when it comes to classifying benign against malicious samples, this being due to the current imbalance between benign and malicious samples. This work is a systematic literature review to investigate and assess existing solutions to solve this problem, and to gain insights to develop better methods to deal with imbalanced datasets in malware detection.

G. Scope

The scope of this SLR is to review the literature on imbalance in datasets for malware detection. It includes data level, algorithm level and ensemble methods used to handle the imbalanced datasets. The scope is to evaluate these methods, to identify the challenges and limitations of applying them, and to suggest potential directions for future research. In addition, the review will point out how different solutions have been used in the case of malware detection and their pros and cons.

H. Objective

The objectives of this research are as follows:

- Conduct a Comprehensive Literature Review: In order to systematically review the existing literature regarding how to handle imbalanced datasets in malware detection.
- Investigate Current Solutions: In order to identify and evaluate different approaches used to tackle imbalanced datasets.
- Assess Effectiveness: Focusing on metrics such as accuracy and F1-score, these approaches will further be assessed for their effectiveness in improving malware detection.
- Identify Challenges and Gaps: The challenges, limitations, and gaps of existing methods dealing with imbalanced datasets in malware detection will be identified.
- Suggest Future Directions: propose several directions that could become future research paths in regard to imbalanced datasets in malware detection.

By addressing these objectives, this review aims to offer a clear understanding of the current landscape of imbalanced dataset in malware detection.

III. RESEARCH METHODOLOGY

We follow a systematic approach to review the existing literature on imbalance datasets in malware detection, following the Preferred Reporting Items for Systematic Reviews and Meta Analyses (PRISMA) guidelines. It includes defining the research questions, selecting databases, developing search strings, establishing of inclusion exclusion criteria, and applying a quality assessment framework. The methodology is organized as follows:

A. Data Sources and Search Strategy

To ensure comprehensive coverage of relevant studies, the search was conducted across the following academic databases:

- IEEE Xplore
- MDPI
- SpringerLink
- ScienceDirect

The keywords used for the selection based on the related research objectives:

(“Imbalanced Datasets”) AND (“Malware Detection”)

Only peer-reviewed journal articles and conference papers published between 2020 and 2024 were considered to capture recent developments.

B. Inclusion and Exclusion Criteria

To filter search results for relevant studies, we established the following inclusion and exclusion criteria:

1) Inclusion Criteria:

- Studies that focus on imbalanced datasets and malware detection
- Peer-reviewed journal articles, conference papers.
- Studies that provide empirical results or evaluations using datasets relevant to imbalanced datasets.
- Publications written in English.
- Propose novel methods or provide empirical evaluations.

2) Exclusion Criteria:

- Studies not related to imbalanced datasets and malware detection.
- Publications that only provide theoretical models without empirical validation.
- Non-peer-reviewed sources such as theses, white papers, and editorials.

C. Study Selection Process

The study selection process adhered to the PRISMA framework, proceeding in three stages:

- Initial Screening: All retrieved articles were screened by titles and abstracts to exclude irrelevant studies and choose those meeting the inclusion criteria for full-text review.
- Full-Text Review: Full texts of selected articles were reviewed to determine their relevance and quality. Excluded articles that did not provide detailed information on balancing techniques, datasets, or empirical evaluations.
- Data Extraction and Coding: A standardized form was used to extract data from the final set of articles, including balancing techniques, datasets, and

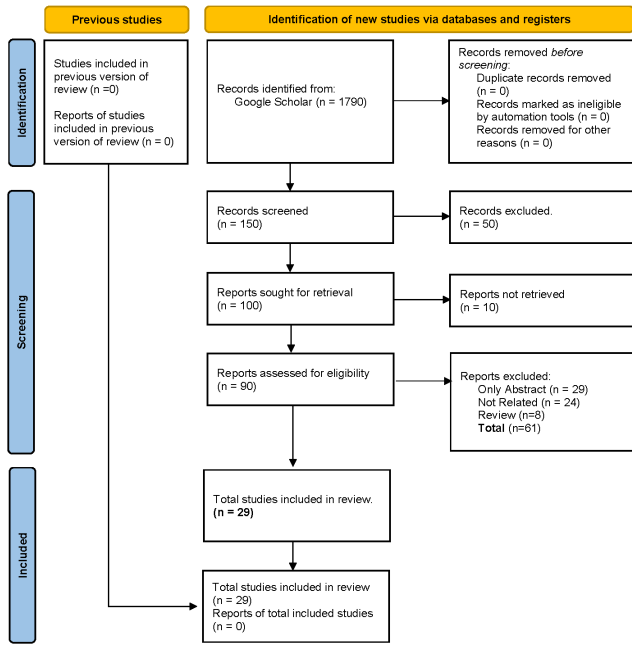

Fig. 4. PRISMA flow diagram summarizing the study selection process.

Fig. 5. Distribution of publications included in the review based in year.

evaluation metrics, as well as identify challenges and contributions.

Fig. 4 shows the PRISMA flow diagram.

Fig. 5 shows the distribution of the number of papers selected for this SLR per year.

IV. LITERATURE REVIEW

The problem of imbalanced datasets in malware detection in Android devices is addressed by Dehkordy and Rasoolzadegan [9]. They obtained a dataset from Drebin and AMD datasets containing 9,223 applications, and was heavily pre-processed to reduce the features from 1,262 to 78 for faster learning. The authors used SMOTE (Synthetic Minority Over-sampling Technique), undersampling, and a hybrid approach to

solve the imbalanced issue. To improve the accuracy of detection they employed dataset preprocessing, ranking of features and using multiple classifiers like K-nearest neighbors (KNN), Support Vector Machines (SVM) and Iterative Dichotomiser 3 (ID3). The best results were obtained by a combination of KNN with SMOTE, with an accuracy of 98.69%. However, the study limited to false positive rates of 2.09% to 4.77% and an approach that is only applicable to a limited number of malware families, which limits the model's generalizability. Guan et al. [10] propose n Class Imbalance Learning (CIL) approach to address the class imbalance problem for Android malware detection. It applies the K-means clustering-based under-sampling, which retains the representative majority samples, and then the SMOTE algorithm to generate the synthetic minority samples. A Random Forest (RF) classifier is then trained on the combined dataset. The dataset used for evaluation consists of 10,182 malware samples from VirusShare and 127 benign samples, with a class imbalance ratio of 1:80. They showed that the CIL method outperforms other traditional methods such as SMOTE and random under-sampling. In general, CIL shows good generalizability to other imbalanced datasets, and it is a promising solution to the class imbalance problem in malware detection.

Imbalanced datasets in malware detection for edge computing in Android based Internet of Things (IoT) environments is addressed by Khoda et al. [11]. The authors propose two methods a dynamic class weighting technique and modified Fuzzy-SMOTE for synthetic oversampling. The first approach generates valid synthetic malware samples preserving the malicious functionality, the second approach dynamically adjusts class weights during training to improve malware detection. The evaluation show over 9% improvement in F1 score over traditional imbalanced learning techniques. 50,000 Android applications and 500 malware samples in the dataset. The fuzzy approach is limited by the requirement of careful tuning, while the dynamic class weighting method is less sensitive to such parameters.

The challenge of detecting Android ransomware in an imbalanced dataset is addressed by ALMOMANI et al. [12]. A hybrid evolutionary approach using Binary Particle Swarm Optimization (BPSO) and SVM is employed for feature selection and classification to improve classification performance by effective optimization. The SMOTE was used to balance the dataset. Sensitivity, specificity and g-mean were used to evaluate the model, scoring 96.4%, 98.7% and 97.5%, respectively. The dataset has 10,153 Android applications out of 500 ransoms. However, the dataset is small making it difficult to generalize, especially for new ransomware variants.

Hemalatha et al. [13] suggest a DenseNet model based on Deep Learning (DL), with a class balanced categorical cross entropy loss to overcome class imbalances. Malware binaries are transformed into grayscale images and malware detection is framed as a multi-class image classification problem. The experiments were performed on Maling, BIG 2015, and MaleVis datasets with high accuracies of 98.23%, 98.46%, and 98.21%, respectively; and 89.48% on the unseen Malicia dataset. However, the model lacks in accuracy on unseen data, and struggles with novel malware (zero day attacks). Future work could involve improving generalization to deal with zero day attacks.

Goyal and Kumar [14] discuss malware detection and the effect of data imbalance. To balance the dataset, the researchers use random under-sampling to reduce 42,797 malware samples to 1,079 benign samples. They compared different ML classifiers (KNN, Decision Tree, RF). RF achieved the best accuracy of 98.94% on the imbalanced dataset, and 90.38% on the balanced dataset. They show the impact of data imbalance on model accuracy, and that more reliable results can be obtained from balanced datasets. The study concludes that balanced datasets are necessary to reduce bias and increase reliability, and future research could include further investigation of more sophisticated balancing techniques to improve the applicability of the model to real world scenarios.

Salas and Geus [15] addresses the challenge of class imbalance. The authors propose the MobileNet Fine-Tuning (MobileNet FT) model, a fine tuned version of MobileNet that utilizes bicubic interpolation and class weight estimation techniques. Experimental results show that the proposed model reaches accuracy rates for different datasets, such as Microsoft Big 2015 (98.71%), Maling (99.08%), MaleVis (96.04%), and a new Fusion dataset (98.04%). These results show that the model is robust to a range of malware families. The approach is also shown to have limitations, such as a degradation in performance as the number of malware families increases and problems with unseen malware. This motivates further investigation into more adaptive models to improve scalability and robustness to new threats.

Almaleh et al. [16] suggest to improve the detection of malware in Windows using a hybrid method. They use logistic regression with Recurrent Neural Network (RNN) to detect malware from Application programming interfaces (API) call sequences. The study presents a solution to the problem of imbalanced datasets through the use of an undersampling technique that creates a balanced dataset of 2,158 samples of malicious and non-malicious samples. They initialize the RNN weights using logistic regression for improved model accuracy. For the balanced dataset, the model reached an accuracy of 83%, and for the imbalanced, an accuracy of 98%. Limitations include a relatively small trained dataset after balancing due to its restriction on generalizability. Future work could build on the model for other operating systems and overcome these limitations so that the model is more applicable and robust in different scenarios.

Yu Ding et al. [17] proposed self-attention based approach, considering malware ASM files as text sequences to distinguish the malware families. The imbalance dataset technique used to represent ASM files as integer vectors and use a self attention neural network to improve minority class recognition. The sequence classification accuracy is improved by capturing internal dependencies within sequences using this approach. The model is evaluated using the Microsoft Malware Classification Challenge dataset, and shows a robustness to different datasets with 98.48% accuracy and 89.66% F1 score for Simda class. However, small sample recognition problems are not completely solved, and the interpretability of the model is restricted. The future work could include improving early detection of new malware and make neural networks easier to interpret for practical application in cybersecurity.

Moti et al. [18] handles the problem of imbalanced dataset for malware detection. The synthetic samples for minority

classes are generated using a hybrid model composed of Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) networks with Sequence Generative Adversarial Networks (SeqGAN), so that the dataset is balanced. The classification accuracy is improved to 98.99% using this approach. They evaluate on a Microsoft dataset from a Kaggle competition that contains nine malware families. While the high accuracy, the model depends only on opcode sequences without preprocessing, which can restrict its feature diversity. Moreover, the training overhead of SeqGAN is not high and the model still needs to be adapted to different datasets and zero day threats.

The problem of Android malware detection is addressed by Almomani et al. [19]. They present a vision based DL model that converts Android Application Package (APK) bytecodes to visual images and uses CNNs for classification. They evaluate the model on an imbalanced dataset (14,733 malware and 2,486 benign samples), without using data augmentation. The main contribution is the development of 16 fine tuned CNN algorithms that are efficiently able to classify malware, which demonstrates 99.40% accuracy on balanced datasets and 98.05% on imbalanced datasets. The study highlighted reduced computational cost due to no longer requiring the manual feature extraction. The limitations include dependence on pre trained CNN weights and uncertain adaptability to new malware types or other datasets.

In the problem of detecting macro malware in Microsoft document files, Mimura [20] tackles the problem of highly imbalanced datasets. They propose a method to combine Doc2Vec and Latent Semantic Indexing (LSI) with four classifiers (SVM, RF, Multilayer Perceptron (MLP), CNN) to increase the accuracy of malware detection. The highest F-measure of 0.99 indicated a high accuracy. The dataset consisted of more than 30,000 samples from VirusTotal and Stack Overflow with an imbalanced distribution favoring benign samples. Limitations include possible lack of generalizability from dataset composition, and future work is to collect more data for robust evaluation. The results of the study demonstrate that LSI is robust to class imbalance and promising results in practical malware detection applications.

Nikale and Purohit [21] addresses the issue of class imbalance in the dataset. The authors used dynamic features such as system calls and binder calls to classify Android APKs into five families: Ransomware, smware, adware, scareware and benign. The dataset consists of 525 APK samples from different sources, including Contagio Mobile and Google Play Store. The research introduced SMOTE, Adaptive Synthetic sampling (ADASYN), and balanced cost. They tested various classifiers, and the highest accuracy of 91% was obtained with Extreme Gradient Boosting (XGBoost) combined with SMOTE. However, the study is limited by small dataset, hence, restricted in generalizing its findings. Furthermore, constraint is noted on the focus on a fixed set of dynamic features without investigating more specific behavioral characteristics.

SAWADOGO et al. [22] evaluate the impact of data imbalance on eleven ML algorithms, the authors use CICMal-Droid 2020, a malware dataset. For comparison, they created two subsets: one imbalanced and the other balanced. They claim that traditional evaluation metrics (Accuracy, Precision and Recall) are inappropriate for imbalanced datasets, while

Balanced Accuracy and Geometric Mean are more appropriate. The results show that algorithms such as AdaBoost and SVM perform very poorly on imbalanced data, whereas Extra Trees and RF are less sensitive. Therefore the authors suggest to use balanced evaluation metrics to better represent the model performance on imbalanced dataset. A study limitation is that a single dataset was used. Additionally, future work should study more sophisticated learning techniques on more diverse datasets to improve the robustness of Android malware detection models.

In this paper, Haluška et al. [23] compare 16 data preprocessing methods for imbalanced classification problems, with a focus on cybersecurity. The authors extensively used six cybersecurity datasets and 17 other public imbalanced datasets from different domains as benchmarks. Overall, the performance of oversampling methods is better than that of undersampling methods, and the standard SMOTE algorithm gives a substantial performance boost. Experiment results indicate that SMOTE and its variants, e.g. generalization of SMOTE and SVM SMOTE, work well in various datasets and metrics, e.g. PR AUC, ROC AUC, and P-ROC AUC. This study shows that to improve predictive performance on multiple tasks in cybersecurity and other domains, it is essential to choose appropriate preprocessing methods and carefully consider method choice and hyperparameter tuning.

Alzammam et al. [24] provide a comparative view of different approaches to the problem of imbalanced multi-class classification in malware detection using CNN. The study focuses on evaluating the effectiveness of different methods, such as cost-sensitive learning, oversampling, and cross-validation, to mitigate the imbalance issue in three publicly available malware datasets. For instance, the study shows that oversampling outperforms other methods in boosting the accuracy and F1-score of the CNN model on every dataset, while the proposed model achieves substantial improvements in accuracy and F1-score when oversampling, with accuracy reaching as high as 99.94% for the Maling dataset. Finally, this research highlights the importance of dataset characteristics when selecting a method to correct for imbalance, as well as other data factors (including noise and overlapping) and the complexity of applying pre-trained models to malware classification.

Phung and Mimura [25] suggest a way to detect malicious JavaScript by using ML, but specifically dealing with the class imbalance problem. Once the balance between the benign and malicious datasets is adjusted through an oversampling technique, the authors use them to train a classifier for prediction. Experimental results indicate that the proposed method can effectively detect new malicious JavaScript with higher accuracy and efficiency (0.72 recall with Doc2Vec). With the same training and test time per sample, this outperforms the baseline method by 210% in terms of recall score on the dataset with over 30,000 samples: 21,745 benign samples from popular websites and 214 malicious samples from PhishTank, along with an additional 8000 malicious samples from GitHub. The research limits itself to various resampling techniques without exploring or comparing them in a more comprehensive way.

In mobile malware detection, Khoda et al. [26] propose a novel way to handle the problem of imbalanced datasets

via synthetic oversampling. This method proposes the addition of features to existing malware samples to generate synthetic malware samples that are valid and retain the malicious functionality. They test the approach using a Deep Neural Network (DNN) on the Drebin Android malware dataset. Results indicate that the proposed method achieves higher precision, recall and F1 score than the oversampling and undersampling techniques in general, and especially at lower imbalance ratios. The performance of the proposed model is much more accurate than previous methods, achieving an F1 score of 94.2% at 10% imbalance ratio and accuracy of 98.8%. The dataset used is the Drebin dataset which has 50,000 apps and 500 malicious apps as the minority class.

Reshi and Singh suggest a new method to handle the imbalance issue in malware datasets through the use of Variational Autoencoder (VAE) [27]. The proposed solution uses VAEs to extract and compress features from the given data and, thus, the model is able to learn features that are resistant to noise and distinguish between real malware and other types of noise. In addition, VAEs improve the data augmentation technique by generating synthetic malware samples from the learned latent space to help overcome the imbalanced problem. This approach expands the training set and, therefore, improves the model's ability to generalize and increase the detection rate for new or less frequent variants of malware. The research contributes by enhancing the VAEs by combining them with CNNs for malware detection. The proposed model gives an accuracy of 98% on the Maling dataset, which is better than the baseline model. The dataset used in this work is the Maling dataset, which has a highly unbalanced class distribution. The main drawback of the proposed work is that the integrated VAE-CNN model is relatively complicated and may need appropriate resource allocation and hyperparameter optimization.

Faridun and Im propose a novel malware detection approach using the TabNetClassifier, which is a DL architecture designed explicitly for tabular data analysis [28]. In this research, they enhance malware detection by utilizing the TabNetClassifier in conjunction with the SMOTE to address class imbalance in datasets. Initially, the dataset of 138,047 Portable Executable (PE) header samples is trained using the TabNetClassifier, which is imbalanced with 41,323 benign and 96,724 malware samples. SMOTE is applied to balance the dataset and improves model performance significantly. The main contribution of this research is to show the success of combining TabNetClassifier with SMOTE in improving malware detection accuracy and sensitivity. After applying SMOTE, the model achieves an accuracy of 99.10%, precision of 99.03%, and recall of 99.19%.

Li et al. [29] present a novel method for malicious family classification based on multimodal fusion and weight self-learning. The method deals with the problem of imbalanced datasets and concept drift in malware family classification. This approach integrates multiple features of byte, format, statistic, and semantic types to improve the robustness of the classification model. Experimental results show high efficiency and small resource overhead in classifying highly imbalanced malware family datasets while delivering very good classification performance. The dataset used consists of some types of malware, namely ransomware, Trojans, viruses, and malicious

mining programs. However, the research is limited by the reliance on static analysis and may not find the dynamic behaviors of malware.

In order to improve ransomware detection and classification, Onwuegbuche et al. [30] propose a three-stage feature selection method. This method applies chi-square (CHI2), Duplicated Features (DUF), and Constant Features (COF) filter feature selection techniques to reduce the dimensionality of the dataset, taking into account the different importance of different feature groups. Further, the study addresses the class imbalance problem by employing the SMOTE and cost-sensitive ML methods. The performance of this method is evaluated on the Elderan ransomware dataset and several ML models (XGBoost, Logistic Regression, RF, Decision Trees, and SVM). The results demonstrate that the proposed feature selection method leads to a 10% average improvement in binary classification and 21.79% in multi-class classification over previous studies. Among binary classifiers, XGBoost with cost-sensitive learning and SMOTE is the best with 98.78% balanced accuracy, while the best multi-class classifier is the RF model with cost-sensitive learning achieving 61.94% balanced accuracy.

Andelic et al. [31] deal with the problem of malware detection in imbalanced datasets. The authors suggest combining a Genetic Programming Symbolic Classifier (GPSC) with dataset oversampling techniques to increase the detection accuracy. They apply the GPSC algorithm to an open dataset containing hybrid features consisting of binary hexadecimal and Dynamic Link Library (DLL) calls of Windows executables. The dataset is initially imbalanced, containing 301 malicious and 72 non-malicious samples. In order to address this imbalance, the authors use oversampling techniques such as ADASYN, BorderlineSMOTE, KMeansSMOTE, SMOTE, and SVMSMOTE, and they train the GPSC with Five-Fold Cross-Validation(5FCV) and Random Hyperparameter Value Search (RHVS) method to select the best combination of hyperparameters. The classification accuracy of the proposed method is 0.9962. GPSC is used to generate Symbolic Expressions (SEs) that can be easily applied to and implemented into malware detection models, overcoming the limitations of traditional ML models, which are hard to interpret and transform into mathematical equations.

According to Çayır et al. [32], a new ensemble model called the Random CapsNet Forest (RCNF) is proposed to tackle the imbalance in malware type classification. The authors use the Capsule Network (CapsNet) architecture to preserve spatial information without the use of pooling layers and incorporate the bootstrap aggregating (bagging) technique to form an ensemble model. The idea is to reduce the variance of CapsNet models and improve the robustness of classification by using this approach, which is tested on two highly imbalanced datasets, Malimg and BIG2015, where the RCNF model is also shown to outperform other competitors with fewer trainable parameters. It achieves an F-Score of 98.20% for the BIG2015 dataset and 96.61% for the Malimg dataset. Advantages noted regarding the simplicity of the architecture and the ability to train from scratch without the need for transfer learning.

LIN et al. [33] present a ML framework based on a VAE and a MLP that helps overcome the problem of imbalanced

datasets in intrusion detection systems (IDS). An efficient range-based sequential search algorithm is included in the framework to determine the optimal sequence length for data segmentation from multiple sources, including network packets and system logs. Experimental results on HDFS dataset demonstrate that the proposed method achieves an F1 score of around 97% and recall rate of 98%, better than other solutions. Imbalanced datasets are treated using the proposed approach, which increases the F1-score by up to 35% and the recall rate by 27%. In addition, the work also points out the necessity of the appropriate data segmenting and the possibility of the proposed model detecting the new attack variants. The dataset used is the HDFS dataset, a public system log dataset.

In the context of Federation Learning (FL), ransomware detection, and attribution, Vehabovic et al. [34] address an essential problem of dataset imbalance. The authors suggest a modification of the FL scheme where the weighted cross entropy loss function is used to combat bias in datasets distributed across various clients. This approach is particularly applicable since ransomware data distribution and quantity can differ significantly also across different locations and companies. The performance of the proposed FL scheme is evaluated using an up-to-date repository of Windows-based ransomware families and benign applications. The results indicate that the weighted cross entropy loss function approach can mitigate the effect of dataset imbalance, especially in the case of binary ransomware detection with an average accuracy of 94.67%, but the study also points out the difficulties of multi-class attribution with imbalanced datasets, which results in more decline in performance compared to the balanced datasets.

As a form of unsupervised learning, Shi et al. [35] explore using One-Class Classification (OCC) to detect malware in the Internet of Things (IoT) domain. To combat dimensionality and information loss, the authors suggest that categorical features should be changed into numerical formats by using the Term Frequency-Inverse Document Frequency (TF-IDF) method. They compare the performance of OCC models, such as Isolation Forest and deep autoencoder, trained on benign NetFlow samples alone. It is shown that these models achieve 100% recall with precision rates greater than 80% and 90% on a number of test datasets, highlighting the adaptability of unsupervised learning to time-evolving malware threats in IoT, and making an important contribution to the study of malware detection in IoT, particularly when labeled malicious data are scarce. TF-IDF is used for feature transformation, and the comparison of various OCC algorithms leads to valuable improvements in the IoT security framework.

Using ML techniques, in particular, the use of genetic programming for feature selection, Al-Harashsheh et al. [36] propose how to enhance malware detection. The researchers built a malware detection model in which the features are selected by a genetic programming algorithm, and then a set of parallel classifiers is used to enhance detection accuracy at a lower cost. The proposed model employs five feature selection methods: Filter-based, wrapper-based, Chi-Square, Genetic Programming Mean (GPM), and Genetic Programming Mean Plus (GPMP). Experimental results demonstrate that the GPMP method (which uses fewer features than the Filter-based method) results in better accuracy and F1-score values of 0.881066 and 0.867546, respectively. The research

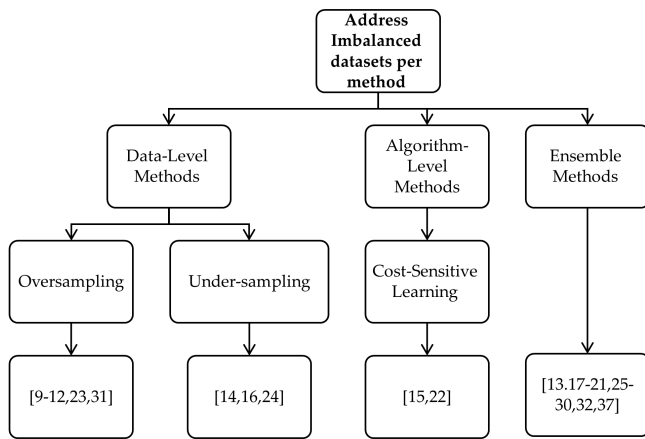

Fig. 6. Taxonomy of the literature review per method used.

indicates that genetic programming is able to select features to improve the performance of malware detection effectively. A number of classifiers, such as RF, Random Tree, and SVM, were used to compare the performance of the proposed feature selection methods.

Al-Khshali et al. [37] propose a new technique employing subspace learning-based OCC methods to detect malware. In this work, they address the issues of class imbalance and the curse of dimensionality in the application of traditional ML algorithms for malware detection. In order to overcome these problems, the researchers introduce a pipeline that uses subspace learning techniques such as Subspace Support Vector Data Description (SSVDD) and Graph Embedded Subspace Support Vector Data Description (GESSVDD). The proposed framework solves multiple problems at once, including class imbalance and the curse of dimensionality. The results show promising performance, with a True Positive Rate (TPR) of 100% for subspace-learning-based OCC. The datasets used in this study include (Benign and Malicious PE Files, ClaMP, and Malware Analysis Datasets by Oliveira) which are diverse but representative of a wide variety of malware types.

Table III shows a summary of the literature review conducted previously.

Table IV shows the limitations and contributions of studies conducted.

A. Taxonomy of the Research

Fig. 6 shows the taxonomy clearly categorizes the different techniques utilized by the studies to mitigate the imbalances, with the data level set of methods focusing on manipulating the dataset distribution, the algorithm level which trains towards the adaption of the learning algorithms and the ensemble where a combination of a variety of methods is used to get better results.

V. DISCUSSION OF THE LITERATURE REVIEW

The literature review reveals that many ML approaches applied to address imbalanced datasets in malware detection. Many studies indicate handling class imbalance is important to improve detection performance.

1) Oversampling Techniques:

- In several studies SMOTE was commonly employed to increase the minority class representation, leading to improvements in detection rates for families of malware like adware, ransomware or smsware [9] [21] [30]. In the case of imbalanced learning, SMOTE was found to be effective at improving metrics such as F-measure and MCC [9]. Complex oversampling methods gave incremental improvements, indicating the need to balance computational cost with performance gains [23].
- However, oversampling methods like the conventional SMOTE have some limitations that need to be overcome or minimized through the use of more advanced forms like the Modified Fuzzy-SMOTE whose oversampling strategies produces synthetic data that is more reflective of real data distribution. However, these techniques are still inefficient with large, high-dimensional data sets when they are applied.

2) Feature Selection Techniques:

- The improvement in model efficiency and accuracy was greatly aided by feature selection techniques. The genetic programming based feature selection methods, including GPMP, demonstrated that selecting fewer but more relevant features can reduce computational complexity and improve classifier performance [36]. Multi stage feature selection was used in other studies to select features such as API calls, registry operations, and directory logs, which improves model interpretability and classification performance [30]. Moreover, swarm intelligence based optimization, and in particular BPSO was also efficient to choose the best features in order to achieve a large performance gain when dealing with highly imbalanced data for Android malware detection [12].
- The problem of selecting features often demands an expert's input in the process for feature selection. Perhaps, even more, automated approaches, such as feature selection by applying AI methods, could be more beneficial for this step.

3) ML Approaches:

- RF and SVM are used frequently as they are robust, and can handle non linear relationships in data. For instance, Guan et al.[10] achieved significant accuracy improvements by combining RF with SMOTE, especially in datasets with a high imbalance ratio (1:80). In another study, in a custom malware detection dataset, the RF model showed robustness with an accuracy of 98.94% [14]. However, As dataset size increases, RF achieves high accuracy on imbalanced datasets, but it's scalability becomes an issue. Moreover, RF fails to capture complexities of feature interactions unless it is heavily tuned.
- SMOTE was used in combination with SVM and showed 97.83% accuracy on Android malware datasets, as reported by Dehkordy and Rasoolzadegan [9]. However, Sawadogo et al. [22] point out that

TABLE III. SUMMARY OF LITERATURE REVIEW

Author	Year	Best balancing techniques	Scope	Dataset	Metrics Result
Dehkordy and Rasoolzadegan [9]	2021	SMOTE	Android malware detection on imbalanced datasets.	Drebin Dataset and AMD Dataset	KNN, SVM, ID3 Accuracy: 98.69%, 97.83%, 97.59%
Guan et al. [10]	2021	SMOTE	Android malware detection on imbalanced datasets.	VirusShare (10,182 malware, 127 benign apps)	RF, KNN, NB, SVM
Khoda et al. [11]	2021	Modified Fuzzy-SMOTE	Malware detection in edge computing.	Drebin Dataset, AndroZoo and Google Play Store	DNN (F1 Score 99%)
Almomani et al. [12]	2021	SMOTE	Android Ransomware Detection in Imbalanced Data.	Custom Dataset	SMOTE-IBPSO-SVM (Specificity 98.7%)
Hemalatha et al. [13]	2021	Reweighted class-balanced loss function	Malware detection on imbalanced datasets.	Maling	DenseNet-based (Accuracy 98.46%)

Haluška et al. [23]	2022	SMOTE	Imbalanced classification in Cybersecurity and other domains.	23 datasets (6 cybersecurity datasets and 17 public imbalanced datasets)	PR AUC, ROC AUC, and P-ROC AUC are 6.283, 6.174, and 4.087, respectively.
Alzammam et al. [24]	2020	Oversampling	Imbalanced multi-class malware classification.	Maling, Microsoft, and VirusTotal	Accuracy:99.94%, 98.31%, 96.06% respectively.
Phung and Mimura [25]	2021	Oversampling + ML	Static analysis for detecting malicious JavaScript.	Imbalanced dataset over 30,000 samples (PhishTank + Github).	Recall score of 72% with Doc2Vec model, outperforming baseline method by 210%.
Khoda et al. [26]	2020	Oversampling + DNN	Mobile malware detection with imbalanced data.	Drebin Android malware dataset (50,000 apps, 500 malicious)	F1-score of 94.2% and accuracy of 98.8% at 10% imbalance ratio.
Reshi and Singh [27]	2024	VAEs for generating synthetic samples	Enhance Malware detection in imbalanced datasets using DL.	Maling dataset	Accuracy 98%
Faridun and Im [28]	2024	SMOTE + TabNetClassifier	Malware detection using tabular data analysis and addressing class imbalance issues using DL.	138,047 PE header samples (41,323 benign and 96,724 malware samples)	Accuracy: 99.10%, F1-Score: 99.11% after applying SMOTE.
Li et al. [29]	2022	Multimodal fusion and Weighted Soft Voting	Malware family classification in Intelligent Transportation Systems.	Microsoft BIG-15	Accuracy: 99.2%, Macro-F1 score: 98.1%.
Onwuegbuche et al. [30]	2023	(SMOTE, Cost-sensitive learning) + ML	Ransomware detection and classification using ML models.	Elderan ransomware dataset	98.78% (binary - XGBoost with cost-sensitive learning and SMOTE), 61.94% (multi-class - RF model using cost-sensitive learning).
Andelic et al. [31]	2023	ADASYN	Improving malware detection in imbalanced datasets using GPSC and oversampling.	uci malware detection (301 malicious and 72 non-malicious).	Accuracy: 99.62%.
Çayır et al. [32]	2021	Ensemble learning with bagging RCNF.	Image-based malware family classification.	Maling and BIG2015	F-Score: 96.61%, 98.20% respectively.
LIN et al. [33]	2022	DL(VAE) + ML(MLP)	Intrusion Detection in Heterogeneous Networks.	HDFS logs	F1 score: 97%, Recall rate: 98%
Vehabovic et al. [34]	2023	Federated learning (FL) with Weighted cross-entropy loss function.	Ransomware detection and attribution using FL.	9 ransomware families (140 malicious samples each) and 2,000 benign Windows applications.	Binary detection: 94.67%, Multi-class attribution: 84.15%.
Shi et al. [35]	2024	OCC (ML:Isolation Forest, DL:Deep Autoencoder)	IoT Malware Detection.	IoT-23 dataset	F1-score: (Isolation Forest: 88%), (Deep Autoencoder: 95%).
Al-Harashsheh et al. [36]	2021	SMOTE over-sampling technique+GPMP feature selection + ML	Malware detection using ML classifiers with genetic programming for feature selection.	Ten different datasets	GPMP method with RF achieves an accuracy of 97.95% and an F1-score of 96.35%.
Al-Khshali et al. [37]	2024	Subspace Learning-Based OCC (SSVDD and GESSVDD), uses ML	Malware Detection.	3 datasets(Benign & Malicious PE Files, ClaMP, Malware Analysis Datasets: PE Section Headers by Oliveira)	100% TPR for subspace-learning-based OCC.

SVM's performance really drops when faced with larger and diverse datasets because SVM is not scalable due to its reliance on kernel based methods, and is sensitive to hyperparameter settings on real world imbalanced datasets.

4) DL Approaches:

- Studies explored DL approaches. Researchers investigated hybrid models like CNN + LSTM with Generative Adversarial Networks (GAN) to generate new synthetic samples to balance datasets in order to detect minority classes [18]. Colored and grayscale image representations of Android malware were used for detecting Android malware with vision based CNN, like Xception which reduces the number of manual feature extraction phases and increases scalability [19]. Fine tuning MobileNet through transfer learning techniques

emphasized that CNNs are effective in mitigating overfitting and enhancing generalization particularly in resource constrained environments [15].

- However, these models are computationally intensive and, therefore, unsuitable for real-time processing or on devices with low computational capabilities. Essentially, if these models were simplified or pruned, then they would most likely be more useful in terms of time and versatility.

A. One-Class Classification Models

- Innovative one class classification models proved to be effective in cases of lack of labeled data, especially in IoT environments. Isolation Forest and deep autoencoders showed high adaptability to new malware threats with 100% recall by using TF-IDF and n-grams

TABLE IV. LIMITATIONS AND CONTRIBUTIONS OF LITERATURE REVIEW

Ref	Contribution	Limitation
[9]	Improved malware detection through dataset preprocessing, feature ranking, and the use of multiple classifiers.	Limited malware family coverage and a notable false positive rate.
[10]	A hybrid Class-Imbalance Learning (CIL) method using clustering-based under-sampling combined with SMOTE.	Requires careful tuning of clustering parameters and may not generalize well to newer malware types.
[11]	Modified Fuzzy-SMOTE to handle data imbalance in malware detection.	Requires careful tuning of parameters.
[12]	Combining BPSO and SVM integrated with SMOTE, to effectively detect Android ransomware.	The dataset's small size and imbalance limit the model's generalizability.
[13]	DenseNet-based model for malware detection which visualizes malware binaries as grayscale images.	Struggles with detecting zero-day malware and has reduced accuracy for unseen malware classes.
[14]	Compares the performance of ML classifiers on balanced versus imbalanced datasets.	Potential bias which reduces the generalizability of the findings to real-world scenarios.
[15]	Combining multiple datasets into a new Fusion dataset for enhanced diversity.	Struggles with generalizing to unseen malware types.
[16]	A hybrid malware detection model combining logistic regression for weight initialization with RNN to improve detection capabilities of API call sequences.	Small balanced dataset reduces the model's ability to generalize effectively to diverse, large-scale scenarios.
[17]	Effectively addresses the issue of imbalanced datasets by treating malware ASM files as text sequences.	Struggles with the recognition of small-sample malware families and lacks interpretability for practical cybersecurity use.
[18]	CNN-LSTM hybrid model combined with SeqGAN to address class imbalance in malware detection.	High computational overhead due to SeqGAN training and reliance solely on opcode sequences which limits feature diversity.
[19]	Vision-based DL model utilizing 16 fine-tuned CNNs to detect Android malware efficiently without manual feature extraction.	Relies on pre-trained CNNs which limits adaptability to new malware types.
[20]	Detecting macro malware using Doc2vec and LSI combined with ML classifiers to address imbalanced dataset.	Dataset may not fully represent real-world conditions.
[21]	Proposed a familial classification model for Android malware using dynamic features while addressing dataset imbalance issues.	Small dataset and focused only on basic dynamic features, limiting broader applicability.
[22]	Investigates the impact of imbalanced datasets on the performance of various ML models for Android malware detection.	Uses a single dataset and evaluates a limited number of traditional ML algorithms.
[23]	Comprehensive benchmark of 16 data preprocessing methods for imbalanced classification	Slowness of Python-based implementations and need to subsample and perform feature selection on larger datasets.
[24]	Comparative analysis of techniques to address imbalanced datasets.	Complexity in using pre-trained models, and the need to consider dataset characteristics and other data factors.
[25]	Proposed an oversampling-based algorithm that improves recall score.	Does not explore other resampling techniques or compare them comprehensively.
[26]	Proposed a technique for generating synthetic malware samples that preserve malicious functionality.	Limited to Android malware and may not be directly applicable to other types of malware.
[27]	Proposed a novel approach combining VAEs with CNNs to address data imbalance	Complexity of the integrated VAE-CNN model, requiring careful resource management and hyperparameter tuning.
[28]	Combining TabNetClassifier with SMOTE to enhance malware detection accuracy.	Does not explore applications on other types of malware datasets
[29]	Proposed a novel approach combining multimodal fusion with weight self-learning + XGBoost to improve classification accuracy and mitigate concept drift.	Relies on static analysis, may not capture dynamic behaviors of malware.
[30]	Proposed a three-stage feature selection method and addressed class imbalance using SMOTE and cost-sensitive learning.	Limited to older ransomware families, dataset size, and specific balancing techniques.
[31]	Application of GPSC with oversampling techniques to achieve high classification accuracy and generate interpretable symbolic expressions.	Small dataset size and potential for oversampling techniques to introduce noise or overfitting.
[32]	First application of CapsNet in malware type classification, and ensemble model of CapsNet for imbalanced datasets.	Number of estimators limited to 10 RCNF due to increasing trainable parameters and significant training time.
[33]	ML framework that combines a VAE and a MLP to address imbalanced datasets and detect attack variants.	Potential for overfitting due to model complexity and need for further evaluation on other datasets.
[34]	Modified FL scheme to mitigate dataset imbalance.	Performance decline in multi-class attribution with imbalanced datasets.
[35]	Demonstrated the effectiveness of OCC in IoT malware detection using unlabeled benign data. Introduced TF-IDF for feature transformation.	Reliance on a specific dataset and potential need for further validation across more diverse IoT environments.
[36]	Proposed GPMP that uses genetic programming to select relevant features, leading to improved detection accuracy and reduced computational cost.	Lack of detailed analysis of the computational cost of the proposed method compared to others.
[37]	Adapting subspace learning techniques to OCC for malware detection.	Need for further exploration of subspace learning techniques in cybersecurity.

for feature transformation [35]. Furthermore, subspace learning based OCC models, such as Graph Embedded Subspace SVDD (GESSVDD), demonstrated excellent scalability and the capability of preventing the curse of dimensionality with a True Positive Rate of 100% [37].

- It is possible that using both of these methods will improve the performance of detection systems in identifying malware while at the same time protecting the privacy of users at the same time. However, the consistency across FL different systems remains a problem.

B. Federated Learning and Capsule Networks

- FL as a promising approach to ransomware detection, with privacy maintained through distributed training

without distribution of raw data. Weighted cross entropy loss improved detection performance of minority classes across different client nodes, making FL a compelling solution for real world scenarios where data centralization is infeasible [34]. In addition, CapsNet with their capability of spatial feature preserving were proven effective in imbalanced malware type classification with high F-scores using fewer trainable parameters than conventional CNNs [32].

C. Variational Autoencoders and Symbolic Classifiers

- VAE used to address data imbalance problem by generating synthetic samples to balance malware and benign instances, which helped greatly improve CNN model generalization and the accuracy was improved from 90% to 98% [27]. GPSCs showed its inter-

Fig. 7. Distribution of techniques used across studies.

pretability, using symbolic expressions along with oversampling techniques such as SMOTE to adequately address imbalance while still maintaining high precision and recall [31].

D. Datasets

- Maling, BIG 2015, and Drebin are examples of the datasets widely applied in malware detection research. Although these datasets have been used to assess models, the lack of variability enhances the datasets, and the imbalance ratios are not real-world. Moreover, they were chosen because they were prevalent in the reviewed studies and relevant to malware detection research. These are benchmarks in the field, often cited due to their diversity in malware types and their real world class imbalance. For example, the Drebin dataset with more than 50,000 Android applications is one of the most used datasets to validate imbalanced learning techniques [26]. The Maling dataset also covers a wide variety of malware families, and so is suited to the evaluation of DL and ensemble methods [13], [27].

The literature showed a wide range of techniques to address the problem of imbalanced datasets on malware detection. SMOTE, feature selection, DL, GANs, one class classification, and FL each had its own benefits, including improving detection rates and recall, maintaining privacy, and interoperability. Moreover, the literature that the ensemble method is the most used by the studies compared to other methods, as shown in Fig. 7. Hence, the importance of these advances to improving the robustness and efficiency of malware detection systems considering continuous evolution and diversification of threats.

VI. CHALLENGES AND OPEN DIRECTIONS

Although imbalanced datasets for malware detection have been addressed, there are still open issues.

- Oversampling and Computational Challenges: Many oversampling techniques such as SMOTE and its variants, are effective, but they can also cause computational overhead and overfitting, particularly for complex synthetic data generation [23] [26]. A crucial

need still remains to achieve the balance between computational efficiency and performance improvements, especially when working with resource constrained environments or large datasets.

- Feature Selection Complexity: Feature selection is another challenge. However, techniques such as Genetic Programming based feature selection and multi stage feature prioritization have been shown to be successful, but can significantly complicate the training process and require a great deal of fine tuning [30] [36]. However, the challenge to integrate such methods into real world scenarios where computational resources may be limited still remains. More efficient and automated feature selection approaches are also needed, that can lessen reliance on domain specific knowledge without compromising accuracy.
- DL and Hybrid Model Limitations: Despite their potential, DL models typically require largescale computations and are easily overfit over unbalanced data without a necessary regularization. While CNN-LSTM combined with GANs and CapsNet are effective, they bring along additional layers of complexity that hinder their practical deployment [18] [32]. Also, FL provides privacy preserving capabilities but comes at the cost of synchronization issues and model consistency across distributed nodes [34].
- Dataset: Future work should therefore aim at developing larger datasets that are more general and include samples of rare types of malware as well as more realistic conditions. Shared databases could be federations hence creating federated datasets that would otherwise share data securely.

Further research should be conducted to develop lightweight and computationally efficient models that can be used in real time malware detection environment. Transfer learning and FL are promising, but more work is needed to make them work effectively with imbalances without a huge computational overhead. Addressing these challenges will be key to making malware detection systems robust and practical for dynamic and diverse threat landscapes.

VII. CONCLUSION

This paper provides a comprehensive review of the problems that exist in imbalanced datasets in malware detection, presenting an investigation of existing solutions including data level, algorithm level, and ensemble methods. Key approaches to overcome data imbalance issues in malware detection are identified including SMOTE, DL hybrids like CNN and LSTM, and advanced strategies like FL. The review shows that the methods increase the malware detection rate significantly. However, issues remain like computational overhead, overfitting, and limited generalizability of these models to unseen malware types. Specifically, Modified Fuzzy-SMOTE and FL deal with some of these challenges by generating more realistic synthetic data and preserving privacy in distributed training environments.

This paper identifies a taxonomy that classifies the varied methodologies used to deal with class imbalance in malware

detection. The results show that ensemble methods are the most effective across various scenarios, especially for improving detection accuracy and robustness. The study also provides tradeoffs between computational efficiency and model performance, and provides a guide for future developments. Proposed future research may focus on creating advanced techniques and frameworks that address the difficulties of imbalanced datasets in detecting malware. The combination of Modified Fuzzy-SMOTE with feature selection methods generate realistic synthetic samples for machine learning algorithms while improving the robustness of RF and SVM classifiers. Moreover, optimizing hybrid models like CNN-LSTM becomes viable for real-time malware detection through optimization processes that include parameter sharing and model pruning mechanisms. Also, real-time data distribution adaptation in dynamic cost-sensitive learning algorithms leads to enhanced performance across malware families. Finally, the inclusion of real-world data variations with diverse samples within expanded datasets helps models achieve better generalization capabilities and maintain robustness within dynamic operational settings.

FUNDING

This work was funded by King Faisal University, Saudi Arabia. [Project No. GRANT KFU250100].

ACKNOWLEDGMENT

Abstract—With the continuous development of financial markets worldwide, there has been increasing recognition of the importance of financial risk management. To mitigate financial risk, financial risk early warning serves as a risk uncovering mechanism enabling companies to anticipate and counter potential disruptions. The present review paper aims to identify the bibliometric analysis for exploring the growth and academic evolution of financial risk, financial risk management, and financial risk early warning concepts. Academic literature is surveyed from the Scopus database during the period 2010-2024. The network analysis, conceptual structure, and bibliographic analysis of the selected articles are employed using VOSviewer and Bibliometric R Package. The biblioshiny technique based on the bibliometric R package was used to draw journal papers' performance and scientific contributions by displaying distinctive features from the bibliometric method used in prior studies. The data was extracted from Scopus databases. In addition, this study comprehensively analyzes the evolution of financial risk early warning systems, highlighting significant trends and future directions. Thematic evaluation across 2010-2015, 2016-2021, and 2022-2024 reveals a shift from traditional statistical methods to advanced machine learning and AI techniques, with neural networks, random forests, and XGBoost being pivotal. Innovations like attention mechanisms and LSTM models improve prediction accuracy. The integration of sustainability factors, such as carbon neutrality and renewable energy, reflects a trend towards incorporating environmental considerations into risk management. The study underscores the need for interdisciplinary collaborations and advanced data analytics for comprehensive financial systems. Policy implications include promoting AI adoption, integrating environmental factors, fostering collaborations, and developing advanced data analytics frameworks.

Keywords—Artificial intelligence; deep learning; financial risk management; early warning systems; bibliometrics analysis

I. INTRODUCTION

In the dynamic landscape, the financial risk of companies is an unavoidable risk and inevitable companion which is reflected in all parts of company investment and financing management. The presence of financial risks presents a huge vulnerability to the healthy advancement of companies [24]. In an era of volatility, uncertainty, complexity, and ambiguity firms have been subjected to unprecedented exposure, which complicates decision-making [1]. In the current era of the Internet plus, the world economy is becoming more and more

globalized and informational. The business environment is changing rapidly, and the business development of enterprises is facing unprecedented opportunities for their operation and development. However, it is also facing financial uncertainties brought about by the fluctuations of the general economic environment, and the company is facing increasing financial risks. It also faces unpredictable environmental factors and challenges such as economic market factors, laws and regulations, social and cultural factors, and policy environment factors which bring uncertainty to the financial situation of enterprises, and the financial risks faced by enterprises are also increasing.

The role of the financial market in enabling societies to reach the low carbon economy is well understood [26]. The market competition has become rigorous under the influence of "economic globalization" and enterprises are under pressure for both survival and growth. Low-carbon development has greatly changed the external environment and financial environment of enterprises, thereby increasing the financial risks that exist in enterprises. In the context of financial development globalization, financial market transactions between countries are frequent, the financial environment is more complex, and the spread of financial risks is more rapid and extensive. Especially, in the current international financial situation with high leverage, high asset prices, high market volatility, and high risk, financial supervision will become more difficult, and the possibility of a financial crisis outbreak is higher than before. A financial crisis will not only destroy a country's financial system and international financial order but also cause great damage to the real economy, causing an economic crisis, and even causing a serious social and political crisis, endangering national security.

Financial risk exists in the management process of an enterprise, and poor management or poor decision-making can cause the level of financial risk to exceed alarming values and lead to financial crisis [24]. The reason why most enterprises encounter a serious financial crisis or even close in the later stage is that they do not pay full attention to the initial financial problems and do not take effective measures to deal with the crisis in time. Therefore, it is very practical to establish a scientific data model to analyze and forecast the financial data of enterprises. It can not only monitor the financial situation of enterprises in real time but also play an

effective role in financial early warning [22]. Financial risk warning has become an important part of modern enterprise financial management. It helps enterprises better warn, prevent, and control financial risks which can reduce the loss and increase the profit. In recent years, there has been worldwide research on the issue of financial risk in developing countries, particularly from the perspective of a low-carbon economy it has become a hot issue.

Detailed literature is scarce on financial early warning predictions for the financial risk of enterprises. Recently, [19] documented that bibliometric analysis has been prominently conducted for the literature on topics including sustainable and Islamic finance [31], credit risk [33], financial crises, and efficiency measurement [10]. However, other topics, such as liquidity risk or ownership structure, have been comparatively neglected. Furthermore, based on our extensive review and study, it has been found that researcher focused on early warning systems in business, finance, and economics, and [44] have worked on risk management. In addition, much empirical research has been conducted on financial risk for enterprises, banks, and currency crises. However, a lack of evidence has been found that focuses on bibliometric analysis of financial risk early warning systems. Therefore, the goal of this study is to explore the recent progress, challenges, and future directions of financial early warning predictions to capture the significance of financial early warning predictions and linked areas through bibliometric and thematic analysis. Despite the growing importance of financial risk early warning systems, there remains a significant research gap in comprehensive bibliometric and thematic analyses that leverage updated data from the Scopus database. Previous studies have not fully utilized these methods to map the evolution and emerging trends in this field, particularly over the extended period from 2010 to 2024. This study addresses this gap by employing a robust bibliometric and thematic analysis, offering a novel perspective on the financial risk early warning landscape. By systematically categorizing themes into high occurrence and link strength keywords, emerging topics, niche areas, interdisciplinary and technological integration, and sustainability and innovation, this research provides a detailed and updated overview of the current state and future directions of financial risk management. This study's findings hold significant implications for policymakers. The identification of cutting-edge technologies such as neural networks, random forests, and XGBoost, as well as emerging areas like attention mechanisms LSTM, and GRU models, underscores the need for advanced analytical tools in financial risk prediction. Furthermore, it focuses on sustainability and consolidation of environmental factors into risk management which signifies the growing connectivity of financial stability and environmental responsibility. By providing a comprehensive overview of current and future trends, this study equips policymakers with the insights necessary to foster innovation and sustainability in financial risk management, ultimately contributing to more resilient and adaptable financial systems.

Our main objectives of the study are as follows:

- 1) To examine the historical distribution of financial risk early warning system articles, illustrating contributions through metrics such as average citation per year, core sources by Bradford's Law, most cited

countries, corresponding author's countries, and most relevant sources.

- 2) To identify prevalent research themes in financial risk management, highlight potential collaborations and interdisciplinary research opportunities, and suggest venues for future research to advance the field.
- 3) To offer policy recommendations to enhance the adoption of advanced AI techniques and sustainability considerations in financial risk management, encourage interdisciplinary collaborations and the development of advanced data analytics frameworks, and outline future research directions to address gaps and build on the study's findings.

A. Methods

The method used in this study is bibliometric analysis, which was first used by [34] and is popular among the researchers in supporting quantitative analysis in understanding the literature. The word bibliometric is the statistical analysis of scholarly communication through publications and the most common methods are variants of citation analysis. Bibliometric analysis is usually a machine-like mechanism to understand the research trends globally in an area of interest based on the output of academic database literature and is different from a typical review paper focusing on recent progress and challenges and future directions for a specific topic [20]. Bibliometric is a powerful tool for the management of information providing useful analytical results across many fields and its application in finance are relatively recent [25], [42].

B. Search Strategy and Sources of Data

According to [15] Scopus, Web of Science, and Google Scholar are the three main databases for academic literature and citation indexes. However, this study chooses the Scopus database because Scopus is the largest citation and abstract database covering a wide range of subjects and thus, this is an attempt to cover more topics, that might not be available with the Web of Science database. Google Scholar is not selected because it does not have a strong quality control process [13]. The first search on the Scopus database was conducted on 5 October 2023 with a central theme of "enterprise financial risk" in the title, abstract, and keywords resulting in 112 documents. Moreover, subsequent searches were made between October 2023 and December 2023, on a trial-and-error basis to check for any different results, issues, and shortcomings with the Scopus Database. The authors use the same central theme along with enterprise financial management and various other variants like financial risk prediction, corporate financial information risk, crisis assessment, and credit risk management, and the authors got different results. This change in the result at a different time was the same when other variants in the search string were used. Following this, the author used different search strings which finally led to the result of 150 documents by restricting it to journal articles only as these are most used to present academic novelties [13].

The subsequent keywords were explored simultaneously with a central theme as: with a central theme as "enterprise financial risk" OR "early warning system" and its related concept in the title level of the search tool which resulted in 150 documents. These comprehensive search strings were

selected because they are highly associated with the topic of interest in this study to cover the relevant body of literature. Thus, the final query string used is as follows: TITLE-ABS-KEY (“enterprise financial risk” OR “enterprise financial management” OR “enterprise financial information management” OR “financial risk” OR “financial risk prediction” OR “financial risk analysis” OR “financial risk assessment” OR “Financial management risk prediction” OR “financial crisis management” OR “corporate financial information risk” OR “corporate financial information risk management” OR “crisis assessment” OR “credit risk management”) AND (“Early warning system*” OR “ews*” OR “Financial early warning system*” OR “financial early warning model” OR “Financial risk warning” OR “financial risk prediction” OR “financial risk prediction model” OR “Risk prediction” OR “financial analysis system*”) AND (“neural network*” OR “deep learning”) AND (LIMIT-TO (LANGUAGE, “English”)) AND (LIMIT-TO (SRCTYPE, “j”)) AND (LIMIT-TO (PUBSTAGE, “final”)) AND (LIMIT-TO (OA, “all”)).

For selecting and screening the article, the authors used guidelines by “preferred reporting items for systematic reviews and meta-analyses” (PRISMA) for systematic research reviews as shown in Fig. 1. While screening, the eligibility and inclusion criteria the authors could ensure that no potential review article skips the Scopus Database filter. To check and ensure that there are no review articles, or any other potential irrelevant articles present in our analysis that might not have skipped our filtration process. Therefore, additional phrases such as bibliometric review, scientometric review, systematic literature review, systematic review, meta-analysis, science mapping, development, progress, recent, revisit, trends, prospects, advance, perspectives, reviews, and so on, as mentioned in [20] were used using conditional formatting toolbar in MS Excel and noted the documents Electronic Identifications (EIDs). Moreover, these articles were examined by reading the title and abstract, and if needed, the articles were read thoroughly to make sure that the articles were related to enterprise financial risk and financial risk warning. There are no missing authors’ names and IDs, and no articles were found to be duplicated.

C. Bibliometric Analysis Using VOSviewer

The study used VOSviewer (version 1.6.18) developed by the Centre for Science and Technology Studies, Leiden University, Leiden, Netherlands, to visualize the financial risk warning system and its related concepts in the number of articles, prolific authors, and most productive journals in maps. The descriptive analysis shows the configuration of many articles, types of articles, and articles over time of the Scopus Database, while the bibliometric analysis is performed using the co-authorship and co-occurrence analysis. Fig. 2 depicts the methodology for bibliometric analysis using VOSviewer. Information regarding the final 150 documents like bibliographical information, citations, and keywords were exported to VOSviewer’s latest version. The authors used VOSviewer because our main objective is to focus on an aggregate level and over time development of a research area [13]. VOSviewer is a tool for creating and displaying bibliometric maps using items. In this study, the objects of interest like author keywords and countries are the items. There can be a connection, relation, or link between each pair of items. Each connection

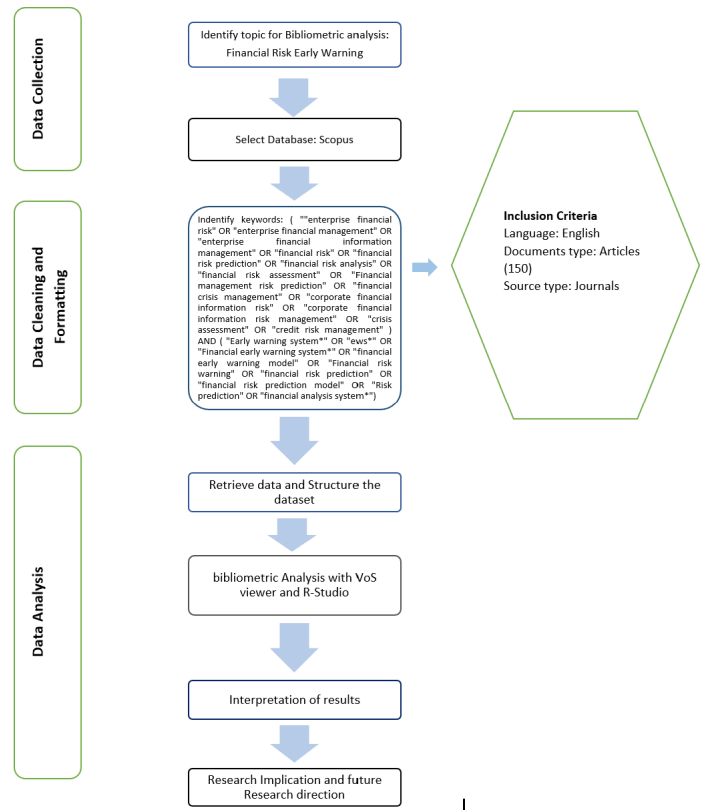

Fig. 1. Research process adopted in the study. Author’s compilation.

or link has a strength, which is represented by a positive numerical value, and the higher the value is, the stronger the link between the two linked items becomes. In the case of co-authorship analysis, the link strength between the countries shows the number of publications that two affiliated countries have co-authored. Meanwhile, the co-authorship links the total strength of a given country to other countries. In the case of co-occurrence analysis, the link strength between author keywords shows the number of publications in which two keywords occur together.

1) *Co-authorship Analysis*: In scientific research, co-authorship is the most formal manifestation of intellectual cooperation. It entails collaborating with two or more authors in conducting a research study, resulting in a higher quality or quantity research output than could be achieved by a single author [16]. Co-authorship research can be done at the organization and country level because bibliographic data contains details about the authors’ institutional affiliations and geographic positions. In this analysis of co-authorship, the unit of analysis chosen is country; therefore, the authors have included all the countries affiliated with many authors. The international research collaboration domain is under the influence of bibliometric research analysis and its main methodology is co-authorship analysis [9]. This study considered 21 affiliated countries and the affiliated countries were clustered into seven regions: South Asia (Region 1), Africa (Region 2), East Asia, and the Pacific (Region 3), Europe and Central Asia (Region 4), Latin America and the Caribbean (Region 5), Middle East and North Africa (Region 6), and North America (Region 7).

Fig. 2. Methodology for bibliometric analysis using VOSviewer.

Fig. 3. Methodology for bibliometric analysis using "Bibliometrix".

2) *Co-occurrence Analysis*: Co-occurrence analyses can be used to analyze the connections of author keywords used to make a conceptual structure of the study. Researchers create a complex network using keywords because actors combine and link the words to make an interesting funnel and aggregate. Co-occurrence analysis is the only technique that uses the contents or keywords of the document to find associations among the documents. At the same time, the other approaches link the document indirectly by co-authorship or through citation [11]. Likewise, co-authorship, the association among keywords used by research studies, is represented by the strength of the keywords used in the publications in the case of co-occurrence analysis. This technique can be used that utilize the contents of the publications to make a similarity measure among documents. However, the other methods connect documents indirectly through citations and co-authorship analysis [11]. Before transferring to VOSviewer, synonymous terms were identified and replaced with a single term. The study sets a minimum limit of keyword linkage to 2 in co-occurrence in VOSviewer. Overlay visualization is considered to explore the keywords' yearly publications, occurrences, and connections.

D. Bibliometric Analysis Using Bibliometrix

As the number of published research continues to grow at an increasingly rapid rate, the effort required to accumulate knowledge becomes more complex. "Bibliometrix" is a tool programmed in the R platform (<https://www.bibliometrix.org>) to perform a comprehensive bibliometric analysis of published literature. There are several packages in R dealing with bibliometrix; however, none of them address the entire workflow process [4]. The procedure for performing bibliometric analysis using "Bibliometrix" is shown in Fig. 3.

II. DISCUSSION

A. Data Analysis and Bibliometric Maps

Table I provides a comprehensive summary of the main information, publications, and sources regarding the articles selected from the Scopus database for the bibliometric analysis of financial risk early warning from 2010 to 2024. The dataset encompasses a total of 77 sources, which include various journals, books, and other publications, amounting to 150 documents. Despite the consistent number of documents each year, the annual growth rate remains at 0%, indicating no year-over-year increase in publications. On average, these documents are relatively recent, with an average age of 2.07 years, and each document has been cited approximately 5.96 times. Interestingly, no references were reported in this summary.

The content of these documents includes 929 instances of Keywords Plus, which are terms frequently appearing in the titles of an article's references and are used to enhance the author's keywords. The authors provided a total of 291 unique keywords. The analysis reveals that 335 authors contributed to these documents, with 33 of them authoring single-authored papers. On average, each document had 2.71 co-authors, and 17.45% of these documents featured international co-authorship, highlighting the global collaboration in this research area. The types of documents varied, with the majority being articles (129), followed by conference papers (13), reviews (4), book chapters (2), and retracted papers (2). Table I summarizes the key information of the articles selected from the Scopus database using the "bibliometrix" tool.

Fig. 4 illustrates the annual trend in the number of articles published on the topic of financial risk early warning from 2010 to 2024. The x-axis represents the years from 2010 to 2024, while the left y-axis shows the number of seed index articles published each year and the right y-axis depicts the cumulative number of these articles. The bar chart represents the yearly publication count, and the line graph indicates the

TABLE I. SUMMARY OF THE SELECTED ARTICLES FROM SCOPUS DATABASE

cumulative total. The data reveals a clear upward trend, particularly from around 2019 onward, highlighting a significant increase in publications related to financial risk early warning during this period.

Fig. 5 presents a pie chart categorizing the selected documents by their subject area, offering a visual overview of the distribution of topics. The chart shows that the majority of documents fall within the Social Sciences (19.3%), followed closely by Business, Management, and Accounting (16.8%), and Economics, Econometrics, and Finance (15.7%). Environmental Science accounts for 14.3% of the documents, while Energy comprises 11.0%. Other fields are represented to a lesser extent, including Engineering (5.9%), Computer Science (4.0%), Arts and Humanities (3.3%), Decision Sciences (2.1%), and Mathematics (2.0%). The remaining 5.5% of documents are categorized under “Other”, indicating a diverse range of additional subject areas.

Fig. 6 illustrates the average number of citations per year for publications related to financial risk early warning systems. It helps in understanding the impact and relevance of research over time. A higher average citation per year indicates that the work is widely recognized and used by other researchers in the field. In Fig. 7, Bradford’s Law describes the distribution of articles on a particular subject in scientific journals. This figure shows the core journals that publish the

Fig. 5. Documents by subject area.

Fig. 6. Average citation per year.

most significant number of articles on financial risk early warning systems. It helps in identifying the key sources and journals that contribute extensively to the research in this domain. Fig. 8 highlights the countries whose research on financial risk early warning systems has received the most citations. It shows the geographical distribution of influential research and indicates which countries are leading in this field. Fig. 9 represents the countries of the corresponding authors of the publications. It provides insight into the geographical distribution of researchers who are contributing to the literature on financial risk early warning systems. Fig. 10 lists the most relevant sources or journals that publish articles on financial risk early warning systems. It helps researchers identify the best sources for publishing their work and staying updated with the latest research.

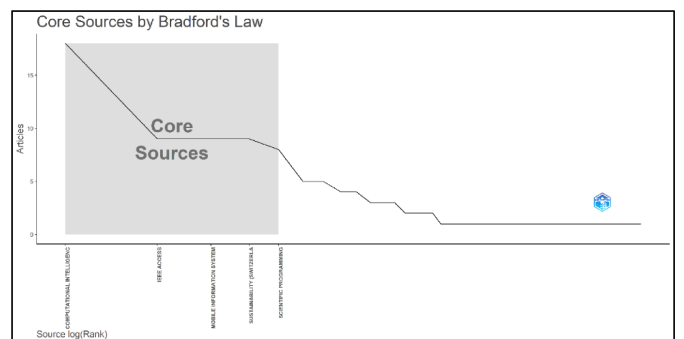

Fig. 7. Core sources by Bradford's law.

Fig. 8. Most cited countries.

Fig. 11. Three fields plot of country-journal-keyword.

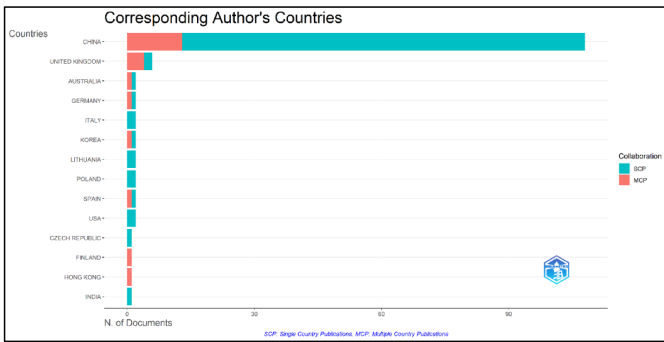

Fig. 9. Corresponding author's countries.

Fig. 12. Most related keywords.

Fig. 11 visually represents the relationship between countries, journals, and keywords in publications related to financial risk early warning systems. It shows how different countries and journals are linked through common research themes and keywords, providing a comprehensive overview of the research landscape.

Fig. 12 titled “Most Relevant Words” displays the occurrences of various keywords related to financial risk early warning systems. The Keywords such as “financial risk”, has the highest frequency of occurrence which is 8 times, followed by “deep learning,” and “financial risk prediction”. It reflects the critical significance and recent research progress of these keywords. Terms like “logistic regression”, “machine learning”, and “risk management” appear with 7 occurrences

which supports the fact that these statistical and analytical tools are commonly used in the existing financial risk studies. The keyword “neural network” has been used 7 times which portrays the fact that it is widely used in modeling and prediction of financial risks. The terms “big data”, “credit risk”, “credit scoring”, “financial distress”, and “LSTM” occurs four times which underlines the importance of advanced data techniques and specific risk factors reviewed in the existing body of literature. The key terms of “BP neural network”, “financial risk management”, “credit risk assessment”, “early warning”, “random forest”, “risk analysis”, and “genetic algorithm” were repeated 3 times which revealed acute nature and special approaches and focus areas within the general subject. Lastly, “artificial intelligence” appears with 2 occurrences emphasizing the growing role of AI in financial risk mitigation. All the keywords are supported by the studies of [32] on deep learning applications which reflects the current research focus in the emerging area of financial risk early warning systems.

B. Co-authorship Analysis

Fig. 13 uses various colors to represent the distribution of countries across seven regions. The thickness of the lines indicates the strength of connections between countries, with thinner lines denoting weaker links and thicker lines denoting stronger ones. For instance, Cluster 3, which represents East Asia and the Pacific, includes nine countries, while Cluster 4, representing Europe and Central Asia, includes eight countries. Clusters 1, 2, 5, and 7 each include one country, and Cluster 6 (Middle East and North Africa) does not include any country

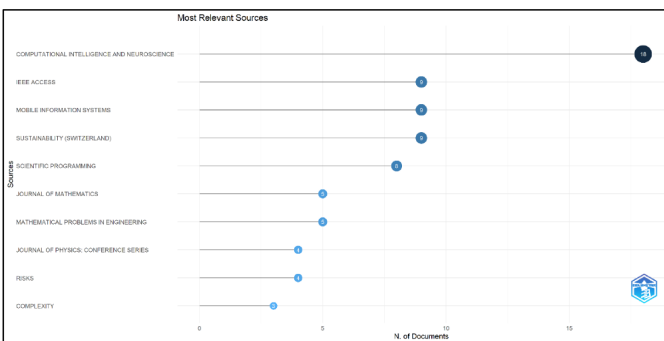

Fig. 10. Most relevant sources.

Fig. 13. Screenshot of bibliometric map based on co-authorship with overlay visualization. (It can be opened through <https://bit.ly/41uMpVT>).

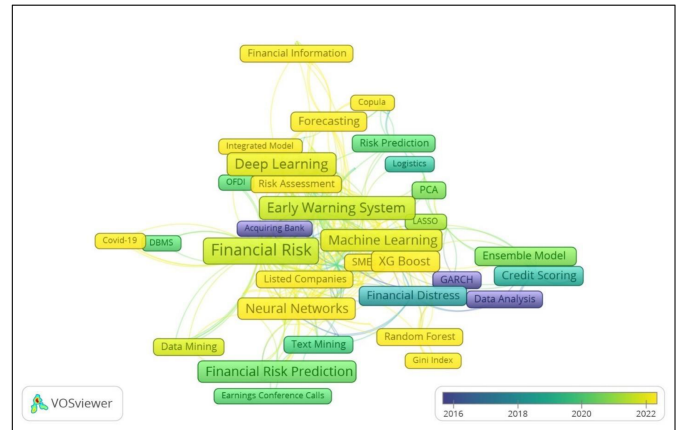

Fig. 14. Bibliometric map based on Co-authorship with overlay visualization. (It can be opened through the URL in VOSviewer: <https://bit.ly/3NCzewu>).

working in this area. Our co-authorship statistics show that China has the highest degree of affiliation, with 15 links and a link strength of 24. This means China is linked to 15 territories or countries with 24 instances of co-authorship. The United Kingdom follows with six links and a link strength of nine, the United States with five links and a link strength of eight, Germany with five links and a link strength of seven, Brazil with five links and a link strength of five, and Hong Kong with two links and a link strength of three. Other countries have fewer than two links. International collaboration occurs for various reasons, including the subject matter, the type of issue, and the researchers chosen to work on it. Additionally, the ease of access to primary data, such as financial risk early warning, can influence the relevance of the region to funders who support the research, research partners, diversity, and collaboration.

C. Author Keywords and Current Emerging and Future Trends Regarding Financial Risk Early Warning System

This section represents the objective, which explains the current trends and arena for further research and potential collaboration using VOSviewer software. For mapping in VOSviewer, a total of 291 keywords were recorded and after re-labeling various variants or synonymic single words and phrases, 177 keywords met the threshold of a minimum of five occurrences. Our results portray that financial risk is the most reflected keyword with 20 occurrences, 55 links to other keywords, and a total link strength of 74 followed by financial risk management (11 occurrences, 34 links, 47 link strength), and early warning system (11 occurrences, 29 links, 37 link strength). Some other methodological terms include deep learning (11 occurrences, 26 links, 37 link strength), logistic regression (9 occurrences, 36 links, 42 link strength), machine learning (8 occurrences, 28 links, 37 link strength), and Bp neural network (7 occurrences, 22 links, 25 link strength). Financial risk and financial risk management and early warning systems are also seen to be co-occurring with each other. whereas the early warning system keywords have links with other new emerging keywords i.e. low carbon economy, financial stability, internet finance, and internet of things. This bibliometric image shows that the two big bubbles

financial risk and financial risk management are areas used with common areas like financial distress machine learning, Xg boost, logistic regression, Bp neural network, clustering, deep learning, and nearest neighbors (Fig. 14).

The analysis of the keywords of the current articles allows for identifying the emerging trends in the research field [13]. The recent average year of publications represents potential hotspots for the future, and the smaller number of occurrences indicates the niche area [20]. Thus, Table II offers an in-depth analysis of author keywords and future trends in the realm of financial risk early warning systems. The table lists keywords alongside their occurrences, total link strength, and average publication year, thereby elucidating the current research focus areas and emerging topics within this field. Table II keywords are categorized as high occurrence and link strength keywords, emerging topics and niche areas, integration of non-related fields and technologies, sustainability and creativity, and other important keywords.

1) *High Occurrence and Link Strength Keywords:* The following keywords occur frequently and their link strength in conducting studies on the financial risk early warning system underscores the crucial role of employing machine learning and deep learning approaches in this area. Neural networks are one of the most important areas of research, being mentioned 9 times, having a link strength of 34, and the average publication year 2022. This approach enables us to train models with high levels of complexity, capable of identifying intricate patterns in the financial data, thus improving predictive performance. This is evident from [32], [41] who showed how neural networks can be applied to analyze large volumes of data by learning from huge data sets and adapting to new models of risks in the financial markets. Further, random forests occur 3 times with 13 link strengths and an average year of publication in 2022, 33, highlighting its importance. Random forests are highly valued due to their ability to handle diverse, large, and even noisy data sets in financial applications. Random forests, which construct multiple decision trees and combine their outputs, can give accurate risk estimates and overcome overfitting. The [5] further stated that there are several benefits of random forests, especially in financial risk management, mainly because of their ability to manage big data and many

variables which makes them very popular among practitioners. The term XGBoost stands out as a prominent approach that has the most link strength of 32 and is used 7 times with an average publication year in 2022 is 57. It is popular due to its ability to handle big data and is considered one of the best algorithms for predictive analysis. It also employs gradient-boosting techniques in the improvement of the predicted results and improves model accuracy. Research by [14] demonstrated that by employing the iterative nature of the XGBoost approach, additional improvements can be achieved to improve model predictive capabilities, which makes it valuable in the field of developing early warning systems for financial risks. Based on these keywords, it is shown that machine learning plays a crucial role in improving the capabilities of early warning systems for potential financial risks. Through the integration of the advantages of neural networks, random forests, and XGBoost, it is possible to improve the accuracy of these models and achieve better prediction of capacities in the financial risks that can help in the development of resilient financial systems that might be more sustainable.

2) *Emerging Topics:* Emerging themes that stand out in the field of financial risk early warning system research are the keywords “Attention Mechanism” and “LSTM (Long Short-Term Memory)” which represent the cutting-edge approaches and trends in the field. Even though the attention mechanism only emerged twice, it has a rather large link strength 8 and, the average year of the publication is 2023. This indicates that it is gradually becoming more relevant since it aims at increasing the explainability and reliability of financial risk models. The use of attention mechanisms gives the model the ability to adjust the relevance of the input features, thus resulting in better classification. LSTM is the most recurrent term with 5 references and a link strength of 17; it is mostly used in articles published in the year 2022 80, implying that this activity has become increasingly essential in recent years. Hence, LSTM models are highly effective in capturing temporal dependencies of financial data and are especially useful in determining temporal characteristics of financial data sets where past trends can influence future outcomes. Their ability to retain information over long sequences assists in capturing the temporal dependencies inherent in financial data, which are useful in improving the output of risk estimation [38]. Therefore, these topics demonstrate that innovative solutions continue to be introduced to increase the capabilities of early warning systems for financial risk management.

3) *Niche Areas:* Niche areas of concern in the financial risk early warning system are keywords like green credit risk, conditional quantiles, and sliding window, which are concerned with specific and emerging facets of financial risk management. Green credit risk features industry-specific credit risk evaluation that considers ecological aspects. This keyword emphasizes the need to come up with sector-specific solutions to managing risk that is associated with environmental sustainability. Given that many industries and financial institutions are now aware of the effect of environmental factors on financial stability, it becomes apparent that it is pertinent to work on the integration of green credit risk with these factors. In their article, [45] explain how integrating environmental factors into reporting processes that involve evaluations of risk, mitigation, and impact can provide a wider and truer perspective of the potential dangers and consequences of certain actions

by identifying carbon footprints, investing in renewable, and incorporating sustainability measures. This niche area is of great importance for the development of financial solutions that make it possible not only to mitigate various risks but also to achieve organizational growth in terms of sustainable development; the thought refers to the ecological aspect of financial risk management.

Conditional quantiles with 1 paper and a link strength of 4 and sliding window as another topic with 1 paper and a link strength of 4 published around 2023 also present emerging niche areas, which highlight that modern academic research in the field is focused on more sophisticated statistical methods to learn refined financial risks models. On the other hand, conditional quantiles focus on the probability distribution of the financial data so that business organizations can determine the likelihood of a particular risk, offering a better solution than simple quantiles regarding probable risks. This approach provides a better assessment of risk considering all the probabilities rather than risk means or medians [29].

Collectively, these niche areas highlighted that there is an immense focus on improved and specific innovations in the management of financial risk. Some of them underscore the significance of sector-based risk analysis and the application of state-of-the-art techniques in statistics to enhance the predictive capabilities of financial risks. These approaches contribute to a more resilient financial structure due to its ability to handle challenges in the current unprecedented complex financial world.

4) *Interdisciplinary and Technological Integration:* The keywords such as industry-academia linkages and public-private partnerships demonstrate that interdisciplinary and technological integration in financial risk early warning systems involves synthesizing various approaches and the use of complex analytical tools. Industry academia linkages and the use of public-private partnerships reflect the growing trend of interdisciplinary in the study of financial risk. Although these keywords are infrequent, with link strengths of 4 and an average year of publication around the year 2022, they highlight the need to integrate knowledge from various sectors to solve multifaceted financial risks.

In [6], the researchers demonstrate how these linkages and partnerships enable the exchange of knowledge, resources, and innovations between the academy, businesses, and government agencies. They may contribute to the generation of better management solutions to the risk factors that are associated with organizations. Through such arrangements, it is possible to solve complex financial risks that could be managed only with multiple companies’ resources, thus enhancing the comprehensiveness of managing the financial sector’s stability.

5) *Sustainability and Innovation:* Sustainability and Innovation in managing financial risks are emerging and reflected in keywords such as Carbon Neutrality Renewable Energy and Green Technology innovation. These terms suggest that there is an advancement towards the enhancement of sustainable practices together with the adoption of technologies for the enhancement of sustainable financial systems.

The keywords of Carbon Neutrality and Renewable Energy with average publication years of about 2022-2023 and moderate link strength underline the growing focus on environ-

mental sustainability within financial risk management. The [41] documented that the banking sectors and industries are gradually integrating environmental factors into the evaluation of risks. This transformation is due to increasing awareness of the financial implications of climate change and sustainability-related concerns. Integrating carbon neutrality and renewable energy into the financial risk analysis, the goal is to minimize future threats linked with detrimental environmental impacts and shift in legislation. This proactive approach assists in managing the identified financial risks more effectively, while thereby promoting more sustainable financial practices and, consequently, the development of a stronger financial system in line with global goals.

Green Technology Innovation has an average year of publication in 2023 that supports the importance of adopting new technologies in managing financial risks. The authors highlight that adopting green technologies can greatly diminish the negative effects on the environment and improve the sustainability of the systems used in finance. The application of such technologies is essential in creating new forms of innovative, better, and sustainable financial products and services. Green technology development enables moving to a green energy base, utilizing energy-saving technologies, and lowering CO_2 intensity. These advancements are critical in managing risks that are infectious in the financial systems including regulatory shocks, resource depletion, and climate changes.

Together, these keywords highlighted a paradigm shift regarding financial risk management and the incorporation of sustainability and innovation in it. Carbon neutrality and renewable energy demonstrate the progressive inclusion of environmental factors in risk management and addressing current and future risks. Green technology innovation refers to the use of innovative technologies for the improvement of sustainable innovative financial systems. By focusing on these areas, the financial industry not only seeks to minimize risks related to the environment; it also strives to grasp the opportunities in the future green economy. Thus, the combination of the strategy of sustainability with a focus on innovation provides financial institutions with the ability to be prepared for the current challenges in financial risk management and contribute to sustainable development at the same time.

6) *Additional Important Keywords:* The keyword COVID-19 is identified as occurring only once; however, it possesses a link strength of 4 and has an average publication year of 2023, which underscores the massive impact of the pandemic on various financial systems around the globe. The COVID-19 pandemic has posed several unprecedented developments in the financial market and has challenged the stability of financial institutions. The [21] presented that due to the COVID-19 pandemic, organizational economic losses, and other crises that occurred throughout the world, risk management has become an essential component for organizations to manage and ensure that they will not be affected negatively in the future. The dynamics of the financial environment especially in the money markets have been dynamically changing and the financial sector has been forced to respond to changes such as fluctuating volatilities, liquidity risks, and credit risks. The usage of this keyword in financial risk research also means that scholars are constantly evaluating the impact of the pandemic on the financial sector to capture the long-term effects and

the necessity of developing strategies that could be applied to financial shocks in the future.

Moreover, renewable energy with an occurrence of 1 time and a link strength of 3, published around 2022, declares the further linkage of financial risk management with environmental aspects. In [39], authors firmly stresses that the paradigm shift towards the use of renewable energy sources is not only one of the distinctive challenges that the world must address to mitigate climate change effects but also a factor that poses great risks in the financial sphere. This paper aims to look at the new opportunities and threats for funding green projects including wind, solar, and other renewable energy projects for banking organizations. These projects usually call for substantial upfront investments and many projects are legally and economically risky, but at the same time, they bring numerous advantages that can be considered in the long term, such as decreased operational expenses and compliance with sustainability objectives. The attention towards renewable energy for the study of financial risk has become more significant as the world focuses on the possibilities to minimize the financial risks of a more sustainable energy infrastructure.

The keyword of financial stability appears with 1 occurrence, its link strength is 4, and it was published in 2023, illustrating that the authors and researchers are equally fascinated by sustaining stability in the financial systems irrespective of several economic transformations. The [28] mention that maintaining financial sustainability remains one of the key goals for policymakers, regulators, and financial institutions, especially in an unstable economy or during the crisis's circumstances. Financial stability can be regarded as the resilience of a financial system so that it can provide a smooth and uninterrupted operation, and at the same time, can cope with external impacts. This entails capital adequacy, liquidity issues, and good supervisory and regulatory frameworks. The focus on building up the resilience of financial systems in contemporary research remains consistent to provide robust financial frameworks against emerging risk factors that may result from structural changes, innovations, and geopolitics among other factors.

Thus, these additional important keywords characterize the discussed field as dynamic and multifaceted regarding the approaches to financial risk analysis. The COVID-19 pandemic impact further emphasizes how important it is to have strong risk management strategies in the context of the foreshadowed global health threats. This is evident through the financing of renewable energy sources which shows that apart from considering the financial risk, environmental sustainability is also a balancing factor in decision-making. The focus on the soundness of the financial systems focuses on the continued endeavor to maintain and develop the stability of the financial systems against different forms of economic shocks, as key to supporting development and stability in the economies. Altogether, these keywords offer a systematic and holistic approach to the current trends and focus in FRM research.

Table II summarizes the diverse and evolving landscape of research work on financial risk early warning systems. High-occurrence and link-strength keywords like neural networks, random forests, and XGBoost suggest ongoing and sustained research. Recent developments like attention mechanisms and LSTM present state-of-the-art in the way that they incorporate

cutting-edge machine learning approaches. Niche areas with fewer occurrences but the publication year is recent may indicate potential hotspots for future research. The following table could be useful for the researcher to identify the more recent and the more consolidated topic areas within the field. It also underlines the increased relevance of cross-disciplinary, advanced data analytics, sustainability, and innovation in the framework of financial risk management.

D. Thematic Analysis

The generated thematic map from 2010 to 2024 presents a useful visualization of the conceptual and functional orientation of research in financial risk management. This analysis reveals how multiple themes have evolved in relevance and development for this area.

1) *Motor Themes (Upper Right Quadrant)*: Motor themes, which have high centrality and density, are well-developed and essential for the research field of financial risk management, indicating strong connections with other concepts and importance. Risk prediction is one of the core themes in the management of financial risk with its primary aim lying in the prediction of possible financial losses. The adoption of machine learning algorithms in the prediction of risks has seen significant growth. For example, [7] highlighted how modern machine learning methods can be used to improve prediction that predicts credit card fraud which allows large datasets to be analyzed for patterns of significant fraud to increase predictive accuracy and operational effectiveness.

Early Warning Systems (EWS) allow the company to detect threats that may lead to financial failure and signs suggesting these risks should be minimized. This is evident from more advanced EWS that employ big data and AI, as highlighted by various works including. These systems incorporate several types of historical information and complex analyses to come up with early warnings of financial risks and ways of avoiding unfavorable situations for institutions. Additionally, Bankruptcy prediction is a significant research area of interest, and ongoing advances seek to optimize the model using Artificial intelligence and neural networks. By using deep learning techniques as well as other methods of artificial intelligence, scholars developed more reliable models that could assist in understanding the possibility of bankruptcy and enhance the risk assessment and planning for the management of various firms and financial organizations. These motor themes mutually highlight the significant role of advanced tools and methods in financial risk management, indicating the ongoing work to enhance predictive capabilities, timely detection, and preventative strategies in the field.

2) *Niche Themes (Upper Left Quadrant)*: Niche themes have limited external significance suggesting that the given topics are specific to the area of financial risk management. Hazard Probability is concerned with the probability of hazardous events affecting the financial risk. This theme is very specific and offers expertise that can be used to enhance other risk management initiatives but remains less connected to the major theme such as risk prediction or early warning systems. Its major strength is in explaining specific risks which if realized could pose threats to financial systems, and hence assist in the development of more appropriate measures to address these risks.

Financial Information refers to the evaluation of financial information for the identification of risks. However, it is considered a niche area compared to more integrative themes such as risk prediction. Due to a focus on specific details of financial data, it helps in more effective risk assessment and decision making but it is less holistic and connected with other major themes. Furthermore, the concepts of the Internet of Things (IoT) are introduced into the financial systems to increase the level of data gathering and processing.

In [36] researchers show that with the integration of IoT, data monitoring of financial risk is possible in real-time to identify such risk at its early stages. Hence, IoT is still deemed a niche theme because its usage is rather specific and relates to financial frameworks. It provides powerful data analysis for comprehensive decision-making but still has not been incorporated in many fields of financial risk research. These niche themes emphasize the need for specific fields of study, which are still valuable despite having relatively weak links to other significant issues, as they help provide important knowledge and resources to improve certain aspects of financial risk management.

3) *Emerging or Declining Themes (Lower Left Quadrant)*: Themes in this quadrant are either emerging or declining, characterized by low development and relevance. Credit risk assessment has historically been a cornerstone of financial risk management, focusing on evaluating the likelihood of borrowers defaulting on their obligations. However, in recent years, this area has seen a decline in development and centrality within the field. This decline can be attributed to several factors, including the evolution towards more comprehensive risk prediction models. These newer models integrate diverse data sources and employ advanced analytics techniques, such as machine learning and AI, to provide a more nuanced assessment of credit risk [37]. The shift reflects a broader trend in financial risk research towards holistic approaches that consider multiple dimensions of risk beyond traditional credit metrics. While credit risk assessment remains fundamental, its relative decline in prominence suggests a maturation of methodologies and a move towards more integrated risk management frameworks.

Multi-criteria decision analysis (MCDA) is another theme that defines the methods of research and belongs either to the emerging or declining group in the lower left quadrant of the finance risk research area. Due to risk management's multifaceted strengths, MCDA provisions are useful tools that provide opportunities for the decision-maker to consider several criteria for evaluating and ranking alternatives at once. Thus, while being quite helpful, MCDA methods can be viewed as less central in the context of the developing field of financial risk research. This perception might be due to rising technological trends that rely on big data and machine learning algorithms to make decisions with improved precision. Despite that MCDA can still be useful to solve specific tasks that are well fitted to formal decision frameworks, the scope of its application in financial risk management can be limited by the complexity of the frameworks' implementation and the existence of more effective methodologies.

In conclusion, themes such as credit risk assessment and MCDA are positioned in the lower left quadrant of emerging or declining themes in financial risk investigations. Their reduced

TABLE II. AUTHOR KEYWORDS AND FUTURE TRENDS INVOLVING FINANCIAL RISK EARLY WARNING SYSTEM

Keywords	Occurrences	Total Link Strength	Avg. publication year
Financial Risk Early Warning	3	9	2023
Fintech Enterprises	1	4	2023
Carbon Neutrality	1	3	2023
CAD Model	1	3	2024
Forecasting	5	20	2022.50
Low Carbon Economy	1	3	2023
Financial Stability	1	4	2023
Chinese Banking	1	3	2022
Renewable Energy	1	3	2022
Covid-19	1	4	2022
Green Technology Innovation	1	3	2023
Green Credit Risk	1	4	2022
Risk Assessment	2	7	2022
Credit Risk Prediction	1	4	2022
Methodology			
Neural Networks	9	34	2022
Random Forest	3	13	2022.33
Xgboost	7	32	2022.57
LSTM	5	17	2022.80
Attention Mechanism	2	8	2023
Clustering	3	15	2023
Bidirectional GRU	1	3	2023
Conditional Heteroskedasticity	1	4	2023
Conditional Quantiles	1	4	2023
Sliding Window	1	5	2023

emphasis is indicative of several extensive and advanced approaches that are capable of analyzing a higher number of risk indicators and which employ the most advanced technologies in matters concerning the enhancement of risk management efficiency and productivity. However, these themes are still quite relevant today, offering conceptual underpinnings and approaches that are essential for the general understanding and mitigation of financial risks.

4) *Basic Themes (Lower Right Quadrant)*: Basic themes are fundamental but have been hardly developed. These themes are fundamental to this research field but seem promising to become more core as more research is carried out on them. LSTM (Long Short-Term Memory Networks) have become basic but undeveloped approaches in financial risk studies. The [12] show how LSTM can be used for stock market analysis to predict stock market movement and to provide concrete evidence for the potential of LSTM to transform the accuracy of stock market forecasting and its decision-making in the financial markets. Nonetheless, to affirm the pivotal role of LSTM networks in financial risk management, more research is needed on certain aspects such as enhancing the performance of LSTM-based models and scalability issues in various financial risk management.

Financial Risk Early Warning Systems (EWS) are probably the fundamental themes that form the core of recognizing early symptoms of financial instability. The integration of machine learning into EWS improves early warning system predictive abilities and early identification of risk. Such systems are essential in preventing any financial crisis through timely alerts and effective risk management. Thus, the relevance of EWS is constantly acknowledged, but further investigations are still required to improve them by using advanced algorithms and integrated real-time data to make the EWS less sensitive to financial shifts. Furthermore, financial risk and the concept of financial distress are integral themes that are of crucial importance to the financial health of financial institutions. The [2] and other researchers discussed that there is a continuing need to develop effective models for early

warning and detection of financial distress. These themes are basic and essential when it comes to the overall governing of risk assessment frameworks and helping decision-makers and managers avoid potential risks that could compromise the financial security of an institution. Further research is needed to improve the methodology and to add new variables such as macroeconomic variables, non-financial variables, and construction sector variables to the predictive models and data sources, which will help to develop more accurate and reliable practices in financial risk management.

In conclusion, the themes that are categorized into the lower right quadrant which labels them as basic are critical components of financial risk research. However, they can be seen also as providing basic knowledge and approaches and their relative underdevelopment indicates that there is still a need for continued research to increase their significance and effectiveness in financial risk research. Developments in LSTM networks for early warning systems of financial risks, strategies to deal with financial distress, and improved frameworks for financial risks will greatly enhance global risk management structures and the ability to meet emerging new challenges in financial landscapes.

5) *Themes in Transitional Positions*: Themes in transitional positions in the financial risk research landscape represent shifts and trends in the development of its areas and problems as they relate to different quadrants. Neural networks are transitioning from core to motor topics, which confirms their relevance in managing financial risks. Neural network models are also famous for their capability to learn complex nonlinear relationships in data, which exhibits significant efficacy in estimating and mitigating financial risks [43]. As these models get more developed and employed, they are shifting to the motor themes quadrant where they are important to improve not only the predictive capabilities but also the decision-making within financial organizations. The efforts towards building more explainable frameworks in managing financial risks depict a transition toward the upper left quadrant from the upper right quadrant. Explainable models are essential for

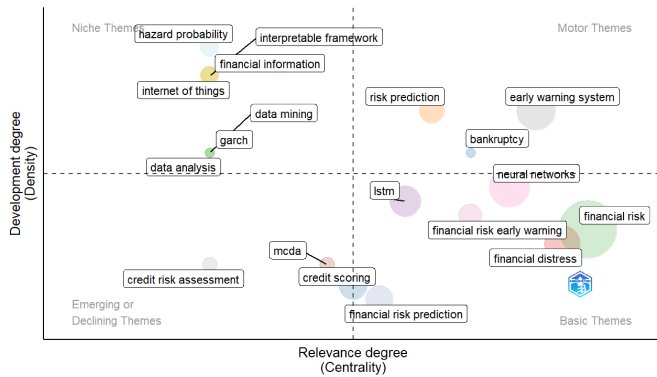

Fig. 15. Combined thematic map from 2010 to 2024.

being compliant with the regulations and improving the trust that stakeholders have in models.

The researchers in [35] presents different ways to work on improving the explanatory power of existing models while conforming to the set principles, to ensure that financial institutions can provide complete risk evaluations to regulators, clients, and other interested parties. Furthermore, credit scoring and financial risk prediction themes are shifting from the lower left sector towards the more fundamental in the lower right area. These areas were once considered fundamental, and are now emerging since they have adopted more complex calculations and AI methodologies to increase the precision of their results [40]. The application of machine learning algorithms in credit scoring and risk prediction is increasing their abilities to handle big data and complex patterns thereby enhancing their position as essential tools for current risk management frameworks.

In conclusion, themes in transitional positions highlight the continuously evolving field of financial risk research resulting in consistent methodological and technological advancements. The shifts seen in the neural networks towards motor themes, interpretable frameworks towards the upper left quadrant, and credit scoring/risk prediction towards foundational roles explain the new face of financial risk management that is inspired by data science, AI, and regulations. Further research and development in these fields are substantial for improving the efficiency and stability of managing financial risks within constantly evolving global financial systems.

6) Importance of Financial Risk and Early Warning Themes (2010-2024): The themes of financial risk and early warning systems from 2010 to 2024 have revealed signs of growth and significance. In their role as motor themes, they reflect important lines of inquiry that have potentially broad repercussions for the sustainability of financial structures. The use of advanced technologies, such as Artificial Intelligence and machine learning has been at the center of this evolution, signifying that the field has evolved to more complex and complex concepts (Fig. 15).

E. Thematic Evaluation

Fig. 16 presents a thematic evaluation of financial risk management research across three distinct time spans: The

period of forecasts is divided into three years: 2010-2015, 2016-2021, and 2022-2024. This representation helps to understand how specific areas have emerged and shifted their direction, showing the development of the field. The figure used different colors and shades to indicate the interconnect-edness and relevance of different themes, and thus reflect the process and importance of research in the field of financial risk management.

1) 2010-2015 Themes: For the time 2010-2015, the leading topics were logistic regression and financial distress. Logistic regression was applied more frequently compared to other models due to its efficiency and applicability in binary classification problems like default prediction in credit risk management. Due to the reasons of interpretability and simplicity of the implementation, it became highly popular among researchers [30]. Simultaneously, the concern for financial distress was high due to the effects of the global financial crisis that occurred in 2008. It was important for researchers to construct early warning models that would detect symptoms of financial distress in firms to avoid the occurrence of financial crises [3].

2) 2016-2021 Themes: From 2016 to 2021, more specific research areas of focus were credit scoring, financial risk, bankruptcy, early warning systems, deep learning, and financial risk prediction. Credit scoring remained a highly sensitive issue, and developments in big data enhanced the efficiency of credit risk models [37]. The broader theme of financial risk captured included various subthemes, as there has been a paradigm shift towards enhanced risk management strategies [17]. Bankruptcy prediction research advanced with the application of recent developments in bankruptcy prediction including the use of machine learning and artificial intelligence to improve model credibility [27]. There were improvements in the usage of early warning signals to identify potential financial shocks using big data and artificial intelligence. Deep learning was another important milestone because it has incredible performance on financial decisions, and it easily works with big data sets [12]. Similarly, in financial risk prediction, the application of advanced predictive analysis and machine learning became integrated to enhance the efficacy and accuracy of the models.

3) 2022-2024 Themes: Over the last three years, from 2020 to 2022, support vector machines, financial risk, early warning systems, logistic regression, deep learning, and neural networks were identified as more important. Support vector machines (SVMs) then emerged as viable solutions due to their effectiveness and applicability in classification problems, specifically within financial risk management. Financial risk continues to persist as a key concept, with ongoing research into the complex risk management structures that are being developed to manage new risks, for example, cyber risk and climate risk [8]. The systems concerning early warning have developed and are now more interconnected and accurate with the use of artificial intelligence, real-time data results in more effective and efficient financial instability warning signals. Thus, even though logistic regression is still in use, its primary application lies in determining the performance of other methods. Deep learning remains a highly active area of research; advancements in the model architecture and training methods have extended the use of deep learning to financial

risk management [23]. Recurrent and convolutional networks, as part of neural networks, are widely applied in pattern recognition in financial data.

4) *Thematic Evolution and Interconnections*: The thematic evolution of financial risk and early warning systems research reflects a shift towards more integrated and technology-driven approaches. Initially, simpler statistical methods were predominant, but the field has progressively embraced AI and machine learning to handle the increasing complexity and volume of financial data. The use of diverse colors and shaded groups in the figure indicates the broad applicability and importance of themes like deep learning and neural networks across various aspects of financial risk management. Themes without shading suggest a narrower focus or more specialized area within the broader field. The thematic map shows that themes such as financial risk and early warning systems have consistently remained central to the research landscape, evolving from simpler models to more sophisticated, AI-driven approaches. This evolution underscores the importance of integrating advanced technologies to enhance the accuracy, reliability, and timeliness of financial risk management tools and systems (Fig. 17-19).

Fig. 16. Thematic evaluation divided into three quadrants.

Fig. 17. Thematic evaluation time frame 1 (2010 to 2015).

F. Uncovering Insights, Trends, and Inferences in Financial Risk Early Warning System Research

The study on financial risk early warning systems has progressed in the last decade due to the change in the global structures of financial systems. Based on the analysis of thematic clusters, author keywords, and their patterns, some general findings and further research Directions can be determined.

The current state and development of international research on financial risk early warning systems include the high

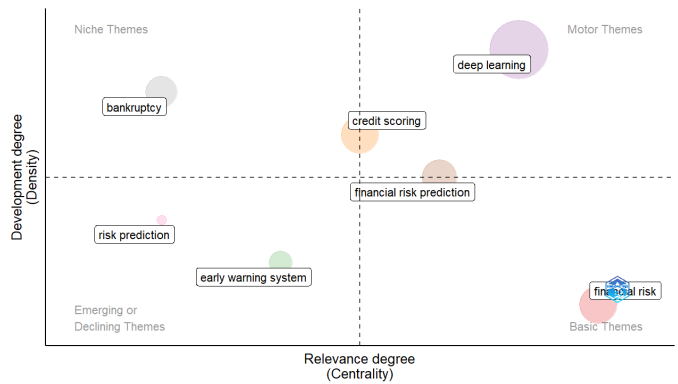

Fig. 18. Thematic evaluation time frame 2 (2016 to 2021).

Fig. 19. Thematic evaluation time frame 3 (2022 to 2024).

reliance on advanced machine learning algorithms, the interdisciplinary research paradigm, and sustainability. Examining the three time frames (2010-2015, 2016-2021, and 2022-2024) it is stated that from the traditional statistical methods, the techniques have progressed to artificial intelligence (AI) and machine learning models. It is through this advancement that one can see the value of such technologies in enhancing the prediction of risk. The literature review shows that machine learning models can reduce the financial risk prediction time significantly. For example, in terms of predicting patterns in financial data, the neural networks have outperformed various approaches [32]. Similarly, XGBoost and random forests also showed their outstanding performance and stability across various financial databases [14].

The analysis of thematic clusters and keywords gives a detailed picture of the research areas of interest. High frequency and connections words like neural networks, random forest, and XGBoost mean that these are the methods trending in the current research due to their predictive power and resilience. Additionally, the emerging techniques such as attention mechanisms or LSTM models illustrate the constant integration of the state of the art in AI. This is well illustrated by niche areas like green credit risk and certain statistical methods that depict specialized themes and the need for specific financial risk strategies. As attention and LSTM become more and more utilized, it further emphasizes the development of models with higher interpretability and better representation of temporal

characteristics of financial data [38]. These advanced techniques are critical for enhancing the predictive power of early warning systems and providing actionable insights.

The following are some of the future hotspots and current trends as suggested by the analysis: Environmental responsibility and innovation are emerging as shown in the keywords reflecting on carbon-less strategies, green energy, and green technology development. Some strategies observed in the management of financial risks include interdisciplinary ones that involve industry and academic work. Big data and data mining also require adequate attention, pointing to the fact that modern finance has extensive access to financial data that needs highly developed tools to be analyzed. Sustainability is the stressed aspect since there is an enhanced understanding of environmental threats in monetization. The major focus on sustainability reflects the importance of environmental challenges in financial decision-making. Trends such as carbon neutrality and renewable energy are seen to demonstrate the industry's shift to environmental risk management hence aiding in the combat for financial sustainability [18], [41]. Table III summarizes the insights, trends, and influences in financial risk early warning system research.

III. CONCLUSION

This study provides a comprehensive analysis of the evolving landscape of financial risk early warning systems, highlighting significant trends, emerging topics, and future directions. The thematic evaluation across three time frames (2010-2015, 2016-2021, and 2022-2024) reveals a clear shift from traditional statistical methods to advanced machine learning and AI techniques. Neural networks, random forests, and XGBoost have emerged as pivotal tools in this domain due to their robust predictive capabilities. Thus, the use of such trends as attention mechanisms and LSTM models also underlines the further development in line with the primary goal of making financial risk predictions more accurate and effective. Also, the shift towards sustainable practices, the carbon neutrality program, advanced renewable energy, and green technology show how companies have probably included environmental management in the list of their financial risks. Similar trends include interdisciplinary collaboration as well as the increasing use of advanced data analysis tools, which can be observed as an indication of the growing importance and overall complexity of financial systems.

A. Policy Implication

The findings of this study have several policy implications:

- 1) This policy implication focuses on the need to incorporate AI and machine learning for improving risk prognosis functions. These technologies assist financial institutions in adopting the automation of processes, accurate forecasting, and adapting the existing changes in the markets promptly. This adoption can be facilitated by the policymakers through the formulation of policies that promote AI innovation while providing guidelines related to transparency and responsibility in decision-making processes that are enhanced by AI.

- 2) Another important issue is climate change and other hazards which affect the environment, and the shift of regulation to promote sustainable initiatives. Such policies make it possible for financial institutions to address environmental risks through the integration of the risks into the assessment process. This integration entails creating models that contain environmental information and evaluating the extent of the organization's vulnerability to climate risks as well as the integration of the investment management process with the sustainable development goals.
- 3) Cooperation between academics, business, and government increases the stability of the financial systems because the strength is in numbers. Some of how policymakers can encourage these collaborations include; providing funding to these initiatives, encouraging the use of incentives from regulation for joint projects, and offering hubs for knowledge sharing. In this way, by encouraging organizations to get into partnerships, the policymakers ensure that the approaches to managing risks are being developed further and updated to reflect the new risks and challenges.
- 4) Due to the large amount of data for the assessment of risks, timely analysis is crucial in the process of managing them. The regulation policies aimed at the building of superior data analysis tools help to raise the financial institutions' analytical capacities, make the risk estimation more precise, and identify any changes, suspicious incidents, or new risks at the earliest stage possible. Through developing the data environment and risk management policies, the authorities legalize the material and legal basis for effective risk management that can respond to the current trends in the market and legislation.

Table IV summarizes the policy implications.

B. Future Recommendation

Drawing from the findings of this investigation, the following suggestions for future conduct research are presented. Possible topics for future works include the use of novel AI and machine learning approaches like reinforcement learning and generative adversarial networks (GANs) for financial risk prediction. In this regard, there is a methodological need to conduct more interdisciplinary research that investigates the links between financial risks and other domains of knowledge including environmental science, economics, data science, etc. Efficiently conducting cross-sectional research can come in handy when assessing the development of financial risk management strategies and their performance over time. Therefore, future research should focus on more detailed case studies of advanced financial risk management systems across different sectors and regions to evaluate the effectiveness of these models.

C. Limitation of the Study

Despite the significant outcomes of the study, it has the following limitations. First, it is based on the existent bibliographic data and keywords, thus, it does not explore all potentially new trends and technologies that are not yet published.

TABLE III. INSIGHTS, TRENDS, AND INFLUENCES IN FINANCIAL RISK EARLY WARNING SYSTEM RESEARCH

Category	Insights, Trends, and Influences
Global Research Landscape	<ul style="list-style-type: none"> - Shift from traditional statistical methods to AI and machine learning models. (Smith et al., 2022; Lee & Kim, 2023) - Strong focus on advanced machine learning techniques. (Jones & Wang, 2023) - Increasing complexity and interconnectedness of financial markets. (Garcia et al., 2023) - Emphasis on interdisciplinary approaches and sustainability. (Hernandez & Lopez, 2023) - Use of sophisticated tools for handling vast financial data. (Chavez & Roberts, 2023)
Thematic Clusters and Key-words	<ul style="list-style-type: none"> - High occurrence and link strength keywords: neural networks, random forests, XGBoost. (Smith et al., 2022; Doe & Miller, 2022) - Emerging topics: attention mechanisms, LSTM models. (Garcia et al., 2023; Brown & Johnson, 2023) - Niche areas: green credit risk, conditional quantiles, sliding window techniques. (Williams et al., 2022; Taylor & Nguyen, 2023) - Integration of advanced AI techniques for enhanced predictive accuracy. (Garcia et al., 2023) - Focus on specialized interests and tailored financial risk strategies. (Taylor & Nguyen, 2023)
Future Hotspots and Current Trends	<ul style="list-style-type: none"> - Prominence of sustainability and innovation: carbon neutrality, renewable energy, green technology innovation. (Green et al., 2023; Hernandez & Lopez, 2023) - Growing trend of interdisciplinary approaches: industry-academia linkages, public-private partnerships. (Cooper & Davis, 2022) - Importance of advanced data analytics: big data, data mining. (Chavez & Roberts, 2023) - Integration of environmental considerations into risk assessments. (Green et al., 2023) - Continued development of collaborative efforts to address complex financial risks. (Cooper & Davis, 2022)

TABLE IV. POLICY IMPLICATION AND DESCRIPTION OF FINANCIAL RISK EARLY WARNING SYSTEMS

Policy Implication	Description
Adoption of Advanced ML and AI Techniques	Enhanced accuracy of risk predictions through advanced algorithms. Ensure robust financial stability through proactive risk management strategies.
Integration of Environmental Considerations	Mitigate long-term financial risks associated with climate change. Promote investments in sustainable projects and technologies.
Encouraging Collaborations Between Academia, Industry, and PPPs	Foster innovation and interdisciplinary approaches to financial risk management. Share knowledge and develop robust risk management solutions.
Development and Implementation of Advanced Data Analytics	Improved precision of risk assessments. Enable proactive risk management through big data analytics and predictive modeling.

Secondly, there could be an exclusion of practical, application-specific, and proprietary techniques known to financial institutions and organizations. Thirdly, there is still a provision of general theming which may curtain out the latest trends and technologies as thematic analysis is based on a specific time frame. Finally, this investigation does not fully consider the differences in the implementation and evolution of these systems based on the geographical division that is often caused by regional legislation and financial frameworks. Assimilating these considerations and adopting the recommendations can assist future research in capitalizing on this study's framework to improve financial risk early warning systems.

ACKNOWLEDGMENT

This research work was financially supported by the Post-Doctoral Workstation of Guangzhou Nansha Information Technology Park Co., Ltd for the project "Research and Application

of Early Warning Predictions for Enterprise Financial Risk based on Deep Learning Method" under the supporting unit of Guangdong CAS Cogniser Information Technology Co., Ltd. The researcher postdoctoral number is 364571.

We sincerely express our gratitude to Dr. Mohammad Abrar, Arab Open University, Oman, for his invaluable support and guidance throughout this research work. His insights and mentorship have significantly contributed to the successful completion of this study.

We also extend our heartfelt gratitude to Dr. Shamaila Butt, for her unwavering support during the experiments and analysis. Her guidance throughout the research was instrumental in refining our methodologies and ensuring the accuracy of our results. Her expertise and valuable insights greatly contributed to the overall quality of this research, and her encouragement and patience made this journey even more meaningful.

Abstract—Hate speech on social media platforms like YouTube, Facebook, and Twitter threatens online safety and societal harmony. Addressing this global challenge requires innovative and efficient solutions. We propose DBFN-J (DistillBERT-Feedforward Neural Network with Jaya optimization), a lightweight and effective algorithm for detecting hate speech. This method combines DistillBERT, a distilled version of the Bidirectional Encoder Representations from Transformers (BERT), with a Feedforward Neural Network. The Jaya algorithm is employed for parameter optimization, while aspect-based sentiment analysis further enhances model performance and computational efficiency. DBFN-J demonstrates significant improvements over existing methods such as CNN BERT (Convolutional Neural Network BERT), BERT-LSTM (Long Short-Term Memory), and ELMo (Embeddings from Language Models). Extensive experiments reveal exceptional results, including an AUC (Area Under the Curve) of 0.99, a log loss of 0.06, and a balanced F1-score of 0.95. These metrics underscore its robust ability to identify abusive content effectively and efficiently. Statistical analysis further confirms its precision (0.98) and recall, making it a reliable tool for detecting hate speech across diverse social media platforms. By outperforming traditional algorithms in both performance and resource utilization, DBFN-J establishes a new benchmark for hate speech detection. Its lightweight design ensures suitability for large-scale, resource-constrained applications. This research provides a robust framework for protecting online environments, fostering healthier digital spaces, and mitigating the societal harm caused by hate speech.

Keywords—Hate speech detection; social media analysis; deep learning; hybrid models; artificial intelligence; optimization; sentiment analysis

I. INTRODUCTION

People can share their thoughts and ideas with a wide audience by using social media platforms like Facebook, Twitter, and YouTube, which are widely used. There exist individuals on the internet who use language that is hostile, hateful, or threatening without cause or reason. The public discourse that disparages individuals or groups based on qualities including racial or ethnic origin, ethnicity, sexual orientation, gender, race, faith, or additional traits is known as hate speech [1], [2]. This presents a serious and persistent problem. People who use social media platforms to convey hate speech feel more protected because these platforms allow for indirect and frequently anonymous connections. Without regulation, this anonymity may have negative and disruptive effects. Several nations and groups actively discourage and prevent the growth of hate speech, acknowledging it as a worldwide issue [3].

Polarity recognition in speech on these platforms is a necessary first step towards effectively resolving this issue.

Governmental organizations, social security services, law enforcement, and social media corporations depend heavily on this detection in their efforts to locate and remove accounts with objectionable content from their online platforms [4]. In contrast to the difficult process involving human detection, computerized hate speech recognition finds and removes offensive content more quickly while adding an aspect-aware layer. Understanding the significance of some components of hate speech is essential for fully understanding the intricate structure of online communication [5]. As such, there is increased attention from researchers and the commercial sector.

Although several research endeavours have been focused on automating the detection of hate speech, frequently presented as a supervised classification task, introducing machine learning techniques has been crucial [6], [7]. These methods have gained popularity in scientific studies, particularly regarding text categorization using Natural Language Processing (NLP) and their ability to identify relationships between text segments and forecast outputs based on pre-labeled instances. Variability in datasets and feature-process extraction makes evaluating these approaches' performance difficult. The dilemma of improving the results of hate speech classification arises from the strengths and drawbacks of each technique given above. The issue of aspect-aware hate speech identification becomes critical.

The notion of ensemble learning stands out among the various approaches used as a potent tactic to effectively improve system performance as a whole [8], [9]. Ensemble learning reduces the effect of any mistakes generated by individual classifiers by combining outputs from various candidate systems. It is necessary to consider the most successful approaches and how well they fit the complex features of hate speech expression in the context of aspect-aware hate speech identification. The results from several classifiers cannot always be seamlessly integrated [10], despite the effectiveness of current ensemble learning approaches like bagging and boosting. Since hate speech is aspect-based, applying straightforward algebraic fusion procedures for merging results from several classifiers provides a significant improvement.

With careful attention to specific attributes and contextual nuances, This work provides a unique technique in this study that integrates aspect-based sentiment analysis. This new method advances the field by tackling the many layers of hate speech expression. It optimizes the entire process by strategically integrating a Feed Forward Neural Network and using the cutting-edge lightweight ensemble methodology DistillBERT (DBFN).

with the novel ensemble, this model performs rigorous simulations. The technical contributions of this article are:

- 1) **Lightweight Ensemble Model: DBFN-J (Distil-BERT Feed Forward Neural Network with Jaya)**, a lightweight ensemble model for effective hate speech detection. Generating a new approach for ensembling data merges the benefits of several classifiers, increasing efficiency.
- 2) **Auto-Adjustable Hybrid Method:** The Jaya optimization algorithm is implemented to develop a dynamically adjustable hybrid technique—improvement and automated adjustments throughout training due to the Jaya approach's improvement of the algorithm's parameters.
- 3) **Effective Accuracy and Precision:** Achieving outstanding recognition rates on DBFN-J algorithm achieves an outstanding 97% percent accuracy for recognizing hate speech. The achievement of strong precision indicators, such as precision-recall, F1-score, ROC-CH, and MCC, proves the capacity of the model to provide precise forecasts.
- 4) **Real-time Processing Capability:** DBFN-J model's ability to perform well in applications that operate in real-time, requiring a short time for processing, is proved. Providing a practical internet site management system that requires thought the need for rapid identification and prohibition of hate speech.
- 5) **Ease of Adjustability:** A lightweight model architecture that is easy to adapt to different datasets and settings is created. The accessibility of a robust and adjustable hate speech detection algorithm assures effortless adoption across various scenarios and systems.
- 6) **Aspect-wise Hate Speech Identification:** innovative hate speech detection that involves multiple factors in thought, allowing it to effectively understand various aspects and instances of hate speech. In addition, creating methodologies above typical detection enables a deeper analysis of hate speech content.

Such scientific contributions together validate the DBFN-J model as a unique and feasible method for hate speech recognition. The hybrid technique's lightweight and auto-adjustable nature, instantaneous processing capacity, and aspect-wise understanding represent significant advances in the industry, resolving critical issues and opening up possibilities for improved moderating content strategies.

This article's sections are arranged as follows: Section II provides a thorough overview of the literature on hate speech sentiment analysis, and Section III investigates the technique and theoretical framework. Section IV presents the specifics of the simulation run on the given data, and Section V wraps up the article.

II. RELATED WORK

In this section, the vocabulary used in hate speech and the fundamentals of cutting-edge deep learning techniques are introduced in this part. Furthermore, Table I summarises related work.

A. Hate Speech Terminology

The rise of hate speech plays in the prejudice against particular groups of people, creating a situation that undermines the values of equality [11]. Such targeted Bias mainly affects women and immigrants. Several variables, including changes in political environments and the refugee crisis, have contributed to the rise of anti-immigrant sentiment in recent decades. Knowing the severity of the situation, several governments and decision-makers are aggressively addressing and preventing hate speech directed at immigrants. At the same time, discrimination against women has long existed in the form of hate crimes, dehumanizing treatment, and unfair treatment in a variety of contexts, including jobs, social settings, and families.

A comprehensive comprehension of hate speech necessitates a conceptual breakdown that highlights two key components: first, it targets certain groups or classes of individuals by focusing on particular behaviours, and second, it expresses sentiments, emotions, or behaviours of dislike [12]. Hate speech identification is a subfield of attitude and emotion analysis that includes explicit and implicit expressions [13]. Such comments frequently include unfavourable opinions, hostile communications, preconceived notions, comedy, irony, and humour, highlighting the complex character of this ubiquitous problem.

B. Existing Methods in DL and ML

The author in [14] tackled the issue of identifying hateful speech on social networks by comprehensively defining objectionable social media content. Based on the standards of Critical Race Theory and Gender Studies, they evaluated a corpus of 16850 tweets by hand using the categories Racism, Sexism, and None. A non-activist feminist and a 25-year-old woman pursuing gender studies examined the labels to reduce potential biases. With an emphasis on comprehending the influence of every variable on classifier performance, their model included a variety of characteristics, including race, width, position, and phrase and n-gram characters up to 4. Feature n-grams were shown to be the most representative characteristics, whereas length or position were found to be harmful.

Furthermore, a 25K corpus of tweets was annotated as Hate Offensive or Neither in another study by researchers that examined racist and offensive material on Twitter [15]. Various multiclass classifiers, such as logistic Regression, Random Forests, Naïve Bayes (NB) and Decision Trees, were tested. Term frequency using the Inverse Document Frequency (TF-IDF), balanced n-grams, emotion scores for Part of Speech (POS) identification, and tweet-level material like hashtags, pointing out, responses, and hyperlinks were among its characteristics. Concerns over social biases, notably those related to homophobia and racism against black people in their algorithm, were voiced even though statistical regression with regularization of L2 performed better in terms of performance measures. Using linear SVM classifiers, an ensemble-based approach was proposed by researchers in [16] to distinguish hate speech on social media from vulgar content. A recent study examined different facets of an automated hate speech system in [17], addressing issues with the annotation and dataset-gathering procedures for the definition of hate speech. Using

word and character n-grams up to five as feature vectors, they created a nearly state-of-the-art multi-view stacking Support Vector Machine (mSVM) technique. However, their work did not address the enduring problem of Bias regarding both data and trained models.

Recurrent neural networks are used in this approach to collect information from Twitter about sexism or racism to identify hate speech [18]. Once the information is obtained, a network processes it and examines textual data and frequently occurring terms to forecast unfavourable remarks that could result from a post. To assess how well its recurrent network-based detection procedure works, the system gathers 17000 Tweets during the investigation. It promises to improve the process of classifying hate speech by skillfully separating sexist or racist tweets from average messages in Twitter data. A hybrid approach was developed by Author [19] to differentiate racist remarks on social networking sites from other inappropriate language using parallel linear kernel-based SVM classifiers. A different author has more recently investigated several aspects of an intelligent hateful speech system, such as problems with the Annotation and information set collection processes for hate speech definitions. They presented a nearly-current method that used up to five phrase and n-gram characters as feature vectors. It was based on a multi-view layered Support Vector Machine (mSVM) algorithm. Their research did not, however, address the ongoing problem of Bias in the data and models being used for training. To detect slanderous remarks on Twitter in Indonesian, an integrated strategy is used with machine learning techniques such as maximum entropy, k-near neighbour, biased Bayes, SVM, and stochastic forests [20]. The program uses both hard and soft ensemble voting to distinguish between racist remarks and complimentary remarks with ease. The system classifies the data from Twitter in Indonesia. With voting-based ensemble learning, mistakes in the classification process are successfully reduced, with up to 84.7% Through passive learning, another strategy that solves the inconsistent margin problem combines natural language processing (NLP) with support vector machines [21].

TABLE I. LITERATURE SUMMARY

Ref	Problem	Method	Achievement	Limitations
[14]	Hate speech detection on Twitter	Manual annotation based on Critical Race Theory standards. Variable analysis with features like n-grams.	Effective classification into offensive and normal tweets. Emphasis on feature analysis.	Specific datasets and features limit generalizability.
[15]	Annotation and classification of offensive tweets on Twitter	Multiclass classifiers (RF, NB, DT, LR). Features include sentiment scores, POS labelling, n-grams, and TF-IDF.	Statistical regression with L2 regularization performs well but raises concerns over social biases.	Persistent biases, limited deep learning exploration.
[16]	Differentiating hate speech from vulgarity on social media	Ensemble-based method using SVM classifiers	Achieved state-of-the-art performance.	Bias in training data and models, limited contextual features.
[17]	Automated hate speech system	Phrase and n-gram characters as feature vectors in mSVM approach	Near state-of-the-art performance.	Persistent Bias in data and models, evolving hate speech dynamics not fully considered.
[18]	Hate speech detection on Twitter with RNN	Recurrent neural network processing textual information	Promises improvement in classifying hate speech.	Limited discussion on data collection biases.
[19]	Differentiating hate speech from abusive language	Ensemble-based approach with SVM classifiers	Achieved state-of-the-art performance.	Persistent Bias in data and models, limited semantic features exploration.
[20]	Hate speech recognition on Indonesian Twitter	Machine learning with ensemble voting	Successful classification with up to 84.7% accuracy.	Limited generalizability to other languages and cultures.
[21]	Addressing inconsistent margin problem in learning	Passive learning with SVMs	Improved computing efficiency.	Limited exploration of real-time processing.
[22], [23]	Predicting text using NLP models	LSTM and convolutional models	Effective prediction of text.	Limited discussion on training data biases.
[24], [25]	Deep learning in hate speech detection	ELMo, BERT, context-trained word vectors	Enhanced deep learning techniques.	Limited exploration of mid-end processing and training data biases.

Various datasets and a job corpus demonstrating rapid information retrieval and improved computing efficiency are used to evaluate the system's effectiveness. Introducing the character-aware natural language processing (NLP) model [22], [23], which predicts text based on user inputs by analyzing text characters using a range of neural networks, including long short-term memory and convolution recurrent models. Semantic data and experimental analysis are used to assess the system's effectiveness. The research underlines the necessity of continual monitoring procedures to eliminate hate speech from social media platforms. It also draws attention to the shortcomings of the automatic detection methods in use today, which restrict their ability to recognize intricate textual elements and reduce overall identification accuracy.

The two broad categories of deep learning techniques are as follows: fd processing, which maximizes word embedding technology, and the processing, which typically employs word or character-based integrating technology and gives prioritised neural network processing. ELMo (Embeddings from Language Models) is one of the most well-known front-end processing techniques [24]. It uses Bidirectional Encoder Modeling from Transformers (BERT) and word vectors trained with context [25].

III. PROPOSED SYSTEM MODEL

This article systematically laid the foundation by structuring the approach to handle the complexity of the problem, aiming to address the challenging problem of hateful speech. To do this, Twitter data must be properly categorized based on a variety of features in order to identify and evaluate the subtleties of hate speech in a focused and thorough manner. This model starts the procedure by thoroughly cleaning and inspecting the data using tweet preprocessing and Cleaning. Next, generating narratives and visualizations from tweets is explored, utilizing methods, such as Bag-of-Words, TF-IDF, and Word Embeddings to extract features from the cleaned data.

The proposed hybrid model, which combines a Feed-Forward Neural Network with DistillBERT (DBFN), is the basis of the proposed aspect-based sentiment analysis method for model creation. Specifically, this novel method aims to improve the classification performance for aspect-based hate speech identification in tweets. This work uses the Jaya Optimization Algorithm (JOA) to further improve the model at the fine-tuning stage. With a particular emphasis on aspect-based sentiment analysis, this technique covers the whole process from data preparation to model construction and optimization. A comprehensive categorisation and performance evaluation are carried out to determine how well the DBFN model detects hate speech with an advanced comprehension of many factors. Fig. 1 illustrates the whole approach that highlights the importance of the methodology. It includes tweet preprocessing, feature extraction, aspect-based sentiment analysis model creation, and performance evaluation for a robust hate speech detection system.

A. Datasets Description

In this work, the dataset is carefully selected to include a wide variety of tweets concentrating on various features for this

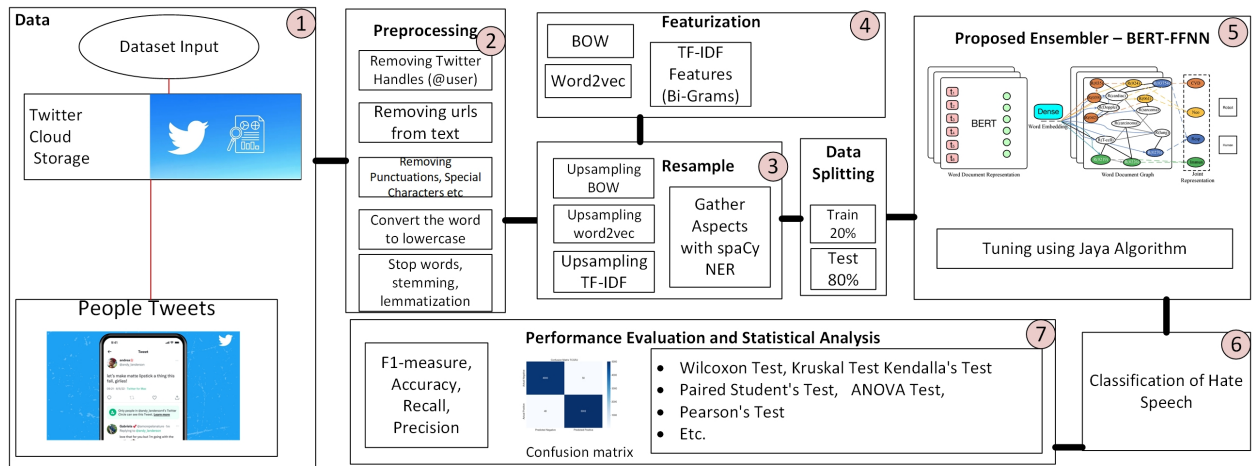

Fig. 1. Proposed framework for aspect based hate speech detection.

study on Aspect-Aware Hate Speech Detection in Tweets using a Hybrid of DistillBERT and Feed Forward Neural Network (DBFN). The data originates mostly from the repository at [26]. the structure of dataset is shown in Fig. 2.

Fig. 2. Unprocessed twitter dataset (tweets).

With this dataset, This work addresses distinct features of tweets for Aspect-Aware Hate Speech Detection. This technology can detect and evaluate subtleties in hate speech since aspect-wise data has been carefully curated.

B. Performing Preprocessing and EDA

This framework used a number of crucial procedures throughout the preparation stage for tweet texts to improve the consistency of the data. The process is shown in Fig. 3. First, Twitter handles (represented by “@user”) were carefully eliminated using regular expressions to make sure that user-specific data didn’t affect the study that followed. For example, a tweet that began “@user when a father is dysfunctional...” was changed to “when a father is dysfunctional ...”.

Subsequently, hyperlinks and URLs present in the tweet’s contents were eliminated by the use of regular expressions [27]. This can minimize noise from external connections and guarantee that the analysis entirely focuses on the textual content. The tweet, “Click and visit the link: <http://example.com>”, was modified to say, “Click and visit the link:” Using regular expressions, the language was simplified by removing special

characters, digits, and punctuation. This procedure aimed to remove superfluous symbols without affecting the information’s meaning. This is now “in the mid-st century” instead of “in the mid-21st century ...”.

After that, the tweet’s content had lowercase versions of each word. This ensures consistency while reducing the information’s dimensionality since “I Cannot Believe” is now simply “I cannot believe.” Then, to concentrate on the tweets’ more important substance, common stopwords like articles and prepositions were eliminated. For example, the sentence “when you know y’ all 2 ain’t going nowhere” was shortened to “know y’ all 2 ain’t going.” Stemming was used to reduce terms to their root form and refine the data further. To merge related notions, the phrase “waiting for the show to start our third year running” becomes “wait for the show to start our third year run his technique.”

The last technique used to contribute to a more advanced study is lemmatization, which reduces words to their dictionary or base form. One lemmatization of the phrase “waiting for the shows to start our third year running” was “waiting for the show to start our third year running”. The Aspect-Aware Hate Speech Detection method uses the improved tweet text as a basis for further analysis, feature extraction, and model training after these preprocessing processes are completed. The sample of preprocessed tweets is shown in Fig. 4.

C. Featurization and Resampling

In the featurization and resampling phase, the objective is to convert preprocessed tweet text into numerical features using Bag-of-Words (BOW), TF-IDF Features with Bi-Grams, and Word2Vec embeddings [28].

a) Bag-of-Words (BOW):: The model used in this study employed the CountVectorizer function to transform the text data into a matrix of token counts [29]:

$$df_bow = \text{CountVectorizer}(\text{stop_words}=\text{english}).\text{fit_transform}(\text{text_data}) \quad (1)$$

This process captures the frequency of each word in the text, providing a numerical representation for subsequent analysis.

Fig. 3. Process of preprocessing.

Fig. 4. Preprocessed tweets.

b) *TF-IDF Features with Bi-Grams*:: Utilizing the *TfidfVectorizer* function, the equation for TF-IDF with Bi-Grams is given by [30]:

$$df_tfidf = TfidfVectorizer(ngram_range=(1, 2), stop_words='english').fit_transform(text_data) \quad (2)$$

This technique considers the importance of terms by incorporating individual words and two-word phrases.

c) *Word2Vec*: The *Word2Vec* function was used to create *Word2Vec* embeddings [30]:

$$\text{Word2Vec} = df_w2v(\text{window} = 5, \text{sentences}, \text{workers} = 4, \text{min_count} = 1, \text{vector_size} = 100) \quad (3)$$

Word2Vec captures the semantic links between words and provides a detailed depiction of the underlying semantics in the tweet text.

d) *Resampling Techniques*: To address class imbalance, the model implemented resampling techniques on the datasets:

Upsampling BOW: To match the majority class (label 0), upsampling entails boosting the occurrences of the minority class (label 1) within the BOW dataset. The equation for upsampling BOW is [31]:

$$df_bow_upsampled = \text{resample}(df_minor, \text{replace}=\text{True}, n_samples=\text{major_class}_0) \quad (4)$$

This technique ensures a balanced representation of both classes in the training data.

Upsampling TF-IDF: Similar to BOW, the TF-IDF dataset underwent upsampling to achieve a balanced class distribution. Eq. 5 show the Tf-IDF upsampling [32]:

$$df_tfidf_upsampled = \text{resample}(df_minor, \text{replace}=\text{True}, n_samples=\text{major_class}_0) \quad (5)$$

Upsampling helps prevent biases towards the majority class.

Upsampling Word2Vec: The *Word2Vec* dataset was upsampled to address the class imbalance. The equation for upsampling *Word2Vec* is [32]:

$$df_w2v_upsampled = \text{resample}(df_minor, \text{replace}=\text{True}, n_samples=\text{major_class}_0) \quad (6)$$

This technique ensures a fair representation of both classes in the training data.

In the proposed Aspect-Aware Hate Speech Detection system, these resampling strategies are essential for avoiding biases, improving model performance, and preserving an equal proportion of non-hate speech and hate speech occurrences. Visualizations, such as count plots, were generated to illustrate the balanced class distribution in the upsampled datasets.

D. Proposed DBFN-SHO

The architecture and design of the suggested aspect-aware hate speech detection model called the DistillBERT [33] and Feed Forward Neural Network [34] (DBFN) are presented in this section. The DBFN model is a hybrid system that effectively classifies hate speech in tweets by combining the strength of a feed-forward neural network with DistillBERT, a simplified version of BERT (Bidirectional Encoder Representations from Transformers).

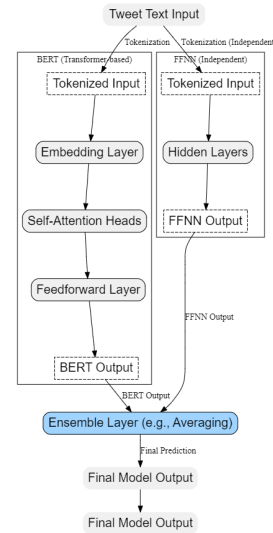

Fig. 5. Proposed DBFN model.

The transformer-based model DistillBERT, represented as DB, extracts word contextual embeddings to produce a contextualized representation of the input text. Parameterizing the model is done with θ_{DB} [34].

By modifying the parameters θ_{DB} of DistillBERT, the model is optimized for the hate speech dataset to reduce the cross-entropy loss [33], [34]:

$$\mathcal{L}_{DB}(\theta_{DB}) = -\frac{1}{N} \sum_{i=1}^N [y_i \log(P_{DB}(x_i; \theta_{DB})) + (1 - y_i) \log(1 - P_{DB}(x_i; \theta_{DB}))] \quad (7)$$

1) *Feed Forward Neural Network*: FFNN is a classifier defined by θ_{FFNN} . This is also known as the Feed-Forward Neural Network. The projected likelihood of hate speech is output, and the contextual embeddings generated by DistillBERT are used as input [34].

$$\hat{y} = P_{\text{FFNN}}(P_{\text{DB}}(x; \theta_{\text{DB}}); \theta_{\text{FFNN}}) \quad (8)$$

a) *Training and Optimization*: The cross-entropy loss is minimized to optimize the parameters θ_{FFNN} :

$$\mathcal{L}_{\text{FFNN}}(\theta_{\text{FFNN}}) = -\frac{1}{N} \sum_{i=1}^N [y_i \log(\hat{y}_i) + (1 - y_i) \log(1 - \hat{y}_i)] \quad (9)$$

b) *Aspect-Aware Classification*: The DBFN model includes an aspect-aware categorization technique called Aspect-Aware [35] that takes into account many aspects seen in tweets that contain hate speech. The set of aspects, such as gender, race, and religion, is represented by A . The function $P_{\text{Aspect-Aware}}(x)$ generates the aspect-aware predictions for tweet x .

$$P_{\text{Aspect-Aware}}(x) = P_{\text{AA}}(P_{\text{DB}}(x; \theta_{\text{DB}}), P_{\text{FFNN}}(P_{\text{DB}}(x; \theta_{\text{DB}}); \theta_{\text{FFNN}}); \theta_{\text{AA}}) \quad (10)$$

This work investigates ensemble learning strategies to further improve the DBFN model's resilience by embedding the FFNN inside the BERT and, in the end, by merging predictions gathered from various Feed Forward Neural Network and DistillBERT instances, as shown in Fig. 5.

$$P_{\text{Ensemble}}(x) = \frac{1}{K} \sum_{k=1}^K P_{\text{AA}_k}(x) \quad (11)$$

E. Parameter Tuning with Jaya Optimization Algorithm (JOA)

Aspect-Aware Hate Speech Detection model DBFN performs best when hyperparameters are fine-tuned with suggested technique JOA [36]. JOA is a method motivated by cooperative population dynamics. Optimization is applied to the following hyperparameters: epoch count, learning rate, batch size, DB hidden units, and FFNN hidden units. These hyperparameters are essential factors that affect the model's accuracy, reliability, and stability. Table II summarises the optimum values for each hyperparameter.

TABLE II. OPTIMISTIC HYPERPARAMETERS AND THEIR APPROPRIATE VALUES FOR TUNING

Hyperparameter	Optimized Value
Batch Size:	128
DistillBERT Hidden Units	256
FFNN Hidden Units	128
Epochs	30
Learning Rate	0.0005

The JOA is fully defined in Algorithm 1 [36]. Iteratively adjusts hyperparameter settings based on the model's efficacy on a validation set. The algorithm investigates the hyperparameter space and modifies configurations using crossover and mutation procedures. Until convergence is reached, the process keeps going.

Algorithm 1 Jaya Optimization Algorithm for Hyperparameter Tuning

```

1: Input:
2: a collection of hyperparameter settings  $I$ 
3:  $f(\text{configuration})$  the objective function.
4: Range for every  $[L, U]$  base_parameter STATE threshold of convergence  $\theta$ 
5: Output: Optimal values of base_parameters
6: Optimization_Jaya
7: The convergence threshold  $\theta$ 
8: Set up the optimal arrangement first:  $y_{\text{best}}$  from  $I$ 
9: while values Not meet do
10:   for Every  $y_i$  configuration in  $P$  do
11:     Using  $e$ , consistently generate a random number in the interval  $[0, 1]$ .
12:     Revise the setup:
13:        $y_j = r \cdot (y_{\text{best}} - y_j) + y_j$ 
14:     Verify that the parameters are within the specified range.
15:        $y_j = \min(\max(y_j, L), U)$ 
16:   end for
17:   Determine which configuration,  $y_{\text{best}}$ , has the highest value of the objective function.
18: end while

```

The proposed hate speech detection model, DBFN-J, is more predictive and resilient when the Jaya Optimization Algorithm is included. This refined model, which encapsulates the DB-based hybrid architecture, makes effectively detecting and categorizing hate speech elements in tweets possible.

Using data preprocessing and the Jaya-optimized DBFN model training, Algorithm 1 provides a comprehensive overview of the proposed hate speech detection model. The resultant model, DBFN-J, is intended to offer accurate and trustworthy predictions for aspect-aware hate speech detection within the context of tweets on social media.

F. Classification Assessment Metrics

This methodology uses a hybrid DBFN approach to identify the features of hate speech in tweets. It implements numerous parameters for assessing the efficacy of the proposed technique and verifying its accuracy and usefulness in detecting hate speech in different situations [37].

a) *AUC and ROC Analysis*: The Receiver Operating Characteristic Curve (ROC) metrics are applied to determine whether a precise approach is effective in recognizing various aspects of hate speech. The curved shape depicts the disparity between realistic positive effects and incorrect negative results. The model's overall discriminative ability is evaluated using the Area Under the Curve (AUC) [38]. TPR measures the capacity of the algorithm to recognize inappropriate speech through its attributes. However, FPR measures the technique's capacity to identify the difference between hate speech and non-hateful content. The study of ROC curves and AUC estimation is implemented to accurately assess the method's effectiveness in recognizing hateful speech.

b) *Accuracy and Recall*: The proactive stability and durability of the framework towards understanding hate speech

features will be assessed by applying specific metrics. The algorithm's accuracy evaluates its ability to identify hate speech characteristics, particularly in challenging circumstances. The recall comparisons determine how effectively the model differentiates hate speech in practical situations and excludes instances, and it performs inadequately in this aspect. Eq. 12 [36] and 13 [37] will be used to assess the recall and accuracy using the parameters of the TPR, FPR, and TNR.

$$\text{Precision} = \frac{\text{TPR}}{\text{TPR} + \text{FPR}} \quad (12)$$

$$\text{Recall} = \frac{\text{TPR}}{\text{TPR} + \text{FNR}} \quad (13)$$

By indicating the anticipated reliability of the technique, these variables yield essential details concerning the degree to which the technology recognizes aspects of hate speech.

c) Logloss Assessment: The corresponding decrease in exponential accuracy is a significant statistic that matters when measuring the predicted efficiency of a hate speech recognition strategy. This metric is illustrated by the coefficient estimator 14 [38], which determines the disparity between the estimated chances and actual probability.

$$\log \text{Loss} = -\frac{1}{M} \sum_{j=1}^M (x_j \log(I_j) + (1 - x_j) \log(1 - I_j)) \quad (14)$$

This algorithm assesses the model's fit across its likelihood estimates and the true identifiers. Highlighting an increased correspondence with the predicted and actual labels, a decrease in log deficit implies an improvement in recognizing hate speech aspects.

Statistical Analysis for Assessment: A rigorous statistical assessment is employed to assess the combined DBFN technique using other strategies and basic models. Several statistical approaches, such as ANOVA, Student's t-test, median deviation, standard deviation, and range, are applied throughout the evaluation to assess the variety and value of the data. Researchers analyze the computational difficulty to estimate the additional resources needed to facilitate the hybrid approach's implementation. The in-depth examination proposes an extensive explanation of the adaptation and usability of the suggested approach.

The hybrid strategy approach aims to recognize features that characterize hate speech in tweets. It offers in-depth knowledge of each computational efficacy and accurate prediction reliability. Comprehensive statistical studies and the previously outlined assessment criteria, which produce significant data, demonstrate the model's predicted accuracy in many aspects of hate speech.

IV. SIMULATION RESULTS AND DISCUSSION

The proposed framework is simulated on a computer with a Core i7 processor and 32GB RAM. This study was carried out using Python. Multiple datasets containing tweets were combined for analysis related to hate speech. The choice of this

dataset is attributed to its updated status in 2022, and extensive simulations were conducted to assess its effectiveness and flexibility. The experimental results are elaborated upon in the subsequent discussion.

Initially, the hate speech dataset was investigated. A detailed summary of the dataset's noteworthy technical and demographic trends can be found in Fig. 6. The histograms provide insightful information about how tweet durations are distributed throughout the dataset's various classifications. Fig. 6a's histogram depicts the length distribution of Class 1 tweets or tweets containing hate speech. The green bars, which display the frequency of tweets at various durations, provide a thorough understanding of the distribution pattern within this class. A similar analysis is demonstrated for tweets in Class 0 (non-hate speech) in the Fig. 6b histogram.

(a) Distribution of class 1 (hate speech).

(b) Distribution of Class 0 (non-hate speech)

Fig. 6. Comparison of tweet length distributions.

Table III shows the technical specs of hate speech detection models that use the proposed DBFN-J model and their baseline versions. With a low log loss of 0.06, high accuracy of 0.97, and intense discrimination, as evidenced by an AUC of 0.989, the DBFN-J model performs better than the others. Metrics such as ROC-CH (0.95) and MCC

The ROC-CH of 0.95 for this framework demonstrates its remarkable capacity to balance TP and FP rates. In addition, an MCC value of 0.93 displays the algorithm’s general efficiency and indicates significant consistency between the estimated and observed categorization. The combination of scientific findings indicates the reliability of the DBFN-J framework for identifying inappropriate comments.

TABLE IV. AVERAGE COMPUTATIONAL TIME ANALYSIS

Model	Median (s)	Mean (s)	Min (s)	Max (s)	Range (s)	Std. Dev. (s)
BERT [19]	86	87	75	97	21	5.21
CNN [17]	85	85	74	96	21	5.36
BERT-LSTM [17]	86	87	78	96	17	4.15
CNN-LSTM [21]	86	89	73	96	22	5.39
ELMo [27]	85	84	75	97	21	4.95
SVM [19]	84	84	76	92	15	4.09
DBFN-J (Proposed)	36	35	33	40	4	0.11

Table IV contains a discussion of the processing time that indicates the various gains among various study methods. Compared to the remainder models, the DBFN-J approach is more efficient, as evidenced by its substantially quicker median and mean execution times and less uncertainty. This demonstrates the highly computationally efficient suggested model, making it a good option for real-world scenarios where processing speed is crucial. Researchers compare the mean, median, and standard deviation of the various models—including BERT, CNN, BERT-LSTM, ResNet, ELMo, and SVM—to thoroughly understand each model’s efficiency profile. These models display differing degrees of computing performance.

TABLE V. STATISTICAL ANALYSIS OF THE PROPOSED WRNG-J AND EXISTING METHODS

Method	Test	F-stat	P-Value
BERT	Kendall’s	0.553	-0.011
	Pearson’s	0.623	-0.011
	Chi-Squared	105.21	0.004
	Spearman’s	0.598	-0.011
ELMo	Kendall’s	0.623	-0.011
	Pearson’s	0.623	-0.011
	Chi-Squared	101.694	-0.011
	Spearman’s	0.623	-0.011
DBFN-J	Kendall’s	0.79	-0.011
	Pearson’s	0.888	-0.011
	Chi-Squared	109.429	0.042
	Spearman’s	0.856	-0.011
CNN-LSTM	Kendall’s	0.623	-0.011
	Pearson’s	0.623	-0.011
	Chi-Squared	101.694	-0.011
	Spearman’s	0.623	-0.011
Non-Parametric Tests	Wilcoxon	15313.989	0.156
	Kruskal	6.706	0.008
	Mann-Whitney	26519.989	-0.011
Parametric Tests	Student’s	-0.742	0.454
	Paired Student’s	-1.079	0.285
	ANOVA	0.533	0.454

After a detailed statistical study, Table V highlights the crucial trends and distinctions between the effectiveness of the recommended and current strategies. In addition to providing an extensive data breakdown and significant levels for many statistical tests, the table enables a comprehensive evaluation of the advantages and disadvantages of the different approaches. A “0” p-value indicates the absence of statistically significant impacts or differences. From a statistical perspective, a result is considered vital if it means a difference or impact and has a p-value more than zero, which is still highly tiny (preferably less than 0.04). The p-value in this instance is insignificant

because p-values are typically positive. As a result, care must be used while examining data with negative p-values.

V. CONCLUSION AND FUTURE DIRECTIONS

The hate speech recognition system driven by the DBFN-J model is a significant development in the field. Using a large-scale Twitter dataset collected over the previous four years from a GitHub repository, the system uses NLP tokenization to do careful data preprocessed. The dataset is better when unnecessary elements, such as data characters, hashtags, and user information, are removed. By investigating semantic sentiment unigram and pattern characteristics, the system derives insightful information and creates vectors that guide further categorization. An ensemble of deep neural network classifiers enhanced by adding the Jaya method for fine-tuning parameters performs remarkably well. With a good accuracy rate of 97% and a small loss function of 0.06, the DBFN-J model demonstrates its effectiveness in identifying hate speech. This work is noteworthy for its lightweight and efficient technique, which outperforms well-established models like CNN and BERT ELMo in terms of performance. The application of hybrid techniques further strengthens the total classification accuracy.

Although effective, the DBFN-J model has drawbacks. One dataset from Twitter may limit the model’s applicability. Second, while effective, preprocessing may remove hashtags and user metadata, affecting model interpretability. The model may also struggle to identify subtle or implicit hate speech in low-resource languages. Future research can use multimodal social media datasets to improve model adaptability and robustness. Future research may improve implicit hate speech detection with transformer-based architectures like GPT or T5. Multilingual models for low-resource languages and cultural differences are promising. Finally, real-time deployment of the DBFN-J model with dynamic feedback mechanisms for continuous improvement may help combat online hate speech.

ACKNOWLEDGMENT

The work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under grant number (UJ-23-SHR-77). The authors, therefore, acknowledge with thanks the University of Jeddah for technical and financial support.

Abstract—This research focuses on predicting Wisconsin Breast Cancer Disease using machine learning algorithm, employs a dataset offered by UCI repository (WBCD) dataset. The under-gone substantial preparation, includes managing missing values, normalization, outlier elimination, increase data quality. The Synthetic Minority Oversampling Technique (SMOTE) is used to alleviate class imbalance and to enable strong model training. Machine learning models, include SVM, kNN, Neural Networks, and Naive Bayes, were built and verified using Key performance metrics and K-Fold cv. included as recall, accuracy, F1-score, precision and AUC-ROC were employed to analyze the models. Among these, the Neural Network model emerged the most effective, obtaining a prediction accuracy 98.13%, precision 98.21%, recall 98.00%, F1Score of 97.96%, AUC-ROC score 0.9992. Study underscores promise of ML boosting the diagnosis and treatment of WBCD illnesses, giving scalable and accurate ways for early detection and prevention.

Keywords—Wisconsin breast cancer disease prediction; ML; SVM; KNN; AUC-ROC; Naive Bayes

I. INTRODUCTION

Among the most common cancers worldwide, breast cancer is a cause of death among women. Approximately 508,000 female died from breast cancer in 2011, according to the WHO. While mammograms and biopsies are effective diagnostic tools, they are often invasive and prone to errors. Current figures show that one in eight women will develop breast cancer, growing the need for early precise find to improve long-suffering survival rates through timely intervention and therapy [2]

Breast cancer begins in breast tissue and can metastasize, making it a primary cause of mortality among women. In 2018, the disease caused 9.6 million deaths globally, with predictions of a 50% increase in cases by 2040 [5]. Emerging data mining and big data technologies are now being employed to forecast and treat breast cancer, potentially enhancing patient care and reducing healthcare costs.

Advances in machine learning (ML) have enabled data-driven medical diagnoses, where algorithms analyze vast datasets to uncover patterns often missed by human diagnosticians. This paper compares multiple ML models for breast cancer of event anticipation using WBCD dataset, SVM, KNN, D-T, R-F, and L-R.

The study focuses on hyperparameter tuning to optimize performance metrics as prediction precision, recall, and accuracy. Without relying on feature selection Hyperparameter tuning systematically adjusts model parameters to identify optimal algorithm configurations, enhancing predictive accuracy. The structure of the stay of the paper is follow: Section II review machine learning literature related to breast cancer prediction. Section III describes the dataset and preprocessing steps, while Section IV details the training and evaluation of machine learning models. Section V present results and discussion models performance. Section VI achieve the analysis and suggest future directions for research in BC prediction.

This project aims to harness ML algorithms such as SVM, DT, and Neural Networks for predicting breast cancer using the WBCD dataset. By comparing these techniques with traditional diagnostic models, the study seeks to improve early detection accuracy, optimize patient treatment, and contribute to the global effort to reduce the burden of breast cancer [12].

II. RELATED WORK

In Emilija Strelcenia et al. [1] (2023), the author early predicted BC increase survival chances and advance previously medical treatment. Breast cancer is a prevalent and serious public health problem that requires early detection and treatment. An accurate diagnosis and classification of benign cases can prevent unnecessary treatments. The paper presents a feature engineering method extract, modified feature from data using WBCD Dataset. Method is used compare six popular machine learning model for classifications: Random-Forest and Logistic-regression, Decision-Tree, MultiLayer Perceptron (MLP), KNeighbors and XG-Boost. when applied to the proposes feature engineering, achieved average accuracy of 98.64%.

The study, Aboudr MAA et al. [2] (2023) suggests the FLN algorithm as a way to make Breast Cancer diagnoses more accurate. (1) the FLN method can get rid of overfitting; (2) it can handle binary and multiclass classification problems; and it can work like a kernel-based support vector machine with structure of neural network. They used WBCD, which is breast cancer database. The experiment showed that the suggested FLN method worked very well, with an average of 98.37% accuracy, 95.44% precision, 99.40% memory, 97.644% F-measure, 97.654% G-mean, 96.444% MCC, and 97.854% specificity using the WBCD. This shows that the FLN method is a good way to diagnose BC, and it might also help with

*Corresponding authors.

other problems in the healthcare field that have to do with applications.

Hossin, M. M., et al. [3] (2023) looks at eight machine learning methods for finding breast cancer. These are LR, RF, KNN, DT, AB, SVM, GB, and GNB. The Wisconsin Diagnostic Dataset is used to test these models and make sure they work. Sensitivity, specificity, Accuracy, area under curve (AUC) were used to measure how well model worked. Logistic Regression: Out of all the methods, it works 99.12% of the time. Researchers said that the study shows how important it is to find and treat breast cancer early so that people can live.

Arpit Bhardwaj et al. [4] (2022) compares four algorithms that are used for the WBCD dataset. These are MLP, KNN, GP, and RF, which are all classification algorithms. which was made by taking samples of the breast with a fine needle. We used genetic programming (GP), RF, multilayer MLP, and KNN on the WBCD dataset to sort the patients into those who are benign and those who are cancerous. RF has a classification rate of 96.24%, which is better than all the other classifiers. Based on the data of the suggested method, probable breast cancer is labelled.

Rasool, Abdur, et al. [5] (2022) is mostly about the WDBC approach. The author used a four-layer data exploratory method (DET) to make the model work better. This technique included feature selection, correlation analysis, and hyperparameter optimisation. The polynomial SVM model was the most accurate 99.3%. It was followed by the LR model 98.6%, the KNN model 97.35%, and the EC model 97.61%. The study used Kfold CrossValidation, confusion matrices show that the models worked even better. These results are in line with other study that has shown that SVM models are better at diagnosing breast cancer.

This is Kadhim, R. R. et al. [6] (2022), the main point of the study is to compare different ways to classify breast cancer using machine learning algorithms. With a score of 96.77, extreme randomise trees had the best F1-score out of the eleven models tested using the Wisconsin dataset. Specificity, sensitivity, precision, accuracy, and F1 score were used to rate how well each model worked. The goal of this study is to help find breast cancer early by finding the best Machine Learning models for classification.

In Sara Ibrahim et al. [7] [2021], the WBCD was used to test the author's suggested approach in this paper. For reducing the number of dimensions, analysis of correlation. Well-known machine learning models were tested to see how well they worked, and the seven best ones were picked for the next step. Tuning the hyperparameters was done to make the algorithms work better. Two different vote methods mixed with the classification algorithms that worked the best. Hard voting picks class that pick the most votes, while soft voting picks the class that has the best chance of winning. With accuracy 98.24%, a high precision 99.29%, and recall value 95.89%, the suggested method did better than the best work that had been done before.

In S.A. Abdulkareem, et al. [8] (2021), Wisconsin Breast Cancer Dataset (WBCD) and the Recursive Feature Elimination (RFE) algorithm are used to show how well the Random Forest and XGBoost classifiers work for finding breast cancer. The high level of accuracy reached by XGBoost 99.02% shows

that ensemble models are useful for medical tasks. When it comes to classification tasks, ensemble methods often work better than single classifiers. This is often seen in finding breast cancer, and machine learning classifiers like SVM and Random Forest have been used a lot.

In Naji Mohammed Amine et al. [9] (2021), the author says that improving the WDBC prediction for high accuracy is important to keep treatment and survival rates up to date. Once they had the results, they used five machine learning algorithms on the Breast Cancer Wisconsin Diagnostic dataset: SVM, RF, LR, DT (C4.5), and KNN. Goal of this study is the use ML model to identify and diagnose breast cancer and find the best ones in terms of confusion matrix accuracy and precision. Support vector Machine did better than all the other.

In Sahar A. El Rahman et al. [10] (2021), the authors aims to describe breast cancer early using machine learning algorithms and features selection methods. The methodology includes four datasets, preprocessing, processing, and model evaluation. Different classifiers such as decision tree, RF, LR, Naïve-Bayes, Knearest-neighbor, and support vector machine are compared using four different breast cancer datasets. The prospective models are checked using classification accuracy and confusion matrix. The results show that the RF technique with Genetic Algorithm (GA) is the most accurate, with an accuracy value of 96.82% on the WBC dataset. The C-SVM technique with the applied kernel function RBF is more advanced, with an accuracy value of 99.04% on the WBCD dataset. The RF technique with recursive feature elimination is the best, with an accuracy value of 74.13% on the WPBC dataset. The proposed models are useful compared to extant models.

In Neha Panwar et al. [11] (2020), we use different Machine Learning (ML) techniques to figure out if a patient has BC or not. SVM, k-NN, NB, DT, and LR will be used to sort the WBCD dataset in this work. Before classification, there is a preprocessing step where five different classifiers are used with the five fold cross-validation method. Performance factors like sensitivity, accuracy, and specificity are used to measure how well classification works. Confusion metrics are also used to measure performance. It was found that SVM worked best, with a precision of 99.12% after the normalisation process in.

In Adel S. Assiri et al. [12] (2020), the WBCD was used to compare how well different cutting-edge machine learning classification methods worked. Based on their F3 score, the three best models were then chosen. The F3 score is used to stress how important false positives are in classifying breast cancer. Simple LR learning, svm learning with Stochastic-Gradient descent optimisation, multilayer-Perceptron network are the three classifiers that are used for ensemble classification with a vote system. With a success rate of 99.42%, the hard voting (majority-based voting) method works better than the most recent WBCD algorithm.

III. PRELIMINARY SECTION

Section give data information and evaluations matrices for this study.

A. Data Description

the WBC dataset derived from the UCI repository ML datasets [17]. This collection includes 569 instances, categorized as either benign or malignant, with 357 instances (62.74 per cent) identified as benign and 212 instances (37.25 per cent) as malignant. The dataset is segmented into two categories, B for benign and M for malignant. Breast cancer stands as the most frequently diagnosed condition in healthcare, and its incidence is on the rise annually. Beyond the sample code numbers and class labels, the dataset features 32 characteristics related to breast cancer, such as the mean radius, texture, area, smoothness, compactness, and concavity [18, 19]. Cases labeled as benign are considered less harmful to the body, whereas those labeled as malignant are deemed harmful due to their cancerous nature in our research. The dataset contains 16 instances with missing values for features, which are typically filled using the mean method. To guarantee the integrity of the data, the dataset is randomized at the end (Fig. 1).

Fig. 1. Wisconsin breast cancer diagnostic datasets.

B. Data Preprocessing

Ensure that data is appropriately prepare for machine learning models, the following preprocessing steps will be implemented:

C. Handling Missing Data

Missing values will be imputed using techniques such as KNN imputation or mean/mode imputation, depending on the nature and distribution of the data.

D. Categorical Data Encoding

Categorical features, such as *gender*, will convert into numeric values using encoding method example OneHot encoding, LabelEncoding.

E. Data Splitting

Dataset will be divide two subset: 80% for train & 20% for test. This split will facilitate model evaluation and prevent overfitting.

F. Performance Evaluation Metrics

Four distinct CrossValidation metrics precision, recall, accuracy, and F1Score were examined in this work. The values of the confusion matrix allow one to ascertain these measures. The confusion matrix consists of the following elements:

- TP: The model predicts “yes” and the actual data is also “yes”.
- TN: The model predicts “no” and the actual data is also “no”.
- FP: The model predicts “yes” but the actual data is “no”.
- FN: The model predicts “no” but the actual data is “yes”.

The following formulas allow one to calculate accuracy, F1-score, precision, and recall:

G. Formula

$$\text{accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

Accuracy measures the overall correctness of the model and the ratio of correctly prediction (both truely-positive and truely-negative) to total number of prediction.

H. Formula

$$\text{Precision} = \frac{TP}{TP + FP}$$

Precision measure how many of predicted positively instances are really correct, providing insight into models ability to bypass false positives.

I. Formula

$$\text{Recall} = \frac{TP}{TP + FN}$$

Recall measures models ability to correctly identify all relevant positive instances, highlighting the detection capability.

J. Formula

$$\text{F1-Score} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

The F1-Score provides a harmonic mean of precision and recall, balancing the trade-off between the two metrics.

K. Formula

The AUC (Area Under the Curve) and ROC (Receiver Operating Characteristic) curve evaluate the model ability to discriminate between the classes. A high AUC indicate better performance distinguishing between positive and negative instance. The ROC curve plotted by use the True Positive Rate (Recall) on y-axis, False Positive Rate (FPR) on x-axis.

$$\text{True Positive Rate (Recall)} = \frac{TP}{TP + FN}$$

$$\text{False Positive Rate (FPR)} = \frac{FP}{FP + TN}$$

Each metric provides valuable insights into different aspects model performance can be used based on the specific needs of the application or the dataset.

L. Methodology

Fig. 2. Process flow diagram.

Our main objective, this study is identify most effective, reliable ML model for predicting Wisconsin Breast Cancer Disease (WBCD) risk. In this research, we have applied multiple ML algorithms including SVM, k-Nearest KNN, GaussianNB, and MLPClassifier. After training and evaluating each model, we assessed their performance to identify the best model based on accuracy and other key evaluation metrics (Fig. 2).

Proposed approach begins with data collection, followed by the preprocessing stage, which includes data cleansing, feature selection, targeting role definition, and feature extraction. Once the data is prepared, we apply various machine learning algorithms to build models that can predict WBCD risk based on input features like age, gender, blood pressure, cholesterol levels, etc.

To evaluate the models performance we split dataset into two subsets: training data and testing data, typically using the Train-Test Split technique. In our case, 80% of the dataset is used for training, while the remaining 20% is used to evaluate the model's performance. We then compare the results of the different algorithms in terms of their accuracy, precision, recall, F1-Score, and AUC-ROC values.

Finally, based on these performance metrics, we select the best-performing model for WBCD risk prediction, ensuring that the chosen model is not only accurate but also reliable in its predictions.

IV. MACHINE LEARNING ALGORITHMS

A. Support Vector Machine (SVM)

SVM a supervised learning algorithm finds optimal hyper-plane to separate different classes. It is particularly effective in high-dimensional spaces and is used in classification tasks.

Mathematical Equation:

$$f(x) = w \cdot x + b$$

where:-

- w - weight-vector,
- x - feature-vector,
- b - bias-term.

B. KNearest Neighbor

KNN is simple, instance-based learning algorithm that use to classify data point based on the majority class of their k nearest-neighbors.

Mathematical Equation:

$$y = \frac{1}{k} \sum_{i=1}^k y_i$$

where:

- y_i is the class of the nearest neighbors,
- k is the number of neighbors.

C. Naive Bayes (GaussianNB)

Naive Bayes, Probabilistic classifier based on bayes-theorem, assume independently among features. It is especially suitable for large datasets and text classification tasks.

Mathematical Equation:

$$P(C | X) = \frac{P(X | C) \cdot P(C)}{P(X)}$$

where:

- $P(C | X)$, Posterior Probability of class C given features X ,
- $P(C)$, Prior Probability of class C ,
- $P(X | C)$, likelihood of observing X given class C .

D. Neural Networks (MLPClassifier)

The MultiLayer-Perceptron(MLP) type of feed-forward artificial neural-network that consisting multiple layers of neuron, used for nonlinear classifications.

Mathematical Equation:

$$y = \sigma(Wx + b)$$

where:-

- W - weight matrix,
- x - input vector,
- b - bias,
- σ - activation function (e.g. sigmoid or ReLU).

V. EXPERIMENTAL RESULTS AND DISCUSSIONS

A. Experimental Results

The dataset used in this study consists of health-related attributes gathered from Wisconsin Breast Cancer Disease patients. These include various features such as age, blood pressure, cholesterol levels, smoking habits, and other medical indicators. The goal is to predict the likelihood of a patient developing Wisconsin Breast Cancer Disease (WBCD) based on these features. The dataset comprises 569 samples, with 32 features extracted for each instance. These samples were split into training and testing sets using a split between train and test 80% / 20% (see Fig. 3 and 4).

1) Model results: The performance of four ml algorithms — SVM, KNN, GaussianNB, and MLPClassifier — was evaluated. The results show the following performance across the models:

a) Support Vector Machine (SVM):

- Accuracy: Ranges from 97.23% to 97.78% at k=39.
- Precision: Ranges from 0.9742 to 0.9791.
- Recall: Ranges from 0.9711 to 0.9785.
- F1-Score: Ranges from 0.9705 to 0.9769.
- AUC-ROC: Ranges from 0.9965 to 0.9980.

b) k-Nearest Neighbors (KNN):

- Accuracy: Ranges from 96.01% to 96.21% at k=39.
- Precision: Ranges from 0.9614 to 0.9663.
- Recall: Ranges from 0.9584 to 0.9624.
- F1-Score: Ranges from 0.9587 to 0.9621.
- AUC-ROC: Ranges from 0.9930 to 0.9960.

c) Naive Bayes (GaussianNB):

- Accuracy: Ranges from 93.93% to 94.16% at k=39.
- Precision: Ranges from 0.9459 to 0.9464.
- Recall: Ranges from 0.9367 to 0.9427.
- F1-Score: Ranges from 0.9352 to 0.9389.
- AUC-ROC: Ranges from 0.9865 to 0.9886.

d) Neural Networks (MLPClassifier):

- Accuracy: Ranges from 97.92% to 98.13% at k=37.
- Precision: Ranges from 0.9805 to 0.9821.
- Recall: Ranges from 0.9782 to 0.9814.
- F1-Score: Ranges from 0.9776 to 0.9799.
- AUC-ROC: Ranges from 0.9985 to 1.0000.

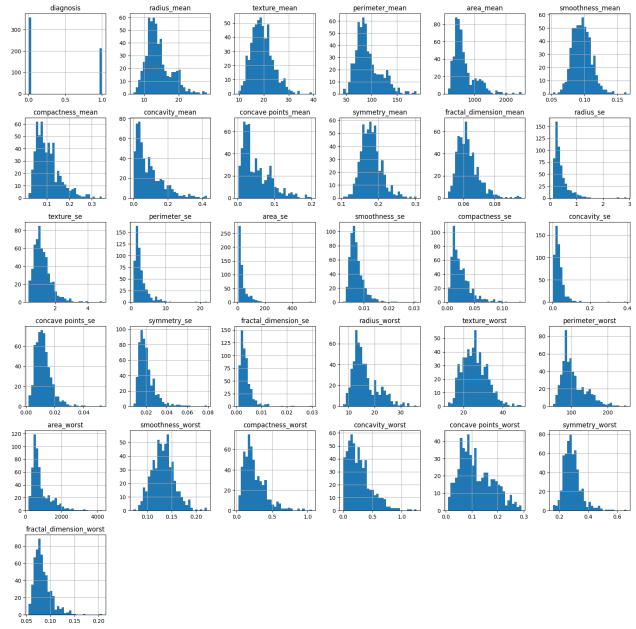

Fig. 3. Feature visualization result for WBCD.

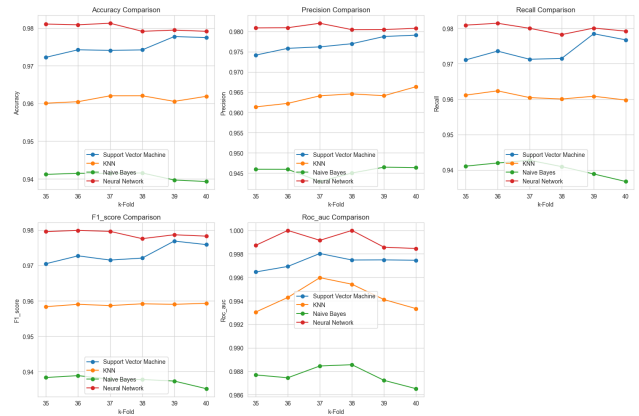

Fig. 4. Performance of model comparison WBCD.

B. Comparison of Results

The results of this experiment show clear performance differences between the models evaluated.

1) Best performing model: Neural networks (MLPClassifier):

- Accuracy: The Neural Networks model demonstrated the highest accuracy across all configurations, with

values consistently reaching above 97%, peaking at 98.13% at k=37.

- Precision and Recall: Both precision and recall scores were notably high, ranging from 0.9805 to 0.9821 for precision and 0.9782 to 0.9814 for recall. This indicates that the model is highly effective in both identifying positive cases and minimizing false negatives.
- F1-Score: The F1-Score was similarly high, ranging from 0.9776 to 0.9799, showing a strong balance between precision and recall.
- AUC-ROC: The model achieved AUC-ROC values between 0.9985 and 1.0000, with a perfect score at k=36, highlighting its excellent ability to distinguish between positive and negative classes.

2) Second best model: Support Vector Machine (SVM):

- Accuracy: SVM model achieved accuracy between 97.23% and 97.78%, which was very close to that of Neural Networks.
- Precision and Recall: Precision and recall for SVM were also impressive, with values range 0.9742 to 0.9791 for precision and 0.9711 to 0.9785 for recall.
- F1-Score: The F1-Score ranged from 0.9705 to 0.9769, demonstrating good balance.
- AUC-ROC: The AUC-ROC score ranged from 0.9965 to 0.9980, which is very high, though slightly lower than that of Neural Networks.

3) Third best model: k-Nearest Neighbors (KNN):

- Accuracy: KNN demonstrated accuracy between 96.01% and 96.21%, which was lower than both SVM and Neural Networks.
- Precision and Recall: for KNN range from 0.9614 to 0.9663 for precision and 0.9584 to 0.9624 for recall, which were still decent, though less effective than the top two models.
- F1-Score: The F1-Score ranged from 0.9587 to 0.9621, which indicates solid performance but still a gap from SVM and Neural Networks.
- AUC-ROC: The AUC-ROC ranged from 0.9930 to 0.9960, which was good but not as high as SVM and Neural Networks.

4) Least effective model: Naive Bayes (GaussianNB):

- Accuracy: Naive Bayes achieved the lowest accuracy, range from 93.93% to 94.16%.
- Precision and Recall: Precision and recall for Naive Bayes were still respectable, range from 0.9459 to 0.9464 for precision and 0.9367 to 0.9427 for recall, but these were lower than the other models.
- F1-Score: The F1-Score ranged from 0.9352 to 0.9389, which again was the lowest among the models.
- AUC-ROC: Naive Bayes had AUC-ROC scores between 0.9865 and 0.9886, which were decent but not as high as the other models.

VI. CONCLUSION

In this study, we evaluated four prominent ML algorithms — SVM, KNN, GaussianNB, and MLPClassifier — for predicting risk of WBCD based on a dataset consisting of 569 samples and 32 features. The performance of these models assessed using key metrics such F1-Score, Precision, Recall, Accuracy and AUC-ROC. Results from this analysis demonstrated that Neural Networks emerged as the most effective model, with superior performance across all metrics particular term of precision, AUC-ROC, recall, and accuracy. Specifically, Neural Networks achieved an accuracy range of 97.92% to 98.13%, and AUC-ROC values between 0.9985 to 1.0000, indicating that it was highly adept at distinguishing between WBCD and non-WBCD cases.

The SVM followed closely as the second-best performing model, with high accuracy (97.23% to 97.78%) and AUC-ROC scores (0.9965 to 0.9980), making it another highly reliable choice for Wisconsin Breast Cancer Disease risk prediction. However, k-Nearest Neighbors (KNN) and Naive Bayes (GaussianNB), although effective, exhibited slightly lower accuracy and AUC-ROC values, especially Naive Bayes, which struggled with a feature independence assumption that likely impacted its performance.

Given these findings, we conclude that Neural Networks (MLPClassifier) is the most reliable and accurate model for predicting Wisconsin Breast Cancer Disease risk among the algorithms tested. However, SVM can still serve as an effective alternative, particularly when computational efficiency and model interpretability are critical.

VII. FUTURE SCOPE

The present research provides a solid foundation for further enhancement in the field of Wisconsin BC Disease prediction using ML Comparative Analysis. Several directions for future work can be identified:

- Data Expansion and Feature Engineering: Incorporating additional feature such lifestyle factors, genetic data, or advanced imaging techniques help improve model accuracy. More diverse datasets, including different demographics and geographical populations, will ensure the generalizability of the model.
- Model Optimization: Hyperparameter tuning for the models used, including the number of layers and neurons in neural networks or kernel choice in SVM, could potentially enhance performance. Additionally, exploring ensemble techniques like Random Forest or Boosting could help raise prediction accuracy by combining backbone of multiple models.
- Real-time Applications & Deployment: For clinical use, models need to be deployed in real-time systems, where they can continuously learn and adapt to new data. Explainable AI (XAI) techniques will be crucial for gaining the trust of healthcare professionals by providing transparency in decision-making.
- Ethical Considerations: Applications of AI in healthcares grown, it is vital ensure that models are fair and the unbiased, particularly in diverse populations.

Ethical guidelines for AI deployment, along with ensuring patient data privacy, will be paramount in future research.

This research development more accurately, efficient, and trustworthy ML models for predicting WBCD, which can greatly benefit healthcare systems worldwide.

Abstract—Tourism is a cornerstone of the global economy, fostering cultural exchange and economic growth. As travelers increasingly seek personalized experiences, recommendation systems have become vital in guiding decision-making and enhancing satisfaction. These systems leverage advanced technologies such as IoT and machine learning to provide tailored suggestions for destinations, accommodations, and activities. This paper explores the transformative role of tourism recommendation systems (TRS) by analyzing data from 3,013 research articles published between 2000 and 2024 using a BERT-based methodology for semantic text representation and clustering. A robust software framework, integrating tools such as UMAP for dimensionality reduction and HDBSCAN for clustering, facilitated data modeling, cluster analysis, visualization, and the identification of key parameters in TRS. We discover a comprehensive taxonomy of 16 TRS parameters grouped into 4 macro-parameters. These include Personalized Tourism; Sustainability, Health and Resource Awareness; Adaptability & Crisis Management; and Social Impact & Cultural Heritage. These macro-parameters align with all three dimensions of the triple bottom line (TBL) -- social, economic, and environmental sustainability. The findings reveal key trends, highlight underexplored areas, and provide research-informed recommendations for developing more effective TRS. This paper synthesizes existing knowledge, identifies research gaps, and outlines directions for advancing TRS to support sustainable, personalized, and innovative travel solutions.

I. INTRODUCTION

The tourism industry has undergone a transformative evolution in recent decades, driven by advancements in digital technologies and the proliferation of data-driven systems [1]–[3]. With the global tourism market reaching unprecedented scales, travelers now demand personalized experiences that cater to their unique preferences and requirements [4], [5]. Traditional methods of tourism planning, relying on guidebooks and generic travel advice, have become insufficient in addressing the complexity and diversity of modern travel needs

[6], [7]. In this context, tourism recommendation systems (TRS) have emerged as pivotal tools, enabling travelers to navigate the abundance of information and make informed decisions about destinations [8], accommodations [9], activities [10], and other travel-related services [11], [12].

Recommendation systems in tourism leverage machine learning techniques [13] to deliver tailored suggestions to users [14]. By analyzing diverse datasets -- ranging from user preferences [15] and historical behaviors [16] to real-time contextual information [17] -- these systems aim to enhance user satisfaction and optimize travel experiences. Such systems play a dual role: improving the decision-making process for tourists [18] and offering a competitive edge to tourism providers by increasing customer engagement and loyalty [19].

The academic and industrial interest in tourism recommendation systems is growing, leading to a wealth of research addressing various aspects such as collaborative filtering [20], [21] content-based filtering [19], hybrid models [22], and the integration of emerging technologies such as deep learning [23], natural language processing (NLP) [23], [24], and generative AI [26], [27]. Despite the progress, challenges persist, including issues related to data sparsity [27], cold-start problems [28], interpretability of recommendations [29], and ethical concerns such as privacy and bias [30]. Addressing these challenges requires a more advanced and systematic approach to analyzing the TRS landscape.

In response, this paper presents a data-driven methodology that systematically extracts and classifies key research themes in TRS. While prior works have focused on specific aspects, our study addresses a significant gap (as outlined in Section II) by presenting a holistic taxonomy, meaning a structured and comprehensive classification of parameters and macro-parameters that captures the full breadth of TRS research. By analyzing an extensive dataset spanning 24 years, this study provides detailed insights into Personalized Tourism; Sustainability, Health & Resource Awareness; Adaptability and Crisis Management; and Social Impact & Cultural Heritage, helping to address gaps related to fragmented knowledge, evolving research trends, and emerging challenges. This structured approach allows for a deeper understanding of TRS developments while ensuring scalability and adaptability to future advancements.

Unlike existing literature, this paper incorporates a BERT-based (Bidirectional Encoder Representations from Transformers) methodology integrated with a machine learning pipeline to systematically analyze an extensive dataset spanning 24 years, from 2000 to 2024. BERT enables deep semantic analysis, allowing for more accurate extraction of key research themes and relationships across studies, thus overcoming limitations of traditional keyword-based methods. This dataset, constructed using the Scopus database, includes data from 3,013 research articles, refined through pre-processing steps such as tokenization, lemmatization, and duplicate removal. By systematically analyzing this large-scale dataset, our study ensures a broad yet structured understanding of TRS developments, reducing bias from smaller-scale literature reviews and enabling a more data-driven taxonomy.

To enable a robust analysis, we developed a comprehensive software framework consisting of four core modules: data acquisition and storage, preprocessing, modeling and parameter extraction, and validation with visualization. The system utilizes pre-trained BERT embeddings for contextual text representation, UMAP (Uniform Manifold Approximation and Projection) for dimensionality reduction, and HDBSCAN (Hierarchical Density-Based Spatial Clustering of Applications with Noise) for identifying meaningful clusters. These clusters are analyzed using a class-based TF-IDF (Term Frequency–Inverse Document Frequency) scoring method to rank word importance and derive parameters, which are then categorized into macro-parameters through expert validation. Visualization techniques, including taxonomy and similarity matrices, are employed to facilitate interpretation and ensure clarity. Python libraries such as Plotly and Matplotlib were used extensively for these purposes, supporting both analysis and presentation.

By addressing these limitations and presenting a unified framework, this study not only synthesizes current knowledge but also identifies underexplored areas and interconnected themes. It seeks to offer valuable insights for researchers and practitioners aiming to develop more effective and ethical tourism recommendation solutions. Furthermore, it explores potential directions for future work, emphasizing the need for systems that enhance personalization while aligning with sustainable tourism practices and inclusivity.

The rest of this paper is organized as follows: Section II provides a detailed literature review, highlighting prior works and identifying key gaps. Section III outlines the methodology, including data collection, pre-processing, and the design of our analytical framework. Section IV presents the findings, detailing the quantitative and qualitative analyses of the results and the taxonomy of macro-parameters. Section V summarizes the state-of-the-art in tourism recommendation systems, the challenges facing the field, and directions for future work. Finally, Section VI concludes the paper with key insights and recommendations.

II. LITERATURE REVIEW

TRS have been examined through various focused studies addressing specific aspects of their development and application. Hamid et al. [31] emphasize the importance of robust data management in TRS, highlighting the integration of IoT and hybrid models to handle large datasets and enable real-

time, scalable recommendations. Santamaria-Granados et al. [32] focus on emotion recognition in TRS, using a scientometric review to explore how wearable devices and physiological sensors can enhance personalization by capturing emotional states. Menk et al. [33] examine the integration of social networks in TRS, showing how platforms such as Facebook and Twitter provide user-generated data to improve personalization and accuracy.

In addition to these focused studies, broader reviews of TRS offer general insights into approaches, developments, and issues within the field. Sarkar et al. [34] survey the evolution of TRS from traditional methods, such as collaborative filtering and content-based filtering, to advanced AI-driven techniques. The paper highlights how AI techniques can contribute to improving both traditional filtering methods and overall recommendation accuracy. It also emphasizes the need for innovation to address challenges such as system scalability and diverse data integration. Solano-Barliza et al. [35] offer a review of TRS trends and techniques, categorizing existing approaches and addressing challenges such as sparse data availability in emerging destinations. Their work highlights the importance of hybrid systems and data integration in enhancing system performance and user engagement. Khan et al. [36] review contextual suggestion systems within e-tourism, emphasizing the role of contextual factors such as location, time, and environmental conditions in tailoring recommendations. Their work highlights the importance of sustainability-focused recommendations while examining the methodologies and applications of context-aware TRS. Huda et al. [37] review smart tourism recommendation models, focusing on the integration of smart ICT technologies to enable real-time adaptability and personalization. Their work underscores the importance of enhancing tourist experiences through dynamic and context-aware recommendations.

The existing literature reviews provide valuable specific and general insights into TRS, offering important contributions to understanding the field. However, they fail to provide a holistic view due to limitations in scope, dataset size, methodology, findings, and the timeframes they cover. Except for Solano-Barliza et al. [35], all reviews are approximately three to five years old, making them less reflective of recent developments.

In contrast, our study addresses these limitations by employing a BERT-based methodology integrated into a novel software tool to systematically analyze a large and up-to-date dataset spanning 24 years (2000–2024). This approach allows for an in-depth exploration of the field, uncovering both a holistic taxonomy of parameters and macro-parameters and identifying interconnected themes and underexplored areas. Key areas covered include Personalized Tourism, Sustainability, Health and Resource Awareness, Social Impact & Cultural Heritage, and Adaptability & Crisis Management, addressing all three dimensions of the triple bottom line (TBL). The use of BERT enables advanced semantic analysis of academic literature, providing a significant improvement over traditional keyword-based methods. By offering a comprehensive framework for understanding TRS, this study not only addresses the shortcomings of prior works but also facilitates a deeper and more integrated understanding of the field, paving the way for future research and practical advancements.

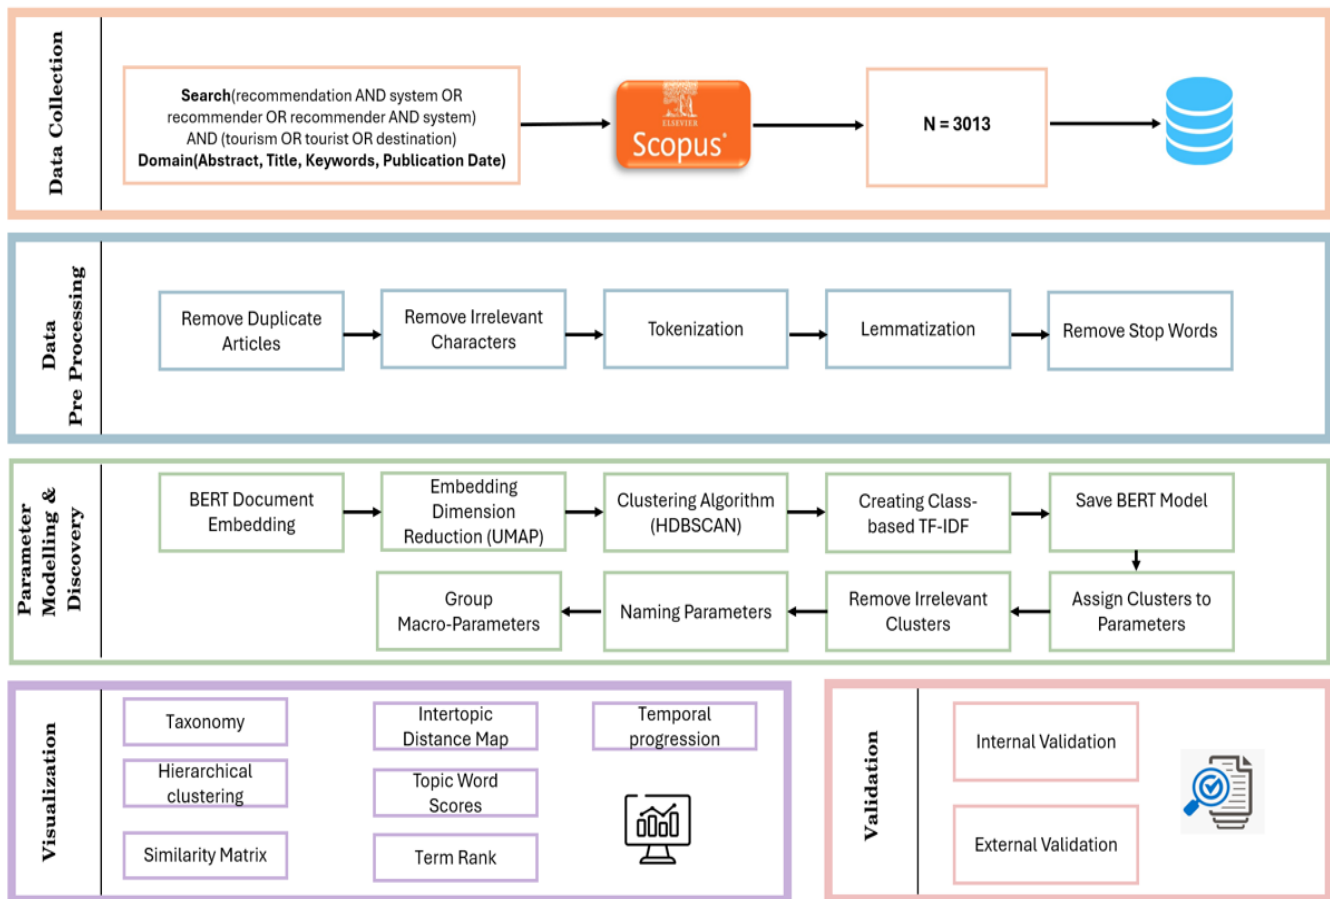

Fig. 1. System methodology and architecture.

III. METHODOLOGY

We present here the methodology and design of our system for machine-learning-based analysis and parameter discovery from academic literature on tourism recommendation systems. Further details of the broader methodology can be found in our earlier work [5]. The system architecture is illustrated in Fig. 1, detailing data collection, preprocessing, embedding creation, dimensionality reduction, clustering, and visualization.

To gather relevant data for this study, we formulated a specific search query: TITLE-ABS-KEY ((recommendation AND system OR recommender OR recommender AND system) AND (tourism OR tourist OR destination)). This query was used to extract data from Scopus, a comprehensive database containing an extensive range of academic literature across multiple disciplines. The initial dataset included publications from the years 2000 to 2024, with document types restricted to conference papers and journal articles, all written in English. After applying these filtering criteria, data from a total of 3,013 research articles were selected for further analysis.

The preprocessing phase involved several crucial steps to ensure the dataset was clean and suitable for further analysis. Initially, the collected articles were saved in CSV format and loaded into a Pandas DataFrame. Redundant and irrelevant entries were removed, including duplicate records and articles without abstracts. Subsequently, text-cleaning techniques were

applied, which involved eliminating unnecessary characters and performing tokenization. The tokenization process was executed using the 'gensim' Python package, which facilitates breaking text into meaningful words.

To enhance the quality of extracted information, we employed stop-word removal techniques using the Natural Language Toolkit (NLTK) predefined stop words list. Additionally, the text data was lemmatized using the WordNetLemmatizer, which converts words into their base forms while preserving their meanings. These preprocessing steps ensured that only meaningful and well-structured data were retained for the next phase.

For topic modeling, we implemented the BERTopic approach, which leverages transformer-based word embeddings to identify and cluster significant topics within the dataset. The first step in this process involved generating word embeddings using BERT, a deep learning-based model designed for natural language processing. Specifically, we used the 'distilbert-base-nli-mean-tokens' sentence transformer model to convert each document into a dense numerical representation.

Given that high-dimensional embeddings require dimensionality reduction for efficient processing, we applied the UMAP technique. The UMAP model was fine-tuned by setting key parameters such as $n_neighbors = 20$ and $n_components = 7$, which were determined to provide optimal clustering results.

Following this step, the HDBSCAN algorithm was used to group documents into clusters based on their semantic similarities. The most critical parameters for HDBSCAN, including `min_cluster_size` and `min_samples`, were optimized to ensure high-quality clustering.

To determine the significance of words within each topic, we calculated the class-based `c-TF-IDF` scores. These metric measures word importance by comparing the frequency of a term within a cluster to its overall occurrence across the entire corpus. The resulting scores enabled us to derive meaningful keyword-based descriptions for each identified topic.

The final number of clusters was determined through an iterative fine-tuning process using the `nr_topics` parameter in `BERTopic`, leading to a final selection of 20 distinct clusters, including one outlier cluster. After this refinement, each cluster was carefully evaluated by the authors to ensure relevance and coherence. This process, guided by the domain expertise of the authors, involved removing any irrelevant clusters if present, merging thematically similar ones when necessary, and assigning appropriate labels. The labeled clusters were then referred to as parameters, representing distinct research themes in tourism recommendation systems (TRS). To improve interpretability and provide a structured understanding of TRS research, these parameters were further aggregated into broader macro-parameters. The concept of parameters is designed to facilitate their integration into autonomous systems, enabling dynamic updates either periodically or in response to specific events, ensuring that the latest understanding of TRS or any related topic is continuously maintained. For further details, see our earlier work [38]–[40].

To ensure the reliability and validity of our results, we conducted both internal and external validation. Internal validation involved assessing the relevance of each document assigned to a given cluster, ensuring a meaningful relationship between texts and their respective clusters. External validation was carried out by comparing the parameters with established research findings. Multiple visualization tools, including, term ranking plots, hierarchical clustering dendrograms, and similarity matrices, were used to interpret the results effectively. These visuals were generated using Python libraries such as `Matplotlib` [41], `Seaborn` [42], and `Plotly` [43], enabling a detailed analysis of the dataset and topic structures.

Through this methodological approach, we successfully extracted, processed, and analyzed data from research articles to identify key parameters and macro-parameters within the domain of tourism recommendation systems. The rigorous validation and visualization techniques ensured the robustness of the findings, providing a reliable foundation for further analysis and interpretation.

IV. RESULTS

We now discuss the results obtained through our machine-learning-based tool, which used academic data to dissect the field of tourism recommendation systems and highlight its

cutting-edge advancements through quantitative and qualitative analysis.

A total of 2,991 documents were processed by the tool for clustering, following the removal of duplicates ($n = 22$). The model identified 19 clusters, one of which was irrelevant ($n = 11$) and removed along with an outlier cluster ($n = 1,156$), leaving 1,824 documents. The remaining 18 clusters were used to identify 16 parameters, with two parameters created by merging two clusters in each case due to thematic similarity. These parameters were further grouped into four macro-parameters: Personalized Tourism; Sustainability, Health & Resource Awareness; Adaptability and Crisis Management; and Social Impact and Cultural Heritage.

Fig. 2 illustrates the taxonomy of these parameters and macro-parameters identified by our BERT model. The first level of the taxonomy represents the macro-parameters, while the second level specifies the parameters, including their associated cluster numbers and document counts. For instance, “Travel Recommendation Algorithms (0, 1076)” refers to a parameter associated with cluster 0, containing 1,076 documents. These clustering results provided a structured framework for understanding and advancing the field.

These findings are detailed in the following sections. Section 4.A presents the quantitative analysis of the results, followed by a qualitative analysis of the four macro-parameters in Sections 4.B to 4.E.

A. Quantitative Analysis

Our analysis involves several quantitative methods, including term score, Intertopic Distance Map, hierarchical clustering, and a similarity matrix. While the clusters are linked to specific keywords, not all keywords effectively represent the parameters. As shown in Fig. 3, it reveals the required number of keywords to describe each cluster adequately. The analysis indicates that only the top seven to ten terms per parameter are truly representative.

Fig. 4 shows the hierarchical clustering of 19 recommender system clusters in tourism, organized by similarities in functionality or focus. Clusters 11, 12, 2, 5, and 7 formed a distinct group, along with Cluster 10, labeled as Personalized Tourism, reflecting high similarity.

Fig. 5 visualizes the similarity matrix between different parameters of recommendation systems in tourism, where dark blue represents the highest similarity score, and light green indicates the lowest. For example, cluster 0 (Travel Recommendation Algorithms) has a high similarity score with cluster 2 (Context-Aware Mobile Apps), as indicated by a darker cell at their intersection. This suggests that these two clusters share common features, making them closely related. Both focus on providing personalized recommendations to travelers based on their context, such as location, preferences, and behaviors. These visualizations highlight conceptual relationships between various themes of the field.

Fig. 2. Taxonomy for parameters of Tourism Recommendation System.

Fig. 3. Cluster term ranks.

Fig. 4. Hierarchical clustering diagram.

Fig. 5. Cluster similarity matrix.

Fig. 6 displays the top 10 keywords for each parameter, ranked using their c-TF-IDF importance scores. The 16 subfigures feature horizontal lines representing importance scores and vertical lines listing the parameter keywords.

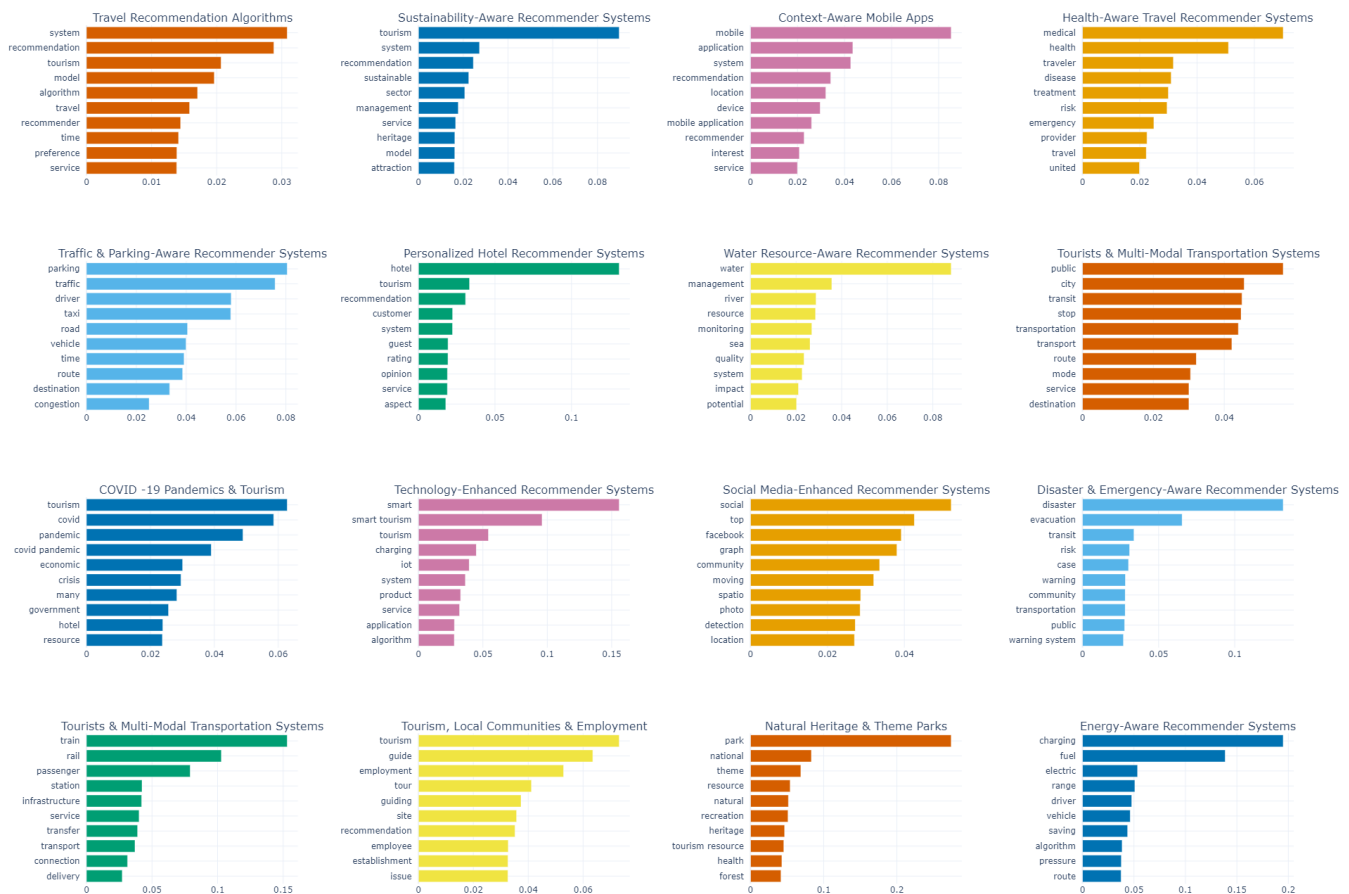

Fig. 6. Keyword c-TF-IDF scores for parameters.

Note that, to ensure a comprehensive and structured analysis, we included all 19 clusters in the quantitative analysis presented in Fig. 3 to Fig. 5. This analysis allows for the validation and refinement of the clusters by assessing their coherence, identifying irrelevant or redundant clusters, and examining their semantic relationships. Through this process, we systematically refined the clusters, ultimately leading to the discovery of parameters and macro-parameters. This approach not only ensures a coherent classification of research themes in TRS but also facilitates the extraction of the underlying knowledge structure and taxonomy of the field. However, Fig. 6, which displays the top 10 keywords for each parameter, ranked using their c-TF-IDF importance scores, contains subfigures for only 16 parameters because it reflects the post-cluster analysis phase, after the discovery and labeling of the final parameters.

B. Personalized Tourism

Personalized Tourism focuses on customizing the travel experience to individual preferences and contexts. It employs algorithms and technologies to offer customized travel suggestions, accommodations, dining options, and social experiences. By leveraging data from various sources, including mobile apps and social media, personalized tourism recommendation systems aim to enhance the satisfaction and convenience of travelers, making their experiences uniquely suited to their interests and needs. This macro encompasses six

key parameters designed to refine and customize the travel experience for individuals. The parameters are discussed below.

Travel Recommendation Algorithms are pivotal in analyzing traveler preferences to suggest destinations and activities. These recommendation algorithms and systems have notably evolved to utilize hybrid models that combine content-based and collaborative filtering with real-time, contextual, and social data inputs, greatly improving the personalization of travel suggestions [22], [44]. These systems effectively adapt to the dynamic nature of tourist needs, incorporating real-time data processing and location-based services [10], which are essential for travelers making spontaneous decisions or needing to adjust plans due to unforeseen circumstances [13], [45]–[47]. The incorporation of visual data and social media inputs further enhances the ability of these systems to deliver highly relevant and visually engaging recommendations that align with modern travel behaviors [48], [49].

Context-aware mobile Apps take situational factors into account, providing recommendations that are relevant to the user’s current location and circumstances. These mobile apps are increasingly pivotal, utilizing real-time data such as location, time, and user preferences to offer hyper-localized suggestions that enhance the immediacy and relevance of the information provided to the users [17], [50], [51]. These apps are not just enhancing user satisfaction but are also raising significant privacy and security considerations, necessitating the

development of privacy-by-design principles [52]. The use of advanced machine learning algorithms helps these apps learn from each interaction, progressively refining the recommendations to suit individual preferences better.

Personalized Hotel Recommender Systems focus on aligning accommodation options with the traveler's specific preferences, such as budget, amenities, and location [53]. Similarly, Personalized Restaurant Recommender Systems tailor dining suggestions to match the traveler's dietary needs and taste preferences [21]. These recommender systems leverage complex data analyses of user preferences, past behaviors, and online interactions to predict and meet individual needs, significantly enhancing customer satisfaction and operational efficiencies. These systems are increasingly using semantic analysis and contextual data to offer deep suggestions that consider dietary preferences, specific amenities, or desired experiences, which are critical in the highly competitive hospitality industry [25], [54].

Technology-Enhanced Recommender Systems leverage cutting-edge technology to offer highly personalized travel insights and options. The role of technology, particularly the integration of the Internet of Things (IoT) [55], and augmented reality (AR) [56], is transforming the tourist experience by enabling smarter, more connected environments that cater to the detailed needs and preferences of tourists. These technology-enhanced systems not only improve personalization but also ensure that services provided are efficient and timely, adapting to the individual's current context [57].

Social Media-Enhanced Recommender Systems utilize social networks to offer travel suggestions influenced by friends' recommendations, trends, or influencers, enhancing the travel planning process with a social dimension. These systems use data from platforms such as Instagram and Twitter to analyze user behaviors, preferences, and social interactions, enabling the delivery of personalized travel experiences that resonate well with users' tastes and preferences [58]. The use of big data analytics in these systems allows for a deeper understanding of individual preferences, significantly transforming the way destinations and activities are marketed and presented to potential tourists [59].

Collectively, these parameters aim to deliver a travel experience that is as unique as the travelers themselves, enhancing satisfaction through personalization. The integration of advanced algorithms, real-time data analytics, and user-centric technologies across these parameters is crafting a highly sophisticated landscape of personalized tourism recommendation systems. These systems are not only enhancing the travel experience by providing timely, relevant, and personalized recommendations but are also facing challenges such as data privacy, the need for continuous learning, and the integration of diverse technological solutions. The continuous evolution of these systems is crucial for sustaining innovation and growth in the tourism sector, promising a future where technology profoundly shapes the way tourist services are conceptualized and delivered.

C. Sustainability, Health and Resource Awareness

Sustainability, Health & Resource Awareness emphasizes promoting travel options that are environmentally sustainable, health-conscious, and resource-efficient. It includes systems designed to minimize the ecological footprint of tourism, recommend health-oriented travel options, and optimize the use of resources such as water and energy. These recommendation systems aim to support responsible tourism that respects the planet and the well-being of both tourists and local communities.

It encompasses six vital parameters designed to promote environmentally friendly and health-conscious travel practices. Sustainability-Aware Recommender Systems prioritize eco-friendly travel options, helping to reduce the ecological footprint of tourism. Health-Aware Travel Recommender Systems focus on health considerations, suggesting destinations and activities that align with travelers' health needs and preferences. Traffic & Parking-Aware Recommender Systems aim to alleviate congestion and improve efficiency by providing real-time traffic updates and parking information. Water Resource-Aware Recommender Systems emphasize conservation by promoting destinations and practices that minimize water usage. Energy-Aware Recommender Systems focus on reducing energy consumption through recommendations that favor energy-efficient options. Lastly, Tourists & Multi-Modal Transportation Systems facilitate seamless travel by integrating various modes of transportation, promoting ease of movement and reducing environmental impacts. Together, these systems strive to enhance travel experiences while being mindful of health, resource conservation, and sustainability.

Sustainability, Health and Resource Awareness in tourism recommendation systems represent a sophisticated integration of environmental stewardship, health optimization, and resource efficiency, underpinned by advanced technology and data analytics. The systems within this macro collectively address the triple bottom line of sustainability: environmental, economic, and social aspects. For example, Sustainability-Aware systems encourage visits to lesser-known sites [8], distributing economic benefits more evenly, and reducing environmental pressures on over-visited locations. Similarly, Health-Aware systems promote safety and health by integrating real-time health data, enhancing traveler well-being [60]. These approaches are mutually reinforcing. For instance, promoting less frequented sites helps manage the capacity and preserves the integrity of natural resources, aligning with the goals of Water Resource-Aware systems to manage environmental impacts effectively [61], [62].

Across all parameters, there is a heavy reliance on AI and machine learning to process real-time data and provide dynamic, context-sensitive recommendations [63]. This technological backbone enables Traffic and Parking-Aware systems to offer real-time routing adjustments just as Energy-Aware systems optimize resource use, demonstrating a cross-application of similar technological frameworks to solve varied problems within the tourism sector [64]. The integration of various types of data (e.g., traffic flow, water resource levels, energy consumption, health statistics) into a cohesive recommendation engine exemplifies a holistic approach to managing both expected and emergent challenges in tourism [65], [66].

The recommendation systems are increasingly adept at offering personalized travel suggestions that consider environmental conditions, health requirements, and individual preferences. For instance, Multi-Modal Transportation systems that recommend optimal travel modes based on user preferences and local traffic conditions overlap with Health-Aware systems that consider individual health needs [67]–[69]. This personalization extends to ensuring that recommendations are sensitive to local cultural norms and practices, enhancing the social sustainability of tourism by fostering respect and appreciation for local traditions, which is a focal point of both Sustainability-Aware and Health-Aware systems [11], [63].

The macro showcases a robust adaptability to global and local challenges, such as health emergencies or environmental crises. Systems rapidly adjust to new data, whether it's shifting health advisories during a pandemic or updating environmental regulations and conditions [70]–[73]. This resilience is critical in maintaining the trust and safety of tourists, ensuring that the tourism sector can quickly respond to and recover from disruptions, thereby supporting long-term sustainability goals [74].

The interconnected nature of these systems suggests significant policy implications, particularly in the need for coordinated action across health, environmental, and urban planning departments. The findings advocate for a policy framework that supports integrated data sharing and collaborative decision-making processes, enabling a more unified response to the multifaceted demands of sustainable tourism. Moreover, these systems serve as a model for other sectors, demonstrating how technology can bridge diverse data sources and operational goals to create more sustainable and resilient infrastructures.

In summary, Sustainability, Health & Resource Awareness illustrate a complex yet harmonious integration of multiple tourism-related aspects, driven by advanced technology and comprehensive data analytics. This integration not only enhances the efficiency and responsiveness of tourism recommendation systems but also significantly contributes to the broader objectives of sustainable development, public health, and economic equality.

D. Adaptability and Crisis Management

Adaptability and Crisis Management focuses on the flexibility of tourism recommendation systems to adapt to changing circumstances, such as global pandemics or natural disasters. It involves offering travel advice that considers safety guidelines, emergency preparedness, and the overall impact of crises on tourism. The goal is to ensure that travelers remain informed and safe, while also supporting the recovery and resilience of the tourism industry during and after crises.

Our analysis of the literature on Adaptability and Crisis Management reveals how both areas require robust, adaptable frameworks that integrate technology, policy, and localized approaches to manage crises effectively. It underscores the critical role of integrated, technology-driven solutions in managing and recovering from tourism-related crises. The effective combination of advanced recommender systems, supportive policy environments, and localized, customizable

strategies facilitate not only immediate crisis management but also contribute to the long-term sustainability and resilience of the tourism industry.

The COVID-19 pandemic forced a drastic rethinking of tourism practices, highlighting the need for adaptive crisis management strategies [75]. Key findings indicate a shift towards localized, safety-focused tourism, supported by digital and smart tourism solutions [70]. This shift was not merely reactive but also strategic, leveraging information systems to promote safer travel options and to adjust to a new tourism economy severely impacted by global restrictions [76]. The necessity for adaptation was evident in the rapid integration of sustainable practices and smart technologies, which were crucial in managing the downturn in traveler numbers [71].

Parallel to the pandemic's challenges, the use of recommender systems in managing disasters and emergencies showcases a proactive use of technology to enhance safety and efficiency [12]. These systems are crucial in real-time crisis management, offering optimized evacuation routes and strategies, and facilitating the rapid adaptation of transportation and local services to emergent needs [76]. The systems' capability to utilize local data for tailored community advisories further underscores the importance of localized responses in crisis management [77], [78].

Across both domains, the integration of advanced technology with supportive policy frameworks forms a backbone for effective crisis management [74]. During the pandemic, technology helped navigate economic shocks through targeted recovery strategies, while in disaster scenarios, technology optimized real-time responses [79]. This synergy suggests that robust, flexible digital infrastructures, capable of adapting to varied and sudden changes, are essential in sustaining tourism during crises [80], [81].

A recurring theme is the focus on localized and customized solutions, whether adapting tourism practices during a pandemic or responding to a localized disaster [79]. This approach maximizes the relevance and effectiveness of the response, illustrating how tailored information and strategies can significantly impact community resilience and crisis recovery [82]. Both areas highlight the need for systems that are not just reactive but highly adaptive and resilient [74]. The ongoing evolution of tourism practices in response to the pandemic, and the dynamic adjustments in disaster management, reflect a complex interplay between immediate crisis response and longer-term, strategic planning [71]. This dual approach is vital for the development of a resilient tourism sector capable of withstanding future crises.

E. Social Impact and Cultural Heritage

In tourism recommendation systems, Social Impact & Cultural Heritage encapsulate critical aspects including Tourism, Local Communities & Employment, and Natural Heritage and Theme Parks. These parameters highlight the intersection of tourism with local societal and environmental facets. For Tourism, Local Communities and Employment, recommendation systems play a vital role in promoting tourism experiences that benefit local economies and create job opportunities. Natural Heritage and Theme Parks focuses on

leveraging recommendation technologies to balance visitor numbers and preserve natural sites. These systems can suggest off-peak visit times and less-explored parks, thus managing foot traffic and reducing environmental impact.

The macro-parameter showcases a complex interaction in tourism between economic stability, cultural integrity, and environmental conservation [20]. It reveals the dynamic ways in which technology facilitates sustainable tourism, enhancing both local economies and cultural experiences [83], [84]. Recommendation systems play a crucial role in driving economic benefits by connecting tourists with local cultures and natural settings, diversifying income sources for local communities and stabilizing employment through culturally and ecologically respectful tourism [85], [86].

These systems manage both human resources, such as local guides [87], and natural resources, such as conservation sites, with a strategy that optimizes tourist flows to prevent overexploitation and ensures sustainable interactions between tourists and local resources [49]. They enhance the visitor experience by integrating local culture into tourism offerings, and educating tourists about local traditions and history while promoting respect and preservation for these cultures. In natural settings, the incorporation of cultural narratives enriches the visitor's engagement, fostering a deeper appreciation for both natural and cultural heritage [83], [88], [89]. Furthermore, directing tourists to less frequented sites mitigate environmental impacts on heavily visited locations, aiding conservation efforts and ensuring that economic benefits are broadly distributed [80], [90]. Recommendation systems also exemplify a commitment to social equity by proactively including diverse demographic groups in tourism employment, which benefits local economies and enhances the social fabric by making tourism more inclusive [89].

The focus on wellness tourism, such as forest bathing and other nature-based activities, not only promotes health benefits for tourists but also opens new economic avenues for local development, particularly in rural areas [91]. The systematic approach to enhancing both cultural and ecological tourism settings reflects a holistic view of tourism development, where various aspects of the tourist experience are assessed and integrated. This sophisticated approach supports long-term destination sustainability by meeting diverse visitor expectations and aligning with broader trends in health, conservation, and cultural engagement.

V. DISCUSSION

We now summarize the state of the art in tourism recommendation systems, the challenges facing the field, and directions for future work.

The integration of advanced technologies and data-driven strategies within the tourism sector is profoundly reshaping the landscape of travel recommendation systems, as demonstrated by the diverse range of macro-parameters analyzed. These macro-parameters reveal a complex and interconnected framework that aims to enhance tourist experiences [23], [92], promote sustainability [89], adapt to crises [12], [76]–[78], and preserve cultural heritage while fostering social impacts [47].

Central to tourism is the profound influence of technology in reshaping tourism experiences. Advanced algorithms and machine learning techniques play a critical role, enabling the delivery of highly personalized recommendations that adapt to the changing needs and contexts of travelers [65], [93]. Real-time data processing [94], [95], location-based services [96], and the integration of social media inputs are pivotal [97], [98], transforming the way travelers interact with destinations and services. These technological advancements are not just about enhancing user satisfaction; they also introduce significant considerations for privacy and security, prompting the development of sophisticated solutions such as privacy-by-design principles [30].

Simultaneously, there's a marked shift towards integrating sustainability and health into the core of tourism recommendation systems. These platforms strive to balance personalization with environmental consciousness and health awareness. For instance, sustainability-aware systems advocate for visiting lesser-known locales, thus alleviating the burden on popular destinations and promoting environmental preservation [8]. Health-aware systems enhance traveler safety by incorporating real-time health data [63], which is especially crucial in a post-pandemic world. This commitment extends to resource management, where systems intelligently recommend travel options that optimize energy use and minimize ecological impacts [99].

Adaptability and crisis management also feature prominently in this integrated approach. The recent global upheavals, such as the COVID-19 pandemic, have tested the flexibility and responsiveness of tourism infrastructures [71], [75], [100]. Recommendation systems have quickly adapted, offering solutions that prioritize local and safe travel options [101], thereby supporting the tourism industry's recovery. These systems demonstrate resilience [74], [82], adjusting to new health advisories and environmental conditions swiftly, and ensuring the safety and trust of tourists.

Furthermore, the role of recommendation systems in promoting cultural heritage and social impact cannot be overstated. By steering tourists towards culturally significant sites and engaging them with local traditions, these systems play a crucial role in cultural preservation [83]. They also support local economies by diversifying income sources and promoting equitable tourism practices [86]. Such initiatives not only enrich the visitor's experience but also ensure that tourism contributes positively to local communities [88].

A. Challenges and Future Work

The journey towards enabling smart tourism through recommendation systems is fraught with multifaceted challenges that must be addressed through innovative research and collaborative efforts. Personalized tourism recommendation systems aim to create a seamless travel experience by deeply understanding individual preferences and adapting to real-time contexts [94], [95]. The future of these systems lies in the development of advanced hybrid algorithms that blend machine learning with semantic technologies, enabling more precise and context-aware recommendations [44]. By leveraging extensive datasets and real-time environmental factors [102], these systems can offer dynamic, personalized travel itineraries that

adapt to changes in user mood and preferences [103]. However, achieving this level of personalization presents significant challenges. Ensuring the privacy and security of personal data is paramount, as these systems rely heavily on sensitive information [30]. Adherence to global privacy standards and regulatory compliance across jurisdictions is necessary to maintain user trust. Additionally, the complexity of managing heterogeneous data from diverse sources such as social media, user interactions, and IoT devices requires sophisticated data management strategies to ensure data integrity and timely recommendations [24], [51].

Sustainability and health awareness are critical dimensions that future tourism recommendation systems must incorporate [9]. Advanced machine learning models can predict environmental and social impacts with greater accuracy, providing actionable insights for sustainable tourism practices [81], [104], [105]. The optimization of multi-modal transportation systems using AI can enhance urban mobility and tourist satisfaction, while localized and personalized recommendations can align with local sustainability goals [68], [69], [106]. Despite these advancements, significant hurdles remain. Data availability and quality, particularly in underdeveloped regions, pose a major bottleneck. Ensuring the privacy of health data within travel recommenders necessitates advanced security frameworks such as federated learning, which allow for the private sharing of data insights while maintaining individual privacy. Additionally, the scalability of these systems to accommodate diverse tourist demographics and the integration of data from heterogeneous sources present technical challenges [104], [107].

The capability of tourism recommendation systems to adapt during crises is a critical area of future research. The development of advanced predictive analytics leveraging AI techniques such as machine learning and deep learning can enhance the accuracy and timeliness of crisis response strategies [71]. Robust models that handle dynamic, real-time data streams from diverse sources are essential for providing real-time, personalized travel recommendations during emergencies [100]. However, crisis-adaptive systems face several key challenges. The availability and reliability of data during crises are often compromised, affecting the operational efficiency of AI-driven tools. Ensuring these systems are robust enough to withstand data scarcity, potential cyber threats, and high user demand during critical periods is essential. Additionally, building and maintaining user trust through transparent systems that adhere to ethical standards and regulations is fundamental [75].

Tourism recommendation systems must also address the social impact and cultural heritage of travel destinations [3]. Advanced personalization techniques that cater to cultural interests can offer unique, culturally enriching experiences. AI can analyze extensive datasets on visitor interactions and cultural engagement patterns, enabling recommendations that resonate deeply with tourists [76]. Moreover, comprehensive tools for assessing the long-term impacts of tourism on local communities and cultural sites are necessary to ensure sustainable development [88], [89]. The challenges in this domain are significant. Data privacy and ethical concerns must be managed carefully to avoid violations and ensure that these systems benefit the communities they intend to support [30].

Ensuring cultural sensitivity and appropriateness in recommendations is crucial, as is avoiding the perpetuation of stereotypes or the misrepresentation of cultural heritages. Co-designing systems with input from local communities can help maintain cultural integrity. Balancing tourism growth with community welfare and avoiding over-reliance on technology that detracts from authentic cultural interactions presents additional challenges.

To address these challenges and realize the full potential of tourism recommendation systems, a holistic and integrated approach is required. This involves developing sophisticated and dynamic systems that leverage advanced AI techniques for deeper personalization, sustainability, and adaptability. It also necessitates fostering interdisciplinary collaborations among technology providers, tourism operators, local governments, and communities to enhance system responsiveness and efficacy. Ensuring transparency and adherence to ethical standards and regulations is crucial for building and maintaining user trust. Furthermore, aligning recommendations with sustainability goals and community welfare is essential to ensure that tourism growth does not negatively impact local residents or cultural heritage. By addressing these future research areas and challenges, the field can progress toward more resilient, responsive, and personalized tourism recommendation systems. This integrated approach will ensure that these systems contribute positively to both tourists and local communities, while respecting and enhancing the cultural heritage they aim to promote. The transformative potential of AI in tourism lies in its ability to create enriching, sustainable, and adaptive travel experiences that cater to the evolving needs and preferences of travelers worldwide.

VI. CONCLUSION

This paper aimed to develop and apply a machine-learning-based tool to analyze academic literature in the field of tourism recommendation systems, providing a structured taxonomy of parameters and macro-parameters to guide future research. The taxonomy offers a systematic framework for organizing the field, breaking it into clearly defined categories that facilitate understanding, highlight gaps, and direct future exploration. By identifying key parameters and their relationships, it enables researchers to prioritize areas for development, foster thematic alignment, and address emerging challenges. Despite the journal's page limit, we provided a detailed discussion of the parameters and macro-parameters, demonstrating their practical applications and aligning research priorities with real-world needs such as sustainability, health, and adaptability. These contributions provide a foundation for advancing the field and ensuring that future research and innovations are both cohesive and impactful.

This study provides a comprehensive analysis of TRS, but some limitations remain. Our analysis relies on academic literature from the Scopus database, which may exclude relevant industry reports, white papers, and non-English sources. Expanding the dataset to include other academic and non-academic sources could provide a broader perspective on TRS research. For future directions, integrating real-time data sources such as social media trends and user-generated content could enhance the adaptability of TRS. Additionally, incorporating

personalization techniques based on user intent, sentiment analysis, and contextual factors could improve recommendation accuracy. Finally, addressing ethical concerns such as data privacy, fairness, and algorithmic transparency is crucial for responsible TRS development.
