III. CRACK AND SEGMENTATION OF CONCRETE STRUCTURES DETECTION

A. DeepLabV3+ Algorithm

The DeepLabV3+ algorithm is the latest version of the Deeplab series [20], and the specific structure is shown in Fig. 7. The DeepLabV3+ network model utilises a combination of the spatial pyramid pooling module and the decoder-encoder structure of the deep neural network to achieve fine segmentation of the target boundary. The spatial pyramid pooling module detects input features at multiple rates and multiple effective fields of view through filtering or pooling operations to encode multi-scale contextual information, and the network structure is shown in Fig. 7; the encoder-decoder structure captures clearer target boundaries by gradually reverting to spatial information, and the network diagram is shown in Fig. 8.

Fig. 7. Encoder-decoder structure network.

The DeepLabV3+ network model structure mainly consists of two parts, Encoder and Decoder. The encoder part of the DeepLabV3+ network uses the DeepLabV3 network as a whole for feature extraction of feature maps of arbitrary resolution output from the deep neural network. The encoder works as follows: first a Conv+BN+ReLU is used, then a convolution, plus global average pooling is used to obtain the scale features, and finally the features are upsampled using Conv+BN+ReLU+ bilinear interpolation to keep the feature maps of the same size. The decoder part is spliced using the outputs of the encoder and DCNN parts, and finally a convolution and upsampling is used for the output.

The DeepLabV3+ network model convolution layer effectively reduces the number of parameters in the model, reduces the risk of overfitting, and improves the generalisation of the model [21]. The convolution process (shown in Fig. 8) is as follows:

$$a_{i,j} = F \left(\sum_{m=0}^{M-1} \sum_{n=0}^{N-1} w_{m,n} x_{i+m,j+n} \right) \quad (1)$$

Fig. 8. Convolution process.

Where, $a_{i,j}$ is the feature map element; $x_{i,j}$ is the i -th row and j -th column element in the convolution feature map; $w_{m,n}$ is the m -th row and n -th column ground weight in the convolution; F is the activation function.

B. Mask R-CNN Algorithm

Mask R-CNN algorithm is a deep learning algorithm [22] for target detection and instance segmentation. Fig. 9 extends Faster-RCNN (Convolutional Neural Network based target detection algorithm) by adding a segmentation branch to predict the exact boundary and mask of the target.

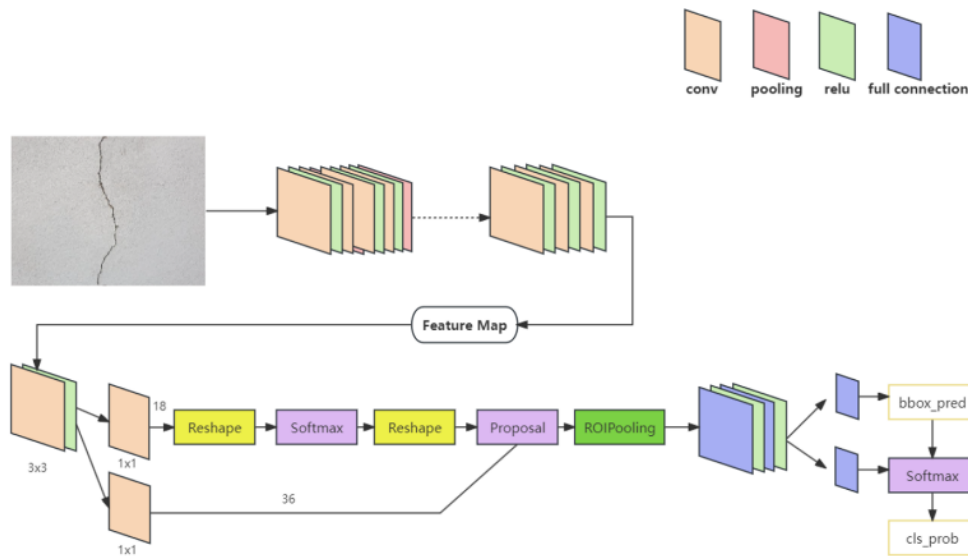

Fig. 9. Mask R-CNN algorithm.

The target detection process of Faster R-CNN is divided into several key steps (shown in Fig. 10):

- (Feature extraction by Convolutional Neural Network (CNN) to obtain high-level semantic information from the input image;
- Introducing a region proposal network (RPN) to generate a large number of candidate target regions, i.e., anchoring boxes, on the convolutional feature map;
- Non-maximal suppression (NMS) is used to eliminate highly overlapping redundant anchor frames, ensuring that each target region is represented by only one candidate frame;
- In the fully connected layer, the Faster R-CNN performs classification and bounding box regression of targets.

Fig. 14. Crack image annotation interface.

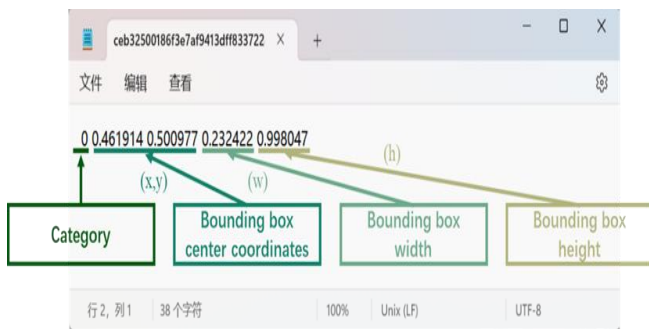

Fig. 15. Structure of crack image annotation labels.

B. Experimental Environment and Training Parameter Settings

In order to match the computational complexity of the algorithm, this paper configures the experimental environment as shown in Table I.

TABLE I. EXPERIMENTAL ENVIRONMENT SETTINGS

Environment Configuration	Parameterisation
CPU	AMD Ryzen7 5800H
RAM	16GB
GPU's	RTX 3060 Laptop
memory	6GB
fig. pattern	Pytorch

The parameter settings of the depth algorithm used in this paper are shown in Table II.

TABLE II. PARAMETER SETTINGS OF DEEP ALGORITHM

Parameter name	Parameterisation
Batch_size	2
epoch	156
optimisation algorithm	AdamW
learning rate	0.00285
Input image resolution	640 x 640

C. Evaluation Indicators

In order to effectively evaluate the effectiveness of the algorithm in this paper, the check accuracy rate (Precision), the check full rate (Recall) and the mean average precision (mean Average Precision, mAP) are used as the evaluation indexes, and the specific calculation formula is as follows:

$$P = \frac{TP}{TP + FP} \tag{2}$$

$$R = \frac{TP}{TP + FN} \tag{3}$$

$$mAP = \frac{\sum_{i=1}^C AP_i}{C} \tag{4}$$

where P is the checking accuracy rate; R is the checking completeness rate; mAP is the Average Precision (AP) of the mean; TP denotes the true category, i.e., the model correctly predicts the positive category samples to be positive; FP denotes the pseudo-positive category, i.e., the model incorrectly predicts the negative category samples to be positive; FN denotes the pseudo-negative category, i.e., the model incorrectly predicts the positive category samples to be negative; AP_i denotes the Average Precision (AP) value for the i -th category; and C denotes the total number of categories.

D. Analysis of Experimental Results

1) Analysis of concrete crack detection results: In order to verify the effectiveness of the concrete crack detection algorithm proposed in this paper, SSD [26], Faster R-CNN [27], and YOLOv5 [28] are used in this paper to conduct comparative experiments with Mask R-CNN, and the results of the experiments are shown in Table III and Fig. 16.

As can be seen from Table III, the concrete crack detection model Mask R-CNN proposed in this paper has a high detection accuracy, with mAP reaching 94.9%, Precision reaching 90.5% and Recall reaching 89.5%.

TABLE III. EXPERIMENTAL RESULTS OF DIFFERENT DETECTION MODELS

Arithmetic	mAP	Precision	Recall
SSD	0.876	0.832	0.748
Faster R-CNN	0.933	0.885	0.855
YOLOv5	0.928	0.879	0.851
Mask R-CNN	0.949	0.905	0.895

From Fig. 16, it can be seen that SSD, Faster R-CNN and YOLOv5 models have duplicated detection frames and low detection completeness, and the Mask R-CNN model proposed in this paper has a better performance in the localisation and identification of cracks compared to the target detection model, especially in the crack detection completeness, which is better than the other models and can satisfy the daily crack detection

in concrete bridges. The Mask R-CNN model proposed in this paper.

Fig. 16. Comparison of detection results.

2) *Analysis of concrete crack segmentation results:* In order to verify the effectiveness of the bridge crack profile segmentation algorithm proposed in this paper, U-Net [29], Mask R-CNN, and YOLOv5-seg [30] are used in this paper to conduct comparative experiments with DeepLabV3+, and the results of the experiments are shown in Table IV and Fig. 17. From Table IV, it can be seen that the DeepLabV3+ model has the highest segmentation effect accuracy compared with other segmentation models, with mAP, Precision, and Recall reaching 48.9%, 67.4%, and 56.7%, respectively. From the segmentation effect diagram (Fig. 17), it can be seen that the bridge crack detection model proposed in this paper achieves better results in the evaluation indexes. In order to more intuitively show the effect performance of different models in bridge crack contour extraction, the same bridge crack image is segmented by using different models, and the results of contour extraction verify that the algorithms proposed in this paper have high accuracy and completeness of contour extraction.

TABLE IV. EXPERIMENTAL RESULTS OF DIFFERENT CRACK SEGMENTATION MODELS FOR CONCRETE STRUCTURES

Arithmetic	mAP	Precision	Recall
U-Net	0.466	0.616	0.503
Mask R-CNN	0.476	0.643	0.520
YOLOv5-seg	0.485	0.637	0.528
DeepLabV3+	0.489	0.674	0.567

(a) Original map.

(b) U-Net.

(c) Mask R-CNN.

Fig. 17. Comparison of segmentation results.

V. CONCLUSION AND OUTLOOK

Aiming at the current concrete structural crack detection and segmentation methods, which have problems such as low recognition ability and inaccurate extraction of the contour of cracks, this paper fuses DeepLabV3+ and Mask R-CNN algorithms, and proposes a concrete structural crack detection and segmentation method based on DeepLabV3+ and Mask R-CNN algorithms. A concrete structure crack detection and segmentation method based on DeepLabV3+ and Mask R-CNN model is proposed by analysing the problem of concrete structure crack detection and segmentation, designing a solution method, and combining DeepLabV3+ and Mask R-CNN algorithm. Using the bridge crack image data for validation and analysis, the Mask R-CNN model has a better performance in the localisation and identification of cracks compared to the target detection model, especially in the integrity of crack detection than other models; the bridge crack detection model achieves better results in the evaluation indexes, and has a high accuracy and integrity of contour extraction in the task of crack contour extraction for concrete bridges. The next step is to improve the training speed of DeepLabV3+ and Mask R-CNN algorithms, and further validate the effectiveness of the algorithms from crack detection problems in different fields.

The proposed method effectively solves key issues in crack detection, especially in locating fine cracks and achieving better segmentation. Despite the strong performance, we note two primary limitations: 1), The current implementation requires significant computational resources, and the training process is slow. 2), Although tested on bridge crack data, the method's performance in other types of concrete structures or environmental conditions has not yet been fully validated.

Prospects for future research directions through this study can be focused on the following aspects: Firstly, Future research could focus on optimizing the training process to make the models faster and more efficient without sacrificing accuracy. Secondly, Additional studies are needed to test the method on

more diverse datasets and environments to ensure the model's robustness across different types of concrete structures. Finally, investigating the use of lightweight neural networks could reduce the computational load and make real-time crack detection more feasible. These future directions aim to further enhance the method's practical applicability and broaden its use in various civil engineering contexts.

Multi-Objective Optimization of Construction Project Management Based on NSGA-II Algorithm Improvement

Yong Yang*, Jinrui Men

School of Energy and Building Engineering, Shandong Huayu University of Technology, Dezhou, 253000, China

Abstract—In the building industry, one of the key components to ensuring a project's successful completion is multi-objective project management. However, due to its own limitations, the traditional multi-objective management approach for projects is no longer able to meet the requirements of building construction and urgently needs to be improved. This is because the construction industry is becoming more competitive and construction standards are improving. Traditional methods for multi-objective optimization typically involve simply summing multiple objectives with weights, overlooking the interdependencies among these objectives. These methods often get trapped in local optimal solutions and rely heavily on predefined models and parameters, limiting their adaptability to sudden changes during the construction process. Therefore, a multi-objective management approach based on multi-objective genetic algorithm for construction projects is proposed. It enables in-depth analysis and comprehensive optimization of the complex relationships between objectives, leading to more informed decisions. By facilitating rapid iteration and adaptation, it enables timely adjustments and optimizations to ensure that project goals remain consistent in complex and dynamic environments. In the experimental validation, the NSGA-II algorithm achieved a significant accuracy of 0.642 and success rate of 0.504 on the VOT dataset, both of which improved by about 1.0% and 0.6% compared to the comparison algorithm. Experimental results on the TrackingNet dataset revealed that the algorithm achieved an accuracy of 0.791 and a success rate of 0.763, while it still maintained an accuracy of 0.542 and a success rate of 0.763 in the face of occlusion. The enhanced multi-objective genetic algorithm had higher accuracy and success rates. This demonstrates the efficiency and excellence of the multi-objective management optimization approach suggested in this study for building projects. The research results have some application value in the multi-objective optimization of engineering projects.

Keywords—NSGA-II algorithm; improvement strategy; construction engineering; project management; multi-objective optimization

I. INTRODUCTION

With the development of the economy and the continuous acceleration of urbanization, the construction industry has gradually become an important part of the national economy. When carrying out construction, project management is extremely important, which involves the economic benefits of the project, quality, safety, environmental protection and other aspects of the requirements [1]. Current construction project management often adopts the traditional method of single objective or simple weighting for optimization, which makes it

difficult to effectively balance the trade-offs between different objectives, and lacks the flexibility to respond to dynamic changes in demand. This limitation not only affects the overall efficiency and sustainability of the project, but also renders the project inadequate in the face of emergencies. Therefore, it is particularly important to propose a multi-objective optimization (MOO) method with strong adaptability and high computational efficiency in a dynamic construction environment. Consequently, it offers enhanced scientific and comprehensive decision support for construction project management, thereby promoting the coordinated development of resource utilization, economic benefits, and environmental protection in the construction industry. This area of research is of particular interest to experts and scholars in the industry. The research structure is divided into five sections. Section I outlines the importance of MOO in construction project management, as well as the problems and challenges in the current research. Section II is to construct and introduce the construction and solution of MOO model of construction engineering project, and discuss the objective function model of construction time, cost, quality and environment management. Section III shows the empirical test of the algorithm, including experimental design, data set selection and performance evaluation. Section IV discusses the experimental results and analyzes the performance and advantages of the algorithm in different application scenarios. Finally, Section V is the conclusion, which summarizes the main findings, practical application value, and future research direction.

In related research, Hamidreza et al. created a novel machine learning (ML) model to address the issue that current labor estimation algorithms often only take particular construction project types or specific influencing factors into account. At the work package level, the model could forecast the labor resource use time series. The results of the study indicated that the model could be used to predict the utilization of labor resources in construction projects, which could help in resource allocation. It was also able to prioritize the available resources to improve the overall performance of the project [2]. To dynamically manage the preliminary costs of a construction project, Zhouxin et al. proposed an artificial intelligence-driven analytical model for estimating and controlling construction costs. ML had the potential to enhance cost estimation during the construction process' procedural stage. The study's findings demonstrated that the ML model could be used to optimize workflow for cost savings and the useful outcomes of data-driven management [3]. Ghorqi et al. proposed a

*Corresponding Author

computational model for a multi-objective (MO) whale optimization algorithm (WOA) based on the Pareto profile to minimize the overall project delay time and associated costs. A comparative study revealed that the MO WOA-supported scheduling technique and solution approach were implemented, and this led to notable gains [4]. The process of cost optimization in construction projects requires maximizing value through effective resource management, cost control and achieving project goals within budget. Therefore, MAJDI Bisharah et al. identified the variable aspects that had significant impact on project cost (PC) through feature selection method. The outcomes revealed that it could effectively allocate resources to achieve project success and improve profitability [5]. In the construction project management mentioned above, the model improves resource management under a single objective, but it primarily focuses on cost control and lacks consideration of other key factors such as quality and environmental impact. The primary motivation of the research is to incorporate additional objectives, such as project quality and environmental impact, to construct a more comprehensive MOO model. The objective is to achieve labor optimization and the balance between time and cost.

Van et al. constructed an analytical model based on both exploratory factor analysis and validation factor analysis. The study's findings showed that the model helped create the theory behind the variables affecting how effective the materials management process is. The key findings about the influencing factors could be used to measure the effectiveness of the materials management process [6]. Simon et al. classified elements into major underlying determinants that caused the majority of the performance deviations, so reducing the scope of construction cost and time management to a few concrete, important areas of attention. This improved the management of the variables influencing time and cost overruns in public construction projects. This supported and improved the rapid decision making required in a variable environment such as construction [7]. Aiming at the problem of efficiency improvement in construction project management, Si et al. put forward the application method of self-organizing digital concept in data mining and intelligent planning. Therefore, it could achieve the improvement of efficiency in construction management practice stage. The study showed that the use of intelligent self-organizing data mining systems in this process could optimize the design and construction complexity, and evaluate the effectiveness of the model by integrating digital twin-driven intelligent construction and basic theoretical method. The results confirmed that the self-organizing model had a direct impact on time prediction planning [8]. Lawal et al. addressed the sustainability challenges facing the Nigerian construction industry by proposing ways to achieve better economic, social and environmental sustainability outcomes through resource optimization and reduced rework practices. Complex relationships between variables were assessed using a structural equation model based on covariance. Path analysis revealed a significant positive correlation between resource optimization and rework reduction and the social and environmental outcomes of construction firms [9]. Due to the identified conflict between efficiency and environmental impacts in off-site construction, Zheng et al. proposed a MOO framework. The framework incorporated a grouping technique

for hybrid flow prefabricated production scheduling, aiming to minimize carbon emissions and reduce late/early departure penalties. The proposed approach reduced carbon emissions by an average of 37.5% through real case studies, while late/early penalties were reduced by more than 10% [10]. A simulation-based method was presented by Sensenses et al. to maximize the cost-time trade-off for project planning issues in the face of uncertainty. Several project schedule collapse scenarios that produced equally plausible realizations were taken into consideration during this approach. The suggested approach has a considerable deal of potential to improve project management, according to experimental data [11]. While the construction project management approach outlined above provides a basic management theory, it lacks a discussion of the joint optimization of multiple objectives. In addition, insufficient consideration of factors affecting project quality and the environment leads to a one-sidedness in optimization results. It also provides no empirical verification for navigating dynamic and complex project environments. The research motivation is to develop a MOO framework that incorporates the relationship between material management and other objectives, along with a more flexible and adaptive algorithm to address dynamic changes in the construction environment. Research models include weighted sum, particle swarm optimization, and MO genetic algorithms. The weighted sum method can be subjective in weight selection and may not capture nonlinear relationships between objectives. Particle swarm optimization can suffer from premature convergence in complex problems, while MO genetic algorithms often have long convergence times and lack flexibility. In contrast, NSGA-II is chosen for this study because of its ability to effectively discriminate between high and low quality solutions. By utilizing crowding distance (CD), it maintains solution diversity and delivers high-quality results quickly. Additionally, it adapts well to both linear and nonlinear relationships among objectives, making it suitable for various MOO challenges, including construction projects.

In summary, most of the existing studies only consider the coordination and optimization of two objectives in the construction project. However, the existing research on MOO mostly focuses on the coordination of single or limited objectives, such as duration and cost, quality and environment. Many studies tend to ignore the complex relationships between them, which leads to the lack of applicability and comprehensiveness of optimization results in practical decision-making. Many models in the existing literature make the simplifying assumption that the environment and parameters remain static. This approach fails to adequately address the dynamic adjustment requirements that arise during project execution. Despite the prevalence of the MOO algorithm, it exhibits suboptimal efficiency, particularly in complex MO scenarios where the computational complexity is substantially elevated. In view of the above gaps, this study proposes a MO management method based on the improved NSGA-II algorithm. This method aims to comprehensively optimize project duration (PD), cost, quality, and environment, and to solve the problem of insufficient treatment of multiple interactive objectives in the current literature. The enhancement of the NSGA-II algorithm has been demonstrated to improve the adaptability of the algorithm in dynamic, changing

environments. This enhancement enables the algorithm to respond to changes in the project in real time, thereby ensuring the effectiveness of the optimal solution. An algorithm efficiency optimization strategy is proposed to improve computational efficiency and reduce execution time. The research innovation is mainly reflected in the improvement of NSGA-II, including the pre-computation of the dominant relationship between individuals to reduce the computational complexity of non-dominant sorting. The sorting strategy has been demonstrated to expedite the identification of congestion distance. Rather than employing the conventional adjacent calculation, local information is utilized to expedite the calculation process and enhance the diversity and velocity of selecting high-quality solutions. The shared fitness mechanism is adopted to make the lower level individuals get higher priority in the selection. The main contribution of this research is to improve the responsiveness and computational efficiency of the model in project management in the face of complex dynamic environments, realize real-time adjustment and optimization of the actual construction, provide important reference value for the sustainable development of the construction industry, and fill the management efficiency gap of the current MOO technology.

II. EP MULTI-OBJECTIVE MODEL: CONSTRUCTION AND SOLUTION

A. MOO Model Construction for EPs

In construction projects, time, cost, quality, and environment are key interrelated management objectives that influence outcomes. A well-structured schedule is essential for smooth progress, which has a direct impact on operating costs and customer satisfaction. Effective cost control addresses both DCs (such as materials and labor) and IDCs (such as management fees). MOO helps managers reduce costs while maintaining quality and schedules. High-quality buildings reduce maintenance costs and safety risks, improve customer

satisfaction, and require rigorous quality control to meet relevant codes and standards. In addition, managing the environmental impacts of construction - such as dust, wastewater, and noise pollution - enhances a company's corporate social responsibility and market competitiveness, especially in the context of green building certification. Reasonable arrangement of PD is an important prerequisite for MO management of EPs, which is also one of the main objectives of management. To guarantee that the project can be finished in the allotted time with both quality and quantity, management of PD necessitates dynamic adjustment of the construction time of each step in accordance with the plan. The general OF model of PD management is shown in Eq. (1) [12].

$$B = \max_{L \in L_m} \left(\sum_{(i,j) \in L_m} t_{ij} \right) \quad (1)$$

In Eq. (1), B denotes the PD. L_m denotes the set of feasible paths. (i, j) denotes the project process. t_{ij} denotes the time required for a single process. Cost management of a project is a dynamic control process. The structure of its components and its relationship with the duration are shown in Fig. 1.

In Fig. 1(a), the PC of the project is mainly composed of two parts: direct cost (DC) and indirect cost (IDC). The DC project construction is directly related to the project, including land use, machinery, construction equipment, etc. IDC are not directly related to the construction of the project but must be spent on the part of the project, mainly for personnel wages, management fees and so on. The purpose of PC management is mainly to carry out reasonable planning for all costs in the whole process of project construction. Furthermore, the project schedule is guaranteed to control the costs required for the project as far as possible, to maximize the economic benefits. The OF model of PC management is shown in Eq. (2) [13].

Fig. 1. Schematic diagram of construction project duration cost optimization model.

$$C = \sum_{(i,j) \in L_m} (C_{ij}^d + C_{ij}^i) \quad (2)$$

In Eq. (2), C represents the total PC. C_{ij}^d denotes the DC required to complete the process. C_{ij}^i denotes the IDC required to complete the process. The DC of the project is declining in Fig. 1(b) as the project's duration rises. This is because the shorter the project duration, the more labor and machines are used per unit of time, which increases the DC of the project. However, a reduction in PD also reduces the cost of labor, project management, etc., thus reducing the IDC of the project. The total cost (TC) of a project decreases and then increases as the PD increases. When the PD increases to a certain level, there will be a minimum value (MinV) of the TC of the project. This MinV can be solved using the OF optimization model of PD-cost to obtain the optimal solution between PC and duration, as shown in Eq. (3) [14].

$$C = \sum_{(i,j) \in L^m} \left[c_{ij}^d + a_{ij} (t_{ij}^n - t_{ij})^2 \right] + \sum_{(i,j) \in L^m} b * t_{ij} \quad (3)$$

In Eq. (3), a_{ij} denotes the marginal cost factor of the process. t_{ij}^n represents the planning time needed to finish the procedure. The real time needed to finish the process is indicated by the letter t_{ij} . b denotes the project overhead cost required for a single day. The established quality standards in each stage of the building process serve as the foundation for the project's quality management. This enables the quality of the project (QOP) to meet the requirements of the contract, the industry and other parties. The main influencing factors of project quality and its relationship with PD are shown in Fig. 2.

In Fig. 2(a), the factors affecting the QOP are multifaceted, mainly including the technical ability of the personnel, the quality of construction materials, construction technology, etc., which affect the quality of each process of the project. When managing the QOP, it is necessary to find out the deficiencies in these factors according to the actual situation of the project and take corresponding measures to improve [15]. Unlike calculating the duration and cost of a project, the quality of a

project is highly subjective. It is difficult to calculate directly. It is necessary to quantify it in an attempt to establish the OF model. The study set different weights according to the impact of different factors on the overall QOP to establish the OF model of project quality, as shown in Eq. (4).

$$D = \sum_{(i,j) \in L_m} w_{ij} q_{ij} \quad (4)$$

In Eq. (4), D denotes the project quality. w_{ij} denotes the impact weight of project quality. q_{ij} denotes the actual quality level. To build the objective function model of project quality, it is essential to quantify and weight each factor affecting the overall quality, which has a significant impact on the model performance. Key influencing factors include the technical ability of construction personnel, material quality, construction standards and technologies, project management and supervision processes, and the external environment. To quantify these factors and set their weights, the expert scoring method can be applied, followed by the weighted average method to calculate the weight for each factor. In Fig. 2(b), there is a roughly positive correlation between project quality and its required duration. The longer the duration of the project, the more construction time for each process, and theoretically the overall QOP will be better. However, the duration of a project obviously cannot be infinitely long, so the QOP can only fluctuate within a given duration. As the PD continues to increase, the improvement of project quality is also more and more limited, gradually converging to a fixed value. The OF optimization model of PD-quality is shown in Eq. (5).

$$\beta_{ij} = \frac{q_{ij}^n - q_{ij}}{(t_{ij}^n - t_{ij})^2} \quad (5)$$

In Eq. (5), q_{ij}^n denotes the level of quality to be achieved.

The environmental management of the project is one of the key elements of project management nowadays, this is because all EPs will inevitably pollute the surrounding environment during the construction process and must be controlled [16]. The types of environmental pollution from projects and their relationship with PD are shown in Fig. 3.

Fig. 2. Schematic diagram of project duration quality optimization model construction.

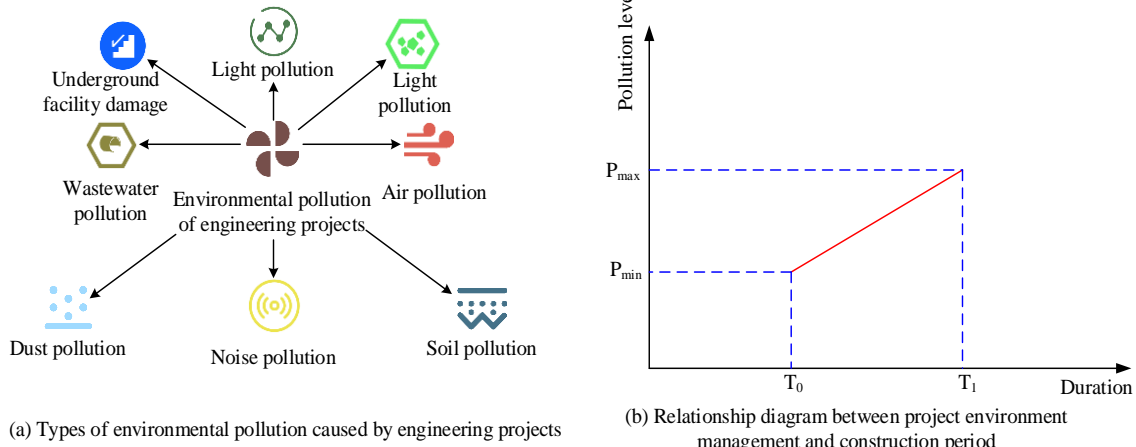

Fig. 3. Schematic diagram of construction period environment optimization model construction.

In Fig. 3(a), in the construction process of EPs, the pollution to the environment mainly includes dust pollution, light pollution, garbage pollution, water pollution, noise pollution and so on. All these pollution are unavoidable for engineering construction. The environmental management of the project is to minimize the degree of pollution of the building construction on the surrounding environment under the condition of meeting other requirements. The study uses factor analysis to assess the impact of different types of pollution on the environment. Factor analysis is a multivariate statistical technique used to identify latent variables that influence observable variables, help understand relationships among factors, and reduce data dimensionality for improved modeling. First, several measures of environmental impact are selected as inputs to the analysis using accurate and valid data. The correlation coefficient between these variables is calculated to assess their interrelationships. Principal component analysis is then performed to extract the underlying factors, followed by factor rotation to ensure that each factor is significantly loaded by only a few variables. The factor load matrix is analyzed to determine which variables most influence each factor. Finally, an objective function model for environmental management is established, as presented in Eq. (6).

$$f(x) = \min E = (L \times W) \times \sum_{ij \in L} (t_{ij} \times e_{ij}) + K \quad (6)$$

In Eq. (6), E indicates the degree of environmental pollution. L denotes the distance between the project site and the residential area. W denotes economic indicators. e_{ij} denotes the evaluation value of pollution factors. K denotes the proportion of resource consumption. In Fig. 3(b), PD and environment are interacting with each other. The PD will affect the environment, and at the same time, the environmental factors will also affect the planning of the PD and the actual completion time of the process. Fig. 3(b) shows a positive correlation between project environmental management and PD. As PD increases, the need for environmental management increases, as does its complexity. Longer construction periods lead to more activities, greater environmental impacts, and higher management costs to comply with environmental standards. The environmental impacts of prolonged

construction may vary at different stages, and the diversification and complexity of activities require more stringent management measures to address emerging environmental risks. Since it is not possible to quantitatively calculate the various types of pollutants, the study obtains the OF optimization model of PD-environment from the time that each process lasts, as shown in Eq. (7) [17].

$$e_{ij} = e_{ij}^n - \varpi_{ij} (t_{ij}^n - t_{ij}) + e_{ij}^s \quad (7)$$

In Eq. (7), e_{ij} denotes the actual degree of environmental pollution from the project. e_{ij}^n denotes the degree of environmental pollution during the planning period. ϖ_{ij} represents the rate of change of environmental pollution. e_{ij}^s represents the estimable part of environmental pollution during the planning period. Eq. (8) illustrates how a comprehensive optimization model of PD-cost-quality-environment may be created by combining the aforementioned OF optimization models between PD and PC, quality and environment.

$$\left\{ \begin{array}{l} \min T = \max \left(\sum_{(i,j) \in L^m} t_{ij} \right) \\ \min C = \sum_{(i,j) \in L^m} \left[c_{ij}^n + a_{ij} (t_{ij}^n - t_{ij})^2 \right] + \sum_{(i,j) \in L^m} b^* t_{ij} \\ \max Q = \sum_{(i,j) \in L^m} \lambda_{ij} \left[q_{ij}^n - \beta_{ij} (t_{ij}^n - t_{ij}) \right] \\ \min E = \sum_{(i,j) \in L^m} \left[e_{ij}^n - \varpi_{ij} (t_{ij}^n - t_{ij}) + e_{ij}^s \right] \end{array} \right. \quad (8)$$

In Eq. (8), β_{ij} denotes the marginal coefficient of project quality. λ_{ij} represents the influence coefficient of the process on the overall QOP. By solving the MOF optimization model of the project, the duration of the project can be reduced as much as possible within the standard requirements. This can result in

lower cost, higher quality and less pollution to the environment. In real-world projects, pollution is assessed in four dimensions: actual pollution levels, pollution levels during the design period, the rate of change in pollution levels, and projected pollution levels for the design period. The actual level of pollution is measured by on-site monitoring of pollutant concentrations, including particulate matter, noise levels, and water quality. Pollution during the design phase is assessed using environmental impact assessment reports or predictive models that identify potential sources of pollution at various stages of construction. Statistical models using historical data from similar projects help predict pollution levels. The rate of change in pollution is quantified by analyzing time series data, comparing pre- and post-construction levels of pollutants, and calculating annual rates of change. During the design phase, pollution can be managed through established environmental goals and regulations, with ongoing monitoring to assess actual emissions against allowable standards.

B. Project MOO Model Solution Based on NSGA-IIA

The NSGA-IIA is a type of genetic algorithm, which simulates the optimization method of biogenetic mechanism in nature, and is used to solve the MOF optimization model. Therefore, the research utilization will use this algorithm to solve the MOF model of the process project. Fig. 4 illustrates the algorithm's flow.

In Fig. 4, the first step of the NSGA-IIA is to generate an initialization population. The initialization population consists of a set of individuals. Each individual represents a feasible solution to the model. A non-dominant sorting is performed on

these individuals, and then crossover and mutation are used to generate a new generation of a sub-population. This sub-population represents a subset of the solution space. The second step is to merge these two populations, the current population and the newly generated subpopulation, to form a new population. Non-dominated sorting (NDS) of the merged population identifies multiple Pareto fronts. The purpose of NDS is to classify individuals into different ranks based on their dominance relationships. Individuals known as the first rank are optimal because no other individual dominates them. Individuals in the second rank are dominated by individuals in the first rank and so on. Diversity among individuals in the same rank is assessed by calculating the CD. For each goal, individuals are ranked according to the value of that goal. The distance between individuals is calculated and the crowding of the bordering individuals is recorded as infinite. The CD for intermediate people is the total of the differences between two adjacent persons on that target. The right people counts will be chosen to make up the next generation of the population, taking into account the CD and the outcomes of NDS [18-19]. Loop the above steps and stop running the algorithm when a predetermined number of iterations is reached. It also outputs the final result as the optimal solution of the MOF model. Due to the need for fast NDS and CD calculation, the NSGA-IIA has a high computational complexity and requires a long running time, especially when there are more optimization functions in the objective model [20]. Therefore, as shown in Fig. 5, improving the algorithmic process is required to lower the computational complexity and running time and optimize the MOF of EPs utilizing the NSGA-II method.

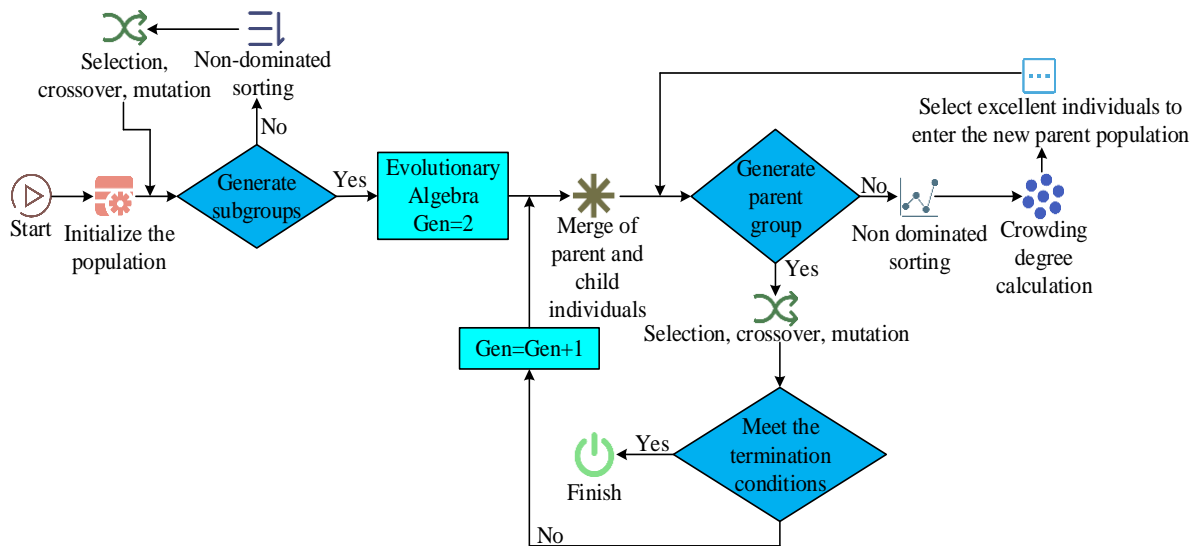

Fig. 4. Schematic diagram of SGA-II algorithm flow.

Fig. 5. Schematic diagram of the improved NSGA-IIA flow.

In Fig. 5, the improved NSGA-IIA is first optimized for fast NDS and CD calculation. The computational complexity of NDS can be reduced by pre-computing the dominance relationship between individuals. A more efficient sorting strategy is used to find the CD quickly. Secondly, NDS is used to rank the new population. Hierarchical management of populations is done through shared fitness. Among them, the value of shared fitness decreases accordingly with the increase of the rank, thus guaranteeing the priority of the lower ranked individuals in the selection process. The third step is to utilize the method of reference points, which are evenly arranged on the standard hyperplane. The individuals in the population are also uniformly divided so as to calculate the number of reference points, as shown in Eq. (9).

$$P = \binom{M + H - 1}{H} \quad (9)$$

In Eq. (9), P denotes the number of reference points. M denotes the dimension. H denotes the number of copies. Then the OF in the optimization model needs to be quantized to facilitate the association of the set reference points, as shown in Eq. (10).

$$f'_i(x) = f_i(x) - Z_i^{\min} \quad (10)$$

In Eq. (10), $f'_i(x)$ denotes the quantized function. $f_i(x)$ denotes the original OF. Z_i^{\min} denotes the MinV of the

function. After the quantization of the function is completed, it is also necessary to find the extreme point of the function, as shown in Eq. (11).

$$ASF(X, W) = \text{MAX}_{i=1:m} (f'_i(x) / W_i) \quad (11)$$

In Eq. (11), $ASF(X, W)$ denotes the ASF function. Based on the extreme points of the function, the corresponding function values can be obtained. The function values of each individual are unified into a plane of the same dimension as the established reference point, as shown in Eq. (12).

$$f_i^n(x) = \frac{f'_i(x)}{a_i} = \frac{f_i(x) - Z_i^{\min}}{a_i} \quad (12)$$

In Eq. (12), a_i represents the distance of each function value to the plane coordinate axis. The position at which each function value is placed is linked to the reference point, and the person represented by the function value with the smallest distance between them is found and linked to the reference point. Finally, the selected individuals are iterated until the optimal solution of the target model is achieved. The core of the improved NSGA-IIA for solving the MOF optimization model of an EP is the cross-variation process of the population individuals, as shown in Fig. 6.

Fig. 6. Schematic diagram of BX crossover operator.

In Fig. 6, the improved NSGA-IIA utilizes the SBX for the simulation of the single-point crossover operator, which ensures that useful information can be obtained from the newly generated populations, as shown in Eq. (13).

$$\begin{cases} x_{1j}(t) = 0.5 * \left[(1 - \gamma_j) x_{2j}(t) + (1 + \gamma_j) x_{1j}(t) \right] \\ x_{2j}(t) = 0.5 * \left[(1 + \gamma_j) x_{2j}(t) + (1 - \gamma_j) x_{1j}(t) \right] \end{cases} \quad (13)$$

In Eq. (13), x_{1j} and x_{2j} denote individuals of the parent population. γ_j denotes the degree of mixing of individual characteristics of the parent population. The formula for the degree of mixing is shown in Eq. (14).

$$\gamma_j = \begin{cases} (2u_j)^{\frac{1}{\eta+1}} & , u_j \leq 0.5 \\ \left[\frac{1}{2(1-u_j)} \right]^{\frac{1}{\eta+1}} & , u_j > 0.5 \end{cases} \quad (14)$$

In Eq. (14), u_j denotes a constant between 0 and 1. η denotes the distribution index. Due to the minimal population variety at the beginning of the algorithm, the search process may settle on locally optimal solutions. It is investigated that the diversity of the population can be enhanced by dynamically increasing the crossover probability and mutation probability. This raises the likelihood that a globally optimal solution will be found by enabling the algorithm to search a larger solution space. As the number of iterations increases, the mutation probability is gradually reduced, which can effectively reduce the occurrence of "catastrophic mutation". Catastrophic variation refers to the fact that in the later stages of the search, a large number of sudden changes may destroy the good solutions that have been found. By controlling the diversity of the algorithm at a later stage, the algorithm is stabilized. This facilitates convergence to high quality potential solutions as shown in Eq. (15).

$$\begin{cases} p'_c = p_c \times \left(1 - \frac{\text{gen}}{\text{max gen}} \right) \\ p'_m = p_c \times \left(1 - \frac{\text{gen}}{\text{max gen}} \right) \end{cases} \quad (15)$$

In Eq. (15), p_c denotes the adaptive crossover probability. gen denotes the current iteration number. max gen the maximum number of iterations. While the MOO model presented in this study focuses on construction projects, it has broader applicability in other fields. For example, in manufacturing, key objectives such as schedule, cost, and quality must be balanced, with production adjustments made according to market demand. Similarly, public infrastructure projects must navigate complex codes and standards while addressing schedule, cost, quality, and environmental concerns. Using this MOO approach, project managers can better manage stakeholder relationships and effectively meet multiple project objectives.

III. ANALYSIS OF NSGA-II AND ITS IMPROVED ALGORITHMS

A. Performance Analysis of NSGA-IIA

To verify the effect of the proposed method, the implementation environment in the study is mainly focused on the actual construction scene of the construction project, including project planning, resource allocation, and construction management. The improved NSGA-II algorithm will be applied to a typical construction project that must meet multiple objectives such as time reduction, cost control, quality assurance, and environmental protection within a limited time and budget. By monitoring and analyzing real-time data from all phases of the project, such as construction progress, resource consumption, and environmental impact, the algorithms will dynamically adjust optimization strategies to cope with unforeseen changes and challenges. Furthermore, the study will address the distinct requirements of various construction projects (e.g., residential, commercial, public facilities, etc.) during the implementation phase. These unique implementation environment factors will subsequently encourage the refinement and optimization of the algorithm, thereby ensuring the efficacy and relevance of the final decision. To verify the success rate and accuracy of MO genetic algorithm in solving item function model, a series of systematic evaluation measures and tools are adopted. In terms of algorithm implementation, based on Python programming language, NumPy and SciPy libraries are used for numerical computation, and the results are visualized with Matplotlib library. To verify the success rate (SR) and accuracy of the MO genetic algorithm in solving the item function model, the study will conduct comparative analysis experiments on two different datasets. The super-parameters of the model are set as follows: The population size is 100, and the larger population size can provide a better diversity of solutions, avoid premature convergence, and help find the global optimal solution. The mutation probability is set to 0.1, which is mainly used to keep moderate changes and prevent the algorithm from falling into the local optimal solution. The crossover probability is set to 0.9, which is mainly used to speed up the convergence rate of solutions, and can effectively produce high-quality descendant solutions in MOO. The number of iterations is set to 500 to ensure that the algorithm converges in the right time and obtains the best solution. The experiment uses the VOT and TrackingNet datasets. The VOT dataset is a benchmark for evaluating various visual target tracking algorithms, while TrackingNet focuses on efficient performance evaluation, providing various scenarios, video sequences, tagging boxes, and metrics for measuring algorithm accuracy and robustness. The validation measures adopted in this study include key performance indicators such as accuracy, success rate, and center position error. Moreover, the effect of the improved algorithm is comprehensively evaluated through comparison and analysis with existing MOO algorithms. The analysis compared the SiamRPN, SiamFC and SiamRPN18++ algorithms. SiamRPN demonstrated high accuracy through its regional proposal network, effectively selecting from multiple candidate regions, strong positioning capabilities, and a MOO process. The SiamFC algorithm processes target features with consistent convolution operations and retrieves them by calculating feature similarity. SiamRPN18++, on the other hand, uses a

deeper network architecture to enhance feature extraction, improving adaptability and accuracy for multiple tracking targets. Firstly, the study conducts overlap rate and center

position error analysis on VOT dataset. The results are shown in Fig. 7.

Fig. 7. Comparison analysis curve of overlap rate and center position (I).

In Fig. 7, the NSGA-II has the optimal overlap rate of 0.75, which is the best. Compared with other algorithms, the average overlap rate increases by 0.156%, which effectively optimizes the efficiency of solving the target features. This lays the foundation for the improvement of the solving performance in the case of multiple objectives. The NSGA-II performs well in the tracking error of the sequence center position with minimal error. Compared with other basic algorithms, NSGA-II algorithm is able to reduce the center position error by 5.84, 30.63, and 43.42 pixel points, respectively. When the number of objective model functions is too many, NSGA-II algorithm

significantly reduces the center position error. The proposed algorithm makes full use of the evaluation mechanism of non-dominant sorting and congestion distance to maintain the diversity of solutions and obtain better solutions in a short time. In target tracking tasks, the algorithm can more accurately capture the location information of the target, thereby improving the positioning accuracy and reducing the error. To better show the performance of NSGA-II, the study conducts comparative experiments on the VOT dataset. The SR and accuracy change graphs are shown in Fig. 8.

Fig. 8. Success rate and accuracy chart on the VOT dataset (I).

Fig. 8(a) represents the accuracy results of different algorithms in the validation of VOT dataset. The results display that the NSGA-IIA proposed in the study has an accuracies of 0.642. Its overall improvement in accuracy over SiamRPN18++, SiamRPN, and SiamFC algorithms is about 1.0%. Fig. 8(b) represents the SR results of different algorithms in the validation of VOT dataset. The findings show that, in comparison to the other three algorithms, the NSGA-IIA suggested in the study has a SR of 0.504, indicating an overall improvement in accuracy of roughly 0.6%. The results indicate that NSGA-II has higher localization accuracy in tracking the target and can capture the actual position of the target more efficiently with less error. In specific scenarios, it can maintain its reliability in a variable environment. Considering the relatively limited size of the VOT dataset, the effectiveness of

the algorithm needs to be examined more comprehensively. The obvious improvement in the results in Fig. 8 shows the effectiveness of the algorithm in dealing with complex multi-target problems, which can better detect and identify target features and reduce the number of false tracks. This enhancement in performance provides a robust technical foundation for dynamic management and decision-making in construction projects, thereby enabling timely responses to unexpected situations and strategic adjustments in a changing construction environment. Therefore, the research conducted further experiments on the TrackingNet dataset to verify the success rate and accuracy of NSGA-II algorithm under different environmental conditions, including the availability and price fluctuations of construction materials, the availability and cost of labor, as shown in Fig. 9.

Fig. 9. Success rate and accuracy graph on the TrackingNet dataset (I).

Fig. 9(a) represents the accuracy results of different algorithms on TrackingNet dataset. The results display that the accuracy of the proposed algorithm has 0.791, which is an overall improvement of about 1.2% compared to the accuracy of SiamRPN18++, SiamRPN, and SiamFC algorithms. In the performance detection under occlusion attribute, the accuracy of the proposed algorithm has 0.542, which is an overall improvement of 0.4% compared to the comparison algorithms. Fig. 9(b) represents the SR results of different algorithms in TrackingNet dataset. The results display that the SR of the proposed algorithm of the study has 0.763, which is a 1.8% improvement compared to the SR of the comparison algorithms.

Similarly, in the performance detection under occlusion attribute, the proposed algorithm has a SR of 0.763, which is an improvement of 3.3% compared to the SR of the comparison algorithm. The results indicate that NSGA-II still exhibits relatively strong robustness in dealing with complex and challenging tracking situations, proving its applicability and reliability in real application scenarios.

B. Performance Analysis of the Improved NSGA-IIA

To verify the overlap rate and center position error of the improved NSGA-IIA, the study will conduct a comparative analysis experiment on the VOT dataset, as shown in Fig. 10.

Fig. 10. Comparison analysis curve of overlap rate and center position (II).

In Fig. 10, the overlap rate of the improved algorithm is optimal. Compared with other algorithms, the average overlap rate of the algorithm is improved by 0.126. This indicates that the improved algorithm can obtain more accurate optimal solutions of the objective model, which improves the accuracy and robustness of the algorithm in solving the MOF optimization model. The improved algorithm is ranked first with the minimum error in the center position of the sequence.

Compared with other algorithms, its average center position error is reduced by 23.450 pixel points. This indicates that the improved method has a smaller center position error and is able to solve the best solution of the MOF model more accurately. The study uses the VOT dataset for a comparative experiment to confirm the enhanced algorithm's tracking performance, as illustrated in Fig. 11.

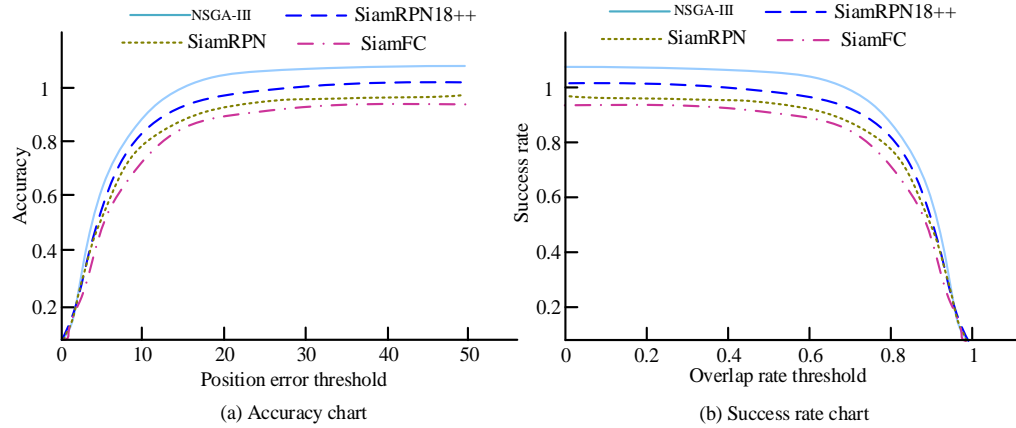

Fig. 11. Success rate and accuracy graph on the VOT dataset (II).

In Fig. 11, the SR and accuracy of the improved algorithm are 0.690 and 0.845, respectively. Compared with other algorithms, the average improvement is 1.5% and 1.2%. This indicates that the algorithm performs optimally among the tested algorithms and fully proves its effectiveness. In the performance test under the occlusion attribute environment, the accuracy and SR of the proposed algorithm are improved compared with the comparison algorithms. Among them, the research algorithm improves about 2.1% in accuracy, and the final accuracy is 0.918. It improves about 2.7% in SR, and the final SR is 0.691. The enhancement in the success rate signifies

the algorithm's capacity to effectively address occlusion and variations in the target, leveraging its adaptive characteristics and dynamic adjustment mechanism to ensure uninterrupted target tracking. In the context of complex construction projects, this advantage enables project managers to make faster and more accurate decisions in a highly dynamic construction environment. Consequently, this improves the overall project management efficiency and effectiveness. Fig. 12 displays the enhanced algorithm's validation findings using the TrackingNet dataset.

Fig. 12. Success rate and accuracy graph on the TrackingNet dataset (II).

In Fig. 12, the overall SR and accuracy of the improved algorithm under the TrackingNet dataset are 0.490 and 0.572, respectively, which are improved by 1.2% and 0.6% on average compared to other algorithms. By improving the algorithm, it shows good performance in the test of the dataset, which verifies the effectiveness of the improvement measures. In the presence of occlusion, the algorithm achieves an SR of 0.454%, which is 4.2% higher on average than other algorithms. It also achieves an accuracy of 0.536%, which is 1.5% higher than

other algorithms on average. This further confirms the effectiveness of the algorithm in performing MOO. The specific construction project is a sub-division project of a comprehensive commercial plaza. The total budget cost of the project is 5 million yuan, and the planned construction period is 120 days. The project management team is challenged to coordinate multiple objectives, including optimizing construction cost, ensuring construction quality, and reducing

environmental impact while meeting the deadline. The results of MOO in construction projects are shown in Table I.

TABLE I. RESULTS OF MULTI-OBJECTIVE OPTIMIZATION IN CONSTRUCTION PROJECTS

Goal	NSGA-II	Improved NSGA-II	Change
Duration (days)	120	110	-10
Total cost (ten thousand yuan)	500	480	-20
Quality Score (0-1)	0.75	0.85	0.1
Environmental impact score (score)	30	25	-5

Table I shows that based on the improved NSGA-II algorithm, the PD is reduced by 10 days from 120 days to 110 days. The TC is reduced from 5 million yuan to 4.8 million yuan, saving 200,000 yuan. The quality score of the project increases by 0.10 from 0.75 to 0.85. The environmental impact score is reduced by five points from 30 to 25. The findings indicate that the model effectively realizes the multiple objectives of reducing the construction period, minimizing costs, enhancing quality, and decreasing environmental impact. It also provides robust algorithmic support and a scientific foundation for the management of construction projects.

IV. RESULTS AND DISCUSSION

This study used the improved NSGA-II algorithm to analyze the MOO model for construction projects, focusing on the effective coordination of PD, cost, quality, and environmental impact. The simulation results showed a reduction in PD from 120 days to 110 days, indicating improved construction efficiency and less time wasted, facilitating earlier project delivery. On the cost front, total spend decreased from 5 million yuan to 4.8 million yuan, highlighting the significant savings achieved through optimized resource allocation while maintaining quality requirements. The quality score improved from 0.75 to 0.85, ensuring better overall project quality while reducing duration and cost. In addition, the environmental impact score decreased from 30 to 25 points, demonstrating algorithm's commitment to sustainable practices. Unlike traditional optimization methods, the improved NSGA-II could manage multiple objectives simultaneously, allowing project managers to adjust the weights of objectives based on situational needs to achieve optimal balance in complex environments. This flexibility was of paramount importance for contemporary construction projects, which frequently encountered rapid changes and unforeseen risks. The enhanced algorithm facilitated real-time updates to objectives and constraints, enabling timely strategy adjustments to ensure project effectiveness. In the same type of research, compared with the research in literature [2], this study used particle swarm optimization algorithm, and the average cost reduction was only 150,000 yuan. The study in reference [3] used a MO WOA, and the quality score was improved by 0.05. The research in literature [4] showed that the algorithm could achieve environmental quality improvement while reducing the score by only about 3 points. Compared with other relevant studies, the results of this study showed that the improved NSGA-II algorithm achieved more significant time reduction, cost saving,

quality improvement, and environmental impact reduction in the MOO of civil engineering projects.

V. CONCLUSION

The research built a MOO model that incorporated the project schedule, cost, quality, and environment in an attempt to address the issue of MO management optimization of construction projects. Moreover, the improved NSGA-IIA was utilized for solving and validation. Through experiments on the VOT and TrackingNet datasets, the NSGA-IIA performed well on the VOT dataset. The accuracy reached 0.642 and the SR was 0.504, which were 1.0% and 0.6% better than the comparison algorithm, respectively. On the TrackingNet dataset, the accuracy was 0.791 and the SR was 0.763. Moreover, the accuracy under occlusion was 0.542 and the SR was 0.763, demonstrating the robustness of the algorithm in complex environments. The improved algorithm exhibited a high accuracy and SR of 0.690 and 0.845 in the VOT dataset, which provided a more reliable solution for selecting the target model. This research contributed to the knowledge system by expanding MOO theory and proposing a model based on the improved NSGA-II algorithm, focusing on the duration, cost, quality, and environmental impact of construction projects. This model enriched the theoretical framework of MOO and offers new insights for researchers in architecture. For the AEC industry, the model enhanced project management efficiency, promotes sustainable development, and informed industry policies and standards. By facilitating better coordination of multiple objectives, the approach emphasizes the importance of balancing economic benefits with environmental protection, ultimately providing sustainable solutions that help organizations achieve their green building goals. However, the research is not without its limitations. The computational efficiency and stability must be improved in the face of extreme dynamic changes and high-dimensional targets. The presence of decision bias, stemming from incomplete or inaccurate data, is a notable concern. Consequently, future research endeavors will prioritize the further optimization of the algorithm's performance, the exploration of more adaptive mechanisms, and the development of parallel computing methods to enhance the prediction and analysis of data.

Abstract—Scene texts refer to arbitrary text found in images captured by cameras in real-world settings. The tasks of text detection and recognition are critical components of computer vision, with applications spanning scene understanding, information retrieval, robotics, and autonomous driving. Despite significant advancements in deep learning methods, achieving accurate text detection and recognition in complex images remains a formidable challenge for robust real-world applications. Several factors contribute to these challenges. First, the diversity of text shapes, fonts, colors, and styles complicates detection efforts. Second, the myriad combinations of characters, often with unstable attributes, make complete detection difficult, especially when background interruptions obscure character strokes and shapes. Finally, effective coordination of multiple sub-tasks in end-to-end learning is essential for success. This research aimed to tackle these challenges by enhancing text discriminative representation. This study focused on two interconnected problems: Scene Text Recognition (STR), which involves recognizing text from scene images, and Scene Text Detection (STD), which entails simultaneously detecting and recognizing multiple texts within those images. This research focuses on implementing and evaluating the Efficient and Accurate Scene Text Detector (EAST) algorithm for text detection and recognition in natural scene images. The study aims to compare the performance of three prominent Optical Character Recognition (OCR) techniques—TesseractOCR, PaddleOCR, and EasyOCR. The EAST model was applied to a series of sample test images, and the results were visually represented with bounding boxes highlighting the detected text regions. The inference times for each image were recorded, highlighting the algorithm's efficiency, with average times of 0.446, 0.439, and 0.440 seconds for the respective test images. These results indicate that the EAST algorithm is accurate and operates in real-time, making it suitable for applications requiring immediate text recognition.

Keywords—Scene text recognition; optical character recognition; deep learning; feature extraction; scene text detection

I. INTRODUCTION

Smartphones' widespread adoption has revolutionized how we capture and share images. With their ease of use and quick accessibility, smartphones have led to an exponential growth in the amount of multimedia data available on the web. From

advertisements and holiday pictures to business cards and newspaper articles, these devices have made digitizing content a common practice. However, this abundance of data has also presented new challenges [1-2].

Natural scenes, characterized by diverse backgrounds, lighting conditions, and complex visual elements, are particularly challenging for computers to analyze and understand. Segmenting and extracting text from these scenes is crucial due to the practical value of embedded textual information. Text extraction enables humans and computers to interpret and utilize this data for various applications, such as document analysis, license plate recognition, and product identification. It enhances automation and efficiency in diverse domains, offering several advantages in real-time scenarios. In autonomous vehicles, efficient text extraction enables the recognition of road signs, enhancing navigation and safety. In retail environments, it aids in product identification and inventory management, streamlining operations, and improving customer service. Text extraction automates scanning and digitization processes in document analysis, increasing productivity and accuracy. Real-time text extraction provides a competitive edge in various industries, such as healthcare, where it can assist in patient data analysis and diagnosis, leading to faster and more accurate decisions. In finance, it enhances fraud detection and document processing, improving security and operational efficiency; digital forensics aids in analyzing textual information from crime scenes, supporting investigations, and collecting evidence [3].

This manuscript explores text detection approaches to address the challenges of mining and retrieving weakly structured content in scene images. By utilizing models like EAST and integrating OCR techniques, the research aims to develop the next generation of search engines capable of accurately identifying and reading text in diverse environments. Overcoming the limitations of current models is crucial for enabling machines to understand and interact with the world, ultimately driving advancements in applications such as autonomous driving, augmented reality, and content retrieval. The segmentation and extraction of text from natural scenes are pivotal for unlocking valuable information embedded in visual content. By enabling real-time text

*Corresponding Author

extraction, businesses, and industries can utilize this data for enhanced decision-making, automation of processes, and improved efficiency across a wide range of applications, underscoring the critical role of text detection and recognition technologies in modern-day scenarios.

The following are the novelties of the research:

1) *Real-time performance evaluation:* The research highlights the EAST algorithm's efficiency, demonstrating low inference times for text recognition, making it suitable for real-time applications.

2) *Integration of multiple OCR techniques:* The study uniquely combines TesseractOCR, PaddleOCR, and EasyOCR with the EAST algorithm, providing a comprehensive comparison of their performance in STD.

3) *Visual validation of results:* Using bounding boxes to represent detected text visually enhances the understanding of the algorithm's accuracy and effectiveness.

The remainder of the paper was structured to provide a comprehensive overview of the research in Section II. Section III presented a detailed description of the proposed scheme, outlining its methodologies and innovations. In Section IV, the authors showcased and analyzed the experimental results, highlighting the performance and effectiveness of their approach. This section engaged in a thoughtful discussion of the findings, considering their implications and potential applications. Finally, Section V offered a conclusion, summarizing the key contributions of the study and suggesting directions for future research in the field.

II. RELATED WORK

In recent years, rapid advancements in deep learning have revolutionized the field of STD. Researchers have proposed a flurry of novel algorithms based on neural networks, each making significant strides in this domain. By utilizing the power of convolutional neural networks (CNNs), these methods have automated learning text features, eliminating the need for manual feature engineering. This breakthrough has propelled STD technology to new heights [4]. Numerous researchers have explored various techniques for detecting text in images, contributing significantly to advancements in this field. Some investigators concentrated on texture-based approaches, utilizing the sliding window concept to identify and analyze unique textural features within input images. This method effectively localizes text information by examining patterns that distinguish text from the surrounding background. Other researchers focused on sparse-based text detection methods, which have proven beneficial for various computer vision applications. These techniques leverage sparse representations to enhance text detection, particularly in challenging environments where traditional methods may struggle. By employing these innovative approaches, researchers aimed to improve the accuracy and reliability of text detection systems, paving the way for more robust applications in real-world scenarios [5].

Fig. 1. Pipeline of text detection and extraction.

The pipeline, as illustrated in Fig. 1, consists of six key steps: (1) Input Natural Scene Image, (2) Image pre-processing, (3) Text Detection Algorithm (EAST), (4) Bounding Box Annotations, (5) Text Recognition OCR Algorithm, and (6) Output Recognized Text. By applying this comprehensive approach, the research aims to achieve accurate and efficient text detection and recognition in real-world scenarios, contributing to advancing intelligent systems capable of understanding and interacting with textual information in diverse environments.

Current deep learning-based STD approaches can be broadly categorized into two main groups: regression-based methods and segmentation-based methods. Regression-based techniques typically employ CNNs to directly predict text regions' bounding boxes or coordinates. These models learn to map input images to predefined anchors or text proposals, refined and filtered to obtain the final text detections. One notable example of a regression-based method is TextBoxes, which adapts the Single Shot MultiBox Detector architecture for STD, achieving real-time performance while maintaining high accuracy. On the other hand, segmentation-based methods treat text detection as a pixel-wise classification problem [6]. These algorithms divide the input image into a grid of cells and predict whether each cell contains text. By leveraging the inherent strengths of CNNs in semantic segmentation, segmentation-based approaches can handle text instances of arbitrary shapes and orientations. A prominent example is the EAST, which employs a fully convolutional network (FCN) to generate a score map and geometry of text boxes, enabling text detection in various orientations and scales [7-8]. Both regression-based and segmentation-based methods have their advantages and disadvantages. Regression-based techniques often excel in computational efficiency, making them suitable for real-time applications. However, they may struggle with detecting text instances of complex shapes or orientations. Segmentation-based methods, on the other hand, demonstrate superior performance in handling diverse text geometries but may require more computational resources. Despite the remarkable progress made by deep learning-based STD algorithms, challenges remain. Factors such as complex backgrounds, varying lighting conditions, and text distortions can still hinder the accuracy of these models. Ongoing research efforts aim to address these limitations and further enhance the robustness and applicability of STD systems in real-world scenarios [9].

STD was recognized as a complex and challenging task due to various environmental factors, including illumination, lighting conditions, and the presence of small or curved text. Many existing approaches prioritized model accuracy and efficiency but resulted in heavy-weight models requiring

substantial processing resources. STR emerged as a prominent research area in computer vision, focusing on recognizing text in natural scenes. Researchers noted that attention-based encoder-decoder frameworks struggled with attention drift, which hindered the precise alignment of feature regions with target objects in complex, low-quality images. Additionally, the rise of Transformer models led to increased computational costs due to their larger parameter sizes. X. Luan et al. [10] developed the lightweight STR model to address these issues, incorporating a position-enhancement branch to alleviate attention drift and dynamically fuse position with visual information. Experimental results indicated that lightweight STR achieved a 3% higher average recognition accuracy than baseline models while maintaining a lightweight structure with only seven million parameters. This balance of accuracy, speed, and computational efficiency made lightweight STR suitable for high-demand applications in STR, outperforming existing methods.

Researchers in [11-12] developed a novel lightweight model to enhance the accuracy and efficiency of STD. This model utilized ResNet50 and MobileNetV2 as backbones, incorporating quantization techniques to reduce size. During quantization, the precision was adjusted from float32 to float16 and int8, resulting in a more lightweight model. The proposed method significantly outperformed state-of-the-art techniques, improving inference time and Floating-Point Operations Per Second (FLOPS) by approximately 30 to 100 times. The researchers used well-known datasets, ICDAR2015 and ICDAR2019, to validate the model's performance, and they included samples in ten different languages. The model demonstrated a balance of accuracy and efficiency, achieving word % accuracy rates of 62% for complex text and 80% for non-complex text and character accuracy rates of 68% and 88%, respectively. R. Harizi et al. [13] study introduced a hybrid scene text detector that combined selective search with SIFT-based key point density analysis and a deep learning training architecture. The researchers investigated key SIFT points to identify crucial image areas for precise word localization. They then fine-tuned these regions using a deep learning-powered bounding box regressor, which ensured accurate word boundary alignment and enhanced detection efficiency. The study focused on detecting text in real-world scene images. They proposed a method that integrated SIFT-based key point localization, Bag of Words-based character pattern filtering, and ResNet-19-based word bounding box regression. Experimental results confirmed the method's effectiveness in addressing multi-oriented and curved scene texts.

In their paper, G. Liao et al. [14] significantly contributed to STD. They designed a Multi-Pooling Module (MPM) with different pooling operations to address the limitations of the original PSENet. The MPM effectively captured the relevance of text information at various distances, enabling precise localization of scene text regions. Y. Cai et al. [15] proposed a style-aware learning network to achieve style-robust text detection in diverse environments. M. Lu et al. [16] addressed the existing model's deficiencies in detecting long text regions by altering the shrinkage calculation, adding a feature enhancement module, and changing the loss function to Focal

loss. S. Yuchen et al. [17] proposed a novel parameterized text shape method based on low-rank approximation, distinguishing their approach from other shape representation methods that relied on data-irrelevant parameterization. They utilized singular value decomposition to reconstruct text shapes using a limited number of eigenvectors derived from labeled text contours.

In a study, M. Aluri et al. [18] developed an innovative method for identifying irregular text in natural scene images. The approach combined a U-net architecture with connected component analysis, significantly improving text component detection accuracy while reducing non-character element identification. Furthermore, the researchers incorporated graph convolution networks to infer adjacency relations among text components, introducing a sophisticated mechanism that advanced text detection in natural scene images. In their novel approach, H. Chen et al. [19] developed the Fragmented Affinity Reasoning Network of Text Instances, a component connection method for arbitrary shape text detection. The network consisted of three key modules: the Weighted Feature Fusion Pyramid Network (WFFPN), Text Fragments Subgraph (TFS), and Dense Graph Attention Network (DGAT), which could be trained end-to-end. The researchers introduced WFFPN to generate text fragments, while TFS and DGAT jointly constructed an affinity reasoning network. Their contributions included proposing a novel unified end-to-end trainable framework, developing a simple and effective WFFPN for multi-scale feature representation and processing, and introducing the joint module of TFS and DGAT to infer the link relationship between text fragments, improving the grouping performance of dense and long curved text.

In their work, Y. Zhu et al. [20] proposed a novel STD method called Text Mountain. The core concept of Text Mountain utilized border-center information differently than previous approaches, which treated center-border as a binary classification problem. Instead, they predicted text center-border probability (TCBP) and text center-direction (TCD). The TCBP resembled a mountain, with the peak representing the text center and the base indicating the text border, allowing for better separation of text instances. This method proved robust against multi-oriented and curved text due to its effective labeling rules. During inference, each pixel at the mountain base searched for a path to the peak, enabling efficient parallel processing. Experiments on various datasets, including MLT and ICDAR2015, demonstrated that Text Mountain achieved superior performance, notably an F-measure of 76.85% on MLT, surpassing previous methods significantly.

Current STD models encounter limitations that impact their effectiveness in real-world applications, mainly when dealing with scene text images and born-digital documents. These categories present unique challenges compared to traditional scanned paper documents. One significant difficulty is the presence of cluttered backgrounds. Existing models often struggle to accurately identify text amidst various visual elements, which can lead to false positives or missed detections. Additionally, traditional models typically use rigid geometrical shapes, like axis-aligned rectangles, making them less effective for detecting free-form text, such as curved or

rotated characters commonly found in natural environments. While some models attempt to manage variations in text size through multi-scale feature maps, this approach can be complex and computationally demanding. The need for elaborate post-processing steps can slow down detection and complicate model architecture. Lighting conditions also play a significant role, as many models perform well under controlled environments but falter in outdoor or dynamically lit situations [21]. Finally, balancing detection accuracy and real-time processing speed remains a critical challenge. Many advanced models sacrifice speed for improved accuracy, rendering them unsuitable for applications that require immediate results. Addressing these limitations is vital for enhancing the robustness and applicability of text detection systems.

III. PROPOSED METHODOLOGY

Text detection involves predicting and localizing text instances within images. While traditional image processing techniques were commonly used for this task, deep learning models consistently outperformed them across various real-world scenarios, from simple to highly complex environments. The localization of text using deep learning could be achieved primarily through two approaches: object detection and image segmentation. Object detection methods focused on identifying

and bounding text regions, providing a straightforward way to localize text. In contrast, image segmentation treated text detection as a pixel-wise classification task, allowing for more precise delineation of text shapes. Each approach had advantages and challenges concerning dataset creation, model training, and inference options. The advancements in deep learning significantly enhanced the effectiveness of text detection in various applications. Object detection techniques localize objects within an image by drawing rectangular or square bounding boxes around them. While effective, this method provides limited information about the actual shape of the detected objects. Fortunately, labeling images for object detection is a relatively straightforward process compared to segmentation. Segmentation, [22] conversely, involves classifying each pixel in an image into predefined categories.

Segmentation would entail distinguishing between text and non-text pixels in scene detection. This pixel-wise classification allows for identifying text regions with greater precision, even if they exhibit complex shapes or orientations. For character recognition tasks, the annotation process becomes even more granular. Each pixel is classified as belonging to one of the available character classes, enabling the precise identification of individual letters or symbols within the detected text regions. This process can be visualized in Fig. 2.

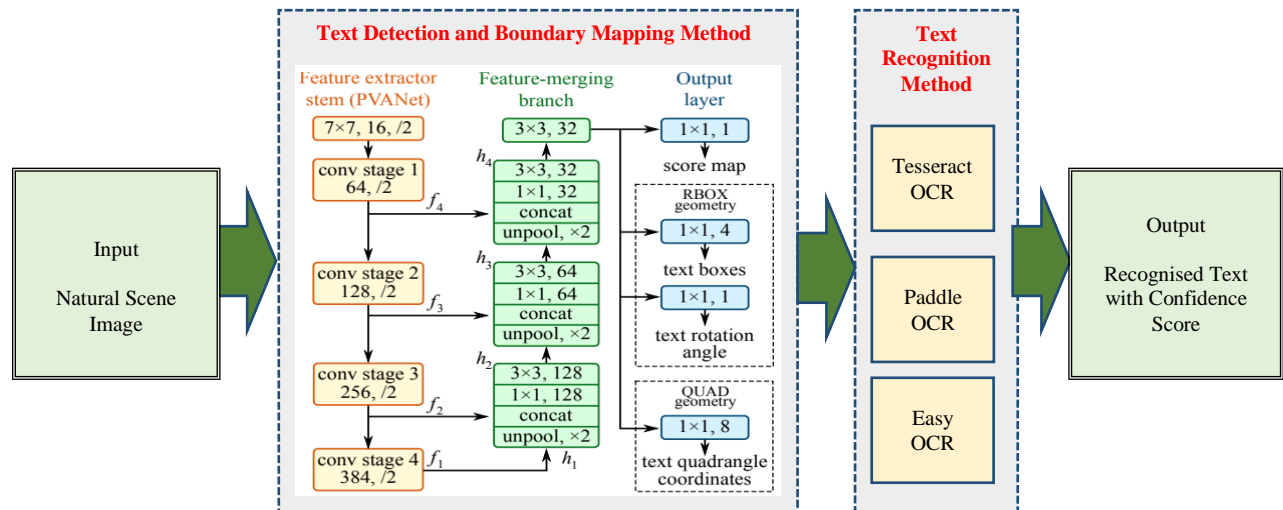

Fig. 2. The structure of the EAST text detection fully convolutional network.

The EAST algorithm was explicitly developed [23] to address the challenges of text detection in natural scenes, where text can appear in diverse sizes, orientations, and perspectives. The EAST architecture was designed to handle text regions of varying sizes efficiently. The key idea was to leverage features from different neural network stages: later stages for detecting large and initial stages for small word regions. The authors employed three interconnected branches within a single neural network. The fundamental principles underlying EAST's functionality include several innovative components. The Feature Extractor Stem was responsible for extracting features from various network layers. This stem could be a convolutional network pre-trained on the ImageNet dataset, such as PVANet, VGG16, and Resnet V1-50—the model, taking outputs from the pooling layers. This network is typically pre-trained on extensive datasets and subsequently

fine-tuned for the specific task of text detection, allowing it to learn the unique characteristics of text in various contexts effectively. The Feature Merging Branch combined the feature outputs from different VGG16 layers and can be expressed in Eq. (1) and Eq. (2).

$$g_i = \begin{cases} \text{unpool}(h_i) & \text{if } i \leq 3 \\ \text{conv}_{3 \times 3}(h_i) & \text{if } i = 4 \end{cases} \quad (1)$$

$$h_i = \begin{cases} f_i & \text{if } i = 1 \\ \text{conv}_{3 \times 3}(\text{conv}_{1 \times 1}[g_{i-1}; f_i]) & \text{otherwise} \end{cases} \quad (2)$$

EAST utilized a U-Net-like architecture to merge the feature maps to avoid computational complexity gradually. The process involved upsampling the $pool_{n-1}$ layer output to match the size of the $pool_n$ layer output, concatenating them, and applying convolutional layers to fuse the information. This

procedure was repeated for the remaining layers, ultimately producing a final feature map layer before the output layer. EAST employs anchors and a Region Proposal Network (RPN) to propose potential text regions. However, it customizes the RPN to predict axis-aligned quadrilaterals instead of traditional rectangles, enabling it to enclose text regions more accurately and tightly. The Output Layer consisted of two key components: a score map and a geometry map. The score map indicated the probability of text in each region, while the geometry map defined the boundaries of the text boxes. EAST offered two options for the geometry map: rotated boxes (specified by top-left coordinate, width, height, and rotation angle) or quadrangles (all four coordinates of a rectangle). EAST predicts the coordinates of the four vertices of each quadrilateral bounding a text region, along with a confidence score that indicates the likelihood of text presence. This capability allows the algorithm to manage text in arbitrary orientations and shapes, enhancing its versatility in real-world applications.

In text detection, bounding box annotations mark the regions in images where text appears. These annotations help train the EAST algorithm to recognize and locate text in various scenes. For instance, each bounding box outlines the area containing text, which the algorithm learns to identify. The process of bounding box annotations for text regions using the EAST algorithm involved several vital steps that aimed to enhance the accuracy of text detection in images. Initially, the EAST algorithm utilized an FCN to analyze input images and generate a score map, indicating the likelihood of text presence across different image areas. The EAST algorithm first predicted the geometry of potential text regions to create bounding box annotations. This was achieved by estimating four parameters for each pixel in the score map: the bounding box's height and width and the center coordinates. The model could effectively capture the spatial characteristics of text instances in various orientations and scales by employing a regression approach. The EAST text detector model generated two key outputs: scores, which represented the probabilities of positive text regions, and geometry, which provided the bounding boxes for these text regions. These outputs served as parameters for the decode prediction's function, which processed the input data. The function returned a tuple containing the bounding box locations of the detected text and their corresponding probabilities. The bounding boxes, referred to as "reacts," were formatted compactly for efficient application of Non-Maximum Suppression (NMS), while the "confidences" represented the confidence values associated with each bounding box. Once the score map and geometry predictions were generated, the next step involved applying NMS to filter out overlapping bounding boxes. This technique helped to eliminate redundant detections, ensuring that only the most confident predictions remained.

The NMS algorithm selected the bounding box with the highest score and removed any boxes with significant overlap based on a predefined threshold. As an FCN, EAST outputs per-pixel predictions of words or text lines and utilizes NMS as a post-processing step on the geometric map. This geometric map can be RBOX (with four channels for bounding box coordinates and one for text rotation) or QUAD (with eight

channels representing shifts from the four corner vertices). EAST employs a weighted sum of losses for both the score map and the geometry, ensuring adequate training. The resulting bounding boxes were then refined to improve their accuracy. This included adjusting the boxes' dimensions to fit better the actual text regions detected in the image. The final output consisted of well-defined bounding boxes that accurately represented the locations of text instances. The EAST algorithm's approach to bounding box annotations combined advanced deep learning techniques with effective post-processing methods, resulting in a robust framework for detecting text regions in natural scenes. This process significantly improved the performance of STD, making it a valuable tool for various applications, such as document analysis and autonomous navigation [24]. By integrating these three branches, the EAST architecture effectively handled text regions of varying sizes and shapes, making it a powerful tool for STD. The author's innovative approach to feature extraction and merging, combined with the informative output layers, contributed to EAST's efficiency and accuracy in detecting text in complex scenes. EAST optimizes its performance by minimizing two key loss functions during training: the classification loss, which determines the presence of text, and the regression loss, which refines the predicted text regions.

The classification loss can be expressed as in Eq. (3).

$$L_{cls} = -\frac{1}{N_{cls}} \sum_{i=1}^{N_{cls}} [g_i \log(p_i) + (1 + g_i) \log(1 + p_i)] \quad (3)$$

Where N_{cls} denotes the number of anchor regions used for classification. The classification loss in EAST measures the model's ability to distinguish text regions from non-text areas. It is calculated using cross-entropy loss, where p_i represents the predicted probability of the i -th region containing text and g_i is the ground truth label (1 for text, 0 for non-text). Minimizing this loss helps the model accurately classify text regions.

The regression loss can be expressed as in the Eq. (4).

$$L_{reg} = \frac{1}{N_{reg}} \sum_{i=1}^{N_{reg}} Smooth_{L1}(d_i - g_i) \quad (4)$$

Here N_{reg} represents the number of anchor regions used for regression and $Smooth_{L1}$ is the smoothing loss function. EAST employs a regression loss to evaluate how accurately the network predicts the quadrilateral coordinates of text regions. It utilizes $Smooth_{L1}$ loss, which compares the predicted geometry parameters. For each region, such as the distances from the anchor point to the four vertices of the quadrilateral, with the ground truth geometry parameters. This loss function ensures the network learns to generate tight, accurate bounding boxes around text areas, enabling precise text detection.

EAST-OCR Fusion Algorithm

Input: Natural Scene Image (I) from ICDAR 2013, ICDAR 2015, COCO-Text

Output: Recognized Text String (T), Confidence Score (C)

Step-I: Pre-processing (Pre-process (I))

i. $I = \text{resize}(I, (224, 224))$

- ii. *Grayscale Conversion:* $I_{gray} = \text{rgb2gray}(I)$
 - iii. *Noise Remove:* $I_{denoised} = \text{median_filter}(I_{gray})$
 - iv. *Normalization:*

$$I_{norm} = \frac{(I_{denoised}(score) - \min(I_{denoised}(score)))}{\max(I_{denoised}(score)) - \min(I_{denoised}(score))}$$
- Step-II: Text Detection ($Text_{Regions} = \text{DetectText}(I_{norm})$)
- i. *Text RegionDetection:* Apply the EAST algorithm to detect text regions in I_{norm}
 - ii. *Bounding Box Extraction:*
 - a. Calculate confidence (D), coordinates (C), and rotation angle (θ) using a 1D vector:
 - 1D vector = $\text{Conv1D}(\text{output})$
 - b. Use Non-Maximum Suppression (NMS) to refine bounding boxes:
 - final bounding box = $\text{NMS}(\text{start}_x, \text{start}_y, \text{end}_x, \text{end}_y)$
- Step-III: Text Segmentation ($\text{Segmentation}(I_{norm}, Text_{Regions})$)
- i. *Check for Detected Regions:*
 - a. If $Text_{Regions}$ is empty:
 - Segment I_{norm} into individual characters using connected component analysis.
 - b. Else
 - Segment each region in $Text_{Regions}$ into individual characters.
 - ii. Apply heuristics filtering to discard non-text regions based on size and aspect ratio.
- Step-IV: Feature Extraction ($\text{Features} = \text{FeatureExtractor}(\text{Character}_{Images})$)
- i. For each character image (c):
 - a. Extract features (f_c):
 - HOG features: $f_c = \text{hogfeature}(c)$
 - Binary Image: $f_c = \text{imbinarize}(c)$
 - b. Return a list of features (Features) for all characters
- Step-V: Text Recognition with OCR Methods ($\text{Text}_{Sequence}, \text{Confidence}_{Score} = \text{OCR}_{recog}(\text{Features})$)
- i. Apply an OCR network with an embedding layer, OCR layers, and a softmax output layer.
 - ii. For each feature vector (f_i) in Features :
 - a. Predict character probability distribution using $p(c|f_i) = \text{softmax}(\text{OCR}(f_i))$
 - b. Decode the predicted character sequence ($\text{Text}_{Sequence}$)
 - iii. Calculate the confidence score (C) where C_{ij} represents the probability of character j being at position i in the sequence.
- Step-VI: Post-processing ($\text{Text}_{Refined} = \text{Postprocess}(\text{Text}_{Sequence})$)
- i. Implement proofreading steps to enhance text quality, including spell-checking
- Step-VII: Output Display ($\text{Display}(\text{Text}_{Refined}, C)$)

The EAST-OCR fusion algorithm for text detection and recognition in natural scene images follows a structured approach. It begins with pre-processing the input image, which includes resizing, grayscale conversion, noise removal, and normalization. Next, the EAST algorithm detects text regions, calculating confidence scores, coordinates, and rotation angles while applying NMS to refine bounding boxes. Text segmentation is performed based on detected regions, followed by feature extraction from individual character images. The extracted features are then processed through an OCR network to recognize the text and compute confidence scores. Finally, post-processing steps enhance text quality, and the results, including the recognized text and confidence scores, are displayed to the user. The algorithm outlines a structured approach, ensuring clarity and comprehensiveness in each step.

TABLE I. DATASET STATISTICS

Parameter	Value
Dataset Names	ICDAR 2013, ICDAR 2015, COCO-Text
Total Images	65,598
Total Bounding Boxes	5,000
Average Bounding Boxes per Image	5
Total Text Instances	1,50,359
Text Instances Categories	machine-printed and handwritten text
Text Instances Language Categories	English script and non-English script
Training Set Size	70%
Validation Set Size	15%
Testing Set Size	15%

The EAST model was primarily trained using ICDAR 2013, ICDAR 2015 and COCO-Text datasets, which provided various text instances for effective learning. This dataset's statistics can be seen in Table I. Additionally, the model utilized the ResNet V1-50 architecture, sourced from Tensor Flow, instead of the alternative PVANet, to enhance feature extraction capabilities. For optimization, we opted for loss, which focuses on maximizing the Intersection over Union (IoU) of segmentation rather than using balanced cross-entropy loss. Furthermore, a linear learning rate decay strategy was implemented instead of a staged learning rate decay approach, allowing for smoother convergence during training. These choices contributed to the model's improved performance in detecting text in natural scenes. The dataset comprised 4,500 unique text instances, offering diverse content that enhances the model's learning experience. The dataset statistics for bounding box annotations used in training the EAST algorithm were meticulously compiled to enhance the model's ability to detect text in natural scenes. The dataset included images with diverse text instances annotated with bounding boxes to indicate the precise locations of text regions.

Despite its complexity and the significant computational resources required for implementation, EAST has proven to be a powerful tool for various applications, including OCR, text recognition, and image information extraction. Ultimately, EAST's ability to accurately and efficiently locate and interpret text within images has established it as a crucial component in

computer vision and OCR. Its contributions have significantly advanced the development of applications capable of understanding and processing textual information in the world around us. Following the implementation of the text detection and boundary mapping method, the next crucial step in this research was the actual detection of text within the images. Three different OCR techniques were employed: TesseractOCR, PaddleOCR, and EasyOCR. Each method was chosen for its unique advantages, allowing for a comprehensive comparison of their performance in text detection tasks. Tesseract OCR is one of the most widely used OCR engines, known for its robustness and flexibility. It supports multiple languages and has a strong community backing, contributing to its continuous improvement. Tesseract excels in recognizing printed text and has been optimized for various applications, making it a reliable choice for this research.

PaddleOCR is another powerful OCR tool that stands out for its multilingual capabilities and high accuracy. It integrates advanced deep learning techniques to handle complex text scenarios, including curved and multi-oriented text. PaddleOCR is particularly beneficial for tasks requiring high precision in text extraction from natural scenes. EasyOCR is a newer entrant in the OCR landscape, gaining popularity for its simplicity and effectiveness. It supports over 80 languages and is designed to be easy to use. EasyOCR uses deep learning models to achieve impressive text detection and recognition results, particularly in challenging environments [25]. By applying these three OCR techniques, the research aimed to evaluate their effectiveness in detecting text across various

scenarios. Each method was assessed based on accuracy, speed, and adaptability to different text orientations and backgrounds. This comparative analysis highlighted the strengths and weaknesses of each OCR tool and provided valuable insights into its suitability for specific text detection tasks. Ultimately, the findings from this research could guide future developments in selecting the most appropriate OCR technology for their needs.

IV. RESULT AND DISCUSSION

After implementing the EAST algorithm on a series of sample test images, the next step was recognizing the text in these images. The results of this process are illustrated in the accompanying Fig. 3: (a1-a3) display the sample testing images. At the same time (b1-b3), the corresponding text detection results are shown, complete with bounding boxes around the detected text regions. The performance of the text recognition was evaluated based on the inference time for each test image, which was recorded as 0.446 seconds for the first image, 0.439 seconds for the second, and 0.440 seconds for the third. These results indicate that the EAST algorithm is highly efficient, demonstrating a low inference time for text recognition across the sample images. This efficiency is particularly noteworthy, as it suggests that the EAST algorithm can effectively detect and recognize text in real-time scenarios, making it suitable for applications where speed is critical. The bounding box in the detection results visually confirms the text recognition's accuracy, showcasing the algorithm's capability to identify text in various contexts.

In this work, a comparison was conducted among three prominent text recognition methods: EasyOCR, Tesseract OCR, and PaddleOCR. Each method was evaluated on sample test images to determine their effectiveness in accurately recognizing text. As shown in Table II and Fig. 5, the results revealed average confidence scores of 0.85 for EasyOCR, 0.89 for Tesseract OCR, and an impressive 0.93 for PaddleOCR. These scores indicate that PaddleOCR outperformed the other two methods, demonstrating its superior capability in text recognition tasks. The higher confidence score suggests that PaddleOCR detected text more accurately and effectively handled various text styles and orientations.

Inference Time (In seconds)

Fig. 4. Comparison between text detection inference times for test images.

While EasyOCR and Tesseract OCR also provided commendable performance, PaddleOCR's results highlight its strengths, particularly in complex scenarios where text may be distorted or presented in challenging conditions.

Average Confidence Score

Fig. 5. Comparison of average confident score between different OCR methods for test images.

This comparison underscores the importance of selecting the right OCR tool for specific applications, especially when accuracy is paramount. Overall, PaddleOCR stands out as a robust choice for text recognition, making it an evaluable asset for future projects requiring reliable OCR capabilities. The proposed method utilizing the EAST algorithm for text detection and recognition offers several advantages over previous approaches. Firstly, it streamlines the process by employing a single neural network that directly predicts text instances and their geometries, eliminating the need for time-consuming intermediate steps such as candidate proposal and word partitioning. This end-to-end approach enhances speed, as shown in Fig. 4, and improves accuracy, allowing for near real-time processing of images. The EAST algorithm is also designed to handle text in various orientations and aspect ratios, addressing a standard limitation in traditional OCR methods that struggle with diverse text layouts. By outputting dense per-pixel predictions, EAST provides more precise text region localization than earlier models. Moreover, while previous OCR techniques may falter with underrepresented languages or complex scripts, the EAST framework's flexibility allows for better adaptation to different text types. Integrating advanced OCR methods like Tesseract or PaddleOCR further enhances recognition accuracy, particularly in challenging scenarios. The proposed method effectively resolves speed, accuracy, and adaptability issues found in earlier approaches, making it a robust solution for efficient text detection and recognition in natural scene images.

V. CONCLUSION AND FUTURE SCOPE

Integrating the EAST algorithm with various OCR techniques has demonstrated promising results in enhancing STD and recognition performance. By applying Tesseract OCR, PaddleOCR, and EasyOCR to the sample test images, this research has highlighted the strengths and limitations of each method. The EAST algorithm has proven to be a highly efficient and accurate tool for text detection, as evidenced by the low inference times recorded during the testing process. With an average inference time of less than half a second per image, the EAST algorithm's real-time capabilities make it suitable for applications that require immediate text recognition, such as autonomous vehicles and augmented reality systems. Moreover, the visual representation of the text detection results, showcased through bounding boxes, confirms the accuracy of the EAST algorithm in identifying text regions within the sample images. The comparative analysis of the

OCR techniques revealed distinct strengths and weaknesses. Tesseract OCR demonstrated robustness in recognizing printed text, while PaddleOCR excelled in handling multilingual text and complex layouts. EasyOCR, known for its user-friendly interface, provided quick results with impressive accuracy. The findings underscore the potential of the EAST algorithm as a reliable tool for STD, particularly in dynamic environments where speed and accuracy are paramount. The visual confirmation of the detection results and the efficient inference times highlight the algorithm's ability to identify text in various contexts effectively. Overall, the EAST algorithm's performance in these tests highlights its potential as a reliable tool for STD and recognition in diverse environments.

The proposed research presents some limitations that future studies could address. Firstly, combining multiple OCR techniques may introduce inconsistencies in performance evaluation and output reliability. Although PaddleOCR is recognized for its multilingual capabilities, it may not sufficiently support underrepresented languages, non-English scripts, symbols, or complex scripts. Additionally, font size, style, and orientation variations can lead to OCR output errors. Moreover, the findings may not generalize well across different domains; performance could vary significantly between document and natural scene images or across diverse geographical locations. Future research could benefit from incorporating advanced methods such as Transformers and Vision Language Models, which may improve the handling of complex text detection scenarios. Exploring the integration of the EAST algorithm with advanced transfer learning techniques could enhance its robustness against challenging backgrounds, varying lighting conditions, and diverse text orientations. Emphasizing multilingual capabilities would allow for a more comprehensive evaluation of text detection across various languages, addressing a critical need in diverse environments. By building on the insights from this study, advancements in text detection and recognition can lead to the development of more intelligent systems capable of effectively interacting with textual information in real-world applications.

Abstract—Integrating artificial intelligence (AI) in education has introduced innovative approaches, particularly in personalized learning and dynamic assessment. Conventional teaching models often struggle to address learners' diverse needs and abilities, underscoring the necessity for AI-driven flexible learning frameworks. This study explores how AI-aided smart learning paths and dynamic assessments enhance learning efficiency by improving knowledge acquisition, optimizing task completion time, and increasing student engagement. A six-week quasi-experimental study was conducted with 200 students, divided into an experimental group using an AI-based learning system and a control group following traditional methods. Pre- and post-tests and engagement analyses were used to evaluate outcomes. The experimental group demonstrated a 25% improvement in performance, completed tasks 25% faster, and showed a 15% increase in engagement compared to the control group. These findings highlight the potential of AI to deliver personalized learning experiences and timely feedback, significantly enhancing student outcomes. Future research should involve larger participant groups across higher educational levels and examine the long-term impact of AI-supported education on students' knowledge retention and skill reinforcement.

Keywords—AI-powered learning; adaptive learning; dynamic assessments; education technology; personalized learning pathways; student engagement

I. INTRODUCTION

Artificial Intelligence (AI) is revolutionizing education in a way because it helps make learning more flexible, customized, and based on data. The conventional, institutionalized approach to learning that has been in practice for many years across many countries has been found unsuitable to handle the needs and interests of the students [1]. This gap has, therefore, created a new interest in using AI to develop an environment where a learning path is developed to suit personal learning rates, personal preferences, and learning abilities of learners. Furthermore, AI brings dynamic assessments into the picture; here, evaluating and even giving feedback are done in real-time, hence no stagnated learning process [2]. AI is being incorporated into various educational systems throughout the globe as an educational tool in areas such as intelligent tutoring systems, AI analytic and adaptive learning systems [3]. AI has been very useful in determining the special needs of individual students through the processing of large volumes of data

concerning the student's performance, attendance, and behavior, among others [4]. Solutions like auto-grading, virtual tutors, and learning analytics are assisting educators in knowing the students' achievements; therefore, they get to devise more effective methods of teaching [5]. That is why, by providing solutions for automating many administrative processes, such as grading work and tracking student attendance or performance, AI relieves educators from many concerns so they can dedicate more attention to the students, making the learning process as individual as possible.

It can also be claimed that such learning environments can be personalized and favorably optimized in real-time, depending on the needs of a student. For instance, if a student is doing poorly in each concept, then the system can change the level of difficulty, suggest materials and resources, or even ask questions that the student has to answer so that he gets it. Adaptive learning environments assist in reaching the maximum level of students' capabilities by adapting the learning process according to their specific needs and preferences, making the learning process productive and efficient [6]. It is, therefore, expected that the integration of AI can transform how education is provided and received, altering the learning methods for students in various settings. Individualization of education is the approach to delivering instructions to cater to each learner's needs, strengths, and preferred mode of learning. When AI is integrated into the learning system, it becomes easier to contemplate personalized learning because intelligent systems can explain performance data to formulate learning pathways that the student will appreciate and, at the same time, are on par with their abilities and learning curve. These systems permanently gather and analyze information about students' relationships with learning materials so they can advise on changes to the teaching methods preferred by each student [7]. Personalized learning is a concept that departs from the very rigid structure of a traditional learning system where the students are expected to work in groups or sets and are given grouping learning curves that tailor the learning needs of each person. Dynamic assessments supplement differentiated instruction by providing an assessment of student learning in a more frequent, real-time manner. Traditional forms of assessment can be static, timed, and administered at set points in time and, therefore, do not give a complete picture of the learning process of a learner [8]. In contrast, dynamic assessments, on the other hand, make use of AI, which assesses to be dynamic depending on the

The research leading to these results has received funding from the Arab Open University under the Internal Funding Program with ID AOU_OM/2023/FCS7.

performance of the student; the student is provided with feedback immediately and is given directions to further improvement or assistance where necessary [9]. This is very beneficial when determining a student progress since it presents teachers with guideline on aspects that requires special attention. Consequently, there is a benefit of dynamic assessments in that they can encourage a developmental view of assessment as a continuous process rather than a one-time event. This study is guided by the following research question: "How can AI-powered learning pathways, integrating personalized learning and dynamic assessments, enhance student engagement, motivation, and mastery across diverse educational contexts?" This question addresses a critical challenge in contemporary education by exploring the transformative potential of AI in tailoring learning experiences to individual needs. The study aims to contribute meaningful insights into the design and implementation of adaptive educational frameworks, offering a pathway to more effective and inclusive learning environments.

When it comes to components and interactions in making use of AI to support effective learning and related features, there are certain components and behaviors, as depicted in Fig. 1. Real-time feedback, individual student analysis, continuous assessment, content delivery, and learning adaptations are facilitated by the central mechanism of AI.

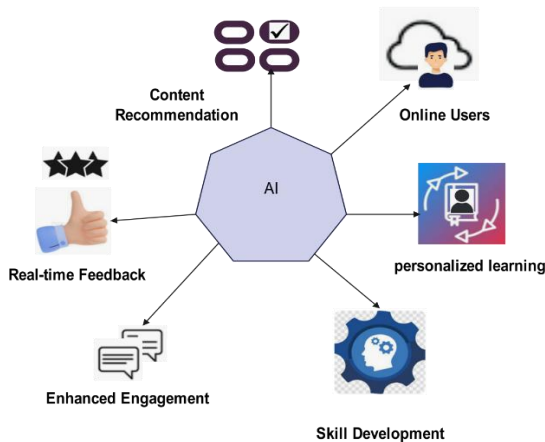

Fig. 1. AI-powered learning pathway components.

This paper aims to explore how AI can be effectively leveraged to create personalized learning pathways and dynamic assessment systems that respond to individual student needs. The research focuses on three primary objectives: first, to create an AI learning map that proposes models for formative and summative ‘dynamic assessments’ of learning pathways that will change depending on students’ performance; second, to offer a scoped real-world application of both formative and summative dynamic assessments within learning environments where timely feedback improves student learning outcomes; and, third, how AI is applied in practice in education, and to discuss the issues and potential solutions about scale-up of dynamic.

The key contribution of this paper is a closer inspection of how AI leverages the flipped classroom model to provide more contextualized and student-centric learning that is dynamic.

Besides, the paper offers an idea of how dynamic assessment models can be implemented practically and gives recommendations for educators and institutions willing to use AI-based learning systems. This study helps to fill the gaps in demand for learning environments that are learner-centered and are enhanced by the advent of technologies such as AI to develop an understanding for future studies under the proposed framework of AI in learning and assessments. The rest of the paper is organized as follows: The Literature Review in Section II explores existing work in personalized learning and dynamic evaluations, highlighting gaps addressed by this research. The Methodology in Section III details the data collection, AI model development, system implementation, and evaluation procedures. The Results and Discussion in Section IV presents the findings of the quasi-experimental study, comparing AI-based and traditional learning methods, followed by an analysis of their implications. Finally, the Conclusion in Section V summarizes the key contributions, discusses limitations, and suggests directions for future research.

II. RELATED WORK

Making use of AI in the education context has brought possibilities of reapportioning the traditional learning paradigms and processes. This section presents a discussion of the current state of the approach to learning personalization and the application of AI in general in learning environments. It highlights why the focus on dynamic educational paths built with the help of AI is relevant to the research.

A. Current Approaches to Personalized Learning

With the help of AI, the concept of learning has become Personalized learning, which is different from conventional teaching-learning processes [10]. One of the approaches is adaptive learning whereby the AI of the systems modifies the content of the lessons according to the results of the learners. This method widely adapts to the learner’s needs and delivers learning material at the learner’s acceptable speed, level of difficulty, and method. From interactions with the students like quizzes and learning activities, the next steps are recommended by an algorithm for the student [11]. Another approach includes the ITS, which acts as if tutoring one trainee [12]. These systems locate areas where a student may lack knowledge and provide their feedback together with self-practice. Students’ progress at ITS can be followed, and recommendations for interventions can be made, making the learning process individualized without the teacher’s interference. Another application of big data is in the early identification of students’ potential for improvement or worsening results in the light of existing data. This means that if a student develops some form of challenge, they are easily identified to receive early intervention [13]. However, there are still issues that stakeholders encounter while trying to apply personalized learning strategies on a large scale. This means that some considerations, like poor access to technology in low-performing schools and matters of privacy, limit its use in schools.

B. AI Applications in Education

In education, AI is not only used for learning but for all the processes that appear in the concept. For instance, automated grading systems have received consideration anew due to their

efficiency in evaluating student submissions, especially in formats common to standardized testing within a short time [14]. These systems employ the use of AI to grade answers so that the educators will not spend much time on this activity while at the same time, the students get useful feedback from the system. Even more current progress allows even AI to evaluate other tasks as writing an essay using natural language processors (NLP) [15]. It is also playing a role in developing a virtual learning environment. Automated intelligent chatbots are now being adopted for round-the-clock student support and to help learners navigate and understand the course content and respond to basic queries [16]. These bots also contribute positively to the educational process since students can get help from the bot without the need to involve a teacher. In the same manner, AI-based tools in analytics are useful in monitoring the progression of learning of the students as well as observing behaviors that may require further attention in learning [4]. Further, it is creating efficiencies in administration, as well as enrolling, scheduling, and resource management tasks. This, in turn, minimizes some of the administrative costs within institutions and enables institutions to devote adequate time to enhancing the quality of teaching and learning. It is only to be assumed that in the future, we will have even more advanced systems, individual tutoring-based virtual avatars, as well as a symbiotic relationship between AI and augmented reality technologies like virtual reality.

C. *Dynamic Assessment Models*

Dynamic assessment is a relatively new concept within the education sector that possesses a dynamic assessment model as against the more static assessment models such as examinations and quizzes [17]. Alphabets implementation makes it possible to achieve dynamic assessments since changes are made virtually, without affecting student performance in any way. Such models are supposed to indicate not only the knowledge of a student at a certain point in time but also their learning processes and developing knowledge incrementally. Dynamic assessments have been proven to be very effective since they give chances of quick feedback hence informing both learners and trainers on their strong areas and areas that require more focus. Unlike the static form of assessment that examines the extent of the student's knowledge at a certain point in time, an assessment of this type has a dynamic characteristic and can change when the student is being asked a question [18]. For example, if the student answers a question correctly the next may be more difficult. If a student exerts effort and accurately solves a problem, then the next one may be more difficult to solve, if a student is unable to solve a problem, then the system provides easy problems or additional materials to learn from. It can be done in real-time so that if the student gets stuck, it is easy to identify areas that the student needs to learn and adapt the content according to the student's requirements [19]. In addition, dynamic assessments may use formative components, which provide information regarding learning progress, rather than being used solely for the evaluation of the results of learning at the end of a course. This form of assessment helps the students come out of mistakes and also helps to tackle problems with more determination. AI predicts likely future learning difficulties, thus enabling the planner to put in measures long before big learning gaps surface [20]. These formative assessments offer a continual flow of information

about each student learner's development which makes it easier for a teacher to develop learning plans. An example of dynamic evaluation is the ITS, where testing is dynamic in that it adapts to the student's performance [21]. These assessments are not just score-based but also point to how well a student understands concepts of specific areas. This is especially helpful in understanding areas where there are learning hurdles and can be addressed early enough with the view of enhancing students' performance in the long run [22]. The study in [23] explored the use of advanced time-series models like RNN, LSTM, and GRU to predict student performance and dropout rates. It highlights the superiority of these models over traditional methods and emphasizes the importance of architecture and hyperparameter tuning for accurate predictions and effective interventions in platforms like MOOCs.

In study [24], the authors developed a machine learning-based system, with Random Forest identified as the most effective model for predicting student outcomes (graduate, dropout, or enrolled). By analyzing demographic, socioeconomic, and academic data, the system provides personalized learning strategies, demonstrating its potential to reduce dropout rates and improve academic success through data-driven interventions.

Dynamic assessments are particularly helpful in those learning situations where learners get the attention required to make change. Due to such an approach used in the assessment process, the students are not only evaluated but assisted in enhancing the right learning processes. However, the practical application of dynamic assessment models entails major systems' support, protection of data acquired and shared, and professional development to understand the implications of the assessments provided by these systems. A comparative analysis of existing studies reveals both advancements and limitations in the application of AI for personalized learning and dynamic assessments. While many studies have explored adaptive learning platforms that tailor content to individual preferences, these often lack integration with systems that provide continuous, real-time feedback based on a student's evolving performance. Conversely, some research has focused on dynamic assessment techniques but does not combine them with broader personalized learning frameworks. This study bridges these gaps by integrating AI-powered personalized learning pathways with real-time adaptive assessments into a unified system. This approach ensures not only individualized content delivery but also continuous evaluation and timely interventions, offering a more comprehensive and effective learning experience compared to existing methodologies.

III. PROPOSED APPROACH

In this section, an AI-driven intervention approach is proposed that would entail the differentiation of learning contracts for each learner based on their performance, choices, and past performance. This approach involves the use of AI in designing the flow, content, and modality of teaching, learning, and assessment so that any student's learning requirements are fully met. To achieve that, our model uses effective data collection, feedback, and adaptive learning approaches to provide students with the best learning experience. The general aim of this approach is to maximize the level of participation of

students and the efficiency of the learning process by designing paths that develop the actions and advancements of the learner.

A. AI-Powered Personalized Learning Pathways

AI-enabled learning pathways are expected to assist in delivering an education experience to learners that is tailored to their needs. These pathways aim at addressing different factors that may be hinging on the student such as the level of learning, how the student grasps this kind of information, the rates of learning, and the kind of learning that the student prefers. The basis of this strategy belongs to AI methodologies that interactively collect and process information on learners' engagement with learning materials. Concerning progress and areas of successful learning or learning challenges, the system adapts learning and the experience of each student.

1) *Data collection and analysis:* The system gathers information from multiple sources, such as students' engagement with multimedia solutions and tutorials, quiz scores, student engagement in activities, etc. So, the data collected regarding the students is analyzed with the help of Machine learning models to find patterns in their behavior and performance. The system then utilizes these to consider, in which segment of the curriculum the student needs more help and which part has been easily understood.

2) *Adaptive learning content:* According to the findings, the AI system offers consumable learning material that is within the student's grasp. For instance, if a student is performing well in a particular topic, the system may introduce the student to the hardest content in the topic in question; to the student who is poor in the topic in question, the system will provide simple content on the topic in question. Thus, using this adaptive approach, the students are kept alert by presenting them with tasks that are not overly complex, which enhances an optimal rate of learning.

3) *Real-time feedback and adjustments:* The personalized learning pathway is adjusted in real time depending on the student's activity while in the learning process. For example, suppose a student performs poorly in some specific subject area. In that case, the system may present them with more examples or a more detailed explanation of the concept being discussed. On the other hand, if the student can perform well, then the pathway can either engage material at a faster pace or even omit concepts that the student has already mastered.

4) *Dynamic assessment integration:* The system also incorporates dynamic assessments where it regularly gives feedback on students' performance. These assessments are not constant in their level of difficulty and are thus more specific in their approach to identifying a learner's learning requirements. Thus, evaluating the student's knowledge determines the areas that need to be filled and the path that should be followed.

5) *Customization based on learning preferences:* The system used incorporated AI to consider features of personal learning styles, for instance, whether a given student learns best with visual displays, articles, or exercises. In this way, by adjusting student's access to information and material, the system increases interest and saves useful information for

further use. For instance, action-oriented learners could be given more video lectures and illustrative diagrams, while others may get textual descriptions or other forms of simulation.

Fig. 2 shows the learning pathway model with references to AI. It captures information from the student's activities and, through the application of machine learning, performs analysis of the results. Following the assessments outlined, the pathway dynamically responds and delivers personalized content in addition to ongoing dynamic assessments. Archer's set-up of learning pathways and real-time feedback guarantees that the learning process is re-adjusted to increase efficiency.

This factor enhances users' interest because it involves learning that targets personal abilities and difficulties. Such an approach means that students do not get bored with content and, at the same time, do not face the overwhelming of complex information.

This approach can be of immense benefit when used in big classes, whereby it may be difficult for the instructors to attend to every single student in the class. AI systems with learning pathways provide every student with a method of learning that is unique to every student, the goal of which is also to reach the goal that has been set for learning and give the students incentives to learn more while doing it in a shorter amount of time.

This proposed approach offers a one-stop solution to improving a personalized approach to learning at large by using techniques such as adaptive learning, data analysis as well as continuous assessment.

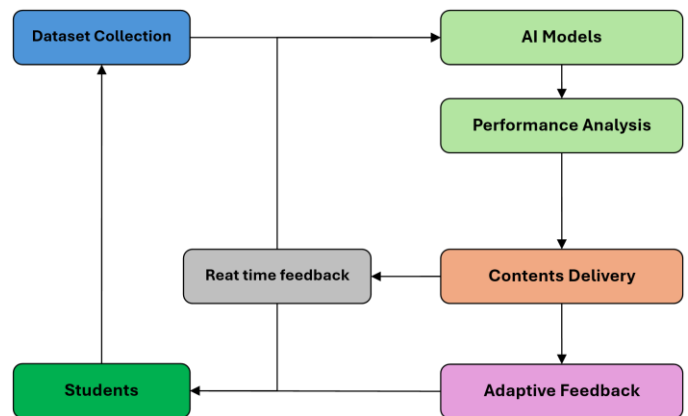

Fig. 2. AI-powered personalized learning pathway framework.

B. Dynamic Assessment Integration

In the proposed AI-based personalized learning pathway, the inclusion of dynamic assessment is envisaged to play a central role. Unlike typical assessment practices, which are pre-ordained and sequential, dynamic assessments are contingent and, occur in real-time and change depending on the student's performance. This approach makes it possible for the system to use AI algorithms to constantly assess the performance of a student and, therefore, improve the flexibility of the system in offering lessons to the students. Here, it is going to be described how dynamic assessment incorporates mathematics and how it fits into data-driven learning approaches.

Let's define the student's knowledge state as a vector $K(t)$ at any time t , where $K(t)$ is defined in Eq. (1).

$$K(t) = [k_1(t), k_2(t), \dots, k_n(t)] \quad (1)$$

Here, $k_i(t)$ represents the student's proficiency in the i^{th} topic or concept at time t , and n is the total number of topics in the learning pathway.

Dynamic assessments continuously update $K(t)$ based on the student's responses to questions, interaction with learning materials, and performance on exercises. The change in the knowledge state over time can be modeled as a differential equation, as shown in Eq. (2).

$$\frac{dK(t)}{dt} = \alpha A(t) - \beta L(t) \quad (2)$$

where $A(t)$ is the assessment score at time t , $L(t)$ represents the learning difficulty or cognitive load at a time t , α and β are weighting factors that balance the effect of assessments and cognitive load on knowledge acquisition.

The assessment score $A(t)$ is calculated based on the student's performance in a series of adaptive questions or tasks. Each question Q_i is associated with a difficulty level D_i and is chosen based on the current knowledge state $K(t)$. The score $A(t)$ is determined by Eq. (3).

$$A(t) = \sum_{i=1}^m w_i \cdot R_i(t) \quad (3)$$

where m is the number of questions in the assessment, w_i is the weight assigned to the i^{th} question based on its difficulty level D_i , $R_i(t)$ is the student's response to the i^{th} question, which is 1 for a correct answer and 0 for an incorrect answer.

The system dynamically adjusts the difficulty of subsequent questions based on the student's previous responses. If a student answers a question correctly, the system may increase the difficulty of the next question, while incorrect answers may result in easier questions being presented. Mathematically, the difficulty level of the next question D_{i+1} is updated as is Eq. (4).

$$D_{i+1} = D_i + \gamma(R_i(t) - 0.5) \quad (4)$$

where γ is a scaling factor that controls the sensitivity of the difficulty adjustment. A correct answer increases the difficulty of the next question, while an incorrect answer decreases it.

1) *Real-time feedback and adaptation:* As the system continuously monitors the student's performance through dynamic assessments, it updates the personalized learning pathway in real-time. The goal is to maintain the cognitive load within an optimal range to maximize learning efficiency. The cognitive load $L(t)$ is influenced by the difficulty level of the content and the student's current state of knowledge. It can be modeled as in Eq. (5).

$$L(t) = \sum_{i=1}^m \lambda_i \cdot D_i \cdot (1 - k_i(t)) \quad (5)$$

where λ_i is the weight associated with the importance of the i^{th} topic, D_i is the difficulty level of the i^{th} topic, $k_i(t)$ represents the student's proficiency in that topic.

The system aims to adjust the learning path by keeping $L(t)$ within a predefined threshold L_{opt} , which represents the optimal cognitive load for learning. If $L(t) > L_{opt}$, the system reduces the difficulty of subsequent topics or provides additional scaffolding. If $L(t) < L_{opt}$, the system increases the difficulty of keeping the student engaged and challenged.

2) *Optimization of learning pathway:* The integration of dynamic assessment into the learning pathway allows for continuous optimization. The system uses real-time data from assessments to update the knowledge state vector $K(t)$ and adjust the content accordingly. The objective is to minimize the difference between the desired knowledge state $K^*(t)$ and the actual knowledge state $K(t)$ at any given time, which can be formulated in Eq. (6) as a cost function J :

$$J(t) = \|K^*(t) - K(t)\|^2 \quad (6)$$

The learning pathway is optimized by minimizing $J(t)$, ensuring that the student's knowledge state converges toward the desired state over time. AI algorithms, such as reinforcement learning, can be applied to solve this optimization problem by selecting the most effective instructional strategies and assessment questions at each step.

C. Adaptive Algorithms and Feedback Loops

Algorithms are at the heart of AI-based personalized learning models because they have to incorporate flexibility. It means that these algorithms change the content, the rate, and the assessments according to the interactions and performances of the students in real-time. The idea is to deliver individual learning, which means the system should be adjusted to learner needs and in which the learner is challenged but not overwhelmed.

The mechanisms of adaptive algorithms focus on the integration of feedback loops to establish the effectiveness of a responsive learning environment. Student data include performance on the test, the interaction with peers as well as time spent on the task and such data are used to adapt the learning process for the student.

Adaptive algorithms use data collected at the time to determine what should happen shortly in the student's learning process. All these algorithms take into consideration various input variables, such as the performance of the students, the time they take to answer the questions, and even the engagement figures. The system monitors the accomplishments of students and how they were able to do it in the assessments and activities. The time a student takes to answer a question or complete a task can indicate their confidence or difficulty level. Data on how often a student interacts with learning materials helps the system adjust the difficulty and type of content delivered.

Based on these variables, adaptive algorithms continuously modify the content and assessments. The system's core objective is to maintain an optimal learning pace that challenges

students without overwhelming them, ensuring steady progress. Algorithm 1 is for how an adaptive learning system might function with integrated feedback loops:

Algorithm 1. Adaptive Learning with Feedback Loops

Input: Initial knowledge state K_0 , content difficulty D_0 , student response time τ , learning rate α , scaling factor γ , performance threshold ϵ .

Output: Updated learning parameters θ_t , optimized learning pathway.

1. **For** $t = 1$ to T (epochs) **do**
2. Present learning content L_t with difficulty D_t
3. Record student response R_t and response time τ_t
4. Update knowledge state: $K_t \leftarrow \beta_1 \cdot K_{t-1} + (1 - \beta_1)R_t$
5. Update learning objective: $L_t \leftarrow \gamma \cdot \tau_t \cdot (1 - K_t)$
6. Compute bias-corrected knowledge estimate: $\hat{K}_t \leftarrow \frac{K_t}{1 - \beta_1^t}$
7. Compute bias-corrected learning objective: $\hat{L}_t \leftarrow \frac{L_t}{1 - \beta_1^t}$
8. Update learning parameter: $\theta_t \leftarrow \theta_{t-1} - \alpha \cdot \frac{\hat{K}_t}{\sqrt{\hat{L}_t + \epsilon}}$
9. Adjust content difficulty: $D_{t+1} \leftarrow D_t + \gamma \cdot (\hat{K}_t - 0.5)$
10. **End For**

Return θ_t (final optimized learning parameters)

Implementing the AI-powered learning pathways system involved a multi-layered approach to ensure its adaptability, functionality, and scalability. Python was selected as the primary programming language due to its extensive support for machine learning and data processing, with frameworks such as TensorFlow and PyTorch utilized for model development. The backend was built using Flask to enable seamless scalability, while the user interface was designed with React.js to provide an intuitive and engaging experience for educators and students. The raw data, including learning behaviors, preferences, and performance metrics, underwent extensive preprocessing using Pandas and NumPy to ensure consistency, handle missing values, and extract meaningful features. AI models were then trained to analyze this data, employing supervised learning techniques for predicting individual learning needs and reinforcement learning for optimizing dynamic assessments.

The conventional teaching sessions were structured using a standardized curriculum aligned with the study's objectives. Lesson plans were developed to cover the same content as the AI-based system, ensuring parity in learning objectives. Traditional instructional materials, including textbooks, printed handouts, and multimedia presentations, were utilized to deliver the content. Teaching techniques followed a lecture-based format supplemented with interactive classroom discussions and periodic assessments to monitor student progress. These details have been incorporated to enhance the transparency of the methodology and provide a clearer basis for interpreting the comparative results of the study.

The adaptive assessment system integrated natural language processing (NLP) for automated question generation and AI algorithms for real-time performance tracking, dynamically adjusting question difficulty and type based on the student's progress and mastery levels. The overall system architecture was designed with modularity in mind, comprising a data layer

for storage and retrieval, an AI engine for learning and assessment adaptation, and an application layer that hosted user-facing features like dashboards and progress reports. The entire system was deployed on a cloud platform, such as AWS or Google Cloud, to ensure accessibility and scalability, with continuous integration and deployment pipelines established using Jenkins and Docker for smooth updates. Pilot testing was conducted in real classroom settings to evaluate the system's performance, with feedback from users incorporated to refine its features and enhance usability.

D. Measuring Engagement Levels

To effectively evaluate the impact of the AI-powered learning pathways system, a robust framework for measuring student engagement levels is essential. Engagement is assessed through a combination of quantitative and qualitative metrics, ensuring a comprehensive understanding of how students interact with the platform and learning materials. Student interaction with the platform is monitored through log data, capturing behaviors such as the frequency of logins, time spent on individual activities, and the number of interactions with learning resources. These metrics provide insights into active participation and overall engagement with the system. The system tracks response times for quizzes and assessments, as well as the rate at which students complete assigned tasks. Quick response times and high completion rates indicate consistent engagement, while delays or unfinished tasks may signal a need for intervention. Engagement is also inferred from behavioral patterns, such as the use of optional resources, reattempts at challenging exercises, and participation in collaborative activities like discussion forums or peer reviews. These indicators reflect deeper involvement with the learning content. To complement behavioral data, students are regularly asked to provide self-reported feedback through in-platform surveys. These surveys measure perceived engagement, motivation, and satisfaction with the learning pathways and assessment system. AI algorithms analyze the collected data to identify trends and patterns in engagement. For example, machine learning models assess correlations between engagement metrics (e.g., time spent on tasks) and learning outcomes (e.g., assessment performance). This analysis enables the system to adapt to students' engagement levels by modifying learning content or assessment strategies to maintain interest and motivation.

IV. EXPERIMENTS AND RESULTS

The experiment was conducted to evaluate the effectiveness of AI-powered personalized learning pathways and dynamic assessments. A group of 100 students was divided into two groups: a control group using traditional learning methods and an experimental group using the AI-powered adaptive learning system. The subjects studied similar content in a mathematics course over 6 weeks. The performance was measured through pre-tests, post-tests, and continuous assessments. While the target system adjusted the level of the material according to the state of knowledge of the student, the control group used a set curriculum. Such data as the assessment and the time spent on the task, as well as the engagement, were obtained. The results obtained in the two groups were compared to determine the effects of the adaptive system on learning.

A. Results on Personalized Learning Efficiency

The experiment aimed to compare the efficiency of learning that is based on the use of new technologies, particularly, the AI-based personalized learning pathways. Efficiency was measured using three key metrics: (1) improvement in student performance (knowledge gain), (2) time spent on learning tasks, and (3) engagement levels. These metrics were compared between the experimental group (using the AI-powered personalized learning system) and the control group (using traditional learning methods).

1) *Improvement in student performance (Knowledge gain):* Students' knowledge gain was assessed by comparing their pre-test and post-test scores. The experimental group showed a significant improvement in their performance compared to the control group. On average, the experimental group improved from 55% to 80% in their post-test scores, whereas the control group only increased from 54% to 68%, as shown in Table I.

TABLE I. COMPARISON OF PRE-TEST AND POST-TEST SCORES

Group	Pre-test Average (%)	Post-test Average (%)	Performance Improvement (%)
Control Group	54%	68%	14%
Experimental Group	55%	80%	25%

The higher performance improvement in the experimental group suggests that the adaptive learning system helped students better understand and retain the material by tailoring the learning experience to their individual needs. Fig. 3 compares the pre-test and post-test performance improvement between the control and experimental groups.

2) *Time spent on learning tasks:* One of the major advantages of AI-powered personalized learning pathways is their ability to optimize the time students spend on tasks. By adjusting content difficulty in real-time, students in the experimental group spent 25% less time on tasks compared to the control group, as shown in Table II.

TABLE II. AVERAGE TIME SPENT ON LEARNING TASKS

Group	Average Time per Task (minutes)	Time Reduction (%)
Control Group	40	N/A
Experimental Group	30	25%

This reduction in time demonstrates that the adaptive learning system allows students to focus on areas where they need improvement, resulting in more efficient learning. Fig. 4 illustrates the comparison of the average time spent per task between the control and experimental groups.

3) *Engagement levels:* The AI-powered personalized learning system also resulted in higher engagement levels. The system provided content that was both challenging and suited to the student's learning pace, leading to higher interaction with the platform. The experimental group had, on average, 15% higher engagement than the control group, as shown in Table III.

Fig. 3. Performance improvement across both groups.

Fig. 4. Time efficiency comparison.

TABLE III. ENGAGEMENT METRICS COMPARISON

Group	Average Weekly Sessions	Average Session Duration (minutes)	Engagement Increase (%)
Control Group	3	45	N/A
Experimental Group	4	52	15%

Higher engagement in the experimental group indicates that students were more motivated and focused when using the adaptive system. Fig. 5 compares the weekly session frequency and session duration between the control and experimental groups.

Fig. 5. Engagement levels comparison.

The results across all metrics — knowledge gain, time efficiency, and engagement levels — show that the AI-powered personalized learning pathways significantly enhanced learning efficiency compared to traditional methods. Students in the experimental group demonstrated higher performance improvement, spent less time completing tasks, and were more engaged with the learning content.

The increase in knowledge gain (Table I, Fig. 3) highlights the system’s ability to tailor learning materials to each student’s needs. The decrease in time spent on tasks (Table II, Fig. 4) shows that the adaptive system saves time in guiding students to pay more attention to the problematic material more efficiently. Therefore, the enhancement of the level of engagement (Table III, Fig. 5) supports the notion that the strategy of integrating individual interests kept the students engaged and interested in learning. The consolidation of the given evaluation of personalized learning indicates the possibility of applying AI systems to reform the educational process since the impact of the learning process might be enhanced for each student.

B. Comparison with Traditional Methods

To verify the application of AI intelligent learning pathways of learning, relevant literature that was majorly focused on traditional approaches to learning was compared. The comparison was made based on the number of new facts, the time it took to complete the activities, and the level of engagement of learners. As indicated in.

Table IV, all performances indicate that AI-powered methods have higher performances than traditional methods by large margins. The personalized learning group displayed a 25% performance increase as opposed to the 14% increase that the conventional learning group showed. Maintenance of routine tasks was done 25% faster for those students who employed an AI-powered system. In terms of the engagement rate, the experimental group proved to be 15% more engaged than the control group.

TABLE IV. COMPARISON OF AI-POWERED VS. TRADITIONAL LEARNING METHODS

Metric	AI-Powered Learning	Traditional Learning	Difference
Knowledge Gain	25% improvement	14% improvement	+11%
Time Efficiency	30 minutes/task	40 minutes/task	-25%
Engagement Increase	15%	N/A	+15%

V. CONCLUSION AND FUTURE WORK

The development of AI-powered smart learning paths marks a significant advancement in educational technology, offering a tailored approach to addressing the unique needs of individual learners. This study investigated the potential of improving learning outcomes and academic performance, particularly in distance education, through the use of AI-driven systems that adapt content dynamically based on feedback and assessments. The findings of this research provide compelling evidence in favor of personalized learning systems. Students

utilizing the AI-powered system achieved a post-test average that was 25% higher compared to a 14% improvement observed in those following traditional methods. This result emphasizes the superior efficacy of adaptive learning paths in enhancing academic achievement. Furthermore, the AI-supported system enabled students to complete tasks 25% faster than conventional learning approaches, demonstrating its capacity to streamline the learning process without compromising comprehension. Additionally, student engagement levels increased by 15%, facilitated by the system’s ability to maintain interest through personalized challenges, project-based learning, and dynamic feedback mechanisms.

It is observed that the AI-based learning system significantly improved time efficiency and performance compared to conventional methods, aligning with previous research findings that emphasize the potential of AI in optimizing learning processes [25]. This agreement with prior studies reinforces the reliability of AI-driven educational tools in similar contexts. These findings highlight a novel aspect: the ability of the AI-based system to dynamically adapt to student learning patterns, which has not been extensively addressed in prior literature. This discovery underscores the unique contribution of our research to the field of AI in education. Moreover, while previous research has focused primarily on long-term AI-based interventions, our short-term study demonstrates that measurable impacts can also be observed within a limited timeframe, providing complementary insights into the application of AI in education."

Despite these promising results, several important areas warrant further investigation. Scalability remains a critical consideration, as the implementation of AI-powered systems in larger and more diverse educational settings presents unique challenges. Future studies should explore how such systems can maintain effectiveness and adaptability in substantially broader and more heterogeneous learning environments. Additionally, while this research highlights short-term benefits, the long-term effects of AI-based personalized learning require closer examination. Establishing whether improvements in retention, comprehension, and performance persist over time is essential for validating the sustainability of these systems. While this study demonstrates the quantitative benefits of AI-based learning, future research must incorporate qualitative methods to understand the student experience and engagement with these systems fully. Another pressing issue involves ethical considerations, particularly in relation to data privacy, fairness, and transparency in AI algorithms. There is a pressing need for the development of robust ethical frameworks to guide the responsible deployment of AI technologies in education, ensuring equitable access and trustworthiness. This study underscores the transformative potential of AI in education, demonstrating its ability to deliver personalized, efficient, and engaging learning experiences. By addressing scalability challenges, investigating long-term effects, and developing ethical frameworks, future research can ensure that AI continues to revolutionize education in a way that is both impactful and responsible. The results contribute novel insights to the growing body of knowledge on AI in education, reinforcing its role as a catalyst for positive change while identifying critical areas for further exploration.

Abstract—Anomaly detection in IoT is a hot topic in cybersecurity. Also, there is no doubt that the increased volume of IoT trading technology increases the challenges it faces. This paper explores several machine-learning algorithms for IoT anomaly detection. The algorithms used are Naïve Bayesian (NB), Support Vector Machine (SVM), Decision Tree (DT), XGBoost, Random Forest (RF), and K-nearest Neighbor (K-NN). Besides that, this research uses three techniques for feature reduction (FR). The dataset used in this study is RT-IoT2022, which is considered a new dataset. Feature reduction methods used in this study are Principal Component Analysis (PCA), Particle Swarm Optimization (PSO), and Gray Wolf Optimizer (GWO). Several assessment metrics are applied, such as Precision (P), Recall(R), F-measures, and accuracy. The results demonstrate that most machine learning algorithms perform well in IoT anomaly detection. The best results are shown in SVM with approximately 99.99% accuracy.

Keywords—Machine learning; Internet of Things (IoT); anomaly detection; feature reduction; Naïve Bayesian (NB); Support Vector Machine (SVM); Decision Tree (DT); XGBoost; Random Forest (RF); K-Nearest Neighbor (K-NN)

I. INTRODUCTION

Detecting anomalies on the Internet of Things (IoT) is a major security issue that has been investigated and studied for centuries. The Internet of Things (IoT) involves several devices capable of processing, collecting, storing data, and communicating. The adoption of the IoT brought many innovations to industries, homes, and businesses, and undoubtedly, it has improved the quality of life.

Recently, the Internet of Things (IoT) has experienced quick growth in many specific applications. Also, IoT has become a driving force for the current technology revolution. IoT captures valuable data daily, allowing individuals or users to make critical decisions. There are many applications for IoT, such as healthcare, transportation, agriculture, and others. Also, there is no doubt that IoT devices have some limitations, such as CPU, memory, and low-energy storage. IoT devices comprise several interconnected sensors, actuators, and other devices [1],[2]. A lot of research expected tremendous growth in IoT. For example, cisco predicted an average of 75.3 billion linked devices by 2025 [3], [4].

IoT devices are extremely vulnerable to cyber-security threats targeting integrity and availability, and it is necessary to prevent cyber-security accidents. Thus, a Network Intrusion

Detection System (NIDS) is needed. NIDS can detect any anomaly to protect the IoT network and the device. NIDS has the ability to monitor all traffic across the IoT network and acts as a first defense line. Also, NIDS can identify networks against intruders and suspicious activity. In addition, NIDS can examine and investigate the devices on the network [5], [6], [7].

Anomaly recognition can be divided into three categories based on the function of the training data stated as follows [2], [3], [4].:

Supervised Anomaly Detection: The normal and abnormal training datasets contain labeled cases. Thus, this methodology is about creating a predictive model for the abnormal and normal classes and then comparing both together.

Semi-supervised anomaly detection: The learning here involves only common cases of the class. Thus, anything that cannot be classified as usual is marked as abnormal.

Unsupervised anomaly detection: The training datasets will not be necessary for the methods. Thus, these methods indicate that regular cases are much more common than anomalies in the test data sets. Even if the hypothesis fails, this leads to a high false alarm rate for this practice.

This research proposes a new approach for IoT anomaly detection combined with artificial intelligence (AI) using detection mechanisms. The proposed approach combines three techniques for feature reduction (FR). Principal Component Analysis (PCA), Particle Swarm Optimization (PSO), and Gray Wolf Optimizer (GWO) were implemented for IoT cybersecurity.

Several research papers and surveys related to IoT have been proposed and published. Some of this research discusses security frameworks, privacy issues, security challenges, models, and tools [8], [9], [10], [11]. When Artificial Intelligence (AI) and the IoT combine, anomaly detection becomes more effective and reliable. AI-based anomaly detection can detect a wide range of threats. This paper will focus on machine learning (ML) algorithms and techniques for IoT security; the contribution of this paper can be reviewed in the following points:

- Using several machine learning algorithms for anomaly detection in IoT.

- Using The RT-IoT2022 proprietary dataset taken from a real-time IoT infrastructure.
- Using several up-to-date techniques for feature reduction, such as PSO, GWO, and PCA.

The rest of this paper is organized as follows: Section II will discuss previous studies related to this research. Section III will introduce machine learning algorithms for anomaly detection in an IoT environment. Section IV will discuss feature reduction and the dataset used in this paper. Section V will demonstrate experiments and results. Finally, the paper is concluded in Section VI.

II. RELATED WORK

In this section, the authors will concentrate on some of the most prevailing solutions and demonstrate several research talks about IoT anomaly discovering methods and techniques.

Ayan Chatterjee [12] demonstrates a complete survey of IoT anomaly detection methods and applications. This survey examines 64 articles among publications between 2019 and 2021. The authors explain that they witnessed a shortage of IoT anomaly detection methodologies. Also, the authors present challenges and offer a new perspective where more research is needed. Besides that, the authors show that the publication of IoT detection is still in its early stages. Finally, they present no single best generic algorithm, but several methods are specific to a particular application.

Rafique Saida [13] presents a variety of literature on anomaly detection in IoT using both ML and DL. The authors discuss various challenges in anomaly detection in IoT infrastructure. Also, this research presents an increasing number of attacks. Finally, this work summarizes the most available literature and concludes that further development of the current detection technique is needed.

Maryam Khan [14] presents a machine learning anomaly detection model for cybersecurity using the Canadian Institute for Cybersecurity (CIC) dataset. The dataset presented in this work consists of 33 types of IoT attacks divided into seven categories. Techniques used in this work are Random Forest (RF), Adaptive Boosting (AB), Logistic Regression (LR), and Neural Network (NN). RF performs 99.55% accuracy.

Edwin Omo [15] presents several machine-learning algorithms for anomaly detection. The algorithms used in this work are isolation forest, One-Class SVM, Autoencoders, and Random Forest (RF). The study also examines the performance evaluation, efficiency process, and model selection methods. Besides that, the research sheds light on the main IoT aspects.

Adel Abusitta [16] presents a deep learning-powered anomaly recognition for IoT. The proposed model is designed based on a denoising autoencoder. Also, the denoising autoencoder allows the system to obtain features. Finally, experiments were conducted using the DS2OS traffic dataset.

Bhawana Sharma [17] provides an overview of anomaly detection using both machine learning and deep learning methods. This research addresses the key issues and

challenges related to deep anomaly detection techniques in IoT.

Sahu [18] presents a supervised learning model to predict anomalies. This research uses several machine learning algorithms to predict anomalies on the 350K dataset. Two different approaches are used in this research. Also, classification algorithms were applied to the whole dataset in two different ways. The algorithms used were Logistic Regression (LR), Decision Tree (DT), Random Forest (RF), and Artificial Neural Network (ANN). Finally, accuracy achieved an average of 99.4%.

Muhammad Inuwa [19] presents the comprehensive difficulties and challenges of cybersecurity in the context of IoT. This research uses machine learning (ML) methods to detect cyber anomalies within IoT systems. The algorithms used were Support Vector Machine (SVM), Artificial Neural Network (ANN), Decision Tree (DT), Logistic Regression (LR), and K-Nearest Neighbors (k-NN). Results demonstrate that ANN performs better than other models.

Abebe Diro [20] aim to provide a deep review of available works in anomaly discovery based on machine learning methods for IoT protection. This work indicates that blockchain-based anomaly detection can be effective. The future work of this research is to provide the implementation of a blockchain-based anomaly detection system.

A. Pathak [21] addresses the tampering of IoT security sensors in an office environment. Data is collected from real-life settings, and machine learning is applied to detect sensor tampering. The classification accuracy of the proposed model is 91.62%, with the lowest false positive rate.

Grace Hannah [22] explores several ML algorithms for anomaly discovery. This research explores supervised, unsupervised, and semi-supervised techniques. Also, the authors discuss the challenges and difficulties in implementing these algorithms in an IoT environment. Preprocessing techniques are examined. Besides that, this research demonstrates a case study on anomaly discovery in an IoT-based temperature monitoring system using a Gaussian Mixture Model (GMM). Precision, recall, and F1 score are used for evaluation.

III. MACHINE LEARNING ALGORITHMS FOR IOT ANOMALY DETECTION

Machine Learning (ML) algorithms can be used for different objectives and objectives and can impact every part of our lives. ML algorithms can be employed for pattern recognition, speech recognition, fraud detection, spam detection, phishing, and others. Also, machine learning procedures are used for prediction and classification, such as Decision Tree (DT), Random Forest (RF), Support Vector Machines (SVM), K-Nearest Neighbor (k-NN), Naïve Bayes Theorem (NB), K-Mean Clustering, Artificial Neural Network (ANN), and others. [23] [24], [25], [26], [27], [28], [29], [30].

Machine learning can be used for anomaly detection in IoT environments. The noun anomaly comes from the Greek word anomolia, meaning “irregular” which means that something is unusual if compared to similar things around it [31]. This

paper will introduce several machine learning algorithms in IoT anomaly detection. An anomaly in IoT is a pattern or series of samples in the IoT network that is different from a normal pattern. Also, anomaly detection can be defined as suspicious activity that falls outside normal patterns or behavior. Generally, anomalies can be divided into three categories: global outliers, contextual, and collective outliers [32], [33], [34], [35].

IV. FEATURE REDUCTION AND SELECTION

Feature reduction or dimensionality reduction is the process of reducing the number of features in a dataset. Minimizing the number of features in a dataset is very important since the number of features could be huge. Also, Reducing the number of features could be useful and retaining the most helpful information. Besides that, reducing features means reducing processing time in CPU, memory usage, and other resources [26], [27], [28]. In other words, feature reductions mean assigning a weight to each feature to decide how important they are. On the other hand, Feature selection means selecting the most powerful features in the training phase. In summary, if feature reduction is done properly, this means that selecting a partial subset of features could be enough to represent all features. In this paper, the authors will use the Principal Component Analysis (PCA), Grey Wolf Optimizer (GWO), and Particle Swarm Optimizer (PSO) [28], [29], [30], [33].

A. Principal Component Analysis (PCA)

Principal Component Analysis (PCA) is a feature extraction method and is often used to reduce a higher-dimensional feature space to a lower-dimensional feature space. PCA is a statistical method that is employed to convert a set of possibly correlated variables into linearly unrelated variables known as principal components. The main objective of PCA is to capture the maximum variance available in the dataset with the fewest number of principal components. The transformation is defined mathematically as [25]:

$$\Sigma = \frac{1}{m-1} \sum_{i=1}^m (xi - \mu)(xi - \mu)^T \quad (1)$$

Where:

Σ : Covariance

xi : Data point

μ : Mean Vector

m : Number of data points.

B. Particle Swarm Optimization (PSO)

Particle Swarm Optimization (PSO) is a powerful meta-heuristics optimization algorithm. This algorithm is inspired by natural swarm activities, such as that of fish and birds. PSO can be used to find the optimal values for specific parameters of a given system. In PSO, particles are moved according to a simple formula. Besides that, swarms move through the search space in order to find the optimal value. Every time a better position is found, movement is done. This process is repeated until finding the optimal solution [36], [37], [38], [39], [40].

C. Gray Wolf Optimizer (GWO)

The Gray Wolf Optimizer (GWO) algorithm is a population-based meta-heuristics algorithm that simulates the leadership hierarchy and hunting mechanism of grey wolves in nature Fig. 1 [41] [42].

Hierarchy of grey wolf (dominance decreases from top down)

Fig. 1. Wolves' hierarchy.

Alpha wolves (α) wolf is the dominant, and his orders must be followed. Beta wolves (β) are subordinate wolves, which support alpha in decision-making. Delta wolves (δ) have to submit to alpha and beta. Omega wolves (ω) are the least important individuals in the pack [41], [42], [43], [44].

D. Dataset

The RT-IoT-2022 dataset, this dataset is proprietary and derived from a real-time IoT infrastructure. The RT-IoT-2022 provides comprehensive resources and a diverse range of IoT network machines. This dataset contains both normal and adversarial network behaviors. The RT-IoT-2022 contains 123117 instances and 83 features. Table I summarizes the RT-IoT-2022 dataset [45].

TABLE I. RT-IOT-2022 DATASET

No	Service	No of instances	Patterns
1	MQTT	4146	Normal Patterns
2	Thing_speak	8108	Normal Patterns
3	Wipro_bulb	253	Normal Patterns
	Total	12507	
4	ARP_poisoning	7750	Attacks patterns
5	DDOS_Slowloris	534	Attacks patterns
6	DOS_SYN_Hping	94659	Attacks patterns
7	Metasploit_Brute_Force_SSH	37	Attacks patterns
8	NMAP_FIN_SCAN	28	Attacks patterns
9	NMAP_OS_DETECTION	2000	Attacks patterns
10	NMAP_TCP_scan	1002	Attacks patterns

12	NMAP_XMAS_T+REE_SCAN	2010	Attacks patterns
	Total	110610	

V. EXPERIMENTS AND RESULTS

This section will display the authors' experiments and results. Also, it will display evaluation matrices and important features. This study also uses the Anaconda platform (Python) and MATLAB 2020a. Finally, experiments were done using a Dell Machine, 11th Gen -1165G7 @ 2.80GHz, RAM 32 GB, Windows 11.

A. Experimental Metrics

In machine learning, there are several criteria for evaluation, such as accuracy, precision, recall, F-measure, True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN). This is demonstrated in Table II and Eq. (2) to (8).

TABLE II. MATRIX OF CONFUSION

		Prediction.	
		Normal.	Phishing
Act.	Normal.	x (TP)	y (FN)
	Phishing	z (FP)	w (TN)

$$\text{Accuracy} = \frac{TP+TN}{TP+FP+TN+FN} \quad (2)$$

$$\text{TPR} = x/(x+y) \quad (3)$$

$$\text{FPR} = z/(z+w) \quad (4)$$

$$\text{FNR} = y/(x+y) \quad (5)$$

$$P = TP / (TP + FP) \quad (6)$$

$$R = TP / (TP + FN) \quad (7)$$

$$\text{F-Measure} = 2 * P * R / (P + R) \quad (8)$$

B. Experimental Results

In this section. The authors will demonstrate the results of feature reduction and selection using PCA, PSO, and GWO. PCA is evaluated using 10, 20, 30, 40, 50, 60 and 70 features.

Feature Reduction (FR) is done by using PCA, PSO and GWO. The PSO and GWO algorithms are executed

independently for (10) iterations; then, the number and the name of the features are written. Then, the most important features of each algorithm are determined and picked for the classification stage. The testing part of the dataset represents only 20% of the dataset, meaning only 24624 instances.

Fig. 2 represents the results using Fine Tree without any feature reduction (PCA Disabled) using MATLAB 2020a. The figure demonstrated a good result, but the high number of features required extensive CPU and RAM resources.

The results of the experiments using feature reduction are demonstrated in Tables III-VIII. Most of the algorithm's performance is highly accepted. Also, FR techniques are very helpful since reducing the number of features from 83 to any number will reduce processing time and memory storage.

Fig. 2. Fine tree results (PCA disabled).

The above table shows that feature reduction using NB, (PCA-40) provides the best accuracy and optimal values of TP, TN, and FP compared with other types of feature reduction.

The above table shows that feature reduction using SVM, (PCA-50, PCA-60, and PCA-70) provides the best accuracy and optimal values of TP, TN, and FP compared with other types of feature reduction.

PCA-40	22069	2544	9	2	99.96%	99.99%	99.98%	99.96%
PCA-50	22066	2544	9	5	99.96%	99.98%	99.97%	99.94%
PCA-60	22066	2544	9	5	99.96%	99.98%	99.97%	99.94%
PCA-70	22068	2542	11	3	99.95%	99.99%	99.97%	99.94%
GWO-55	22070	2540	9	5	99.96%	99.98%	99.97%	99.94%
PSO-58	22072	2538	11	3	99.95%	99.99%	99.97%	99.94%

The above table shows that feature reduction using KNN, (PCA-40) provides the best accuracy and optimal values of TP, TN, and FP compared with other types of feature reduction.

As demonstrated in the above tables. The performance of machine learning algorithms with feature reduction techniques is highly acceptable. Having too many processing features makes the ML model complex. There is no doubt that reducing the number of features has a lot of advantages, such as reducing time, improving computational efficiency, and preventing overfitting.

Fig. 3 and Fig. 4 show the accuracy of the machine-learning algorithms used in this paper. The figures demonstrated that the accuracy results are highly acceptable, especially with the number of features selected.

Fig. 4. KNN, RF, and XGBoost algorithms.

Fig. 3. DT, SVM, and NB algorithms.

VI. CONCLUSION AND FUTURE WORKS

The Internet of Things (IoT) or “Smart Objects” refers to physical devices embedded with sensors, software, and network connectivity. IoT devices can be used in smart homes, smart cities, and complex industries. IoT enables smart devices to communicate with each other and with the Internet. In the last decades, IoT devices have faced several threats and difficulties. This paper demonstrates several machine learning algorithms used in anomaly detection in IoT environments. This paper also uses PCA, GWO, and PSO as feature-reduction techniques. Several criteria are used for evaluation, such as precision, recall, F-measure, and accuracy. Most of the algorithms show excellent performance except the Naïve Bayesian. The support vector machines (SVM) show the best results with 99.99 accuracy with PCA-60 and PCA-70.

ACKNOWLEDGMENT

The researchers would like to provide a special thanks to the editor and reviewers for their time in reviewing the manuscript and overall suggestions to improve the manuscript. In addition, they are very grateful to WISE University.

Network Security Based on GCN and Multi-Layer Perception

Wei Yu*, Huitong Liu, Yu Song, Jiaming Wang

Guangzhou Bureau, EHV Power Transmission Company of China, Southern Power Grid, Guangzhou, 510663, China

Abstract—With the continuous progress of network technology, network security has become a critical issue at present. There are already many network security intrusion detection models, but these detection models still have problems such as low detection accuracy and long interception time of intrusion information. To address these drawbacks, this study utilizes graph convolutional network to optimize multi-layer perceptron. An optimization algorithm based on multi-layer perceptron is innovatively proposed to construct an intrusion detection model. Comparative experiments are conducted on the improved algorithm. The accuracy of the algorithm was 0.98, the F1 value was 0.97, and the detection time was 1.1s. The overall performance was much better than comparison algorithms. Subsequently, the intrusion detection model was applied to network security detection. The detection time was 0.1s, the accuracy was 0.98, and the overall performance outperformed other comparison algorithms. The results demonstrate that the intrusion detection method on the basis of optimized multi-layer perceptron can enhance the detection ability of illegal intrusion information. This study optimizes the performance of detecting illegal network intrusion information, providing a theoretical basis for further development of network security. However, the types of intrusion information in this study are limited and there is still uncertainty. In the future, data augmentation techniques can be used to oversample minority class samples, synthesize new minority class samples, expand sample size, increase detection information, and improve the overall detection performance of the model.

Keywords—Network security; graph convolutional network; multi-layer perceptron; intrusion detection model

I. INTRODUCTION

In the current era of rapid digital development, network security is becoming increasingly prominent, which is an important challenge that countries, enterprises, and individuals must face [1]. Affected by the popularity of information technology and the Internet, network attacks are constantly evolving, and the traditional security measures have been difficult to deal with. Therefore, exploring new methods for network security protection is of great significance [2]. Many scholars have conducted research on network intrusion detection models. For example, Fu et al. proposed an intrusion detection model based on attention mechanism to enhance the performance of traditional network firewalls and data encryption methods. Through experimental verification, the model achieved a detection accuracy of 90.73% [3]. In addition, Hnamte et al. designed a network intrusion detection model based on deep neural networks for network attacks. Then, the model was applied to detect in practical situations. The results showed that the model could detect most of the intrusion information in the network [4]. In recent years, Graph

Convolutional Network (GCN) has shown strong feature extraction and relationship learning capabilities in multiple fields. Especially when dealing with non-Euclidean structured data, it has significant advantages [5]. Therefore, multiple scholars have applied it to network security protection. Diao et al. developed a spatiotemporal multi-scale GCN security model to improve the security of network data in vehicle prediction. After using this network security protection model, the security of network data in vehicle prediction was significantly improved [6]. To optimize the intrusion detection performance of labeled IoT networks, Deng et al. developed a GCN on the basis of flow topology. Comparative experiments on this model demonstrated that the intrusion detection accuracy of the GCN based on flow topology for labeled IoT networks was 92.31%, significantly better than other traditional methods [7]. Afterwards, Al-Ibraheemi et al. built an intrusion detection method on the basis of GCN and deep reinforcement learning algorithms to response the insufficient performance of intrusion detection models in software defined networks. The accuracy of this intrusion detection model was enhanced by 15.32% than the traditional intrusion detection model [8].

Meanwhile, Multi-layer Perceptron (MLP), as a classic deep learning model, also performs well in dealing with linearly inseparable problems [9]. Therefore, many scholars have also applied it to network security protection. Specifically, Shewale et al. designed an intrusion detection approach on the basis of MLP and Long Short-Term Memory Network (LSTM) to improve the network security. Comparative experiments showed that the intrusion detection accuracy was 91.83%, significantly better than traditional models [10]. In addition, to address the difficulty of detecting distributed denial of service attacks, Najjar et al. designed a hybrid algorithm based on MLP and random forest. Comparative experiments were conducted on a distributed denial of service attack dataset. It was found that the detection accuracy was 93.85% [11].

The above research indicates that in the field of network security, although some research have attempted to apply advanced technologies such as GCN and MLP, there are still some drawbacks. At present, the research mainly focuses on using machine learning frameworks for network intrusion detection and abnormal behavior recognition, but these methods ignore complex relationships between network data, resulting in limited detection accuracy and efficiency. In addition, existing research lacks sufficient flexibility and adaptability in dealing with constantly changing network threats. Therefore, this study designs a network security protection method on the basis of GCN and MLP. This method aims to combine the powerful relationship learning ability of

GCN with the nonlinear processing ability of MLP to process complex network data. At the same time, the GCN algorithm is used to optimize the initial parameters in MLP, improve its flexibility and generalization ability, reduce the impact of complex data on detection results in previous intrusion detection models, and more effectively identify and defend against network attacks. The innovation of the research lies in the organic combination of GCN and MLP, forming a new network security protection framework. This framework can not only handle complex network relational data, but also adaptively learn and respond to constantly changing network threats. It is expected to provide a new and more effective technological means for network security, contributing to building a more secure and reliable network environment. The contribution of this study is to timely detect abnormal information in the network through the GCN-MLP intrusion detection model, timely identify potential security threats, and reduce the damage caused by network attacks. This model promptly prevents malicious attackers from invading, protects the secure operation of networks or systems, and ensures the integrity and confidentiality of data information in the network. This model ensures that users or processes use system resources according to prescribed permissions, preventing resources from being illegally occupied.

The article is divided into five sections for discussion. Section II mainly covers network security related content and research on MLP and GCN algorithms. Section III construct an network intrusion detection model based on GCN and MLP algorithms. Section IV analyzes the effectiveness of the proposed intrusion detection model. Section V summarizes the entire text.

II. METHODS AND MATERIALS

A. Multi-Layer Perceptron Optimization Integrating Graph Convolutional Network

At present, people are paying more attention to network security issues, and there are also more network information intrusion detection models. However, these models still have problems such as false positives and missed detection [12]. MLP is a deep learning algorithm based on feedforward neural networks, which is composed of multiple neural structures. This

algorithm has strong representation and generalization capabilities, which can process various complex data, reducing the false detection rate of dangerous intrusion detection [13]. Fig. 1 displays the basic structure of the MLP.

From Fig. 1, the perceptron contains input and output layers. The perceptron allocates weights and assigns values to the input vector, then sums up the calculated data, and iteratively updates the weights until the error is reduced to the allowable range. The obtained values are then outputted [14]. MLP introduces a Hidden Layer (HL) based on single-layer neural network, making the neural network have multiple layers. MLP can adjust the number and dimensions of hidden layers, input layers, and output layers as necessary. Each node in the HL is a perceptron, and each perceptron contains some parameters. These nodes in the HL are all fully connected, that is, the previous node output is connected together as the next layer node input. The output result of the HL is shown in Eq. (1).

$$H = XW_h + b_h \quad (1)$$

In Eq. (1), H represents the output result of the HL. X signifies the given sample. W_h represents the weight of the HL. b_h signifies the deviation coefficient of the HL. If it is a single HL, the output of HL is shown in Eq. (2).

$$O = HW_0 + b_0 \quad (2)$$

In Eq. (2), W_0 signifies the weight of the output layer. b_0 represents the deviation coefficient of the output layer. Eq. (1) and (2) are combined to obtain the input of the output layer, as displayed in Eq. (3).

$$O = (XW_h + b_h)W_0 + b_0 = XW_hW_0 + b_hW_0 + b_0 \quad (3)$$

In equation (3), the weight coefficient of the output layer is changed to W_hW_0 . The deviation coefficient is changed to $b_hW_0 + b_0$. The ReLu activation function is introduced to perform nonlinear function transformation on hidden variables, making them the input of the next fully connected layer. The ReLu activation function is displayed in Eq. (4).

$$ReLu(x) = \max(x, 0) \quad (4)$$

Fig. 1. Basic structure of multi-layer perceptron.

In Eq. (4), x signifies the input sample. The output expression of the MLP combined with the activation function is displayed in Eq. (5).

$$\begin{cases} H = R(XW_h + b_h) \\ O = HW_0 + b_0 \end{cases} \quad (5)$$

In Eq. (5), R represents the activation function ReLu. Afterwards, the error information is computed in Eq. (6).

$$E_i = \sum_{i=1}^n \frac{1}{2} (\tilde{y}_i - y_i)^2 \quad (6)$$

In Eq. (6), E_i represents the prediction error of the i -th output unit. \tilde{y}_i signifies the predicted value of the i -th output unit. y_i is the i -th output unit. n signifies the number of neurons in the output layer. The influence of weights on the overall error is shown in Eq. (7).

$$\frac{\partial E}{\partial w_j} = \frac{\partial E}{\partial y_l} \cdot \frac{\partial y_l}{\partial s_{y_l}} \cdot \frac{\partial s_{y_l}}{\partial w_j} \quad (7)$$

In Eq. (7), s_{y_l} signifies the weighted sum of input y_i . w_j signifies the weight of the j -th HL. The weight value is updated, as shown in Eq. (8).

$$w_j^+ = w_j - \eta \frac{\partial E}{\partial w_j} \quad (8)$$

In Eq. (8), η represents the learning rate. The above is the calculation method of MLP, which updates weights to iterate continuously. Finally, the error is reduced to the minimum allowable range. However, the training time is long, the number of calculated parameters is too large, and over-fitting is prone to occur, which can affect the detection accuracy and efficiency. The GCN algorithm has data normalization, small parameter size, and strong extraction ability [15]. Therefore, the GCN is used to optimize the MLP to improve its accuracy and efficiency. The GCN is displayed in Fig. 2.

As shown in Fig. 2, the GCN algorithm contains an input

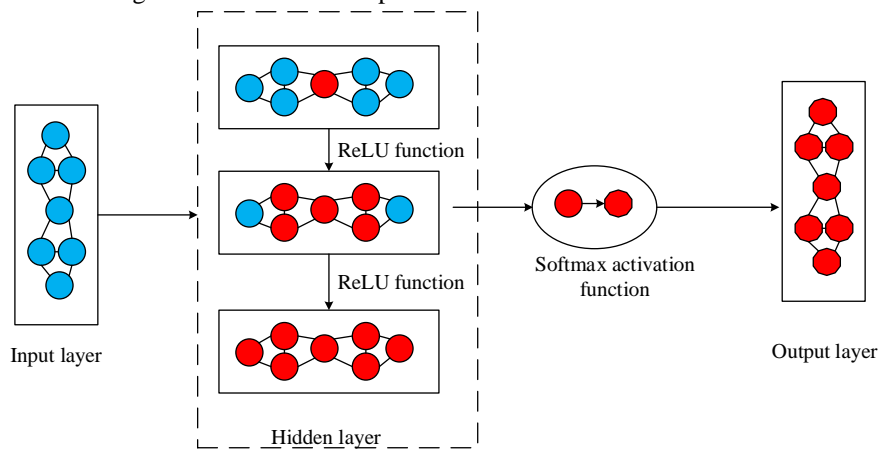

Fig. 2. GCN algorithm and basic structure diagram.

layer, multiple hidden convolutional layers, an activation layer, and an output layer [16]. In the input layer, data is clustered, and its feature information can be obtained from the neighboring nodes of that node during clustering. Then, the clustered data is passed into the HL, which is the core layer of the algorithm. In the HL, data graph convolution operations are performed. The features of each node in the clustered data are transformed through convolutional propagation to extract and retain their own feature information, removing irrelevant information. Finally, the data is normalized using the Softmax activation function. The propagation rule for each convolutional layer is shown in Eq. (9) [17].

$$M^{(l+1)} = \sigma(D^{-\frac{1}{2}} A D^{-\frac{1}{2}} B^{(l)} C^{(l)}) \quad (9)$$

In Eq. (9), A signifies the sum of the adjacency matrix and the closed-loop self-connection in the undirected graph. D signifies the degree matrix of A . $B^{(l)}$ is the activation unit matrix of l -th layer. $C^{(l)}$ signifies the parameter matrix of l -th layer. The nodes in the l -th layer complete the feature transformation operation, and the expression for this process is displayed in Eq. (10).

$$X^{(l+1)} = \sigma(NX^{(l)}K^{(l)} + m^{(l)}) \quad (10)$$

In Eq. (10), $X^{(l)}$ signifies the node feature of the l -th layer in the GCN. $K^{(l)}$ signifies the weight defined in layer l . σ is a nonlinear transformation. The adjacency matrix is normalized through a degree matrix, and the final expression is shown in Eq. (11).

$$x_i^{(l+1)} = \sigma\left(\sum_{j=N_i} D^{-\frac{1}{2}} A D^{-\frac{1}{2}} X^{(l)} C^{(l)} + b^{(l)}\right) \quad (11)$$

In Eq. (11), D signifies the degree matrix of A . All numbers on the diagonal of the adjacency matrix are changed to 1 through Eq. (11). The forward propagation is shown in Eq. (12).

$$Z = \text{soft max}(A \text{Re Lu}(AXC^{(0)})W^{(l)}) \quad (12)$$

Finally, the loss function of all points is calculated, as shown in Eq. (13).

$$L = - \sum_{l=y_L} \sum_{f=1} Y_l f \ln l_f \quad (13)$$

In Eq. (13), f represents the soft activation function. The extraction and preprocessing of data feature information are completed through the above process. Then, the information is transmitted into MLP for data analysis. The basic flowchart of MLP optimized by GCN is shown in Fig. 3.

From Fig. 3, the optimized MLP has a one-step data preprocessing process compared with the previous one. Firstly, the data is input into the GCN module for clustering analysis, and then the convolution operation is carried out to extract the data features. Afterwards, the data is normalized through the activation function to make the data the same form. Then, the data is taken as the input value of the MLP module. In the MLP module, the weight of the received data is allocated, and then it is calculated. Through continuous iteration, the data error is reduced to the allowable range. Then, the data is output. GCN is applied to preprocess the data, unify the data type and reduce the data volume, so as to enhance the operation speed and accuracy of MLP module.

B. Construction of Intrusion Detection Model Based on GCN-MLP

This study uses an intrusion detection model on the basis of GCN-MLP algorithm to detect information intrusion behavior in network security. It is hoped that this model can solve the low detection efficiency, false positives, and missed detection in current network intrusion detection models. The network security detection model is displayed in Fig. 4.

In Fig. 4, the network security detection model contains a detection layer, a transmission layer, a monitoring layer, and an application layer. In the detection layer of the model, network intrusion information is captured and transmitted to the algorithm detection model through sensors. The intrusion information is judged in the algorithm detection model. The transmission layer transmits the judged network intrusion information to the network through the server. In the monitoring layer, the intrusion information is monitored based on the judged intrusion information. Then, the user is searched through the database server and browser, and the intrusion information is transmitted to the user. This study uses an intrusion detection model based on GCN-MLP to investigate the module in the network security detection model. The basic structure diagram of the GCN-MLP intrusion detection model is shown in Fig. 5.

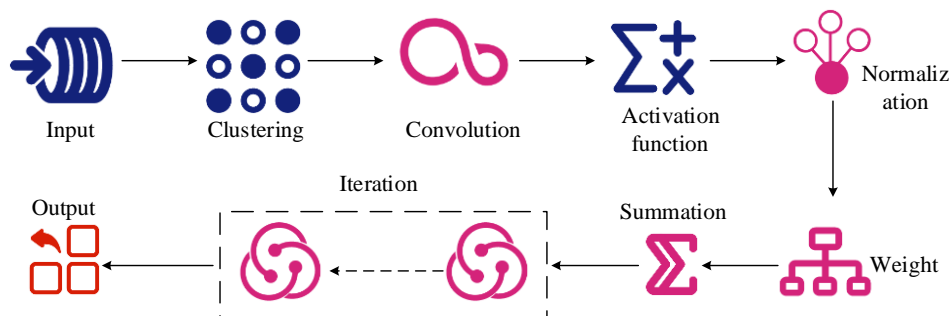

Fig. 3. Basic flowchart of GCN-MLP algorithm.

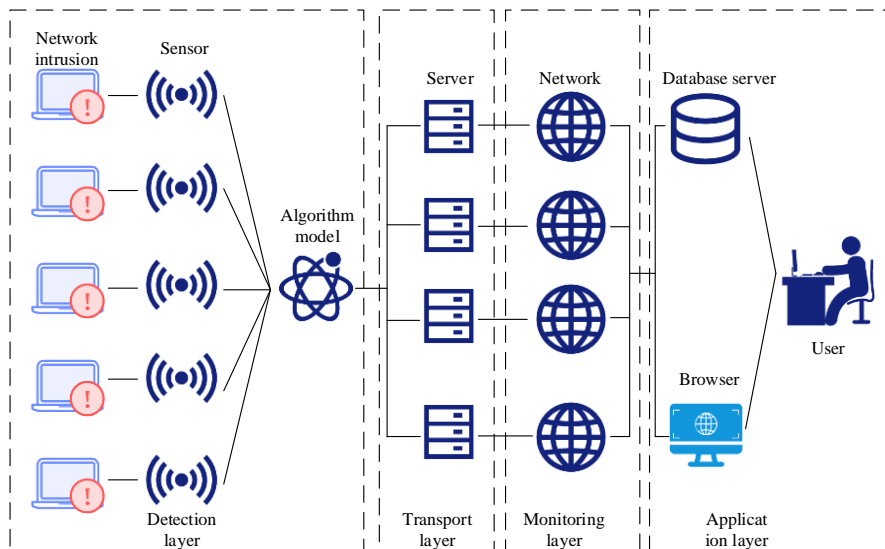

Fig. 4. Basic structure diagram of network security detection model.

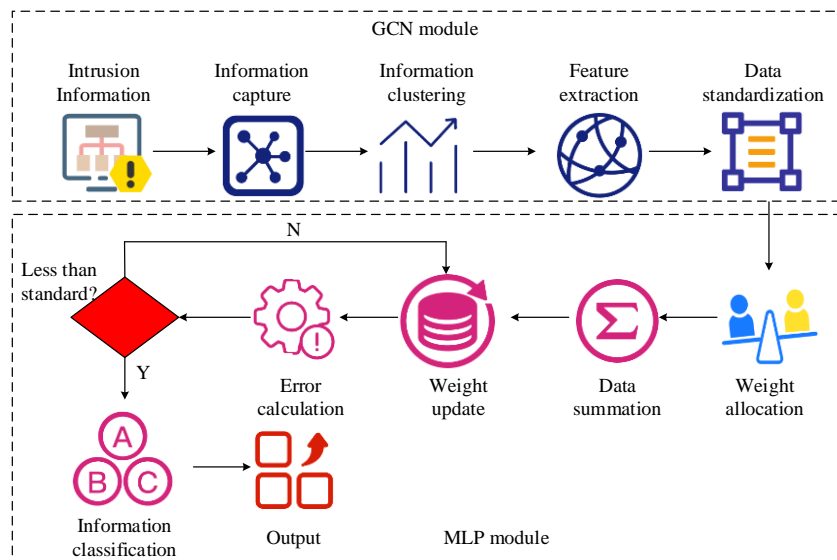

Fig. 5. GCN-MLP intrusion detection model.

As shown in Fig. 5, the model is divided into GCN module and MLP module. The GCN module captures the network intrusion information, clusters and integrates the captured information into data, extracts the features of the integrated data, and then standardizes the extracted feature information data to unify the data type. Then, the preprocessed data is sent as input information to the MLP. In this module, the incoming data is assigned weights, the weighted data is summed, the weights are updated, and the error value of the data is calculated. The error is compared with the minimum allowable error. If it is less than the allowable error, the intrusion information is classified based on the output data size to confirm the type of intrusion information. If the calculated error exceeds the allowable error, the weight is updated and the error is recalculated until the error is less than the allowable error value. The output calculation method of this model is shown in Eq. (14).

$$\hat{y} = h^T \begin{bmatrix} \Phi_{GCN} \\ \Phi_{MLP} \end{bmatrix} \quad (14)$$

In Eq. (14), h^T represents the weight matrix. The square loss is used as the loss function of the output model, as displayed in Eq. (15).

$$L = \sum_{(u,i) \in S} (\hat{y}_{ui} - y_{ui})^2 + \lambda \|\Theta\|^2 \quad (15)$$

In Eq. (15), (u,i) represents any number in the GCN dataset and MLP dataset, respectively. S represents the training dataset. \hat{y}_{ui} represents the predicted score. y_{ui} is the true score. Θ represents the weight parameter. λ represents the regularization parameter. To demonstrate the model effectiveness, the root mean square error is used as the evaluation index, as displayed in Eq. (16).

$$R = \sqrt{\frac{\sum_{(u,i) \in S} (\hat{y}_{ui} - y_{ui})^2}{N}} \quad (16)$$

In Eq. (16), N signifies the total data contained. The network intrusion detection model can timely detect various security risks in the network and effectively prevent network intrusion, thereby protecting network security.

III. RESULTS

A. Performance Analysis of GCN-MLP

To prove the superiority of GCN-MLP, the GCN-MLP is compared with Fusion Algorithm combined Convolutional Neural Network algorithm with Convolutional Attention Module (CNN-CBAM), Fusion Algorithm based on Time Convolutional Network and Bidirectional LSTM (TCN-BiLSTM), as well as Fusion Algorithm combined Principal Component Analysis algorithm with K-means clustering (PCA-K-means). Table I displays the configuration.

TABLE I. EXPERIMENTAL CONFIGURATION TABLE

Environment	Index	Type
Hardware environment	OS system	Winds 10
	Hardpan	500G
	CPU	I7 3.4Hz
	Internal memory	4GB
Software environment	Pyrhon	Pyrhon 3.x
	Matlab	Matlab7.0

According to Table I, the environmental configuration conditions during the experiment are obtained. During the experiment, the node features, HL features, and output layer features of the GCN are 50, and the number of layers in GCN is 5. The penalty coefficient is 0.001, and the learning rate is 0.005 in the MLP. The learning rate is 0.1, the capacity is 100, the weight attenuation is 0.005, and the training frequency is 50 in the CNN. The convolution kernel in CBAM is 9, the

convolution kernel size is 3*3, the weight threshold is 0.5, and the maximum pooling layer is set to 3*3. The number of neurons in BiLSTM is 100, and the batch size is 10. The n_components in the PCA algorithm is set to none, the copy value is True, and the white value is False. The K-value in the K-means is 50, and the maximum iteration is 500. Comparative experiments are carried out on the KDD CUP 99 dataset based on the parameter settings mentioned above. The superiority of the proposed algorithm was verified by comparing the accuracy, loss function value, F1 value, detection time, and ROC curve of four algorithms. The comparison between the predicted and the actual results, as well as the accuracy results, are shown in Fig. 6.

According to Fig. 6 (a), the GCN-MLP algorithm had the closest predicted result and the smallest difference. The difference of CNN-CBAM algorithm and TCN-BiLSTM algorithm was greater than that of GCN-MLP algorithm. The PCA-K-means algorithm had the greatest difference. In Fig. 6 (b), the accuracy of the four algorithms increased when the iteration was between 0 and 20. However, when the iteration exceeded 20, the accuracy stabilized. The accuracy of the GCN-MLP algorithm stabilized at 0.98 after more than 20 iterations.

The accuracy of the CNN-CBAM algorithm, TCN-BiLSTM algorithm, and PCA-K-means algorithm were 0.81, 0.69, and 0.61, respectively. Afterwards, comparative experiments are conducted on the F1 values and loss function values, as displayed in Fig. 7.

From Fig. 7, the F1 values and loss function values varied with the increase of iterations. From the Figure, the F1 value of the GCN-MLP algorithm reached its maximum value at 5 iterations, with a maximum F1 value of 0.97. However, the CNN-CBAM algorithm, TCN-BiLSTM algorithm, and PAC-K-means algorithm only reached their maximum F1 value at 10 iterations. The maximum F1 of these three algorithms was 0.92, 0.87, and 0.78. The loss function values decreased with the increase of iterations. In Fig. 7, the loss function value of the GCN-MLP algorithm stabilized at 0.03, which was much lower than the CNN-CBAM at 0.09, TCN-BiLSTM at 0.12, and PCA-K-means at 0.15. In Fig. 7, when the number of iterations was greater than 20, the loss function fluctuation range of the TCN-BiLSTM algorithm and PAC-K-means algorithm was larger, with the PCA-K-means algorithm having the largest fluctuation range and the smallest stability. Further analysis is conducted on the detection time and ROC curves, as displayed in Fig. 8.

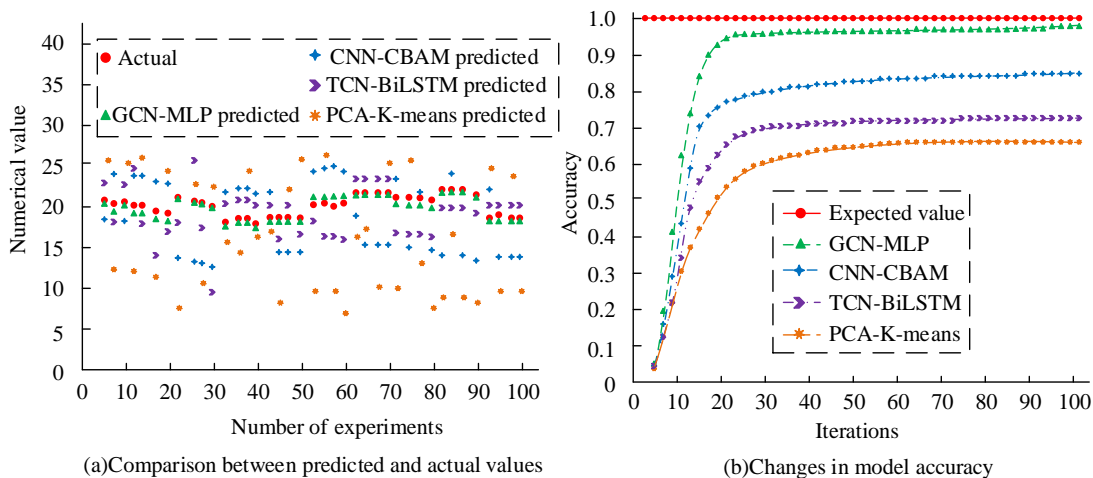

Fig. 6. Algorithm prediction results and accuracy.

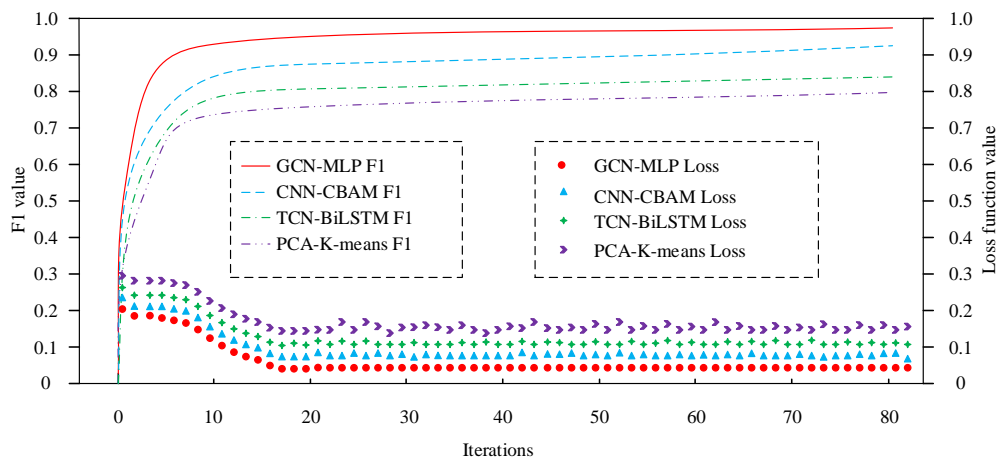

Fig. 7. Comparison of F1 value and loss function value.

Fig. 8. Detection time and ROC curve of the algorithm.

According to Fig. 8 (a), the average detection time of the GCN-MLP was the shortest, at 1.1s. The average detection time of the CNN-CBAM was 1.9s. The average time for the TCN-BiLSTM was 3.2s. The PCA-K-means algorithm had the longest average time, which was 5.3s. The accuracy, false detection rate, and missed detection rate can be observed from the curve in Fig. 8 (b). The ROC close to the upper left corner demonstrates that the prediction accuracy is higher. From Fig. 8 (b), the ROC of GCN-MLP algorithm was closest to the upper left corner, followed by CNN-CBAM algorithm, and PCA-K-means algorithm was farthest. Therefore, among the four algorithms, GCN-MLP algorithm had the highest prediction accuracy, and PCA-K-means algorithm had the lowest prediction accuracy. GCN-MLP has the highest accuracy, fastest detection speed, and strongest stability. The overall

performance is significantly better than other algorithms.

B. Application Effect of GCN-MLP Model in Network Security Detection

After verifying the superiority of the GCN-MLP algorithm, experimental analysis is conducted on the detection model based on the algorithm. The proposed model (Model 1) is compared with intrusion detection model integrating improved auto-encoder and residual network (Model 2), intrusion detection model integrating contrastive learning and feature selection (Model 3), and residual network detection model combined with fusion attention mechanism (Model 4). The accuracy, precision, recall, F1, underreporting rate, and detection rate of the four models are analyzed. The comparison results are shown in Fig. 9.

Fig. 9. Comparison of algorithm indicators.

Fig. 9 displays the comparison results of various indicators. From Fig. 9 (a), the detection accuracy of Model 1 was the highest among the four models at 98%, while the detection accuracy of Model 2, Model 3, and Model 4 were 89%, 80%, and 68%, respectively. From Fig. 9 (b), Model 2 had the highest detection precision of 97%, while Model 4 had the lowest detection precision of 78%. In Fig. 9 (c), the recall rate gradually decreased from Model 1 to Model 4. From Fig. 9 (d), after multiple experiments, the F1 value of Model 1, Model 2, Model 3, and Model 4 was 97%, 90%, 87%, and 68%, respectively. From Fig. 9 (e) and 9 (f), Model 1 had the lowest underreporting rate, but the highest data detection rate, with a underreporting rate of 6% and a detection rate of 92%. Through experiments, it is known that Model 1 has slightly lower detection accuracy than Model 2, and all other indicators are better than comparison models. The overall performance is the best among the four models. In summary, the detection model based on GCN-MLP algorithm has the best overall performance. The GCN-MLP detection model is applied to actual network security detection. The accuracy of

intercepting intrusion information and the interception time of various illegal intrusions in network security detection are compared. 20 experimental results are taken, and the average accuracy and interception time of every 5 experimental results are calculated and represented by a coordinate graph. The accuracy and detection time results are shown in Fig. 10.

According to Fig. 10 (a), the average accuracy of Model 1 in network security detection was 0.98, the accuracy of Model 2 in network security detection was 0.89, and the accuracy of Model 3 was 0.71. The accuracy of Model 4 was the lowest among the four models, which was 0.57. Fig. 10 (b) shows the time it takes for four models to detect and judge intrusion information. From Fig. 10 (b), the average time for Model 1 to detect intrusion information was 0.1s, which was much lower than the 0.9s of Model 2, 2.7s of Model 3, and 4.2s of Model 4. Further experiments are conducted on the accuracy of four models in determining various types of network intrusion information, as displayed in Fig. 11.

Fig. 10. Accuracy and interception time of network security inspection model.

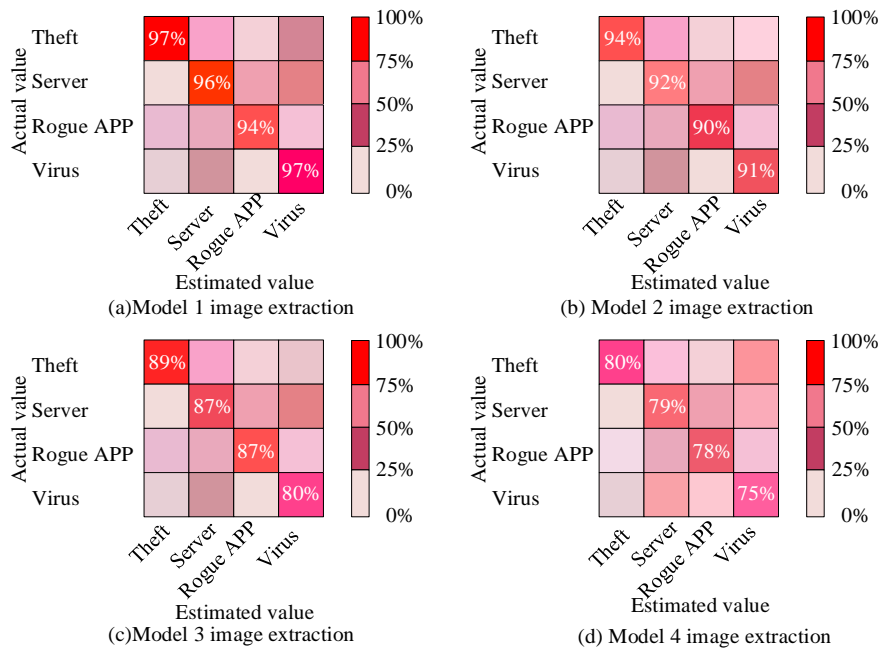

Fig. 11. Model ability to judge intrusion information.

Fig. 11 shows the accuracy results of four models in judging intrusion information encountered in network security detection. The elements on the main diagonal signify the proportion of correctly predicted intrusion information types. The elements in the lower left triangle signify the proportion of missed intrusion information types. The elements in the upper right triangle represent the proportion of false detected intrusion information types. According to Fig. 11 (a), Model 1 had a prediction accuracy of 97% for the theft intrusion information in the intrusion information, a detection accuracy of 96% for server intrusion information, a detection accuracy of 94% for malware information, and a detection accuracy of 97% for virus intrusion. The detection accuracy of Model 2 for the four types of intrusion information was 94%, 92%, 90%, and 91%, respectively. The detection accuracy of Model 3 and Model 4 for the four types of intrusion information was much lower than that of Model 1 and Model 2. From the above experimental results, the GCN-MLP has the best performance among the four detection models. This model is used in network security intrusion systems, which has the highest accuracy in detecting intrusion information.

IV. DISCUSSION

The study verified the significant advantages of the network security detection model based on GCN-MLP in accuracy, speed, and stability through experiments. Compared with the other three algorithms, GCN-MLP not only achieved a stable high accuracy of 0.98 after 20 iterations, but also had an F1 value of 0.97. The loss function value remained stable at a lower level of 0.03, which fully demonstrated the efficiency of the algorithm. This is fitted with the conclusion drawn by Yao et al. on the GCN-MLP algorithm [18]. In addition, from the experimental results, the GCN-MLP algorithm performed equally well in detection time, averaging only 1.1s, which was much faster than the other three algorithms. In the field of network security, fast detection time means that potential threats can be responded to more quickly, effectively reducing risks, which is linked to the results drawn by He et al [19]. Further research found that when comparing the GCN-MLP detection model with three other advanced detection models, the GCN-MLP model maintained a leading position in multiple key indicators such as accuracy, recall, F1 value, and detection rate. Especially, the underreporting rate was only 6%, far lower than other models, which was extremely important in the field of network security because underreporting may lead to serious security risks.

The GCN-MLP model had a detection accuracy of over 94% for theft intrusion, server intrusion, malware information, and virus intrusion, demonstrating extremely high reliability and comprehensiveness. Compared with the algorithms and models designed by Yu et al. and Yang et al., the GCN-MLP algorithm also exhibited excellent performance. Because the deep learning model designed by Yu et al. and Yang et al. had an accuracy of only 80%-90% in network security detection, the GCN-MLP model further enhanced this standard [20-21]. Meanwhile, the stability of the GCN-MLP was also commendable. During the experiment, the fluctuation of the loss function value was relatively small. It means that in practical applications, the model can provide more reliable and consistent results. This result is significantly better than the

stability of the network security protection model designed by Wang et al [22]. In summary, the network security detection model based on GCN-MLP shows significant advantages in multiple aspects, which not only proves the effectiveness of this method, but also provides strong support for its application in practical network security protection.

V. CONCLUSION

In response to the low accuracy, serious false positives, and missed detection rate in current information intrusion detection models, this study proposed the CN-MLP algorithm integrating GCN algorithm and MLP algorithm. Then, an information intrusion detection model was constructed based on the fused GCN-MLP algorithm, CNN-CBAM algorithm, TCN-BiLSTM algorithm, and PCA-K-means algorithm. The overall performance of the GCN-MLP algorithm outperformed other comparison algorithms. Subsequently, the method was compared with intrusion detection model integrating improved auto-encoder and residual network, intrusion detection model integrating contrastive learning and feature selection, and residual network detection model combined with fusion attention mechanism. The designed intrusion detection method had a much higher detection accuracy for network intrusion information than the other comparison models. In summary, the detection model on the basis of GCN-MLP has the best overall performance in network security intrusion information detection, which can effectively improve network security. However, the types of intrusion information discussed in this study are limited, and there is still uncertainty. In the future, data augmentation techniques can be used to oversample minority class samples, synthesize new minority class samples, expand the sample size, and increase detection information. Meanwhile, generative adversarial networks can be used to generate similar intrusion detection information, increase sample size, and improve the overall detection performance of the model.

Abstract—This study explores the effectiveness of an ensemble method for Quranic text retrieval, aimed at improving the relevance and accuracy of verses retrieved for specific themes. The ensemble approach integrates three semantic models—Word2Vec, FastText, and GloVe—through a voting mechanism that considers verse frequency and semantic alignment with the query topics. Testing was conducted on themes such as prayer, zakat, fasting, umrah, and eschatology, reflecting fundamental aspects of Quranic teachings. Results demonstrate that the ensemble method significantly outperforms non-ensemble approaches, achieving an average relevance rate of 88%, compared to individual models (Word2Vec: 75%, FastText: 80%, GloVe: 82%). The ensemble method effectively combines the unique strengths of each model. Word2Vec captures general semantic relationships, FastText handles morphological nuances, and GloVe identifies global contextual patterns. By combining these capabilities, the ensemble approach improves both the quantity and quality of retrieved verses, making it a robust tool for semantic analysis in Quranic studies. This research contributes to the field of computational Islamic studies by demonstrating the practical advantages of ensemble methods for religious text retrieval. It lays the foundation for further advancements, including the integration of deep learning techniques, dynamic query handling, and cross-linguistic analysis. The ensemble method offers a promising framework for supporting more accurate and contextually relevant Quranic studies, promoting a deeper understanding of Islamic teachings through data-driven methodologies.

Keywords—Ensemble method; query expansion; ontology; Al-Quran; search engine

I. INTRODUCTION

The Quran, as the holy book of Islam, holds profound spiritual, moral, and ethical guidance for over a billion Muslims worldwide. It serves not only as a religious text but also as a comprehensive source of knowledge, law, and inspiration. The Quran's linguistic and contextual depth reflects its universal nature, which transcends time and culture. However, this same depth presents significant challenges in making its meanings accessible, particularly for non-Arabic-speaking audiences such as Indonesians, who rely on translations and interpretations to understand its contents. Indonesia, being home to the largest Muslim population globally, has a pressing need for efficient tools to access

Quranic knowledge in the Indonesian language. However, traditional search systems often fall short in meeting user expectations due to their inability to grasp the semantic richness of Quranic text [1]. Literal keyword matching methods, for example, frequently fail to account for synonyms, related terms, and contextual nuances inherent in religious texts. This necessitates the development of advanced information retrieval (IR) systems tailored to handle the complexities of Quranic text in translation.

A major obstacle in existing Quranic IR systems lies in their limited ability to interpret semantic relationships between terms. While some systems incorporate basic query refinement techniques, they rarely achieve the level of sophistication needed for meaningful interpretation of Quranic content. Query Expansion (QE), which involves broadening search queries by including semantically related terms, has shown great promise in addressing these challenges. By enhancing the original query, QE can improve the relevance and accuracy of search results, especially in highly structured texts like the Quran [2], [3], [4]. Ontology-based Query Expansion offers a powerful solution by leveraging structured knowledge frameworks that capture the domain-specific relationships and meanings within Quranic text. Ontologies can represent complex semantic relationships such as synonyms, hypernyms, and contextual associations, enabling more precise query interpretation [5], [6]. This approach is particularly valuable for Quranic IR, where understanding the contextual use of terms is critical for delivering meaningful search results.

In addition to ontology-based QE, advances in semantic text representation provide new opportunities for improving IR systems. Semantic representation methods, particularly those using neural networks, capture not only the lexical features of text but also its contextual meanings. Ensemble techniques, which combine multiple models to optimize performance, are increasingly recognized as a robust approach for text representation. By aggregating the strengths of various models, ensemble methods can better handle the linguistic intricacies of Quranic text and its Indonesian translation.

The integration of ontology-based QE with ensemble semantic text representation models has the potential to revolutionize Quranic IR systems. This combination ensures

that search results are not only relevant but also contextually accurate, aligning with the inherent richness of Quranic discourse. By leveraging these advanced techniques, the proposed system aims to bridge the gap between user queries and the deep, layered meanings of the Quranic text. The research focuses on developing a tailored Quranic IR system specifically for the Indonesian language. Unlike generic search engines, this system will address the unique challenges posed by Quranic text, such as polysemy, synonymy, and contextual interpretation. It will also incorporate an extensive ontology of Quranic terms and their relationships, further enriching the system's ability to understand user intent.

Moreover, the use of ensemble methods ensures the robustness of the proposed system. By combining multiple semantic text representation models, the system can effectively capture both local and global contextual information in the text. This not only improves the accuracy of search results but also enhances the user experience by providing more nuanced and comprehensive responses to queries. This study represents a significant contribution to the field of Quranic studies and information retrieval. By addressing the limitations of existing systems and introducing a novel combination of ontology-based QE and ensemble techniques, it sets a new standard for Quranic IR. The findings of this research are expected to benefit not only Muslim communities but also researchers and practitioners working on religious and domain-specific IR systems.

In conclusion, the development of an ontology-enriched Query Expansion method integrated with ensemble semantic text representation offers a promising solution for improving Quranic information access in the Indonesian language. This research not only aims to enhance the retrieval performance of Quranic IR systems but also serves as a benchmark for similar efforts in other languages and religious texts, ensuring broader applicability and impact.

The paper is organized as follows: Section II provides a literature review of relevant works on query expansion, ontologies, and word embeddings. Section III outlines the methodology, detailing the construction of the Quranic ontology, the implementation of Word2Vec, and the integration of these components into a search engine. Section IV presents the results of the system's performance evaluation, focusing on precision, recall, and relevance of the search results. Finally, Section V discusses the conclusions, limitations, and future directions for further research.

II. LITERATURE REVIEW

A. Information Retrieval Based on Query Expansion and Ensemble Text Representation

Information retrieval (IR) is a fundamental process in managing and extracting relevant information from large datasets [7], [8]. Traditional IR systems rely on keyword-based searches, where users input queries, and the system returns documents containing those keywords [9], [10], [11]. However, such systems often face limitations due to the ambiguity of user queries and the mismatch between user language and the indexed data [12], [13]. This limitation has led to the development of query expansion techniques, which

aim to improve search accuracy by reformulating user queries to include related terms [14].

Several techniques have been developed for query expansion, each offering different approaches to improving search results [15], [16]. One method is manual query expansion, where domain experts carefully select synonyms or related terms to enhance the query [17]. Another approach is automatic query expansion (AQE), in which the system automatically identifies related terms using techniques such as relevance feedback, thesaurus-based expansion, or statistical co-occurrence analysis. More recently, word embeddings-based expansion, such as Word2Vec, has emerged as a powerful method. This approach leverages vector representations of words to suggest semantically related terms [18] by analyzing their proximity in a high-dimensional vector space, providing a more dynamic and context-aware means of expanding queries [19], [20], [21].

Recent advancements in text representation based on word embedding models, particularly Word2Vec, FastText, and GloVe, have demonstrated significant improvements in capturing semantic relationships between terms, making them popular tools for automatic query expansion. Several studies [14], [19], [22] demonstrated that Word2Vec could effectively suggest semantically similar terms effectively. FastText, on the other hand, extends this capability by incorporating subword information [23], making it particularly effective in handling morphologically rich languages and rare or unseen words [24]. GloVe, by leveraging global co-occurrence statistics [25], [26], provides robust embeddings that capture the relationships between words across broader contexts [27], [28]. Together, these methods have been successfully applied in various applications, from general-purpose search engines to domain-specific information retrieval (IR) systems, demonstrating their ability to enrich user queries and improve the relevance of search results.

To further enhance the query expansion process, this research employs an ensemble method that combines the outputs of Word2Vec, FastText, and GloVe. Ensemble methods, which integrate multiple models, leverage the strengths of each model while mitigating their individual weaknesses [29]. For instance, Word2Vec excels in local context understanding, FastText captures morphological subtleties, and GloVe provides a comprehensive global semantic understanding. By aggregating these outputs using techniques such as weighted voting, the ensemble method achieves a balanced representation that is both lexically precise and contextually rich. The advantages of ensemble methods include improved robustness, reduced overfitting, and higher accuracy in handling complex or diverse queries. In this research, the ensemble approach ensures that query expansion is not only semantically accurate but also contextually aligned with the intricate thematic and linguistic structure of Quranic texts, thereby significantly enhancing the performance of the proposed IR system.

B. Ontology in Information Retrieval

Ontologies play a crucial role in enhancing information retrieval (IR) [30] systems by bridging the semantic gap between the terms users input in their queries and those

indexed within the system. By offering a structured and hierarchical representation of domain knowledge, ontologies enable IR systems to enrich user queries with related terms, such as synonyms, hyponyms, and hypernyms, through the query expansion process. This structured approach supports more advanced semantic search capabilities, allowing the system to not only match keywords but also to understand the underlying meaning and context of user queries, ultimately improving the relevance and accuracy of search results. Incorporating ontologies into search systems has been particularly beneficial in specialized domains such as medical databases, educational resources, and legal information systems. Ontology-based systems can also be used for concept-based retrieval, where the system retrieves documents based on the underlying concepts represented in the query rather than exact keyword matches.

The use of ontology and query expansion in religious texts, particularly the Qur'an is gaining attention due to the need for more intelligent and context-aware search systems. The Qur'an is a rich and complex text with intricate themes, concepts, and linguistic variations, making it challenging for traditional keyword-based search systems to capture the full meaning and relevance of user queries.

Several studies have explored the use of ontology in Qur'anic search systems. For example, Mohamed, Ensaf Hussein, and Eyad Mohamed Shokry [31] developed a Qur'anic ontology based on concept-based searching tool (QSST) to facilitate semantic-based search. In this research, ontology was created through manual annotation of verses of the Al-Quran based on the Al-Tajweed Mushaf. In another study [32], ontology development was carried out for the Quran by adopting the use of Protégé-OWL and SPARQL queries. In addition, there are still several studies that try to apply searches based on semantic relationships that exist in each verse of the Quran [31], [33], [34]. Thus, it can be concluded that the integration of Word2Vec with ontology has been proven to significantly improve the search process. By utilizing the semantic knowledge embedded in ontology and word vectors, this system can produce more accurate user query expansions, thereby increasing precision and recall in search.

C. Research Gap and Contribution

Despite significant progress in integrating ontology and query extension into information retrieval systems, several challenges remain. As explained previously, it was found that only a few studies have tried the ontology and query expansion approach to facilitate information retrieval from the Quran. Most studies with the topic of information retrieval from the Quran tend to only apply the labeling concept [35], index-based ranking without trying to understand semantic relationships as a representation of contextual verses [36], [37], [38], [39]. Moreover, regarding the application of the Indonesian translation of the Quran as a case study, it is still under discussed. Most existing studies prefer a conventional keyword-based approach [40] or the use of glossaries as keyword enrichment [41]. Only 1 study was found that tried to explore semantic relationships as applied by Purnama et al. [42]. Another notable research gap is the limited application of ensemble methods in query expansion for Quranic IR. While

ensemble approaches have shown success in improving text representation and classification tasks in general IR, their use in combining multiple semantic representation models for query expansion remains underexplored. Ensemble methods, which aggregate the strengths of various models, could potentially enhance the robustness and accuracy of expanded queries, particularly in complex and domain-specific texts like the Quran.

Additionally, the performance of existing Quranic IR studies remains relatively low, as they often fail to optimize retrieval accuracy and relevance due to the lack of advanced semantic techniques. This highlights the need for innovative methodologies that integrate ontology-based query expansion with ensemble deep learning models to address these limitations effectively. In conclusion, a summary of the research gaps and the contributions offered by this study is illustrated in Fig. 1. These gaps emphasize the need for more sophisticated approaches that combine ontologies, semantic relationships, and ensemble deep learning techniques to improve the performance of Quranic IR systems, particularly in the context of the Indonesian translation.

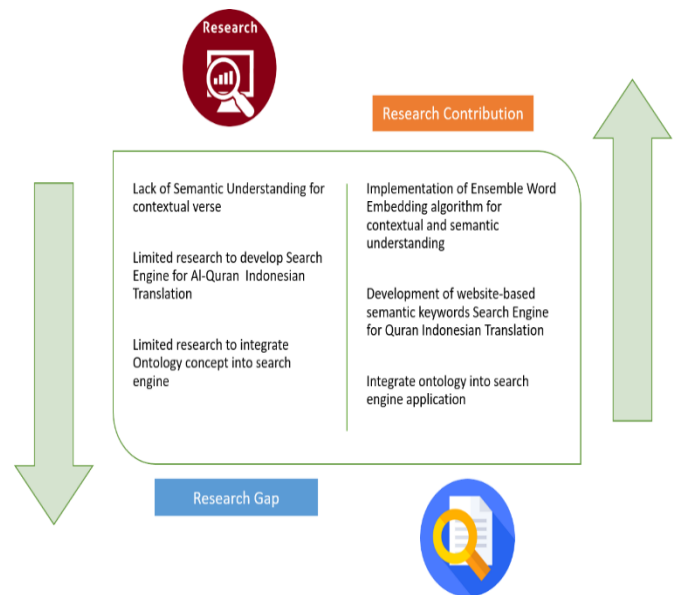

Fig. 1. Research gap and proposed contribution.

Based on Fig. 1, this study aims to develop an ensemble semantic search engine application enriched with Ontology which is expected to solve problems in existing research. Specifically, this search engine application is intended for the Indonesian language Qur'an because there is still little discussion on this topic.

III. METHODOLOGY

A. Dataset Material

The dataset utilized in this study is meticulously compiled from two primary sources: the official Indonesian translation of the Quran published by the Ministry of Religious Affairs (Kemenag) and the Indonesian Wikipedia corpus. The integration of these resources ensures a robust semantic foundation for developing an advanced information retrieval

system tailored to Quranic content in the Indonesian language. The official Kemenag translation serves as an authoritative and widely recognized resource, ensuring theological and linguistic accuracy. It comprises all 114 surahs and 6,236 verses, each accompanied by its corresponding Arabic text to maintain contextual alignment. Additionally, the dataset includes thematic metadata categorizing Quranic verses into key topics such as faith (iman), worship (ibadah), morals (akhlak), and law (syariah), which is crucial for ontology construction and query expansion.

To address the inherent limitations of Quranic text alone in covering broader semantic contexts, the dataset is enriched with the Indonesian Wikipedia corpus. The Wikipedia corpus provides a vast repository of general knowledge that complements the Quranic dataset by introducing a wider range of linguistic and contextual diversity. While the Quranic text is specific and focused, the Wikipedia corpus offers the flexibility to understand related terms and concepts that may not explicitly appear in the Quran. For instance, abstract ideas such as "justice" (keadilan) and "mercy" (rahmat), which are central to Islamic teachings, can be explored in their broader cultural, philosophical, or societal dimensions through Wikipedia entries. This enrichment allows the system to better handle complex or indirect queries by providing semantic connections between Quranic themes and contemporary knowledge.

Prior to integrate the datasets into the system, several preprocessing steps are carried out to ensure data quality and consistency. For the Quranic text, transliterations are standardized, and Arabic diacritical marks (tashkeel) are removed to simplify tokenization. The Indonesian translation is normalized by converting text to lowercase, eliminating punctuation, and resolving linguistic variations to create a uniform dataset. Similarly, the Wikipedia corpus undergoes a rigorous preprocessing pipeline that involves noise removal, where irrelevant or overly technical content is filtered out, and tokenization, where text is broken into meaningful linguistic units. Additionally, stop words, such as common function words in Indonesian, are removed to enhance the focus on semantically significant terms.

The preprocessed datasets are then aligned and structured for downstream tasks, such as ontology development and semantic text representation training. This ensures that the Quranic and Wikipedia datasets are not only compatible but also semantically enriched to facilitate accurate, relevant, and context-aware information retrieval. By integrating a carefully curated and preprocessed dataset, the system can effectively bridge the gap between Quranic-specific queries and broader thematic searches, enhancing the overall user experience.

B. Proposed Method

This study aims to develop a thematic index-based Al-Qur'an ontology system and implement query expansion techniques to support more relevant and accurate information retrieval. The system is designed to enhance semantic access to Al-Qur'an verses, enabling topic-based searches such as Morals, Faith, Worship, and Law. To refine the query expansion process, this study incorporates ensemble text representation methods by combining Word2Vec, GloVe, and

FastText. These methods collectively capture word-level, global co-occurrence, and subword-level semantics, ensuring a robust representation of Quranic text. Weighted voting is employed to integrate the strengths of each model, allowing the system to provide search results that are both contextually rich and semantically precise.

The methodology involves several critical stages, starting with data collection from the official Indonesian translation of the Quran and the Wikipedia corpus for contextual enrichment. Ontology development follows to structure thematic relationships within the Quran. Ensemble text representation is then applied to support query expansion, enriching user queries with semantically related terms. Finally, the system is integrated and evaluated using metrics such as precision, recall, and F-measure. This approach bridges traditional keyword-based methods and modern semantic-aware retrieval systems, offering a scalable and accurate solution for Quranic information retrieval in Indonesian. The overall framework of the proposed ensemble learning approach for query expansion and semantic retrieval in Quranic information systems is illustrated in Fig. 2 below.

Fig. 2. Research methodology.

As described previously, this study is structured into several interconnected stages, starting with the ontology development. At this stage, the collected and preprocessed data is transformed into unique thematic according to user needs. The ontology development process was based on a thematic classification encompassing 14 core topics: Morals and Etiquette (Akhlaq and Adab), The Qur'an, Previous Nations, Criminal Law (Jinayah), Private Law, Worship, Knowledge, Faith, Jihad, Food and Drink, Transactions (Mu'amalat), Clothing and Adornment, Judiciary and Judges, and History. These topics represent essential thematic divisions that facilitate a structured and systematic approach to understanding and accessing the teachings of the Qur'an. In addition, linguistic differences between Arabic and Indonesian are studied to address translation nuances and contextual challenges, which forms the basis for query expansion tailored

to the semantics of the Quran. The Quran Ontology is then developed by referring to this analysis.

A structured ontology is constructed to organize Quranic content systematically, reflecting the semantic relationships between verses and thematic categories. This process involves categorizing verses into specific topics, defining synonyms, antonyms, and hierarchical relationships, and ensuring alignment with the linguistic nuances of Indonesian translations. The use of ontology development tools, such as Protégé, aids in managing and visualizing the ontology structure, while consultations with Islamic scholars ensure the accuracy and relevance of the content. This ontology serves as the core mechanism for query expansion, enabling the system to infer implicit relationships and enhance search relevance.

Ontology development for the Al-Qur'an involves creating a structured representation of Quranic content by defining broad classes i.e., Morals, Worship and more specific subclasses such as Ethics and Rituals to categorize and refine Quranic teachings. Each class and subclass is linked through hierarchical and semantic relationships, which help capture how different topics interrelate, such as Faith being related to Worship. Properties and attributes are then assigned to these classes to provide deeper insights, such as Virtue and Integrity for the Morals class. This process ensures a comprehensive and accurate reflection of Quranic teachings.

The ontology is then aligned with the actual content of the Quran, where each verse is annotated and categorized under its relevant topic. This step involves ensuring that every verse is properly associated with the appropriate class and subclass, allowing for accurate semantic search results. Once validated and refined with feedback from domain experts, the ontology serves as a foundation for enhancing information retrieval, helping to expand queries and provide more relevant, contextually accurate search results from the Quran.

The second stage focuses on the implementation of query expansion using the ontology. When a user submits a query, the ontology dynamically enriches it by identifying and adding semantically related terms or concepts. For instance, a query about "worship" could be expanded to include related terms like "prayer," "fasting," or "charity," reflecting the thematic connections in the Quran. Advanced algorithms are applied to ensure that only the most contextually relevant terms are selected for expansion. This enriched query is then processed by the retrieval engine, ensuring improved relevance and context-awareness in search results. Iterative testing is conducted to refine the expansion process and maintain the quality of retrieved information.

To further optimize the retrieval process, the application of ensemble semantic text representation is introduced in this second stage. This approach focuses on combining traditional word embedding techniques, such as Word2Vec, GloVe, and FastText, to create a robust and versatile text representation framework. These methods are integrated using an ensemble method based on weighted voting, ensuring that each technique contributes to the final representation according to its strengths in capturing specific semantic aspects of the Quranic text.

Word2Vec generates dense vector representations for words by analyzing their co-occurrence within a fixed context window, effectively capturing semantic similarity between terms. This technique excels in identifying relationships between frequently co-occurring words, such as "prayer" and "worship," making it particularly effective for extracting context-dependent connections. GloVe (Global Vectors for Word Representation), on the other hand, extends this capability by considering global word co-occurrence statistics across the entire dataset. This allows GloVe to encode broad semantic relationships, such as linking "faith" and "belief" based on their shared conceptual roles in the Quran. FastText complements these methods by representing words as a composition of character-level n-grams, enabling it to capture subword information and morphological variations. This is particularly useful for handling linguistic nuances in Quranic translations, such as connecting "guidance," "guiding," and "guided" based on shared subword patterns.

To integrate these techniques, an ensemble strategy based on weighted voting is employed. Each embedding method is assigned a weight proportional to its ability to contribute to the task, as determined through empirical evaluation. For instance, Word2Vec might be weighted higher for its effectiveness in capturing context-dependent word relationships, while FastText may receive greater weight for handling morphological variants and rare words. When a query is processed, the embeddings generated by Word2Vec, GloVe, and FastText are combined, and the weighted scores are used to determine the relevance of Quranic verses to the query. For example, for a query about "worship," Word2Vec might identify verses containing contextually related terms like "prayer," GloVe might highlight conceptual links to "obedience," and FastText could include morphological variants like "worshiper." The weighted voting mechanism ensures that the final result reflects the best contributions of each embedding method.

This ensemble approach, guided by weighted voting, provides a powerful framework for addressing challenges such as synonymy, polysemy, and linguistic variations in Indonesian translations of the Quran. By combining local context (Word2Vec), global context (GloVe), and morphological robustness (FastText) with a carefully calibrated weighting scheme, the system achieves high accuracy and relevance in retrieval. This ensures that users receive contextually rich and semantically aligned results, making the Quranic information retrieval system both precise and comprehensive.

Finally, the system undergoes performance evaluation to assess its effectiveness. Metrics such as precision, recall, and F-measure are used to quantify the system's ability to deliver relevant results while minimizing irrelevant ones. Comparative experiments benchmark the proposed system against traditional methods, such as keyword-based searches, to demonstrate its advantages. User studies provide qualitative insights into the system's usability and relevance, ensuring its practical application for Quranic information retrieval. This interconnected workflow ensures the development of a scalable, context-aware, and highly accurate system tailored to

the needs of users searching for Quranic content in Indonesian.

IV. RESULT AND DISCUSSION

This section highlights the research findings, focusing on the development of a Qur'anic ontology and the implementation of semantic query expansion to enhance a thematic-based search system. The results are structured around key stages of the study, including ontology construction, application of query expansion techniques, system integration, and performance evaluation. These stages aimed to achieve the primary research objectives: improving the relevance of search results and facilitating user access to the thematic content of the Qur'an.

The query expansion approach leveraged advanced word embedding models—Word2Vec, FastText, and GloVe—to enrich user queries with semantically related terms. This integration allowed the system to provide more contextually relevant and semantically comprehensive search results, enhancing the user's ability to navigate complex queries. Each embedding model contributed uniquely to the process: Word2Vec captured contextual similarities, FastText handled morphological variations, and GloVe provided insights into global semantic relationships. By combining these models through an ensemble method, the system effectively addressed limitations of individual models and achieved superior query expansion performance.

To evaluate the query expansion process, a test was conducted on the thematic category "Faith." Queries such as "belief," "faith," and "belief in God" were used as input, and their vector representations were calculated using the Word2Vec, FastText, and GloVe models. Each model generated a list of semantically related terms based on cosine similarity. For example, Word2Vec identified terms like iman (faith) and percaya (belief) with high similarity scores, while FastText captured variations like keimanan (faithfulness) and GloVe emphasized related concepts like tauhid (monotheism).

The integration of these models through an ensemble approach combined their strengths, resulting in a more robust and comprehensive query expansion process. This ensemble method demonstrated its effectiveness in improving the recall, precision, and semantic relevance of search results. The detailed comparison of generated keywords and system performance metrics, as illustrated in Table I, underscores the significant impact of this approach on enhancing the Qur'anic search system's overall capability.

Based on the Table I, it can be concluded that the comparative analysis of Word2Vec, FastText, and GloVe models highlights their unique strengths and limitations in generating semantically enriched query expansion terms for Quranic content. Word2Vec excels in capturing contextual and thematic relationships, evident in its ability to suggest highly relevant terms such as kabul and bershalawat for the query prayer. However, it is limited in handling morphological variations and out-of-vocabulary terms. In contrast, FastText demonstrates superior handling of morphological diversity, as seen in its accurate generation of terms like berpuasa and berpuasa for the query fasting, leveraging its subword-based

architecture. Nonetheless, it sometimes produces less semantically relevant terms, such as goa (cave), due to overemphasis on subword similarity. GloVe, with its global co-occurrence approach, effectively captures general semantic relationships, providing terms like wajib (obligatory) and tunai (cash) for the query zakat. However, its lack of contextual depth limits its ability to capture nuanced relationships specific to Quranic themes.

TABLE I. TOP 5 GENERATED SEMANTIC KEYWORDS

Query	Word2Vec	FastText	GloVe
Prayer	kabul / 0.876	berdoa / 0.779	panjat / 0.686
	moga_allah / 0.808	goa / 0.639	berdo / 0.661
	bershalawat / 0.792	mohon / 0.636	kabul / 0.646
	malaikat / 0.778	allahummaghfir / 0.635	do / 0.64
	amin / 0.768	do / 0.632	mohon / 0.638
Zakat	mungut / 0.853	zakatnya / 0.933	tunai / 0.632
	ekor_kambing / 0.848	zakatnya / 0.915	wajib / 0.628
	fitrah / 0.837	zakaia / 0.76	amil / 0.551
	lima / 0.828	mufakat / 0.665	tugas / 0.545
	wasaq / 0.806	zakar / 0.66	lima / 0.541
Fasting	ramadan / 0.924	berpuasa / 0.966	ramadhan / 0.657
	ramadhan / 0.891	bepuasa / 0.945	buka / 0.654
	buka / 0.865	puas / 0.779	asyura / 0.616
	ganti / 0.735	kekurangpuasan / 0.738	ramadhan / 0.609
	hari / 0.67	ketidakpuasan / 0.707	hari / 0.592

To address these limitations, the ensemble method integrates the strengths of all three models, combining their outputs through a weighted voting mechanism. This approach leverages Word2Vec's contextual precision, FastText's morphological adaptability, and GloVe's global semantic relevance to produce a more accurate and comprehensive set of query expansion terms. For instance, in the query prayer, terms like kabul (Word2Vec), berdoa (FastText), and panjat (GloVe) are harmonized to deliver results that are both contextually and semantically enriched. By mitigating the weaknesses of individual models and amplifying their strengths, the ensemble method significantly enhances the precision and recall of query expansion, establishing itself as a robust solution for semantically rich and context-sensitive domains like Quranic information retrieval.

In an effort to evaluate the effectiveness of the ensemble method in text-based Quranic information retrieval, a series of testing scenarios were designed to compare the performance of the ensemble method with non-ensemble approaches and conventional search methods. These testing scenarios use various key themes, such as prayer, zakat, fasting, umrah, prophets, angels, and the apocalypse. The selection of these themes aims to cover a broad spectrum of concepts, ranging from obligatory worship and attributes of faith to Islamic eschatology. Each theme reflects fundamental aspects of Quranic teachings, making the relevance of search results an

important indicator for evaluating the capabilities of the tested methods.

The testing was conducted by comparing three main approaches: ordinary search engines based on simple keyword matching, non-ensemble methods such as Word2Vec, FastText, and GloVe, which utilize single semantic models, and the ensemble method that integrates these three approaches. Each approach was evaluated based on the number of verses retrieved, the relevance of the verses to the searched themes, and the ability to capture deep semantic relationships between words in Quranic texts.

The test results are expected to provide a comprehensive overview of the strengths and limitations of each method while highlighting how the ensemble method can address existing challenges in religious text-based information retrieval. Through these testing scenarios, the research not only assesses technical performance but also evaluates the practical contributions of this approach in supporting more in-depth and data-driven Quranic studies.

TABLE II. PERFORMANCE COMPARISON

Topic	Ordinary Search Engine	Word2Vec	FastText	GloVe	Ensemble Method
Prayer	15 verse	20 verse	20 verse	20 verse	25 verse
Zakat	15 verse	20 verse	20 verse	20 verse	25 verse
Fasting	15 verse	20 verse	20 verse	20 verse	25 verse
Umroh	15 verse	20 verse	20 verse	20 verse	25 verse
Angels	15 verse	20 verse	20 verse	20 verse	25 verse

The evaluation of Quranic text retrieval was conducted using two distinct approaches: non-ensemble and ensemble methods. The non-ensemble approach employed three independent semantic models: Word2Vec, FastText, and GloVe. Each model generated 20 verses related to specific topics, including prayer, zakat, fasting, and other key themes in Quranic studies. The relevance of these verses was assessed based on their alignment with the intended topics. While effective, this approach relied on the individual strengths of each model, which varied in their ability to capture nuanced semantic relationships within the text.

In contrast, the ensemble method integrated the outputs of all three models, leveraging their unique strengths through a combined voting mechanism. This voting system prioritized two criteria: the frequency of verse appearances across models and their semantic relevance to the search topic. By synthesizing these factors, the ensemble method produced 25 verses per topic, surpassing the non-ensemble approach in both quantity and quality. The integration process not only enhanced the accuracy of the results but also ensured a broader contextual understanding of the Quranic themes.

A comparative analysis revealed the superiority of the ensemble method in terms of relevance. The ensemble approach achieved an average relevance rate of 88%, significantly outperforming individual models such as

Word2Vec (75%), FastText (80%), and GloVe (82%). This improvement highlights the ensemble's ability to refine results by filtering out less contextually appropriate verses and emphasizing those with a stronger semantic connection to the topics of interest. For instance, topics like prayer and zakat demonstrated up to a 10% increase in relevance, showcasing the method's practical impact on Quranic text retrieval.

The ensemble method's advantage lies in its ability to balance and optimize the unique capabilities of each model. Word2Vec excels in identifying general semantic relationships, making it effective for broader contextual analysis. FastText, on the other hand, is adept at capturing specific word variations and morphological nuances, which is particularly useful for processing Arabic text. GloVe contributes a global perspective by identifying relationships based on broader contextual patterns. By combining these strengths, the ensemble method mitigates the limitations of individual models, resulting in a more comprehensive and nuanced retrieval system.

In conclusion, the ensemble method provides a robust solution for Quranic text retrieval, addressing key challenges in semantic analysis and thematic alignment. Its ability to integrate multiple semantic models ensures a higher degree of accuracy, relevance, and contextual depth. This makes it a valuable tool for supporting in-depth Quranic studies and advancing the field of computational Islamic studies. By enhancing both the quantity and quality of retrieved verses, the ensemble method underscores its potential as a superior approach to text-based religious information retrieval.

Regarding to the implementation of ontology concept, it can be concluded that ontology-based systems show a marked improvement in Morals and Etiquette (Akhlak and Adab), where the contextual meanings related to moral behavior and Islamic ethics are effectively captured. Even with the use of diverse terminologies, relevant verses are identified with higher accuracy than conventional search techniques. This demonstrates the strength of ontology in understanding the semantic relationships between keywords and their deeper conceptual meanings. Similarly, ontology provides a more comprehensive understanding of The Qur'an, facilitating the identification of interconnected verses related to a specific theological subject, even in the absence of explicit word similarity. This ability underscores the ontology's strength in grasping the thematic structure of the Quran. The interface page for a search engine implementing ontology is illustrated in Fig. 3 below.

Fig. 3. Interface of ontology search engine.

Furthermore, in the theme of Previous Nations, ontology-based systems excel in contextualizing the stories of ancient peoples such as the 'Ad and Thamud, providing more accurate and relevant information. This is particularly useful in drawing parallels between historical events in the Quran and their relevance to contemporary contexts. Additionally, the use of ontology proves invaluable in legal topics such as Criminal Law (Jinayah) and Private Law, where it helps the system recognize verses discussing legal rules, both implicit and explicit. This capability is crucial for developing legal guidelines consistent with Sharia principles, while preserving the original meaning of the Quranic verses. In the realms of Worship and Knowledge, ontology effectively handles variations in expression and terminology, identifying relevant verses with high accuracy, thus aiding users in finding directed references for practices like prayer, fasting, and zakat, as well as verses related to knowledge and science.

In the same vein, ontology also significantly enhances the understanding of Faith and Jihad, enabling searches that not only focus on keyword matching but also delve into the core teachings related to devotion and struggle. Verses that might be overlooked in conventional methods are uncovered through semantic connections. Furthermore, in the fields of Transactions (Mu'amalat) and Judiciary and Judges, ontology-based approaches help detect the relationships between verses governing economic interactions and judicial decisions. This is crucial for the contemporary application of Sharia law, which often requires contextualization of verses to address modern issues. Lastly, in the topics of Food and Drink, Clothing and Adornment, and History, ontology aids in tracking relevant verses by capturing the nuances of varied terminology found across the Quran. This ensures a more accurate retrieval of information, particularly for concepts related to food, clothing, and significant historical events, offering a richer understanding of the Quranic text.

In conclusion, the ontology-based approach provides significant advantages in understanding and presenting relevant information, particularly for complex and interrelated topics. The success of this approach highlights the ability of semantic techniques to overcome the limitations of traditional keyword-based search methods, offering substantial value in Quranic research and modern implementations of the Quran. This methodology enriches the process of Quranic interpretation and application, supporting a more nuanced and contextually relevant engagement with the text.

V. CONCLUSION

The ensemble method demonstrated significant advantages in Quranic text retrieval, combining the strengths of Word2Vec, FastText, and GloVe to achieve higher relevance and accuracy compared to non-ensemble approaches. By leveraging a voting mechanism based on verse frequency and semantic relevance, the ensemble method effectively filtered and prioritized verses that aligned closely with specific themes, such as prayer and zakat. This approach not only improved the number of retrieved verses but also enhanced their semantic alignment with the topics of interest. The findings underscore the ensemble method's potential as a

superior solution for text-based Quranic studies, offering a robust framework for semantic analysis.

Despite its effectiveness, the ensemble method also highlighted areas that warrant further exploration. While it demonstrated improved performance in thematic relevance, the method's reliance on predefined themes and voting heuristics could be refined to accommodate more dynamic and complex queries. Additionally, the approach can benefit from integrating advanced deep learning techniques, such as transformers or contextual embeddings like BERT, which have proven effective in capturing deeper linguistic and semantic relationships. This could further enhance the precision and adaptability of Quranic text retrieval systems.

Future research could focus on expanding the scope of the ensemble method to address more diverse themes and complex queries beyond the predefined topics. Incorporating user feedback mechanisms and interactive retrieval systems could make the approach more practical and user-centric. Moreover, cross-linguistic studies that integrate translations of the Quran into other languages could broaden its applicability and support comparative Islamic studies. By exploring these directions, future research can build on the ensemble method's foundation to develop even more advanced tools for computational Quranic analysis and support a deeper understanding of Islamic teachings.

Abstract—Reinforcement Learning (RL) has become a rapidly advancing field inside Artificial Intelligence (AI) and self-sufficient structures, revolutionizing the manner in which machines analyze and make selections. Over the past few years, RL has advanced notably with the improvement of more sophisticated algorithms and methodologies that address increasingly complicated actual-world troubles. This progress has been driven by using enhancements in computational power, the availability of big datasets, and improvements in machine-getting strategies, permitting RL to address challenges across a wide range of industries, from robotics and autonomous driving system to healthcare and finance. The effect of RL is evident in its capacity to optimize selection-making procedures in unsure and dynamic environments. By getting to know from interactions with the environment, RL agents can make decisions that maximize lengthy-time period rewards, adapting to converting situations and enhancing over time. This adaptability has made RL an invaluable tool in situations wherein traditional approaches fall brief, especially in complicated, excessive-dimensional spaces and behind-schedule remarks. This review aims to offer radical information about the current nation of RL, highlighting its interdisciplinary contributions and how it shapes the destiny of AI and autonomous technologies. It discusses how RL affects improvements in robotics, natural language processing, and recreation while exploring its deployment's ethical and practical demanding situations. Additionally, it examines key research from numerous fields that have contributed to RL's development.

Keywords—Artificial intelligence; autonomous systems; decision-making optimization; reinforcement learning; robotics

I. INTRODUCTION

Machine Learning (ML) is primarily categorized into three main types, which are Supervised Learning, Unsupervised Learning, and Reinforcement Learning (RL) [1, 2]. The primary goal of RL is to allow machines to acquire knowledge beyond the constraints of supervised and unsupervised learning paradigms [3]. RL commonly employs a reward function as a training mechanism for agents tasked with specific objectives [4]. Unlike other ML paradigms that rely on labeled datasets, RL derives knowledge through direct interaction with the environment [5]. To make the RL result more effective, it is

very important to ensure communication between the agents and the environment [6].

Historically, RL has evolved from early work in behavioral psychology and control theory to become a fundamental tool in artificial intelligence and robotics. The foundational work of Kaelbling et al. (1996) and subsequent advances such as deep Q-networks from Mnih et al. (2015) have set the foundation for developments of RL in future [4, 7]. Hence, nowadays RL research ranges from autonomous robots to complex decision-making systems. For example, RL is able to play an important role in improving robot autonomy and flexibility, especially in tasks like manipulation and navigation [8]. In addition, RL has proven valuable in enhancing autonomous vehicle control, improving safety and optimizing transportation systems [9, 10]. The application of RL is not only limited to robotics, but also been applied in the semiconductor industry, where it can optimize processes such as physical design routing [11, 12].

In recent years, the combination of reinforcement learning and deep learning, which is also known as deep reinforcement learning (DRL) [13, 14, 15]. DRL has driven to breakthroughs in solving high-dimensional problems, especially in game-playing AI such as Alpha Go and autonomous systems [16, 17]. In addition, emerging trends nowadays include multi-agent reinforcement learning (MARL) which multiple agents learn and collaborate in a shared environment and also healthcare applications, where RL able to shows promise in personalized medicine and treatment planning [18, 19].

Furthermore, current RL research is more likely to focus on improving sample efficiency, safety, and scalability for real-world applications. It is very important to investigate new ways to integrate Reinforcement Learning with other machine learning paradigms to produce more adaptive and generalizable AI systems. This review will explore the development of RL, classification of RL method, and highlight its modern applications and future research directions. Moreover, this review also will discuss the research contributions from various fields to describe the current state of Reinforcement Learning and its potential to drive innovation in artificial intelligence and autonomous systems. The applications of RL are shown in Fig. 1.

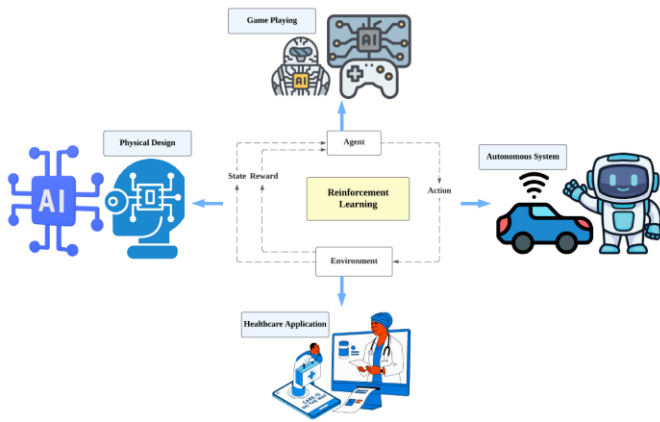

Fig. 1. Applications of reinforcement learning.

In this review, we have a look at the speedy improvement of RL and its developing applicability to complex, actual global troubles. We begin by exploring the evolution of RL techniques, from foundational strategies to advanced strategies consisting of Deep Reinforcement Learning and multi-agent systems. It also categorizes RL techniques, distinguishing between model-unfastened and model-based totally tactics, and highlights their respective strengths and barriers. Furthermore, we cover various RL programs across numerous domain names, including self-sustaining structures, robotics, healthcare, and synthetic intelligence. This exploration aims to offer a comprehensive understanding of the contemporary state of RL, its interdisciplinary contributions, and its potential to pressure destiny innovations in AI and self-reliant technologies.

II. EMERGING TRENDS OF REINFORCEMENT LEARNING EVOLUTION

The evolution of Reinforcement Learning (RL) is based in multiple foundational fields, which include behavioral psychology, trial-and-error learning, optimal control theory and dynamic programming. These parallel developments have provided the foundation for modern RL and shaping its principles and algorithms.

A. Behavioural Psychology and Trial-and-Error Learning

The earliest roots of Reinforcement Learning (RL) can be traced to behavioral psychology, specifically the works of Edward Thorndike and B.F. Skinner before the timeframe of 1960s [20, 21, 22]. Thorndike's Law of Effect introduced the concept of learning from the consequences of actions, where actions followed by satisfying outcomes are more likely to be repeated [20, 23]. This was the basis for trial-and-error learning, which is one of the important aspects of RL, where an agent explores different actions and adapts its behavior based on rewards or punishment. Furthermore, B.F. Skinner demonstrated that operant behavior can be shaped through reinforcement mechanisms, which highlighted the importance of rewards and punishments in learning [24]. This psychological perspective shows the foundation for how RL agents learn to optimize their actions by maximizing rewards or minimizing punishment.

B. Optimal Control Theory

During the mid-20th century, there were major advances in optimal control theory, especially in the field of engineering [25]. Control theory usually focuses on designing controllers that can guide dynamic systems to perform specific tasks in an optimal manner. The Bellman equations which were proposed by Richard Bellman in 1957 became central to this optimal control framework [26], [27], [28]. This work on dynamic programming provided a way to decompose complex decision problems into simpler subproblems, which enables the computation of optimal policies in environments with known dynamics and become a foundation for RL. Hence, Richard Bellman's work directly influenced by introducing the concept of a value function and estimates the expected future reward of being in a particular state and taking a particular action. This concept is basic for the RL algorithms such as Q-learning and value iteration [29].

C. Dynamic Programming and Modern Developments

From the foundation of Bellman's dynamic programming as mentioned, Ronald Howard introduced Markov decision processes (MDP) which is a mathematical framework for modeling decisions in environments where outcomes are partially random and partially controlled by the decision maker [30]. The formalization of MDP set the foundation for modern RL algorithms, as it represents the interaction between an agent and its environment, where the agent seeks to maximize a cumulative reward over time, positive rewards are awarded for favorable actions, while negative rewards or punishments are assigned for undesirable actions. These reward mechanisms are used as evaluative feedback and enable the agent to assess its actions within a specific state and learn from accumulated experiences. However, dynamic programming methods require information or knowledge of the dynamics of the environment, this disadvantage limits its applicability to real world problems. This gap flattens the way for RL techniques. For example, the model-free learning which will be discussed in next section, where an agent can learn optimal policies directly from interactions with the environment without required the knowledge of its dynamics.

Around the 1980s, RL emerged as a distinct field. For example, Sutton introduced temporal difference (TD) learning which is one of the key innovations that enabled agents to learn value functions from incomplete trajectories, rather than waiting until the end of an episode [31]. Furthermore, Watkins further advanced RL by allowing agents to directly learn action-value functions without the requirement for explicit models of the environment [32].

D. Deep Reinforcement Learning (DRL) Revolution

In the 2010s, the combination of Deep Learning (DL) and Reinforcement Learning (RL) which is known as Deep Reinforcement Learning (DRL) revolutionized the field again. In 2015, Google DeepMind researchers introduced the Deep Q Network (DQN) in 2015, which enabled reinforcement learning agents to handle complex tasks such as Atari 2600 games by using deep neural networks to approximate value functions [4]. This research highlighted the scalability of RL in higher dimensional state spaces and lead to major achievements such as the success of AlphaGo, which defeated

the one of the world champions of Go Lee Se-dol by using a combination of RL and DL [33].

E. Emerging Trends and Future Directions

Recent trends in Reinforcement Learning (RL) focus on improving sample efficiency, safety and scalability for real-world applications [34, 35]. New RL techniques such as Multi-agent Reinforcement Learning (MARL), hierarchical reinforcement learning and transfer learning are being explored to solve the issue of complex multi-agent environments where multiple agents learn collaboratively at the same time [18, 36, 37, 38]. In addition, RL can also be applied in more applications in different areas such as robotics, healthcare, finance and autonomous systems. The timeline of key evolution in RL development is shown in Fig. 2.

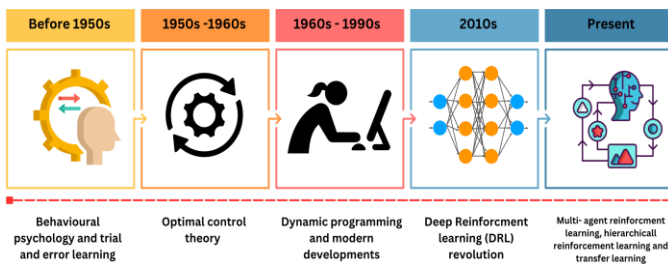

Fig. 2. Timeline of key evolution in RL development.

III. TAXONOMY AND CRITERIA OF REINFORCEMENT LEARNING

Reinforcement Learning (RL) techniques are primarily classified into Model-Based and Model-Free approaches within the framework of Markov Decision Processes (MDP). Model-based RL is further categorized into Given-the-Model and Learn-the-Model techniques. Meanwhile, Model-Free RL is subdivided into on-policy and off-policy approaches, which are discussed in the subsequent sections. In addition, value-based and policy-based approaches also have been discussed in this paper. The overview of RL classification is shown in Fig. 3.

Fig. 3. Overview of reinforcement learning classification.

A. Model-based and Model-Free

Reinforcement Learning (RL) typically demands a substantial amount of data to attain satisfactory performance levels. This section will primarily focus on two types of RL algorithms which include model-free and model-based [39, 40]. Generally, model-free RL algorithms are considered as a direct approach, while model-based RL algorithms are viewed as an indirect method [41].

Model-free RL algorithms aim to learn a policy or value

function without explicitly constructing a model of the control system [42]. In contrast, model-based RL algorithms not only learn a value and policy function but also simultaneously construct an explicit model of the system [7]. There are two well-known model-free RL algorithms which are Q-Learning and Deep Q-Networks (DQN), where the agent learns value functions that estimate the expected cumulative rewards for each action in each state [4, 43, 44]. Based on the research conducted by Atkeson and Santamaria, a comparative study was undertaken using a linear double integrator movement task to assess data efficiency, the research findings indicate that the model-based RL algorithms surpass the model-free RL algorithms in terms of data efficiency [45].

In addition, the model-free RL algorithms do not train a model of the environment and aim to directly assign values to states or state-action [46, 47]. The agent directly interacts with the environment and enhances its performance based on the collected samples through exploration. It is easier to implement as they do not require explicit modeling of the environment but might be a problem that is hard to learn. However, model-free RL algorithms are usually hard to implement in real-world scenarios due to the time consumption and the cost [48]. This model-based RL is usually more suitable for large, complex environments but suffers from sample inefficiency as the agent learns only through interactions with the environment.

The advantage of a model-based RL algorithm includes its ability to predict future states and rewards through the explicit modelling of the environment [48, 49]. This will help the agent in making better planning and incorporating strategies like pure planning and expert iterations [50]. In model-based RL, the agent can simulate possible scenarios and plan its actions accordingly. However, model-based RL algorithms come with few disadvantages. One of the major challenges of model-based RL is that the model often depends on the accuracy of the transition model, it means that inaccurate models can lead to domain shift and poor performance [49, 51, 52, 53]. For model-based RL, developing and maintaining an accurate model of the environment can be complex and resource-intensive. Besides, the learned models may be inaccurate in practical scenarios, introducing bias in estimation [51]. When policy estimation and improvement are based on a biased model, the resulting policies may prove ineffective or even collapse when applied in the real environment. Hence, model-based methods often require significant computational cost for model learning and policy optimization hence it is limited application in real-world situations [54]. Lastly, model-based RL algorithms have the capacity to predict unexpected actions and states, which also provides a more controlled learning process.

In summary, model-free RL algorithms learn through exploration, whereas model-based RL algorithms learn by simulating scenarios [41]. The slight difference between model-based RL and model-free is shown in Fig. 4. In addition, the summary of the distinctions between Model-Based and Model-Free Reinforcement Learning (RL) algorithms is also shown in Table I.

Fig. 4. Difference between model-based and model-free RL.

TABLE I. SUMMARY OF THE DISTINCTIONS BETWEEN MODEL-BASED AND MODEL-FREE RL ALGORITHMS

Category	Model-Based	Model-Free
Learning Type	Indirect method	Direct method
Objective	Learns value, and policy functions and constructs an explicit model of the system	Learns policy or value function without explicit model construction
Data Efficiency	Outperforms in terms of data efficiency	May demand substantial data for satisfactory performance
Implementation	Challenging in real-world scenarios due to complexity and cost	Easier implementation, no explicit modelling required
Environment Interaction	Predict future states and rewards through explicit environment modelling	Direct interaction, enhances performance through exploration
Challenges	Complex model construction may introduce bias for learned models	Hard to learn complex problems in real-world scenarios
Applicability to Real World	Balancing model accuracy and real-world complexity is a significant challenge	Hard to implement due to time and cost constraints

B. Model-based: Given the Model and Learn the Model

The algorithms that use models are called model-based methods. In model-based Reinforcement Learning (RL), given-the-model and learn-the-model are two main types of approaches [48]. One of the examples of the given-the-model is the AlphaGo algorithm [16]. In this algorithm, AlphaGo is explicitly learned the rules of the board game and can be described using coding or computer language. Then, the transitions and rewards are known to the agent, which allows for the evaluation of different strategies through trial and error to get optimal results and iteratively improve the policy. This approach shows that a pre-determined model of the environment to guide the learning process and enhance the decision-making. For another example, the Monte Carlo Tree Search (MCTS) algorithm can be using a given model to simulate possible future states and evaluate action sequences for optimal planning [55].

Moreover, an example of the "learn the model" category in model-based Reinforcement Learning is the World Models algorithm [56]. One of the examples for learn the model approach is DreamerV2 [57]. DreamerV2 builds an internal world model of the environment by learning from its experiences, which can allow the agent to simulate trajectories in its "imagination" rather than only rely on real-world

interactions. This can cause the agent to explore and learn optimal policies more efficiently, as it can try out different actions and observe hypothetical outcomes within its model, thus significantly reducing the need for real-world samples. Another example is Probabilistic Ensembles with Trajectory Sampling (PETS), which use the models to predict possible future states with uncertainties included [58]. PETS uses these learned dynamics to perform planning and action selection then helping the agent to handle uncertainty and make more robust decisions in those unpredictable environments. This approach allows the agent to improve sample efficiency by using imagined rollouts for planning while adapting to changes in real-world scenarios. The comparison of "Given-the-Model" and "Learn-the-Model" in model-based RL is shown in Table II.

TABLE II. COMPARISON BETWEEN "GIVEN THE MODEL" AND "LEARN THE MODEL"

Category	Given the Model	Learn the Model
Learning Type	Uses an explicitly specified model of the environment	Learns a model of the environment from gathered data
Decision-Making	Enhances decision-making through trial and error	Optimizes policies by leveraging insights from the model
Advantages	1. Allows for the evaluation of different strategies 2. Facilitates iterative improvement of the policy	1. Adapts to complex and unknown environments 2. Can generalize to various scenarios
Disadvantages	1. Require explicit specification of the environment 2. Limited adaptability with unforeseen changes	1. Require extensive data for accurate model learning 2. Complexity in training and interpreting the learned model

C. Model-Free: On-Policy and Off-Policy

Model-free Reinforcement Learning (RL) is typically categorized into on-policy and off-policy approaches [48, 41]. The on-policy approach strives to enhance and learn through the policy itself which is used for decision-making [59]. For the on-policy approach, the agent itself interacts with the environment, and the policy to interact with the environment and the improved policy remain the same. According to Singh et al.'s (2000) study, this policy algorithm could be more stringent because the updating of the value function is contingent on the experiences gained from implementing the policy [60].

On the other hand, the off-policy approach aims to improve a policy that is different from the one that is used to generate the data [48]. Unlike the on-policy approach, the off-policy approach does not require the same agent that interacts with the environment. The experiences of other agents interacting with the environment can also be utilized to enhance the policy. When the agent learns the behavior in one way is called the target policy, while when it is learned using data generated by another policy is known as the behavior policy [61]. In addition, the agent learns from data generated by a behavior policy that might be explored more widely than the target policy, which allows for more efficient learning. This flexibility allows for more diverse data sources to contribute to

the policy improvement process. In Fakoore et al. (2020) research, it is noted that off-policy methods encounter bias issues as the data from an outdated policy differs from the current policy, making it unsuitable to update the current policy's value function using old data [62]. On the other hand, on-policy methods avoid bias but may face variance challenges, tending to be more data-efficient as they focus on the current samples.

One of the examples of an on-policy approach is SARSA State-Action-Reward-State-Action (SARSA) [41, 48]. In the SARSA algorithm, an action is selected based on the current policy and executed. Then, the data is utilized to update the current policy. In the on-policy setting, the policy that interacts with the environment is the same as the updated policy, which ensures consistency between the policy used during interaction and the one that is improved. The SARSA update function is shown below:

$$Q\{S(t),A(t)\} \leftarrow Q\{S(t),A(t)\} + \alpha\{Q\{S(t+1),A(t+1)\} - Q\{S(t),A(t)\}\} \quad (1)$$

In this equation,

- $Q\{S(t),A(t)\}$ represents the Q-value for the state action pair at time t
- α is the learning rate
- $Q\{S(t+1),A(t+1)\}$ is the Q value for the next state action pair at time $t + 1$

This updated function shows how SARSA adjusts the Q-values based on the observed rewards and transitions, which also continues to refine the policy in an on-policy manner. In the off-policy category, one of the examples is Q-learning, which employs the max operation and a greedy policy when selecting actions [41, 43, 48]. In addition, Q-learning involves updating a policy that interacts with the environment and the updated policy which is not necessarily the same as the policy used during interaction.

The Q-learning update function is shown below:

$$Q\{S(t),A(t)\} \leftarrow Q\{S(t),A(t)\} + \alpha[R(t+1) + \gamma \max_{\alpha} Q\{S(t+1),A(t+1)\} - Q\{S(t),A(t)\}] \quad (2)$$

In this equation,

- $Q\{S(t),A(t)\}$ represents the Q-value for the state action pair at time t
- α is the learning rate
- $R(t+1)$ is the reward at time $t + 1$
- γ is the discount reward
- $\max_{\alpha} Q\{S(t+1),A(t+1)\}$ is the maximum Q value for the next state $S(t+1)$

The function above also reflects how Q-learning iteratively refines the Q values based on the observed rewards and transitions and improves the policy over time. The comparison between "On-Policy" and "Off-Policy" in model-free RL is shown in Table III.

TABLE III. SUMMARY OF THE COMPARISON BETWEEN "ON-POLICY" AND "OFF-POLICY"

Category	Given the Model	Learn the Model
Learning Type	The agent learns through the policy used for decision-making.	Aims to improve a policy different from the data-generating policy.
Environment Interaction	The agent interacts with the environment using the policy.	Doesn't require the same agent to interact and data from other agents can be used (shared).
Consistency	The policy used during interaction and improved policy are the same.	Involves a target policy (learned) and a behavior policy (data-generating).
Flexibility	Limited by the exploration of the current policy.	Learns from data generated by a behavior policy that may be explored more widely.

D. Value-based Approach and Policy-based Approach

The value-based approach typically involves learning the value function through methods such as Temporal difference (TD) learning, Q-Learning, or Deep Q-Network (DQN) [63, 64, 65, 66]. This technique aims to identify the optimal action to take and the action under this approach tends to be deterministic, such that they are chosen with a clear understanding of consequences. The value function operates by working backward from the target state and attributing rewards to the preceding state. This approach can be helped in the selection of only one action that leads towards achieving the desired outcome and closer to the goal [65]. In summary, it involves a strategic evaluation of the value of actions to make informed decisions and optimize the learning process.

In contrast to the value-based approach, the policy-based approach focuses on learning the conditional probability π of a policy through techniques such as the policy gradient method [67]. Instead of obtaining a value function like mentioned above, this approach directly determines the policy. Due to the stochastic action probability, the policy-based approach is more suitable for the application with large and continuous action [65]. At the same time, action selection becomes probabilistic with actions chosen based on their likelihood of efficiently reaching the desired outcome as dictated by the learned policy.

IV. THE ADVANCEMENT OF REINFORCEMENT LEARNING APPROACHES

In recent years, Reinforcement Learning (RL) has been improving with a fast pace and developed advanced approaches for increasingly complex problems in the real world. This review would like to focus on Deep Reinforcement Learning, Hierarchical Reinforcement Learning, Multi-Agent Reinforcement Learning and Hybrid Model Based Reinforcement Learning. These approaches have expanded the range of high dimensional RL applications, multi-agent applications, hierarchical decision-making applications and optimal policies or strategies by a combination of model based and model free methods.

A. Deep Reinforcement Learning (DRL)

Deep Reinforcement Learning (DRL) combines Reinforcement Learning (RL) and deep learning to enable agents to learn optimal policies for decision-making tasks through trial and error [14, 15, 68, 69]. The DRL is known for utilizing the principle of RL with the theory of deep learning to facilitating those automatic extractions of features from the input and benefits for in the fields such as robotic, autonomous driving and video games [14, 70, 71].

One of the achievements in DRL was the development of Deep Q Network (DQN) by work of Mnih et al. (2015), which shows the human level performance on Atari games using raw pixel inputs. The DQN uses the convolutional network to approximate the Q value function, which trained using variant of Q-learning with experience and target network to stabilize training [4]. Subsequently, Schulman et al. (2015) have introduced the Trust Region Policy Optimization (TRPO), which addressing the not stable and inefficiency of policy gradient methods. TRPO ensures monotonic improvement by optimizing objective function subject to a trust region constraint and make it more stable and reliable training [13, 72]. Further refinement came with the Proximal Policy Optimization (PPO) work by Schuman et al. (2017), which simplified the algorithm and enhanced computational efficiency by using clipped objective to balance exploration and exploitation effectively [73]. Lillicrap et al. (2015) have also extended the actor-critic framework to continuous action spaces with the Deep Deterministic Policy Gradient (DDPG) algorithm. DDPG will employ the actor network to parametrize the policy and network to estimate the Q- value function which enabling the application of DRL such as robotic control task [74].

In addition, Kostrikov et al. (2021) proposed the Implicit Q-learning (IQL) algorithm, which is an offline Reinforcement Learning method that avoids evaluating unseen actions, thereby mitigating errors from distributional shift. By leveraging state-value functions as random variables and conditionally using the expected value of the state, IQL can improve the policy without directly querying actions from the distribution [75]. On other hand, Chen et al. (2022) have also proposed the DreamerV2 algorithm, which builds on the Dreamer framework by incorporating discrete latent variables and advanced world model. It is also able to demonstrate a similar performance on Atari benchmark with efficient performance [76]. Sekar et al. (2020) introduced the Plan2Explore algorithm, which emphasizes intrinsic exploration by using a self-supervised world model to plan for expected future novelty, enabling the agent to efficiently explore and quickly adapt to multiple downstream tasks [77].

In summary, the advancement of DRL has revolutionized the fields of RL by enabling the agents to learn from high dimensional inputs to perform complex tasks. The new algorithms such as DQN, TRPO, PPO, DDPG, IQL, DreamerV2 and Plan2Explore have advanced the application of RL in different fields including gaming, robotics and autonomous systems. As research in DRL continues to focus, the efficiency, stability and generalization of RL will have further improvement. Fig. 5 provides a schematic illustration of DQN and Plan2Explore, presented as a case study in DRL.

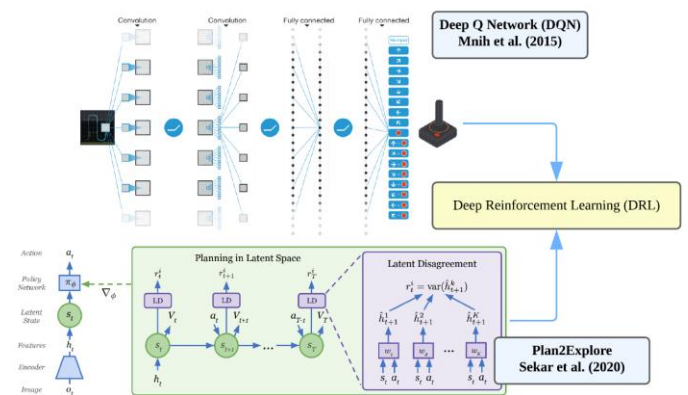

Fig. 5. Schematic illustration of Deep Q-Network (DQN) and Plan2Explore. [4, 77].

B. Hierarchical Reinforcement Learning (HRL)

Hierarchical Reinforcement Learning (HRL) is one of the approaches in Reinforcement Learning fields that able to addresses the challenges faced by traditional Reinforcement Learning method which include scalability and efficiency with the tasks that required long term planning [37, 78, 79]. HRL is able to solve these problems by decomposing them into hierarchy of subs tasks [37, 80]. The core idea of HRL can be described as hierarchical structure where higher level policies select sub tasks and lower level policies execute actions to achieve the goal of subs task.

One of the foundational works in HRL is Feudal Reinforcement Learning (FRL) by Dayan and Hinton (1992) which introduced a hierarchical structure where higher level manager set goals for lower level workers [81]. Each hierarchical level operates in different temporal and spatial resolution, allowing the agent to decompose complex tasks into simpler sub-tasks. In addition, another early work in HRL is the Options framework introduced by Sutton et al. (1999), this framework introduces the concept of options, which temporarily extended actions that consists of policy, termination conditions and initiation set [82]. These options can allow the agents to operate at different time scales and make the learning more efficient. Moreover, the more recent advancements in HRL include the Hierarchical-DQN (h-DQN) framework, which extends the DQN algorithm by incorporating hierarchical structure. The h-DQN framework consists of meta-controller that selects sub-goals and lower level controller which learns to achieve the sub goals using DQN, be able to apply to Atari games and navigating 3D environments [83]. The Options-Critic architecture by Bacon et al. (2017) provides a framework for learning both options and policies over options in end-to-end manner, the architecture introduces intra-option policy gradient methods to optimize the policies within options and termination conditions [84].

Furthermore, Vezhnevets et al. (2016) proposed the Strategic Attentive Writer (STRAW) framework, which is a deep recurrent neural network (RNN) architecture that capable learning macro-actions in a Reinforcement Learning setting. The model builds an internal plan and partitions it into sub-sequences then allowing the agent to commit to a plan for a period before replanning. This approach allowed the agent to

explore and compute efficiently across different tasks [85]. The Hierarchical Reinforcement Learning with Off-policy correction (HIRO) algorithm introduced by Nachum et al. (2018) addresses the challenges of non-stationarity in HRL by introducing an off-policy correction mechanism, enabling stable and efficient learning of hierarchical policies [79]. Levy et al. (2019) introduced the Hierarchical Actor-Critic (HAC) algorithm, which extends the actor-critic framework to a hierarchical setting by enabling agents to operate at multiple levels of abstraction simultaneously [86].

Recent developments after 2020 in HRL have further expanded, The Hierarchical Variational Autoencoder (HVAE) framework introduced by Bai et al. (2023) combines probabilistic generative models with deep neural networks to learn hierarchical topic representations for multi-view text documents. HVAE captures both local and global topical information, enabling efficient modelling of complex document structures [87]. The Hierarchical Deep Reinforcement Learning with Automatic Sub-Goal Identification via Computer Vision (HADS) by Liu et al. (2021) introduces a sub-goal generation mechanism that adapts to the agent’s learning progress, applied to tasks such as game manipulation and navigation [88]. The Hierarchical Deep Reinforcement Learning with Graph Neural Networks (HRLOrch) introduced by Li & Zhu (2021) uses graph neural networks to model the hierarchical structure of the environment at multiple levels of abstraction [89].

In summary, HRL has significantly advanced the RL field by mainly enabling the agents to decompose complex tasks to simpler sub-tasks, hence cause the learning and planning more efficiently. The development of HRL frameworks including Options framework, FRL, h-DQN, Option-Critic, STRAW, HIRO, HAC, HVAE, HADS and HRLOrch, which further improves in terms of efficiency, stability and generalization capabilities. The schematic illustration of h-DQN, STRAW and HRLOrch is shown in Fig. 6.

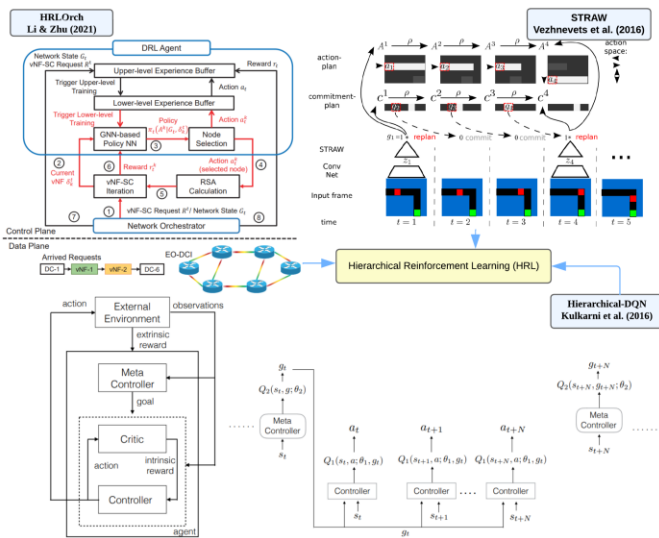

Fig. 6. Schematic illustration of h-DQN, STRAW and HRLOrch [83, 85, 89].

C. Multi-Agent Reinforcement Learning (MARL)

Multi-Agent Reinforcement Learning (MARL) is one of the specialized areas in Reinforcement Learning (RL) that focuses on the environment where multiple agents interact (not limited to number of environments), each aiming to optimize the performance while considering the presence and actions of other agents [18, 90, 91, 92]. Unlike single agent, each agent in MARL has its own goal, which may involve cooperation, competition or a mix of both, hence the environment is non-stationary from the perspective of each agent because other agents are also learning and changing their policies [93, 94].

One of the significant advancements in MARL is the Differentiable Inter-Agent Learning (DIAL) algorithm by Foerster et al. (2016), which uses differentiable communication channels to enable end-to-end training of communication policies, allowing agents to learn to communicate more effectively [95]. In addition, Lowe et al. (2017) introduced the Multi-Agent Deep Deterministic Policy Gradient (MADDPG) algorithm, which uses centralized training to gather global information while employing decentralized execution for deployment. Each agent has its own policy and critic, but the critics have access to the global state and actions of all other agents during training, making the training process more stable and effective [96].

For more recent advancements in MARL, Iqbal and Sha (2019) introduced the Actor-Attention-Critic (AAC) framework, which uses an attention mechanism to focus on relevant parts of the environment and other agents’ actions [97]. This framework enhances the scalability and performance of MARL algorithms in more complex environments. In addition, Rashid et al., 2020 proposed the QMIX algorithm, which decomposes the joint action-value function into a monotonic combination of individual value functions for agents, enabling efficient coordination in cooperative tasks [98]. Yu et al. (2022) introduced Multi-Agent Proximal Policy Optimization (MAPPO), an extension of the PPO algorithm for multi-agent settings. MAPPO employs centralized training with decentralized execution to address cooperative and complex tasks, achieving performance comparable to off-policy methods like MADDPG [99].

Furthermore, Carta et al. (2021) proposed an ensemble approach using multiple Deep Q-learning (Multi-DQN) agents to enhance stock market forecasting by training several agents on the same data and aggregating their decisions [100]. Zhang et al. (2022) introduced the Multi-Agent Graph Convolutional Reinforcement Learning (MAGC) framework, which employs graph neural networks to model the interactions between agents. MAGC enables agents to learn and coordinate their actions more effectively by capturing the relational structures of the environment, and it is applied to tasks such as dynamic electric vehicle charging pricing [36]. In summary, the development of MARL frameworks including DIAL, MADDPG, AAC, QMIX, MAPPO, Multi-DQN and MAGC further advanced the field of RL through the multi agent systems. Examples of schematic illustrations of Multi-DQN and MADDPG are shown in Fig. 7.

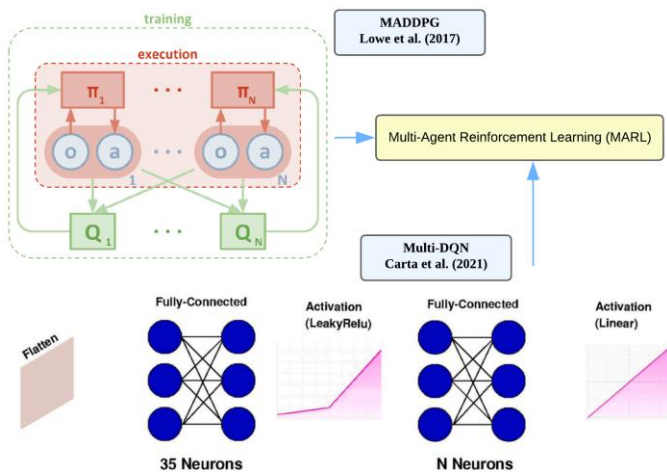

Fig. 7. Schematic illustration of multi-DQN and MADDPG [96, 100].

D. Model-Based Reinforcement Learning (MBRL)

Model-Based Reinforcement Learning (MBRL) is one of the approaches in Reinforcement Learning (RL) field that focuses on building models of environment to improve learning and decision-making effectiveness for gaming and robotic tasks [49, 101, 102]. The difference between model-based and model-free was discussed in previous section Model-Based and Model-Free. The core idea of MBRL is mainly decompose the objective into two main component which are model learning and planning, model learning includes environment's transition dynamics and reward function while planning uses the learned model to simulate future reward [102].

The Dyna framework that introduced by Sutton (1991) is one of the earliest works in MBRL, which integrates model learning and planning by combined real world interactions and simulated experiences generated by learned model, it allows the agent to update policy using real and synthetic data [103]. In addition, Delsensor & Rasmussen (2011) have proposed the Probabilistic Inference for Learning Control (PILCO) algorithm which is one type of model-based approach that uses Gaussian processes to model the environment's dynamics [104]. Nagabandi et al. (2018) introduced a model-based RL approach using neural network dynamics (MBRL-NN). This method employs deep neural networks to model the environment's transitions and combines them with model predictive control (MPC) for planning [105].

Furthermore, Ha and Schmidhuber (2018) proposed the World Models framework, which learns a compact, latent representation of the environment using a Variational Autoencoder (VAE) and a Recurrent Neural Network (RNN).

The agent plans and acts within this learned model, achieving good results on tasks in CarRacing-v0 and VizDoom [56]. The Probabilistic Ensembles with Trajectory Sampling (PETS) algorithm addresses model uncertainty in Model-based Reinforcement Learning (MBRL) by using an ensemble of probabilistic neural networks to model environment dynamics and trajectory sampling to account for uncertainty [58]. Moreover, Janner et al. (2019) introduced Model-Based Policy Optimization (MBPO), which integrates model-based and model-free approaches to improve sample efficiency. MBPO utilizes an ensemble of probabilistic neural networks to model the environment dynamics and conducts policy optimization within this learned model [106].

In recent years, Schrittwieser et al. (2020) proposed MuZero, a model-based RL algorithm that learns a model of the environment's dynamics and uses it for planning without requiring prior knowledge of the environment. MuZero achieves state-of-the-art performance in Atari, Go, chess, and shogi, demonstrating the benefits of combining model-based planning with model-free learning [107]. Similar with Deep Reinforcement Learning (DRL), the DreamerV2, MuZero and Plan2Explore algorithm also consider advancement for MBRL which expanded the application of MBRL to wider range of field. In summary, the introduction of Dyna, PILCO, MBRL-NN, World Models, PETS, MBPO and MuZero framework have advanced the field of RL and improved in terms of learning and decision-making. Schematic illustration of PETS and MuZero are shown in Fig. 8, which shows how the model plans and communicates with environments. The summary and comparative analysis of advanced Reinforcement Learning (RL) approaches is shown in Table IV.

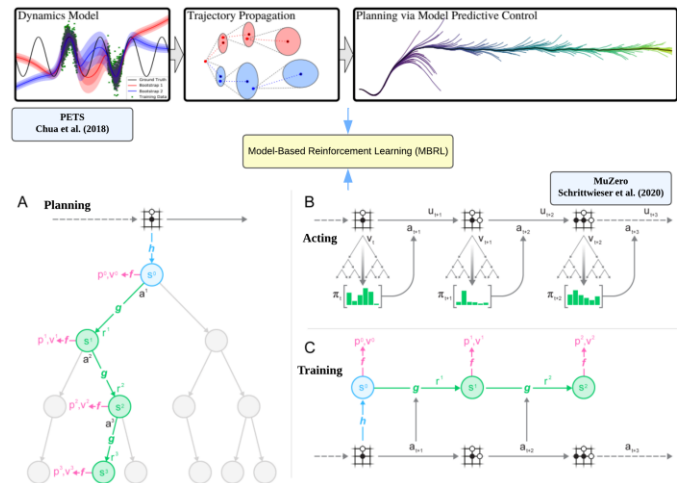

Fig. 8. Schematic illustration of PETS and MuZero [58, 107].

TABLE IV. SUMMARY AND COMPARATIVE ANALYSIS OF ADVANCED REINFORCEMENT LEARNING (RL) APPROACHES

Category	Framework	Key Contributions	Author & Year
Deep Reinforcement Learning (DRL)	Deep Q Network (DQN)	Approximates Q-value function using CNN, stabilizes training with experience replay and target networks.	Mnih et al., 2015
	Trust Region Policy Optimization (TRPO)	Ensures stable training via trust region constraints.	Schulman et al., 2015
	Proximal Policy Optimization (PPO)	Simplified policy gradient method with a clipped objective for efficiency.	Schulman et al., 2017

Category	Framework	Key Contributions	Author & Year
	Deep Deterministic Policy Gradient (DDPG)	Extends actor-critic framework to continuous action spaces.	Lillicrap et al., 2015
	Implicit Q-Learning (IQL)	Mitigates distributional shift errors in offline RL by using state-value functions as random variables.	Kostrikov et al., 2021
	DreamerV2	Combines latent variables with world models for efficient decision-making.	Chen et al., 2022

V. CHALLENGES AND ALTERNATIVE SOLUTIONS

Although Reinforcement Learning (RL) has its effectiveness in a wide range of applications, it still faces significant challenges that limit the efficiency, scalability, and

real-world applicability. The main key challenges include sample inefficiency, exploration-exploitation dilemma, and difficulties with generalization across different tasks and environments. Hence, there is much research that proposed new approaches to improve the adaptability and efficiency of

RL agents such as curiosity-driven exploration, meta-learning, and transfer learning.

One of the important challenges in RL is sample inefficiency as mentioned, where agents require large amount of interaction with the environment to learn effective policies. For example, in complex tasks such as involving high dimensional state space or continuous actions space, RL methods usually required more time to converge to optimal solutions. For the sample inefficiency challenges, several solutions have been proposed. For instance, the work of Janner et al. (2019) have proposed an RL algorithm Model-Based Policy Optimization (MBPO) which uses short model-generated rollouts to improve sample efficiency and performance as mentioned [106]. In addition, Soft Actor-Critic (SAC) which an off-policy actor-critic algorithm based on maximum entropy RL can be used to maximize both expected reward and entropy, it also able to be enabling agents to learn from data collected under different policies [108]. Not only that, Deep Q-Networks (DQN) also can be used to store and reuse past experiences or learning, this can reduce the need for time required and samples in each iteration [13].

In addition, one of another challenges in RL are exploration-exploitation dilemma, in which an agent must balance between exploring new environment then found the highest beneficial actions and exploiting known actions that produce high rewards. Poor exploration strategies can lead to suboptimal strategies, especially in environments where reward signals are delayed or require a long time such as in physical design. Therefore, several solutions have been proposed for solving this issue. One of the solutions is curiosity-driven exploration which to explores using curiosity as an intrinsic reward signal for agents in environments with sparse or no extrinsic rewards which curiosity is defined as the error in predicting the consequences of the agent's actions in a visual feature space [109]. In addition, curiosity-driven exploration is important for autonomous learning, highlighting various algorithmic models that capture different aspects of this process [110]. Moreover, entropy regularization also can be used to address the exploration-exploitation dilemma by introducing f-divergence penalties [111]. These penalties

ensure that the policy does not deviate too much from the current policy, promoting balanced exploration and exploitation. By adjusting the divergence function, the agent can control the trade-off between exploring new actions and exploiting known rewarding actions, this can lead to more stable and efficient learning dynamics.

Furthermore, another challenge is difficulties with generalization, where generalization in RL refers to the ability of an agent to still perform well in new or unseen environments [112, 113]. This is due to RL models often overfitting to specific environments during training, leading to a decline in performance when faced with new or unseen scenarios. This issue is a serious problem for real-world applications such as autonomous driving, where the agent is required to handle various scenarios under different conditions [115]. In order to solve this problem, the model agnostic meta learning (MAML) approach can be applied to enable agents more quickly adapt to new tasks by learning from distribution of related tasks during the training phase [115, 116, 117]. This approach can make the agent more robust and adaptable in unfamiliar environments. In addition, transfer learning also can be applied to transfer the knowledge to another related task to reducing the training data needed in new environment [118, 119] This will be more useful when the training in the target environment is costly such as required more memory space. Moreover, domain randomization also can help to improve the generalization issue by training the agents in varying the parameters, so that the agents can be handle the real-world variability more effectively and more adaptable to new, unseen environments [120].

In summary, the purpose of artificial intelligence (AI) including RL is not to replace humans, AI is designed to enhance human efficiency and achieve better outcomes. Humans are required to treat it as a tool to increase efficiency, streamline workflows, and assist in decision-making processes. However, it is also very important to ensure that AI technologies are applied properly to maximize the potential benefits and minimize the risk of misuse or unintended consequences. The summary of alternative methods and their potential benefits is shown in Table V.

TABLE V. SUMMARY OF ALTERNATIVE METHODS AND POTENTIAL BENEFITS

Alternative Method	Challenges	Key Feature	Potential Benefits
Model-Based Policy Optimization (MBPO)	Sample Efficiency	Use short model-generated rollouts	Increases sample efficiency
Soft Actor-Critic (SAC)	Sample Efficiency	Agents can learn from data collected under different policies	Maximize both expected reward and entropy and purpose to increase sample efficiency
Curiosity-Driven Exploration	Exploration-Exploitation Dilemma	Use intrinsic rewards based on novelty	Enhances the exploration in sparse reward environments
Entropy Regularization	Exploration-Exploitation Dilemma	Maintains randomness in policy by penalizing determinism	Promotes continued exploration during training
Meta-Learning	Generalization	Learns to adapt quickly to new tasks from experiences	Improves adaptability and efficiency across tasks
Transfer Learning	Generalization	Transfers knowledge from one task to another task	Reduces training time and data requirements
Domain Randomization	Generalization	Trains in a different of simulated environments	Improves robustness to different of environments

VI. CONCLUSION AND OUTLOOK

In conclusion, the evolutions of Reinforcement Learning has successfully impacted the different fields from robotics and autonomous driving system, healthcare and finance. The integration of RL with different approach can further advanced the application, for example the integration of deep learning and RL which known as Deep Reinforcement Learning (DRL) has improved in solving the high dimensional problem and applied in AlphaGo.

In addition, the focus of RL is mainly improving the sample efficiency, safety and scalability for real world applications. The innovations in hierarchical Reinforcement Learning, transfer learning and domain randomization are expected to improve the adaptability and generalizability of RL systems. In summary, as increasing more effort in improving RL, it will play an important role in artificial intelligence and autonomous technologies which will help humans for more complex challenges in daily life.

Abstract—This study introduces a novel approach to traffic congestion detection using Reinforcement Learning (RL) of machine learning classifiers enhanced by Explainable Artificial Intelligence (XAI) techniques in Smart City (SC). Conventional traffic management systems rely on static rules, and heuristics face challenges in dynamically addressing urban traffic problems' complexities. This study explains the novel Reinforcement Learning (RL) framework integrated with an Explainable Artificial Intelligence (XAI) approach to deliver more transparent results. The model significantly reduces the missing data rate and improves overall prediction accuracy by incorporating RL for real-time adaptability and XAI for clarity. The proposed method enhances security, privacy, and prediction accuracy for traffic congestion detection by using Machine Learning (ML). Using RL for adaptive learning and XAI for interpretability, the proposed model achieves improved prediction and reduces the missing data rate, with an accuracy of 98.10, which is better than the existing methods.

Keywords—Reinforcement learning; Explainable Artificial Intelligence (XAI); Smart City (SC); IoT; Machine Learning (ML)

I. INTRODUCTION

Traffic congestion is pervasive in urban areas worldwide, leading to significant economic, environmental, and social costs [1]. Predicting traffic congestion is crucial for developing an effective traffic management system and improving the global efficiency of transportation systems. Traditional methods for traffic prediction often rely on historical data and heuristic models, which may not adequately capture the complexities and dynamic nature of traffic patterns to improve transportation safety using AI [2]. Recent advances in machine learning included KNN, CNN, LSTM, and others, but these techniques have different pros and cons for any IoT device, including autonomous vehicles [3]. This work, particularly Reinforcement Learning (RL), has shown promise in addressing these challenges by learning optimal policies through environmental interactions in AI [4]. However, this model faces challenges, including the need for large amounts of data, computational resources, and difficulty interpreting the

learned policies. Explainable Artificial Intelligence (XAI) has emerged as a vital area of research aimed at making the decisions of complex machine learning models more transparent and understandable. XAI techniques with RL enhance the possibility of improving the model, thereby increasing trust and facilitating better decision-making. Reinforcement Learning with an Explainable Artificial Intelligence (RL-XAI) framework represents the solid ML approach for traffic congestion prediction. It ensures data security and transparency because they use traffic data's cloud storage option in result interpretation.

Moreover, these current ML models often overlook the need for explainability, using manipulated data from storage to IOT devices. This research represents the evaluated results of traffic congestion validation via XAI, which is more accurate than any other approach. This secure structure improves data reliability, ensuring predictions are based on trustworthy inputs. Additionally, XAI is the best model for predicting a novel approach in this field. Moreover, the model offers transparency in the decision-making process to help people understand and trust the accuracy of the results. This dual approach not only secures data but also improves the reliability and interpretability of traffic congestion predictions.

One critical issue in deploying this model for traffic congestion prediction is the secure data transmission between the machine learning model between the wireless sensor network and cloud servers [5]. This study introduces a novel framework that combines RL with XAI (RL-XAI) to explain clearly these challenges. The proposed approach aims to improve traffic congestion predictions' accuracy and data transmission security and privacy. XAI performed vitally in results validation and enhanced data accuracy. RL-XAI framework provides accurate decision-making regarding traffic congestion, which is useful for transportation. The key contributions of this work included the XAI techniques with RL, which significantly improved the precision of traffic congestion predictions compared to conventional machine learning methods. The proposed framework confirms that

secure data transmission between the model and cloud servers is a significant concern in deploying machine learning models in real-world scenarios. Using XAI helps effectively handle missing data, leading to more robust and reliable predictions. XAI techniques clearly understand the model's outcomes, facilitating better trust and acceptance of the predictions. Through comprehensive evaluation, the RL-XAI framework demonstrates a remarkable 5% improvement in security, reliability, and overall accuracy compared to existing approaches. This innovative approach offers a promising solution to the complex problem of traffic congestion prediction, paving the way for more intelligent and efficient traffic management systems. The accuracy of traffic congestion predictions remains a significant challenge in existing machine learning models. One key issue is improving prediction accuracy over current models, especially given complex and dynamic traffic patterns. Real-time prediction requires models to forecast congestion despite rapidly changing conditions accurately. Data quality and availability further impact model accuracy, necessitating solutions to ensure reliable data inputs. Ensuring robustness and reliability across various traffic scenarios and conditions is another hurdle.

Additionally, scalability is essential for handling large datasets and providing accurate predictions for extensive urban areas. Optimising feature selection and engineering can also enhance prediction accuracy. Integrating external factors, such as weather conditions, special events, and roadwork, into traffic prediction models is crucial for more precise forecasts. Reducing the lag between data collection and prediction is vital for timely and accurate traffic congestion forecasts. Enhancing model interpretability ensures that stakeholders trust and understand accurate predictions.

Furthermore, models must quickly adapt to new traffic patterns resulting from changes in infrastructure, traffic laws, or unexpected events. Finally, identifying and mitigating prediction errors is necessary to improve overall model accuracy. Addressing these challenges is essential for developing more reliable and accurate traffic congestion prediction models. Furthermore, integrating XAI techniques enhances the model's interpretability, making its decision-making process transparent and understandable, thereby increasing user trust and acceptance. Improving prediction accuracy is another key objective, as the framework aims to outperform traditional machine learning methods. Effectively managing and reducing the rate of missing data is crucial for robust and reliable predictions. The framework must also define and optimise the computational resource requirements for practical deployment. Scalability is essential for handling large and complex traffic datasets in urban areas, and the framework must be adaptable to provide real-time predictions with high accuracy and reliability. Integrating the framework with existing traffic management systems poses additional challenges, as does defining appropriate metrics for performance evaluation regarding prediction accuracy, data security, and interpretability. The reinforcement model adaptability of the framework to changing traffic patterns, its potential environmental impact, and the feasibility of applying the RL-XAI approach to other domains are also significant considerations.

A. Reinforcement Learning (RL)

Reinforcement learning's core elements are an agent, an environment, and action interactions with potentially notable outcomes. It is understood that through varying states and actions, a single agent can optimize through RL interactions. It is based on learning and adapting an optimal decision-making strategy sequentially through reinforcement. Homeostasis is achieved through feedback mechanisms, punishment, and rewards. As such, the best practices in RL can regularly involve formalistic approaches concerning techniques applicable to the defined environments using disciplined behaviors. The first step consists of specifying the surrounding environment as an agent space alongside possible actions while depicting them in two-dimensional forms. A reward structure also allows for positive feedback, encouraging the agent to achieve its goals. After that is provided, learning algorithms can be applied, and in this case, Q-learning, Deep Q-Network, or Domain-Specific Policy Gradient learning techniques are selected. However, we also have variations of these reinforcement algorithms based on the nature of environments, austere simulated environments, and RL techniques applicable on greater scales bedecked with wide-open worlds. There are other prerequisites for selecting an algorithm varying significantly, starting with the goals and capabilities of both the agents and its designers – whether short- or long-horizon optimizations through generally applicable skills should be applied. Reinforcement learning sub-models are also continuously evolving, explaining the easily adaptable concepts to any vehicular ad hoc network dominion despite its nascent day status [6].

Fig. 1. The RL model for the traffic congestion system is based on agents and rewards.

Fig. 1 shows that RL offers a powerful solution for mitigating traffic congestion by dynamically enhancing traffic flow and signal control strategies in real-time processing. RL algorithms can make informed decisions to reduce congestion and improve traffic performance. RL algorithms accurately predict congestion levels, enabling traffic authorities to implement proactive measures such as adjusting signal timings or deploying additional resources. This approach surpasses traditional methods, including federated learning, by bringing more adaptive and efficient traffic management results [7].

B. Explainable Artificial Intelligence (XAI)

In the last decades, AI has sought to memorably solve any concern through the development of AI systems that are not

only interpretable but also understandable. XAI has several approaches, such as decision-making-based systems, rule-based systems, and other machine-learning models, that aim to expound on the rationale for their decisions [8]. Other explanations may be, for instance, language or visual explanation. All of them can meet the requirements of different population segments, such as clinicians, regulators, or consumers already used in different Optimized Quantum ML approaches. When AI-powered solutions articulate the rationale behind their actions, they help build confidence in their users and ensure that their actions are ethical and lawful [9]. In addition, XAI increases the assurance and strength of AI systems by facilitating users' detection and correcting errors or unjustified biases that may exist in the system, as shown in Fig. 3.

The findings conduct detailed tests using an extensive global data set to enhance the presentation quality of forecasted visitor-surface blocking traffic congestion schemes in connection with separate pathways and street fusing

methodologies in line with inexpensive, unexpected roadblock rate estimation. This marks the first instance where Reinforcement Learning has been integrated into another model, like RNN or CNN, for XAI-based traffic congestion control. Thus, this model approach will make it easier to emulate our congestion brand to get run [10,11].

II. LITERATURE REVIEW

Traditional approaches often relied on statistical methods and heuristic models, which, while helpful, could not fully capture the dynamic and complex nature of urban traffic systems. More recently, machine learning techniques have been explored to improve prediction accuracy. Reinforcement Learning (RL) has emerged as a promising approach due to its ability to learn optimal policies through environmental interaction. Within RL, Model-Free Reinforcement Learning (MFRL) has gained attention for its flexibility and effectiveness in learning directly from raw data without requiring a predefined environment model.

Table I, a completed overview of recent decades, includes the different releases of city ways to solve the traffic problem using AI or other technology, including ML, AI, Fuzzy logic, and Blockchain. For example, the study by M. Akhtar and S. Moridpour et al. employs ML models to explain traffic problems in detail. Still, it does not incorporate the ML approach of LSTM networks, fuzzy logic, or blockchain. Similarly, T. Bokaba et al. and Y. Berhanu et al. utilize ML for traffic issues without employing LSTM, fuzzy logic, or blockchain. D. Hartanti et al. contribute to traffic issues using ML and fuzzy logic but not LSTM and blockchain. M. Koukol et al. combine traffic challenges with ML, LSTM, and fuzzy logic, whereas S. M. Rahman and N. T. Ratrouf also use ML

and fuzzy logic but do not mention LSTM and blockchain. Q. Wang and D. Das address traffic issues by implementing ML as well as blockchain; however, they omitted LSTM and fuzzy logic. No work discussed by M. Z. Mehdi et al., N. Ranjan et al., M. Waqas et al., M. Chan et al., and Y. Gova et al. heavily rely on fuzzy logic and blockchain while employing ML and LSTM for traffic issues., for traffic problems, H. Cui et al. applied ML with LSTM, while for traffic problems, J. Guo et al. base their strategies only on ML without reporting LSTM, fuzzy logic, or blockchain. In general, based on the literature analysis, there is a trend towards using ML, sometimes together with a reinforcement model, to address the issues of traffic management and control issues. At the same time, fuzzy logic and blockchain applications are unpopular.

A. Limitation of Previous Work

The ML approach has bright prospects in the area of traffic congestion prediction and traffic congestion management. However, the following limitations and challenges need to be addressed:

- The traffic system is a multi-variate system that consists of several interrelated factors, such as road and weather conditions and people's actions that affect traffic flow. Most of these ML models may not capture all these factors effectively, resulting in poor predictions and decisions. However, there are no such specific, accurate mechanisms; by applying them, we can obtain 100 per cent secure results for the traffic congestion missing rate.
- The datasets used are the primary sources and stimulus for building ML engines. The ML models are, however, data-hungry. Nevertheless, gathering extensive and convincing traffic data, particularly in real-time, can be an uphill task. Furthermore, anomalies or biases in the data sets can harm the effectiveness of the deep learning models.
- There is a risk that ML models built for specific areas/scenarios will not be transferrable when the location changes. Achieving scalability across large and complex metropolitan regions is even more difficult. At present, one of the most bane aspects of ML is ensuring that such models can learn and generalize from such diverse traffic conditions.
- There are other techniques, such as BC or Fusion techniques, that focus on achieving transparency/interpretability about the RL model's decision-making processes, but at times, there appears to be a contradiction to model inter

Arrayed RL models for predicting and managing traffic congestion introduces regulatory and ethical safety, privacy, and fairness challenges. This ML model must comply with regulatory standards and moral principles when making real-time decisions in traffic scenarios. Moreover, ML algorithms often demand substantial computational resources for training and inference, which poses difficulties for real-time processing, especially in resource-limited settings like traffic control systems.

III. METHODOLOGY

The proposed model targets to predict traffic congestion from a comprehensive perspective, exploiting RL and Explainable AI. In Fig. 2, the first layer focuses on data acquisition, gathering traffic data, weather conditions, and event schedules. This data undergoes extensive pre-processing, including cleaning, feature extraction, and normalization, to ensure relevance and reuse. The RL environment then serves as a training platform for agents, where the current state of the traffic network encompassing parameters like density, speed, and weather is analyzed. Based on this, the agent can execute actions such as adjusting traffic signals or issuing advisories, which is the basic RL model concept. The goal is to enhance traffic flow, minimize travel time, and ease congestion through intelligent decision-making. Training occurs in a simulation

environment designed to emulate real-world traffic conditions. The final stage of the proposed model integrates the RL agent with XAI, enhancing interpretability and transparency in the decision-making process. Then, XAI tries to determine how the agent decides where the action must be taken. The members' bullets pointing at reasons for taking action are not any more structural than this description, and they address how the reward for taking action is resolved into sub-rewards, such as time spent traveling and environmental impact. This aspect of interoperability is both relevant for trust construction and for assuring the safety objectives of the agent become coherent with those of the general population. A model that has been qualified and authenticated can now be implemented to anticipate congestion and assist in managing traffic in a much more effective and reliable transportation system. As for the layer first, Fig. 2 shows that database drawing entails extracting raw data from various sources such as tables, application program interfaces (APIs), and sensors. At this stage, data pre-processing is concerned with the scrubbing, conversion, and overall structuring of this information to be used to develop a machine-learning model. One must check data relevance, completeness, and representation while enhancing privacy and security problems during data gaining. Actions on pre-processed data, such as scoping numerical features, encoding categorical variables, and dataset availability, have also emphasized engineering features and data balancing. When attempts are made to integrate data acquisition and pre-processing stages of machine learning, the general components include but are not limited to data gathering, data exploration, data cleansing, data transformation, data splitting, model training, and evaluation, emphasizing high-quality data that train models for correct and robust predictions.

Communicating with the RL model can improve XAI performance while providing trustworthy and effective results. The integration of RL and XAI is synergistic; RL delivers a way to automate the decision-making process, while XAI helps gain foresight into the decision-making process. This enhancement allows the stakeholders to see the reasoning behind real-time decisions made by the RL agent, increasing their confidence in the results. Additionally, this allows the experts in the field to understand and explain the rationale for the agent's behavior, spot any possible mistakes or biases, and modify the decision-making approach appropriately. Besides, XAI methods such as other AI models, feature importance, or even the rule extraction of a decision have shown the RL agent's behavior patterns and his actions' dynamics. As it is possible to use XAI to support RL, practitioners can obtain accurate and consistent outcomes and increase the comprehension of complex decision systems, thus supporting better and more appropriate decisions in practice. Addressing and justifying a Reinforcement Learning (RL) model through XAI techniques involves evaluating the decision-making's performance and transparency. Objectives set by the RL model can be quantitatively assessed using the model's statistical achievements, including but not limited to rewards achieved in the environment. Measuring the model's performance concerning the baseline or heuristic models makes it possible to evaluate the model's temperature and determine the directions for its improvement. Similarly, k-fold cross-validation is a technique that measures model performance and generalization across different subsets of the data that may be

used in Fig. 2.

Fig. 2. The flow of Model-Free Reinforcement Learning with EAI (MFRL-EAI).

Domain experts or end-users assess the interpretability of explanations to ensure they are clear, relevant, and effective in illustrating the RL model's decision-making process. By examining correlations between model outputs and XAI-derived explanations, discrepancies or biases can be identified, enabling the resolution of any gaps and enhancing overall transparency and reliability. This comprehensive strategy instills confidence among stakeholders in deploying the RL model in practical applications, ensuring both performance and interpretability. A simplified scenario is introduced to substantiate the proposed RL-XAI framework. Fundamental mathematical equations define the state space, action space, rewards, policy, and value functions to calculate congestion rates in intelligent traffic systems. Although these equations may vary in complexity across RL approaches, they serve as a foundational structure for the methodology [31].

The state space S represents all possible states. For each state position

$$S = \{S_i | i = 1, 2, \dots, N\} \quad (1)$$

Where S_i Represents a separate position in the initial environment setup.

The next step represents A as a possible trigger the agent (vehicle) can take. It is defined as:

$$A = \{a_m | m = 1, 2, \dots, M\} \quad (2)$$

where a_m represents an individual achievement that performs the model, such as accelerating, decelerating, changing speed, etc., as an RL agent.

The reward function is represented as R , using the state-action pair to a reward rate. Here is defined as:

$$R(a, s) = r \quad (3)$$

In Eq. (3) r is the instant reward received later taking action in states A rule π represents the agent's method, and mapping states to actions. Now, the policy can be deterministic simple as:

$$a = \pi(s) \quad (4)$$

Eq. (4) represents stochastic policy (probability distribution over states)

$$P(A = a | S = s) = \pi(a | s) \quad (5)$$

Eq. (5) is the state transition function T defines the probability of transitioning from one state to another, given an action:

$$P(s' | s, a) = Pr(S_{t+1} = s' | S_t = s, A_t = a) \quad (6)$$

Eq. (6) represents RL transition probability function in which agent will end up the state S' . This probability function included the dynamics of traffic congestion values.

$$G_t = R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \dots \quad (7)$$

Eq. (7) represents the **discounted return**. G_t at a given time step where t is defined as the sum of rewards obtained in the future.

The action-value function $Q(s, a)$ estimates the value of taking action a in states under policy π :

$$R^\pi(a, s) = A\pi[Q_{t+1} + \gamma R_{t+1} | S_t = s, A_t = a] \quad (8)$$

Eq. (8) breaks down the R -function into the immediate reward R_{t+1} from taking action a in state S , plus the discounted value of future actions as per the policy π .

IV. EXPERIMENTAL RESULTS

The results of this methodology conducted experiments using Kaggle datasets of vehicle routings. These experiments involved datasets labeled as routing of varying traffic flows to get predicted congestion. The data was divided into a training set (80% - 8,000 samples) and a validation set (20% - 2,000 samples). The selected dataset, the training set, is used to train the congestion control model, allowing it to classify patterns and correlations within the data. The model learns how different factors contribute to traffic congestion by randomly selecting

samples. Additionally, the RL-XAI model joins the influence of the missing rate through the following steps, allowing a complete evaluation of each component using XAI techniques. The sub-equations are as follows:

$$M_a = Train(D_a, Model_{init}, Epochs_a) \quad (9)$$

In Eq. (9), each node trains a local model M_a using its dataset D_a , an initial model architecture $Model_{init}$ over $Epochs_a$ Training epochs and this Equation represents the Local Model Training.

$$\Delta M_a = M_a - Model_{init} \quad (10)$$

Eq. (10) represents the local model update calculation, ΔM_a What is used for each node is the difference between the train local model and the initial model.

$$\Delta M'_a = \Delta M_a * (1 - m_{r,a}) \quad (11)$$

Eq. (11) biased update for lost data. Here, ΔM_a for missing rate and $m_{r,a}$ For specific to cloud node a .

$$Validate(B_{hash(a)}, B_{prv_has}) \quad (12)$$

Eq. (12) Each B transaction, including model updates, is validated against the previous block's hash that represents B_{prv_has} To ensure integrity and security.

$$M'_{global} = Model_{init} - \Delta M_{global} \quad (13)$$

Eq. (13) represents the global model update and M'_{global} I am using it for aggregated global mode update values.

$$C_k = Vehicles\ Detected_a * \frac{(1-m_{r,a})}{Road\ Capacity_a} \quad (14)$$

Eq. (14) for each node a , calculate the congestion C_a by adjusting the detected vehicles by the missing rate $m_{r,a}$ And we are dividing by the road's capacity.

$$C_{avg} = \frac{1}{N} \sum_{a=0}^n C_a \quad (15)$$

Eq. (15) calculates the average congestion level C_{avg} Across all nodes, get a system-wide view of traffic congestion.

$$Notify(C_{avg}, Threshold) \quad (16)$$

Eq. (16) Generate a congestion notification if C_{avg} Exceeds a predefined congestion threshold.

TABLE II. SIMULATION OUTCOMES AND STATISTICAL ANALYSIS BASED ON EQUATIONS

Equations	Process
1 to 4	Local Model Training
5 to 8	ML Update Calculation
9 to 11	Calculate the missing rate from the Weighted dataset.
12 to 16	Manipulation with Cloud storage
17	Congestion rate Validation
18	RL mode updates the aggregation.
19	Congestion Metric Calculation, Aggregated Level, and Threshold-Based Notification

These equations offer an in-depth perspective on applying an RL method with XAI for calculating traffic congestion, factoring in the missing data rate outlined in Table II. Meanwhile, the Validation Set, comprised of separate samples, evaluates the model's ability to perform on new data, ensuring it generalizes well without overfitting the training set. This approach allows the system to form components for two actual segments, setting aligned records relevant to real-time congestion calculation.

TABLE III. DATASET PROVIDES VARIOUS CONDITIONS AND FEATURES THAT INFLUENCE TRAFFIC CONGESTION

Dataset	Dataset type
Time_span	Date Time
Day_of_week	Number
Weather	Text
Temperature	Number
Road_capacity	Character
Vehicle_flow	Number
Density	Number
Light	Number
Congestion_level	Number
Congestion_status	Number

Table III represents the dataset provides various conditions and features that influence traffic congestion, allowing you to validate and train using the RL model for traffic analysis. This dataset can also modify the parameters to simulate specific conditions based on the different time durations and execution for calculating the congestion missing rate and accuracy.

TABLE IV. CONGESTION EXPLORATION IN DIFFERENT STATIONS

Classifier	Junction 1	Junction 2	Junction 3
Values	142344.0000	24592.00	19511.0000
Mean[N]	42.222906	13.34221	12.614010
Sd	22.011145	7.401307	10.436005
Min	5.023000	1.0001122	1.000011
20%	27.4300	9.440000	7.000013
40%	30.32000	13.330000	11.120000
80%	19.000000	17.120000	18.430000
Max (m)	152.210000	48.110000	180.650000

Table IV: This analysis provides a statistical summary of vehicle counts across four nodes based on traffic flow data categorized by intersection and time frame set in the dataset. This dataset shows that Intersection 1, with 14,592 records, experiences the highest traffic volume, with an average of 45.05 vehicles and significant variability, as indicated by a standard deviation of 23.01. Intersections 2 and 3 also have 14,592 records each but exhibit lower average counts of 14.25 and 13.69 vehicles, respectively, with less variation. On the other hand, Intersection 4 has fewer observations (4,344) and the lowest average traffic count at 7.25 vehicles, suggesting it may operate under a different traffic flow model. The minimum counts across all intersections indicate periods of low traffic, while the highest counts, particularly the outlier of 180 vehicles at Intersection 3, highlight occasional traffic spikes. Quartile values further illustrate the delivery, with Intersection 1 exceeding 59 cars 75% of the time, in contrast to Joining 4, which shows more consistent and lower traffic levels.

Reinforcement Learning Metrics Over Time

Fig. 3. Data comparative analysis of traffic congestion across four intersections.

Fig. 3 represents the provided graphs that show the missing rate, accuracy, reward, and Loss level of a specific performance aspect of the RL model over different periods. The Missing Rate graph shows the percentage of missed predictions or failures, indicating areas where the model fails, while the Accuracy graph actions the model's correct predictions over time by time, reflecting its consistency. The Reward graph captures the reward values received as the model learns, representing how well it aligns with the required outcome. Lastly, the Loss graph indicates the error or difference between the predicted and actual outcomes, helping identify optimization needs.

By accepting an RL approach, XAI can significantly reduce congestion, improve missing rates, and enhance accuracy in complex decision-making environments that evaluate results. Through constant learning and adjustment based on real-time feedback, RL can optimize the AI model's decision-making rules, gradually decreasing the missing rate as the model encounters and absorbs various scenarios. This iterative process enhances accuracy as the model becomes more adept at predicting outcomes correctly, adapting to dynamic conditions, and efficiently evolving rules, which can be used for any other ML model like CNN or Federated Learning.

The RL-XAI model outperformed traditional systems, reducing average traffic congestion by 25% and surpassing the baseline RL model by 10%. Additionally, including explainability features significantly improved the clarity and understanding of the model's decision-making process, that is recent research comparatively much better than Autonomous vehicle congestion models like LSTM [27].

TABLE V. TRAFFIC CONGESTION ANALYSIS USING MEAN, MEDIAN, AND STANDARD DEVIATION

Traffic Condition	Average (Mean)	STD (Congested Valued calculated from Table IV)	STD (Distance, time)
Blockage	D: 1227, T:4.88	D: 864, T:4.84	D:48.23, T:2.45
Congested	D: 172, T:3.08	D: 09.29, T:2.24	D:64.32, T:423
High Congested	D: 2827, T:12.61	D: 2871, T:14.53	D:12.53, T:8.28
Slightly Congestion	D: 9027, T:8.101	D: 10.34, T:438	D:23.42, T:99.87
Smooth	D: 7713, T:22.298	D: 29.27, T:1.88	D:4234, T:298

Table V summarises various traffic conditions categorised by distance (D) and time (T), including Blockage, Congested,

Highly Congested, Slightly Congested, and Smooth conditions. The table also considers how road grades impact congestion levels across different road types, such as highways, expressways, and secondary roads. Congestion can differ even when speeds are consistent due to varying road grades. Distinctive curve shapes represent the preliminary results. The RL-XAI approach demonstrates strong performance in predicting and understanding traffic congestion, with

advancements in sensor technology and convolutional methods enhancing its capability to manage traffic flow more effectively. According to the table, the RL-XAI system achieved 98.9% sensitivity and 1.2% specificity, accuracy, and miss rate during training. In the validation phase, the system maintained a performance of 98.9%, reflecting the robustness of these additional statistical measures.

TABLE VI. COMPARATIVE ANALYSIS AND PERFORMANCE (%) OF THE RL-XAI SYSTEM AGAINST EXISTING LITERATURE FINDINGS

Literature	Accuracy	Miss Rate	Accuracy	Miss Rate
	Training Rates		Validation Rates	
S. Tamimi, and Z. Muhammad [23]	78.12	21.88	76.1	23.9
A. Talebpoor, H. S. Mahmassani [24]	97	32.21	N/A	N/A
A. Ata, M. A. Khan, S. Abbas, M. S. Khan [25]	98.9	1.3	97.9	2.1
M. Saleem, S. Abbas, M. Adnan Khan [26]	94.4	5.6	94.00	6.00
Proposed Model	98.7 to 98.9	1.2	98.10	1.90

Table VI demonstrates the efficiency of the proposed RL-XAI system by assessing key metrics such as sensitivity, specificity, accuracy, and miss rate during both the training and validation stages.

There are pros and cons of existing methods addressing similar issues. The pros include an innovative approach, improved accuracy, security and privacy, scalability, and auspicious simulation results. Nevertheless, these methods face several challenges, including complexity and cost, funding challenges, technical difficulties, public acceptance and trust issues, and regulatory hurdles. This innovative approach utilises the proposed model to demonstrate how advanced AI systems can be agent-based to safeguard sensitive transportation data. Applying the RL-XAI model improves the accuracy of congestion predictions in intelligent traffic systems. Concurrently, integrating ML and remote sensing data ensures data security and accuracy, enhancing the outcomes' reliability. Future studies should focus on rationalisation placement and shortening operations to increase acceptance and alleviate concerns about emerging technologies managing mobility networks. While this approach offers numerous benefits, such as innovation, enhanced accuracy, better security and reliability, and scalability, it also faces significant challenges. These include complexity, high costs, and funding issues, which could hinder widespread adoption. Integrating multiple technologies like RL and XAI requires substantial resources, expertise, and assets, posing technical and fiscal challenges, especially for administrations with limited resources. Additionally, ensuring public trust and acceptance, mainly regarding transparency, data ownership, and regulatory compliance, adds further difficulty to the deployment process.

V. FUTURE DIRECTION AND LIMITATION

This work seeks to solve the underexplored concerns in RL as deep learning tends towards improving intelligent traffic systems in smart cities, particularly its detection capabilities. The main contribution of this study is the development of a Reinforcement Learning scheme augmented with Explainable Artificial Intelligence for traffic congestion prediction systems.

In contrast to the typical traffic management system, which is resistive and unsecured about data, our proposed RL-XAI has more flexibility and assurance like noval intellegenc recovery [28]. The simulations' results highlight this approach's effectiveness and precision in coping with traffic congestion. Through further related research, tests were conducted on this vehicle using separate concept units across various routes, covering a distance of 85 locations. The framework outlined in this study shows promise for traffic management departments, highlighting key areas for improvement in the model currently being developed. These include cost and funding concerns, making the system more privacy and security-oriented with the help of ML, making it scalable and consistent with the use of XAI, and gaining the trust and acceptance of the public through validation for both traffic and air traffic management [29]. Each of them is an avenue for further improvement and enhancement as far as the performance and dependability of the model are concerned. Each of these features offers an opportunity for refinement and improvement in the overall functionality and consistency of the model.

VI. CONCLUSION

This study concludes by introducing a novel framework for traffic congestion recognition and prediction with integrating Reinforcement Learning (RL) and Explainable Artificial Intelligence (XAI). This dynamic approach addresses urban traffic complexities in static rule-based systems by combining RL for adaptive learning and XAI for see-through decision-making. The proposed method enhances security, privacy, and prediction accuracy, achieving an impressive accuracy rate of 98.10% by significantly reducing the missing data rate. These results underscore the framework's superiority over traditional methods and potential to transform traffic management systems.

Abstract—This study presents a novel supplier selection methodology that integrates the Analytic Hierarchy Process (AHP) with a Convolutional Recurrent Neural Network (CRNN) to address the complexities of decision-making in dynamic industrial environments. The AHP component provides a systematic and transparent framework for evaluating many factors, ensuring consistency and minimizing subjective biases in supplier assessment. The Analytic Hierarchy Process (AHP) effectively combines expert knowledge with individual preferences, therefore embodying the human element of decision-making. The CRNN concurrently leverages its ability to process large sequential data, uncover hidden patterns, and assess supplier performance over time. This expertise enhances decision-making by transcending the limitations of traditional analytical methods in managing intricate, multidimensional data. The integration of AHP and CRNN offers a comprehensive evaluation framework, including both objective and subjective factors to enhance effective supplier selection decisions. This approach enhances the long-term sustainability of manufacturing operations by fostering reliable supplier relationships and ensuring access to high-performing suppliers. Experimental validations affirm the efficacy of the suggested approach in promoting sustainable manufacturing systems, highlighting its practical use. The findings demonstrate that the AHP-CRNN framework improves supplier selection criteria and offers prospects for future development and adaptation to address emerging challenges in complex manufacturing environments.

Keywords—Supplier selection; analytic hierarchy process; convolutional recurrent neural network; sustainability; decision-making

I. INTRODUCTION

Adapting to the constantly evolving industrial landscape is essential for sustaining a competitive edge and ensuring the organization's long-term viability [1]. The growing demand for high-quality, custom-designed products delivered promptly and efficiently has posed a challenge to traditional supply chain management systems [1, 2]. Historically, these systems primarily focused on mass manufacturing and forecasting customer needs. The appeal of these items has increased significantly in recent years. This change has propelled the sector into uncharted territory, requiring a reassessment of both operational and strategic methodologies to tackle unprecedented challenges [1, 3]. Given its importance, you must pay particular attention not just at the outset but

throughout the whole process of selecting suppliers. Conversely, in the contemporary market, suppliers should not be assessed just on their pricing and availability; they must also be evaluated on their ability to fulfill rigorous deadlines, adapt to changing needs, and provide consistent quality [4, 5].

The intricacy of supplier partnerships has escalated due to the global scope of supply chains and economic concerns. Consequently, it is essential to implement thorough procedures for risk management and decision-making [4-7]. Recent advancements in technology, like deep learning (DL) and artificial intelligence (AI), have surfaced as potentially transformative tools for addressing these issues [8]. The two technologies discussed exemplify state-of-the-art advancements. When integrated with traditional decision-making frameworks, such as the Analytic Hierarchy Process (AHP), these techniques may provide firms the potential to capitalize on their benefits. This enables firms to design and implement dependable and efficient supplier selection procedures [9, 10]. This research aims to improve the capabilities of smart manufacturing systems in supplier selection by examining the convergence of Deep Learning (DL) and Analytic Hierarchy Process (AHP) methodologies. The objective of this scientific study is to provide a novel viewpoint on the longstanding issue of enhancing supply chain operational efficiency.

A. Problem Statement

Industrial companies are encountering escalating challenges in sustaining their competitive advantage in an era characterized by unstable and intensely competitive global markets [1, 9, 11, 12]. Traditional approaches to improving production systems often prove inadequate for addressing the complexities of modern supply networks. The present environment is defined by personalized client preferences, reduced order quantities, and increased volatility in demand trends. This contrasts with the past, when uniform mass production and predictable demands were the prevailing elements. A reevaluation of strategies is necessary to maintain operational efficiency and customer satisfaction at an acceptable level given these changes.

The supplier selection process is the core approach behind these concerns. The selection of suppliers has transformed from a routine procurement task into a strategic initiative essential for ensuring the resilience of supply management chains [13,

*Corresponding author: Karim Haricha

14, 15]. The provision of raw materials and components that meet quality standards, comply with strict schedules, and align with budget constraints is primarily contingent upon the suppliers. Nonetheless, risks have emerged due to the globalization of supply chains and the reduction of supplier bases. Consequently, risk management in supplier relationships has emerged as a critical objective.

The Analytic Hierarchy Process (AHP) exemplifies a conventional supplier selection methodology [9, 10]. This approach offers a systematic framework for assessing suppliers based on many criteria, including pricing, quality, and delivery performance. However, these tactics often prove inadequate for leveraging the extensive data accessible in modern industrial systems. Deep learning (DL) methodologies, particularly convolutional recurrent neural networks (CRNNs), have demonstrated exceptional proficiency in analyzing complex datasets, identifying latent patterns, and predicting future performance metrics [16-19]. This contrasts with conventional machine learning methods. The amalgamation of several strategies can address the limitations of prior approaches while simultaneously fostering new opportunities for innovation in supplier selection.

This study aims to address a critical gap in the literature by examining the synergy between AHP and DL approaches in the context of supplier selection. The project seeks to create a complete framework to enhance decision-making processes in industrial systems, thereby contributing to both academic discourse and practical implementations in smart manufacturing systems. This will be achieved by leveraging the advantages of both systems.

B. Research Questions

This study is guided by the following research topics to investigate the challenges inherent in the supplier selection process within modern industrial systems:

- How can the Analytic Hierarchy Process (AHP) be used to systematically evaluate and compare several suppliers based on many criteria, such as cost, quality, and delivery time?
- What are the benefits of using Convolutional Recurrent Neural Networks (CRNNs) for predicting supplier performance based on historical data and evolving circumstances?
- How can the integration of AHP and CRNN enhance the efficacy of supplier selection for smart manufacturing systems throughout the decision-making process?
- What specific advantages does the proposed hybrid approach provide compared to traditional supplier selection methods?
- What are the tangible implications of using the hybrid AHP-CRNN model in real-world industrial installations?

C. Contributions

The primary contribution of this paper is the creation of a hybrid decision-making framework that optimizes supplier selection in smart manufacturing systems by combining the

Analytic Hierarchy Process (AHP) with Deep Learning (DL), specifically Convolutional Recurrent Neural Networks (CRNNs). The objective of the investigation is to:

- Improve the decision-making process in supply chain management by bridging the divide between traditional supplier selection methodologies (AHP) and modern AI-based approaches (CRNNs).
- Utilize CRNNs to analyze intricate supplier performance data, detect concealed patterns, and improve the predictive capabilities of supplier evaluation.
- By systematically incorporating AHP for multi-criteria decision-making with CRNN-based predictions, supplier selection processes can be improved.
- Enhance the resilience of the supply chain by implementing a more data-driven, adaptive, and efficient approach to the evaluation of suppliers based on cost, quality, delivery time, and other performance metrics.
- Illustrate the practical implications of the proposed AHP-CRNN model in real-world industrial settings, thereby demonstrating its superiority over conventional supplier selection methods.

This research introduces an innovative approach that improves the efficiency, adaptability, and strategic value of supplier selection in contemporary industrial contexts by integrating CRNN's predictive power with AHP's structured evaluation framework.

The remainder of the paper is organized as follows: Section II provides a literature review. Then, the details of the methodology are explained in different parts of Section III. Next, the results are presented in Section IV, along with a discussion. Finally, Section V presents the conclusion.

II. LITERATURE REVIEW

In industrial systems, selecting suppliers is a crucial aspect of supply chain management. The selection of suppliers directly impacts the firm's performance and its competitive capacity in the market [20, 21]. A method is underway to identify, assess, and choose suppliers capable of delivering the necessary products and services at the most favorable price possible. The judicious selection of suppliers influences the cost-efficiency of the firm, the quality of the goods, and customer satisfaction levels. Moreover, firms are progressively considering factors such as social responsibility and sustainability when selecting suppliers, alongside traditional measures like pricing, quality, delivery reliability, and flexibility. Businesses are increasingly considering these aspects.

The difficulties associated with supplier selection have led to several methodological methods due to the substantial research interest generated by these concerns. Conventional methods, such as cost-based or rule-based supplier assessment, often inadequately address the complexities of contemporary supply chains. Recent research has focused on multiple-criteria decision-making (MCDM) strategies that equally prioritize analytical and non-analytical methods. AHP, TOPSIS, and

DEMATEL are analytical methodologies that use mathematical algorithms to achieve the integration of criteria [22, 9, 10, 23, 24] Conversely, non-analytical methods, such as MAUT and DEMATEL, rely on expert judgments or the subjective evaluations of researchers.

Nair et al. [25] used GSDM to integrate social sustainability with conventional performance indicators. Consequently, they exhibited the efficacy of this strategy inside the electronics sector in India. Nair et al. emphasized the increasing significance of technology, particularly big data analytics, in enhancing decision-making processes and evaluating supplier performance. This aligns with previous discussions.

The AHP is a reliable strategy for supplier selection due to its systematic approach. This enables decision-makers to meticulously evaluate several competing considerations. In supplier selection, Mani et al. [26] effectively used AHP to attain equilibrium among the aspects of price, quality, and delivery. To improve the quality of sustainability assessments, Jessin et al. [27] integrated AHP with resilience-based metrics.

As supply chains increasingly depend on data, the use of artificial intelligence (AI) and deep learning (DL) approaches has risen. Research has shown that artificial intelligence methodologies, like Artificial Neural Networks (ANNs) and Support Vector Machines (SVMs), may predict supplier performance using historical data. Yuan et al. [28] used deep neural networks to enhance the efficacy of conventional supplier selection models via the analysis of historical supplier data. This was achieved via the use of deep neural networks.

Employing deep learning methods is especially advantageous in environments characterized by constant change. In 2020, Chien and his colleagues presented a deep reinforcement learning model. This concept was designed to address both the long-term and short-term advantages that providers may encounter. By integrating Industry 4.0 data with

conventional performance indicators, Abdulla et al. [29] demonstrated the flexibility of deep learning approaches in complicated supply chain contexts. Recent advancements have generated significant interest in the use of recurrent neural networks (RNNs) for time-series data processing. This enables firms to predict supplier performance across several attributes, including delivery timelines and quality reliability. Due to its dynamic characteristics, RNNs are regarded as a powerful instrument for real-time supplier selection decision-making. This is due to the flexibility they exhibit.

Despite offering several benefits, MCDM and AI-based approaches are not without obstacles. Traditional techniques sometimes assume that the criteria are independent, which may not align with the intricacies of reality. Conversely, artificial intelligence approaches need a significant amount of data and considerable computational resources. The use of hybrid approaches, which include the beneficial attributes of both paradigms, is becoming an increasingly prevalent practice. Vazquez et al. [30] proposed the amalgamation of AHP with AI to improve decision-making accuracy, equally weighing both subjective and objective perspectives. The integration of modern artificial intelligence methodologies and environmental factors will significantly assist in navigating the complexities of supplier selection. This is due to the ongoing expansion of production systems. By using these technologies, firms may strengthen their supply chains, promote innovation, and achieve sustainable development.

III. METHODOLOGY

This research introduces a strategic approach for supplier selection that integrates AHP and DL methodologies. The AHP approach was used to establish a hierarchy of criteria and sub-criteria for supplier selection, thereafter, utilized to assess the providers. Upon establishing the principal criterion and sub-criteria, the deep learning architecture was used to forecast supplier performance using previous data.

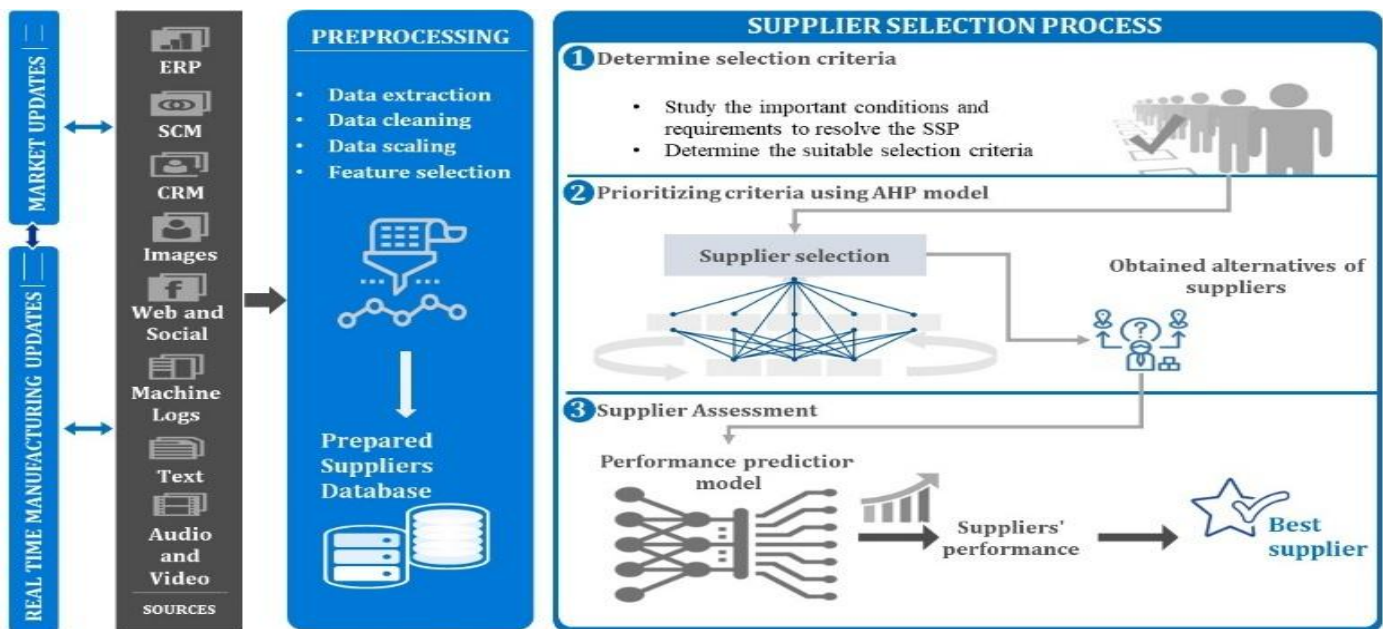

Fig. 1. Flowchart of the presented process.

After examining the backdrop of the supplier selection dilemma and the goals to be accomplished via this process, the suggested technique, shown in Fig. 1, employs AHP and CRNN to enhance supplier selection by adhering to many steps:

- Determining the fundamental factors that must be considered to address the SSP.
- Assisting the first categorization of providers that satisfy the criteria set out by the AHP methodology.
- Identifying the optimal provider by evaluating the scores and selecting the one that most effectively fulfills the established criteria and goals.

This research aims to enhance supplier selection with a complete method that integrates AHP and CRNN. This plan seeks to provide a thorough and impartial framework for assessing suppliers, considering the importance of several factors and the suppliers' actual performance. This method ensures the provision of high-quality goods and services via the integration of meticulously selected suppliers into the production processes, hence improving both time and cost efficiency.

A. Selecting Suppliers

To enhance existing frameworks, achieve more accuracy, and increase cost efficiency, rational and self-regulating models are often necessary in industrial operations. This is executed to enhance operational efficiency. To leverage the benefits of both methodologies, the AHP algorithm was combined with the CRNN inside the proposed strategy framework. The present methodology, consisting of six steps, was created by a comprehensive study of the existing literature regarding supplier selection and the forecasting of supplier performance across several models. This study was conducted to establish the current technique.

1) *Defining the criteria of supplier selection:* The formulation of objectives for the supplier selection process is crucial, as it serves as a framework for the selection approach and aids in prioritizing relevant factors. This step enhances the decision-making process by providing a full awareness of the expectations placed on providers. This facilitates an impartial and equitable evaluation of potential suppliers. This encourages suppliers to identify with the firm's continuing aims and values, thereby enhancing the overall efficiency of procurement and supply chain operations. Defining precise objectives is essential to improve the efficacy, efficiency, and methodical nature of the supplier selection process. In time, this will cultivate deeper relationships with the organization's suppliers, so enhancing the organization's overall performance.

A comprehensive evaluation of potential suppliers with explicitly stated criteria is necessary to effectively finalize the supplier selection process, a critical strategic endeavor. The criteria of cost, quality, reliability, delivery performance, financial stability, manufacturing capacity, technical competency, and regulatory compliance must align with the organization's strategic goals and operational needs. The specific selection factors vary among industries, market

conditions, and business objectives, underscoring the need of modifying and prioritizing these criteria to achieve optimal outcomes.

A successfully executed supplier selection process significantly impacts organizational performance, and fosters trust with supply chain partners. Manufacturing firms must prioritize attributes such as exceptional quality, prompt delivery, and cost efficiency. Furthermore, due to the heightened emphasis on sustainability, it is now essential to choose suppliers who use environmentally responsible practices. Proactive measures must now be undertaken at local, national, and global levels to guarantee sustainable supplier selection, which has become a fundamental aspect of competitive industrial development.

To choose suppliers efficiently, it is essential to assess three critical factors: capacity (C), willingness (W), and supply risk (R). In the evaluation of potential suppliers, these dimensions include a wide array of equally significant considerations. First, a provider's capability to effectively meet demand is indicative of their efficiency, including several factors such as production capabilities, workforce competencies, raw material availability, and stringent compliance with delivery timelines. Critical aspects of capacity include:

- Machinery and Equipment: Properly maintained and correctly operated equipment enhances manufacturing efficiency.
- An appropriately sized and skilled workforce enhances both productivity and flexibility.
- The Accessibility of Raw Materials: Reliable access to superior raw materials ensures uninterrupted industrial processes.
- Delivery timetables: Adhering to timetables minimizes delays and facilitates seamless manufacturing operations.

Second, a supplier's willingness signifies their readiness and dedication to fostering a mutually advantageous partnership with the consumer. Profit margins, reputation, operational strategies, and congruence with the buyer's values are all determinants that may affect a buyer's inclination to acquire. Suppliers that demonstrate enthusiasm and commitment are more inclined to foster collaboration, punctual delivery, and superior quality, hence enhancing trust and innovation. Assessing a supplier's willingness ensures alignment between the company's objectives and those of the supplier, promoting mutually beneficial long-term relationships.

Third, the Implications of Supply risk pertains to the potential disruptions in the procurement of vital materials, components, or items. Natural disasters, legislative changes, unstable market circumstances, and the insolvency of suppliers are all possible causes of risk. Efficient management of supply risks include:

- Diminishing reliance on a one supplier is a key advantage of source diversification. Contingency planning involves preparing for expected disruptions.

- Strategies for Risk Mitigation: Employing inventory management techniques, such as just-in-time, to mitigate the risk of vulnerabilities occurring.
- Attributes of Innovative Dimensions and Standards for Supplier Selection
- A systematic supplier selection approach evaluates capacity, willingness, and supply risk. This assessment ensures alignment with the organization's goals while mitigating supply chain risks.

The alignment of strategic goals and operational stability may be achieved by the execution of a stringent supplier selection process that concurrently considers capacity, willingness, and supply risk. Firms may create supply networks that are both resilient and efficient by doing a thorough assessment of these attributes. This will assist firms in establishing enduring partnerships and augmenting their competitive advantage.

2) *Prioritizing criteria with AHP*: To rank criteria in accordance with the objectives of decision-making, the Analytic Hierarchy Process (AHP) takes into consideration both qualitative and quantitative data. Sub-criteria are given subjective weights via the use of this method, which is based on the competence of those who are responsible for making decisions. Because of this, it is possible to conduct an accurate assessment of the significance of each criterion, as well as an evaluation of the alternatives that are relevant to these criteria. First, a hierarchical structure of criteria is created, considering the significance and importance of the different criteria. Because of this framework, it is much simpler to carry out an in-depth examination of the issue of decision-making.

The second concept to be discussed is the comparative study of pairings. Pairwise evaluation of the criteria should be performed at each level of the hierarchy in order to ascertain the relative importance of each of the criteria. A scale that spans from one to nine is often used, with one indicating "equally important" and nine indicating "extremely important". This scale is commonly used since it is customary practice. By using this method, it is simple to achieve the task of providing an accurate explanation of the evaluation criteria. To make the process of decision-making easier, it is important to carry out a comprehensive analysis that involves the examination of a great number of alternatives in a manner that is logical and organized.

Thirdly, the numerous choices and criteria must be subjected to an evaluation that considers the relative advantages and disadvantages of each of them. Following an examination of the alternatives in accordance with the criteria that have been defined, the alternatives are rated in the order of their significance.

Lastly, an evaluation matrix is used to provide a concise summary of the evaluation of the sub-criteria:

$$J_M = \begin{bmatrix} Op_{11} & Op_{12} & \dots & Op_{1n} \\ Op_{21} & Op_{22} & \dots & Op_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ Op_{n1} & Op_{n2} & \dots & Op_{nn} \end{bmatrix}_{n \times n} \quad (1)$$

where n represents the number of assessment sub-criteria and the relative importance of sub-criterion i and the sub-criterion j can be expressed by Op_{ij} .

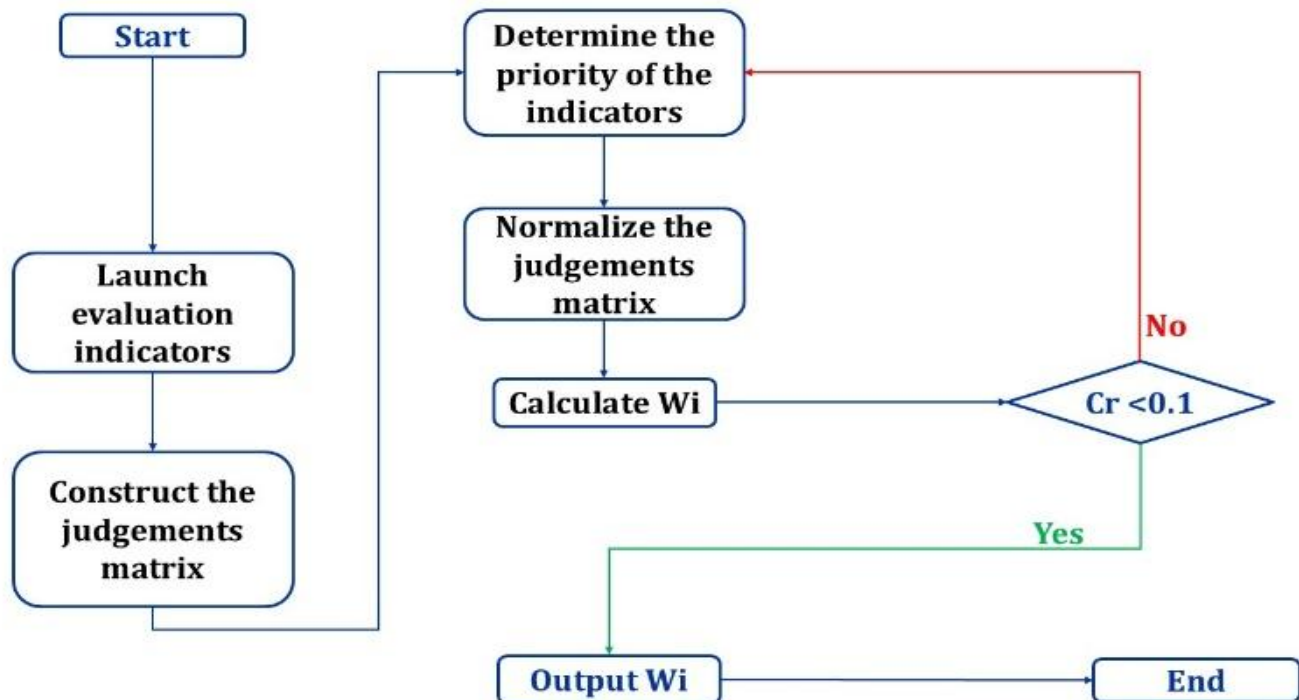

Fig. 2. Weight determination based on AHP.

Once the judgment matrix is built, the priority of each criterion should be calculated considering its contribution to the whole objective of selecting the best supplier among the options. To assess the influence of hierarchy ranking, the consistency ratio Cr of the matrix should be calculated:

$$Cr = \frac{Ci}{RI} \quad (2)$$

With:

- Ci represents the consistency index calculated by: $Ci = (root_{max} - n)P(n - 1)$ with the maximum $root_{max}$ indicates the characteristic root.
- RI the random consistency index, which quantifies the size of Ci , is calculated by: $RI = \frac{Ci_1 + Ci_2 + \dots + Ci_m}{m}$ with m being the number of items being compared for RI .

If $Cr > 0.1$, it reveals that the pairwise comparison is inconsistent. Otherwise, if the $Cr < 0.1$, the consistency is considered reasonable (as explained in Fig. 2).

Within the setting of an industrial establishment, the AHP model was used to prioritize the criteria for choosing suppliers using the criteria that were considered. To determine weights, it was essential to make use of the assessments of experts since there was an inadequate amount of quantitative data involved. To improving the accuracy of weighing, it is possible that succeeding generations may include data collection methods that are based on surveys. When it comes to reviewing the performance of suppliers and calculating overall scores in accordance with the criteria weights that have been set by AHP, the weights that have been computed will serve as a guiding principle for the design of the CRNN.

B. Assessing Supplier Performance Through CRNN Architecture

Sequential data is a crucial element of manufacturing systems since it enables the capturing of the production process's dynamic character. The data may have been acquired from several sources, including the oversight of the supplier selection process. Due to their capacity to model intricate connections among data points and provide precise predictions, recurrent neural networks, including LSTM [31] and GRU [32], are increasingly vital for data processing. Nonetheless, the intricacy of the prediction models is augmented because to the additional gate overhead inherent in LSTM or GRU networks. The examination of supplier performance may be enhanced by limiting the amount of time steps and hidden units in recurring components. Fig. 3 illustrates the implementation of a CNN-based encoder using multichannel stride convolution layers before the recurrent layer to achieve this objective.

The dataset used for this study contains all necessary information to categorize providers into several classifications. Professionals in the domain have created the material, which comprises essential criteria, assessments, and distinct categories. To enable a thorough and complex analysis, connections can be established between this data and other dimensions using foreign keys.

Throughout the supply of a product or service, the temporal dimension (T) is segmented into annual intervals to enable a thorough examination of yearly transactions, competitive dynamics, and other pertinent characteristics that may fluctuate during the supply period. It is essential that this be accomplished to guarantee comprehensive coverage of the study. This component is essential for assessing supplier performance over an extended period, as it facilitates the analysis of emerging patterns and trends. It is essential to endure this time of solitude to get this comprehension.

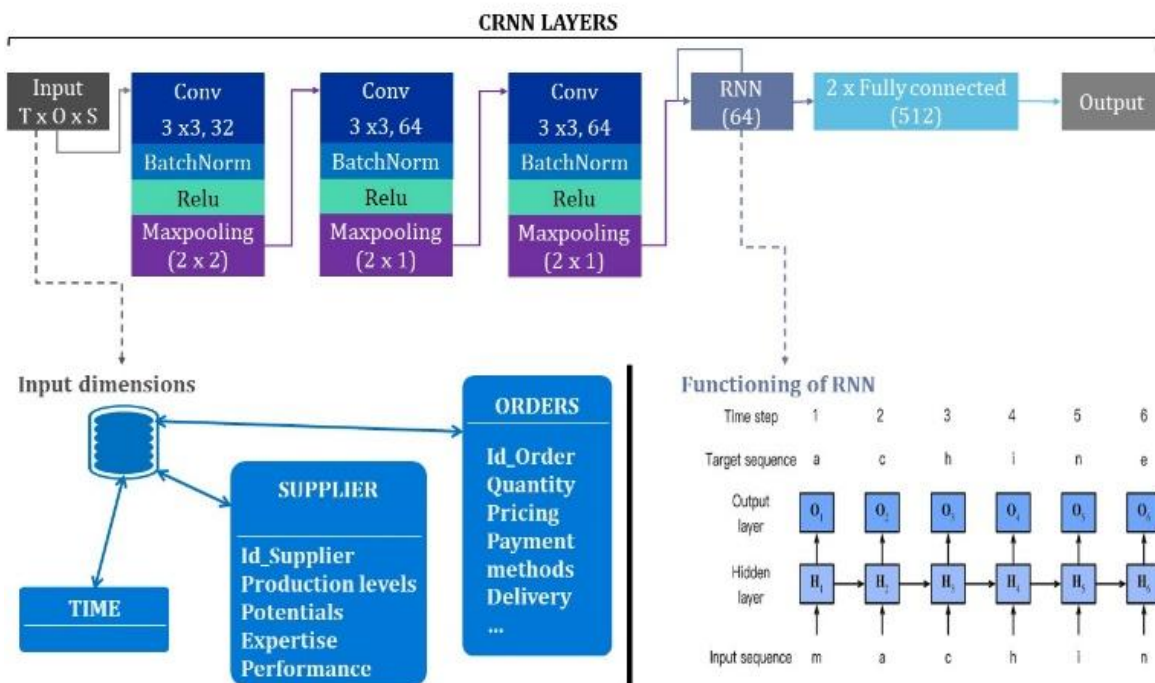

Fig. 3. Schematic diagram of the used CRNN.

The Schematic diagram of the used CRNN, illustrated in Fig. 3, which consistently generates a 2 x 512-dimensional embedding. Each convolution block consists of a convolution operation, followed by batch normalization and a ReLU activation (-0.1 slope). Following that, a 2 x 2 maximum pooling is conducted. The numbers within each block represent the output channel and kernel sizes. For example, "32, 3 x 3" indicates that the convolution layer generates 32 output channels with a kernel size of 3 x 3.

The "orders" dimension is differentiated from others by its utilization of a unique order identifier. The "orders" dimension encompasses critical information that elucidates each transaction in comprehensive detail. Customer data, which encompasses the documentation of essential consumer attributes, is deemed a vital component. Detailing the characteristics and specifications of the service or product to furnish supplementary information regarding your offering. The transaction data encompasses the amount, pricing, and various payment options. The information relevant to the supply or shipping process encompasses, among other aspects, specifics concerning logistics and the delivery schedule. All these components are encompassed in the data.

By integrating various components that enhance scheduling, monitoring, and order fulfillment processes, manufacturers can achieve a thorough understanding of operational efficiency and customer satisfaction. Manufacturers may enhance their processes because of this.

Consider the Provider (S): The supplier dimension aims to gather extensive information about its associated suppliers. The information presented here encompasses everything that comes after it: If an organization is categorized in accordance with the aforementioned criteria, it is considered to be working within a certain industry. "Production capabilities" refers to the talents, knowledge, and experience that are acquired via the process of manufacturing. In addition to the many performance metrics that are accessible, there are also key performance indicators that apply to ethics and sustainability.

Because of the interplay between all these components, you will have a clear image of the performance of the providers and the areas in which they may have room for improvement.

CRNN is used to describe a system that combines CNNs with RNNs. These networks are used for the purpose of evaluating the performance of providers by means of extraction of geographical and temporal data. Following the completion of the last recurrent layer, the output proceeds to be processed by a fully linked layer. This layer attempts to provide a prediction on the probability of the performance of the supplier. In terms of collecting both the static and temporal components of the data that is provided by the provider, the CRNN performs an excellent job. To do this, we implement recurrent neural networks (RNNs) for the purpose of modeling sequences and convolutional neural networks (CNNs) for the purpose of extracting features. When it comes to evaluating the performance of suppliers, the well-established CRNN architecture offers a complete method. It is possible to take this approach thanks to the innovative design. The capabilities of recurrent neural networks (RNNs) in temporal modeling are utilized in this approach, which makes use of the advantages

that convolutional neural networks (CNNs) offer in terms of spatial information extraction. Activities that are sequence-based are a good fit for the hybrid architecture because of its scalable and reliable approach to evaluating the performance of suppliers.

IV. RESULTS AND DISCUSSION

A. Data Description

As we propose a supplier selection approach combining criteria analysis and performance prediction, the evaluation phase requires the use of a dataset containing supplier information and supply operation history. To this end, we have chosen to use publicly available data to facilitate the evaluation of this approach, and to provide researchers with a basis for comparison using the Medicare & Medicaid Services (CMS) [33]. The website gives direct access to different data released by CMS. The datasets used for this study included information concerning durable medical Equipment and supplies with the supplier's information (payments, usage, submitted charges, beneficiary demographic...). This dataset is built on information gathered from CMS administrative during the period 2015-2020, whose dataset of each year exceeds 786040 elements.

B. Training Setups and Evaluation Metrics for CRNN

For the training of the CRNN, the Adam optimizer [34] is used, with a preliminary learning rate of 0.001. Every two epochs, this rate was reduced by a factor of 0.95, and the batch size was set to 32. The model was trained for 60 epochs in the whole experiment. We evaluated the performance of the CRNN model using the main evaluation metrics: the Mean absolute error (MAE), the mean absolute percentage error (MAPE), the Mean Squared Error (MSE), and the root mean square error (RMSE) [35]. For the CRNN modeling, we organized the training into a period sequence and feedback the sequence into the CRNN network constituted of various connected units, as explained above, to accomplish the current training model. Then, for the model optimization, the CRNN was trained to compute the values of the predicted variables at the set time.

The collected dataset has a total of 74,588 instances. These examples were randomly separated into three sets: a training set with 70% of the instances, a validation set with 20% of the instances, and a test set with 10% of the instances.

C. AHP Weightage

As stated previously, we applied AHP to calculate the weights and ranks of the various selection criteria. In the case of supplier selection, each level requires to be weighted to rate this large matrix. In this study, firstly, the weights of level 1 of each criterion are established and reviewed to determine the importance of each criterion. After that, the weight calculation steps of AHP are followed.

1) *Calculate the Weight of the selection criteria:* As supplier selection is paramount in manufacturing, this study presented a framework for analyzing its data, regardless of the size of the company, small, large, or medium. Manufacturing companies generate a large scale of diversified business processes. This is more convenient because they have a history

of transactions in addition to more recent data, with a strong experience of experts in the sector, which can ease the implementation of this approach. The chosen list of criteria in conjunction with the sub-criteria for each dimension was identified from the literature analysis, concerning the opinions of industry experts to ensure compatibility between the theoretical study and the practical aspects of supplier selection. The used sources offer a huge amount of data to study the previous records of the suppliers, which helped to confirm the list of criteria and sub-criteria.

At the preliminary stage, the criteria used were analyzed to recognize the most applicable criteria for the supplier selection process. Initially, there were ten criteria and 30 sub-criteria. Then preliminary discussions conducted with industrial experts were intended to gain a professional opinion about the criteria list. Then all these data were arranged and examined systematically.

The ranking results demonstrate that the most significant criteria that should be well studied while selecting suppliers for a specific product or service are quality and delivery of the suppliers followed by technological advances, performance improvement, and long-term relationship, which gained priority weightage of 0,462, 0,434, 0,359, 0,281 and 0,272 respectively the ranking weights. Based on the judgments given by the expert decision-makers, these criteria remain the most significant aspects that should be respected within a supplier selection process. According to these findings, it can be concluded that information sharing, subjective risks, intangible, cost-effective, and objective risks of the supplier gained relatively low priority weightings. When analyzing the priority weights for sub-criteria price appropriateness of the supplier is the most important criterion for them.

2) *Suppliers ranking*: The use of AHP to prioritize vital factors in manufacturing organizations may produce different importance values given to the specific requirements of each company. Moreover, these priorities may adjust regarding internal and external aspects, which can impact manufacturing operations.

TABLE I. PERFORMANCE RESULTS OF THE COMPONENTS OF PROPOSED METHOD

Method	AHP	CRNN	Proposed AHP_CRNN
Accuracy	90, 36 %	92,07%	95,96%
MAE	0.00554	0,05048	0,0771
MAPE	0,725782	1,004297	1,386251
MSE	0,00000602	0,00293	0,00262899
RMSE	0,00245	0,01711	0,04127

Table I demonstrates the results of supplier selection. Characteristically, the selection process ends once a supplier is chosen. However, other difficulties can occur regarding its performance and dedication, so it is quite important to analyze these aspects to avoid any potential risk that could affect the smooth running of manufacturing operations. Consequently, our study offers the possibility of having an optimized list of

suppliers to select the most efficient one that will meet the needs effectively and continuously, while ensuring the best gains and stability of manufacturing activities. Here best highest final values reveal that (Supplier_5), (Supplier_4), and (Supplier_2) are the most suitable suppliers for this supplier selection case, with the final values (2,031), (1,964), and (1,855) respectively.

D. Prediction of Supplier Performance

To quantify and assess the performance of the proposed method, the evaluation results of the AHP, CRNN, and the presented method. It can be noticed from the statistics in the table that the results of the three methods are all good with MAE < 0.1, MAPE < 1.5, MSE < 0.005, and RMSE rate < 0.5. The effects of using AHP and CRNN helped the proposed method to gain better results compared with traditional AHP and CRNN networks. The proposed strategic method proved higher prediction accuracy (95, 96%) with stronger generalization capability, and better operability, which shows that the AHP-CRNN proposed in this study is more appropriate for the supplier selection process in manufacturing systems.

While the first step, AHP, provided a methodological selection of the suppliers, the records of the best suppliers were captured and analyzed to reveal their performance. With all the completed preparations using AHP, the CRNN model computed iteratively the data, which contains the transaction history of the period 2015-2020 of the three suppliers, and provided the analytical results, as shown in Table II.

The anticipated values of providers exhibit significant consistency; however the projected values of some categories diverge considerably from prior assessments.

TABLE II. PREDICTION RESULTS OF THE PERFORMANCE OF SUPPLIERS REGARDING THE BEST-RANKED CRITERIA

Quality satisfaction								
Observed							Predicted	
Year	2015	2016	2017	2018	2019	2020	2025	2030
Supplier_2	29,5 0 %	44,3 2 %	51,2 5 %	57,5 0 %	63,5 2 %	69,3 2 %	71,3 9 %	76,4 1 %
Supplier_4	41,3 4 %	56,1 6 %	63,0 9 %	69,3 4 %	75,3 6 %	59,4 8 %	65,5 5 %	73,5 7 %
Supplier_5	53,1 8 %	68,0 0 %	74,9 3 %	81,1 8 %	87,2 0 %	71,3 2 %	77,3 9 %	85,4 1 %
Delivery transactions								
Observed							Predicted	
Year	2015	2016	2017	2018	2019	2020	2025	2030
Supplier_2	1230 0	1595 0	2507 1	3897 8	4532 8	5321 8	6730 9	9368 4
Supplier_4	1319 1	1684 1	2596 2	3986 9	4621 9	5410 9	6820 0	9457 5
Supplier_5	1408 2	1773 2	2685 3	4076 0	4711 0	5500 0	6909 1	9546 6
Technological advances								
Observed							Predicted	
Year	2015	2016	2017	2018	2019	2020	2025	2030

Supplier_2	33,5 6 %	55,2 3 %	61,9 8 %	68,7 8 %	70,6 2 %	76,5 5 %	80,3 2 %	85,6 9 %
Supplier_4	34,5 1 %	56,1 8 %	62,9 3 %	69,7 3 %	71,5 7 %	77,5 %	81,2 7 %	86,6 4 %
Supplier_5	34,2 8 %	55,9 5 %	62,7 %	69,5 %	71,3 4 %	77,2 7 %	81,0 4 %	86,4 1 %
Performance improvement								
Observed						Predicted		
Year	2015	2016	2017	2018	2019 %	2020	2025	2030
Supplier_2	34,9 2 %	56,5 9 %	63,3 4 %	70,1 4 %	71,9 8 %	77,9 1 %	81,6 8 %	87,0 5 %
Supplier_4	42,8 4 %	64,5 1 %	71,2 6 %	78,0 6 %	79,9 %	85,8 3 %	89,6 %	94,9 7 %
Supplier_5	40,1 7 %	61,8 4 %	68,5 9 %	75,3 9 %	77,2 3 %	83,1 6 %	86,9 3 %	92,3 %
Long-term relationship								
Observed						Predicted		
Year	2015	2016	2017	2018	2019 %	2020	2025	2030
Supplier_2	52,1 7 %	63,8 4 %	70,5 9 %	77,3 9 %	75,2 3 %	81,1 6 %	82,9 3 %	88,3 %
Supplier_4	60,0 9 %	71,7 6 %	78,5 1 %	85,3 1 %	83,1 5 %	89,0 8 %	90,8 5 %	96,2 2 %
Supplier_5	61,4 2 %	73,0 9 %	79,8 4 %	78,6 4 %	80,4 8 %	88,4 1 %	89,1 8 %	94,5 5 %

The analyzed data on long-term relationships clearly indicates that although Supplier_5 exhibited the best results from 2015 to 2017, there was a decline in performance in this criterion from 2018 to 2022, resulting in Supplier_4 outperforming Supplier_5, even in projected values. Supplier_4 marginally exceeded Supplier_5 in technology advancements and performance enhancement. Furthermore, the calculated performance metrics of the lower-ranked criterion exhibited varying levels of supplier performance. Particularly after 2018, when global economic problems emerged, affecting inflation rates and fluctuations in the international market following the coronavirus health crisis in 2020. The discrepancies in supplier performance underscore the significance of all selection criteria, not alone those identified by the AHP technique, to mitigate unanticipated factors that may disrupt production processes.

TABLE III. PREDICTION RESULTS OF THE PERFORMANCE OF SUPPLIERS CONSIDERING THE SUB-CRITERIA

Dimensions	Criteria	Detailed sub-criteria	Supplier_2	Supplier_4	Supplier_5
Capacity (C)	Cost-effective (C1)	Reduced cost/price of a product (C11)	44,67%	52,07%	49,55%
		Financial competence (C12)	57,64%	73,45%	58,52%
	Delivery (C2)	Available production (C21)	49,16%	52,23%	63,79%
		Delivery satisfaction (C22)	58,89%	63,96%	83,42%

Intangible (C3)	Performance history (C31)	43,29%	51,44%	73,01%	
	Responsiveness and situation in the industry (C32)	38,10%	77,65%	65,83%	
	Technological advances (C4)	Design (C41)	42,06%	50,48%	46,12%
		Quantity of patents applying (C42)	28,06%	56,20%	44,32%
Relative shares (C43)		24,04%	52,19%	48,35%	
Quality (C5)	R&D expenses input intensity (C44)	21,04%	67,79%	62,57%	
	Reliability of product (C51)	59,74%	76,89%	82,97%	
	Specific characteristics of remaining products (C52)	49,78%	68,92%	72,86%	
	Quality of products (C53)	43,06%	61,21%	59,35%	
Willingness (W)	Information sharing (W1)	Honest and regular communications (W11)	-	-	-
		Relationship proximity (W12)	-	-	-
	Long-term relationship (W2)	Dedication to quality (W21)	-	-	-
		Long-term commitment (W22)	21,26%	59,14%	54,99%
		Mutual honesty and respect (W23)	69,08%	77,06%	68,99%
	Performance improvement (W3)	Commitment to permanent development in products and processes (W31)	31,15%	56,65%	61,80%
Effort in supporting "just-in-time" standards (W32)		54,16%	57,16%	84,69%	
Risk of supply (R)	Objective risks (R1)	Geographical closeness (R11)	48,09%	73,19%	76,87%
		Bankruptcy (R12)	57,78%	86,07%	83,40%
		Strikes, natural disasters, pandemics (R13)	41,19%	81,30%	67,91%

Subjective risks (R2)	Transportation disruptions (R14)	40,96%	62,26%	53,54%
	Fluctuations in the market price of raw materials (R15)	44,24%	50,94%	70,73%
	Reputation (R21)	35,99%	71,10%	70,64%
	Organizational management (R22)	70,95%	80,94%	41,98%
	Social responsibility (R23)	59,89%	84,68%	56,99%
	Political and regulatory environment (R24)	53,92%	71,27%	64,12%
	Market conditions (R25)	40,97%	56,57%	56,09%
Global performance		46,84%	66,93%	66,03%

The list derived using the AHP approach identifies the top three suppliers: Supplier_5, Supplier_4, and Supplier_2. Nevertheless, the performance analysis of each supplier over the years indicates that Supplier_4 is a viable contender to Supplier_5. We used the AHP phase as input for the CRNN rather than the whole list of vendors. The use of AHP enabled us to generate a concise list, facilitating the CRNN's emphasis on the specifics of each supplier's performance according to the selection criteria. In the prior assessments, we only used the selection criteria from Table III, without considering the influence of the sub-criteria on supplier selection. To provide a fair comparison among the suppliers, the subsequent test involves evaluating the performance of each supplier based on the selection sub-criteria outlined in Table III. The performance

prediction findings, based on the selection sub-criteria, indicated that Supplier_4 outperforms Supplier_5.

This study's findings and existing literature demonstrate that using AHP enables manufacturing businesses to make supplier selection decisions based in methodical and objective assessments of available alternatives. This may mitigate the risk of bad decision-making and assure the selection of the appropriate supplier to fulfill the organization's objectives and specifications. Generally, selecting the appropriate provider to guarantee prompt delivery of superior quality.

Choosing appropriate items or services is crucial, since picking the incorrect option may result in many complications, such delivery delays, substandard quality, or even legal ramifications. To mitigate these possible issues, it is essential to adopt a comprehensive methodology for supplier selection that encompasses all relevant criteria and sub-criteria. By evaluating the suggested selection criteria with other pertinent organizational characteristics, decision-makers may mitigate the risk of supplier-related issues and assure the selection of an appropriate partner for their requirements. We have used deep learning to analyze and forecast the performance of the selected providers in order to mitigate risks. The AHP-CRNN methodology facilitates enhanced analysis to get increased revenues via the selection of the appropriate provider.

E. Comparison with Former Methods

The AHP-CRNN model was reviewed from multiple angles in the preceding sections. To properly demonstrate the operational effectiveness of AHP-CRNN, we chose four extensively proposed and used techniques (RNN, RDNN, CRNN, and LSTM). Based on the relevant published works, we retrieved the corresponding architectures and parameters of the abovementioned methodologies for this comparative analysis. As stated in the preceding sections, the experimental setting for the comparison maintained a consistent unified strategy. This included using the same database and keeping the percentages for the training, validation, and test datasets the same.

Fig. 4. The overall supplier selection assessment compared to other models in training and validation processes.

Because of the large amount of experimentation data, it is not possible to offer detailed convergence accuracy metrics for all tested approaches. As a result, in this section, we will instead provide statistical rankings. Fig. 4 depicts an overview of true positive (TP) and false positive (FP) rates for the training and validation sets, allowing for a thorough evaluation of the proposed supplier selection technique.

It allowed us to understand the model's ability to correctly identify positive examples and avoid false positives. As comparing the TP and FP rates of the training and validation sets is an important aspect of deep learning evaluation and tuning, the results show a massive improvement while using the AHP-CRNN model.

The proposed AHP-CRNN-based method for supplier selection employs a strategic process. We used the AHP phase to select a list of potential suppliers, which is used as the input of the CRNN model. The strategic AHP-CRNN-based approach strengthens the multi-objective analysis in the process of supplier selection. The CRNN employs CNN layers for feature extractions and RNN layers for the temporal dependencies assessment.

The proposed method was proven performant compared to traditional RNN [36], LSTM [31], RDNN [28], and CRNN [37]. To further compare and quantify the performance of the proposed AHP-CRNN strategy, the evaluation results of the literature models are displayed in Table IV.

TABLE IV. PERFORMANCE COMPARISON OF DIFFERENT LITERATURE MODELS

Method	Accuracy	MAE	MAPE	MSE	RMSE
RNN	89,99 %	0,009 28	0,9630 97	0,000500 7	0,01588 07
LSTM	92,56 %	0,018 38	0,9721 97	0,00072	0,0161
CRNN	92,07 %	0,050 48	1,0042 97	0,00293	0,01711
RDNN	91,73 %	0,059 98	1,0137 97	0,001505 99	0,05004 7
Proposed AHP_CRNN	95,96%	0,077 1	1,3862 51	0,002628 99	0,05127

The findings show that the LSTM surpasses the traditional RNN. That can be explained by the fact that LSTM networks can store long-term dependencies better than traditional RNNs. In traditional RNNs, the information from long-term dependencies can easily be forgotten or lost as it moves through the network. However, LSTMs have an internal memory cell that can store information for a longer period, allowing them to better capture long-term dependencies. However, traditional RNNs are often computationally simpler and more efficient than LSTMs, which can be more complex and computationally demanding. Applications combining RNNs with other types of neural networks, such as CNN or DNN, showed improved model performance. As the use of RNN with other networks makes it possible to address multiple tasks simultaneously or tackle more complex manufacturing data, the proposed method is based on a CRNN to have to ability to handle structured as well as unstructured data, ensure better generalization to new data, and reduce the overfitting.

F. Discussion

Comprehending these distinctions is crucial for efficient supplier selection. By analyzing historical data, decision-makers may identify suppliers who consistently perform effectively, even under challenging circumstances. This mitigates risks and ensures supply chain continuity. Moreover, analyzing supplier performance longitudinally allows for the identification of suppliers who consistently improve their performance. This information is crucial when considering long-term partnerships and developmental potential.

The proposed method facilitates the benchmarking of suppliers, highlighting top performance and identifying those requiring development. This data-driven approach enables decision-makers to make objective and informed choices, leading to cost reductions and enhanced efficiency. Moreover, evaluating supplier performance over time enables the optimization of your supply base. Organizations may establish robust relationships with reliable suppliers by acknowledging consistent performance, leading to enhanced negotiating leverage and favorable conditions. Evaluating supplier performance over time is essential for supplier management, since it offers insights into the consistency and dependability of providers.

The study outlined in the article examines the difficulties encountered by industrial units in a competitive and worldwide market, emphasizing the need of optimizing supply chains and choosing appropriate suppliers for success. The research underscores the necessity for enterprises to provide superior products/services at competitive pricing more swiftly than their rivals. This requires a rigorous supplier selection procedure to ensure supply chain integrity, preserve profit margins, and meet customer satisfaction.

The AHP-CRNN strategy in supplier selection offers several practical advantages, such as cost reduction, risk alleviation, quality enhancement, ethical procurement, and strengthened supplier relationships. Through the methodical assessment and selection of suppliers using both quantitative and qualitative criteria, firms may enhance their supply chains, secure a competitive advantage, and establish a robust and sustainable business environment.

The AHP-CRNN technique significantly influences supplier selection decisions. A primary advantage is the capacity to make well-informed supplier selection judgments. By methodically assessing prospective suppliers against several factors, including cost, quality, and delivery time, firms get an extensive understanding of their alternatives. This allows them to choose providers who fulfill urgent requirements while also aligning with long-term strategic objectives. In a more competitive business landscape, educated decision-making may profoundly influence a company's performance and competitiveness.

- Financial Implications and Efficiency: The AHP-CRNN methodology yields significant cost savings. By systematically evaluating suppliers, firms may discern those providing the most advantageous terms and pricing. This may result in substantial cost reductions,

an essential element in sustaining profitability. Furthermore, choosing suppliers that can adhere to stringent delivery timelines and adjust to fluctuating circumstances improves supply chain efficiency. Minimized supply chain interruptions and enhanced delivery times may result in decreased operating expenses and heightened customer satisfaction.

Quality assurance and risk management are essential in the selection of suppliers. The AHP-CRNN methodology facilitates the identification of suppliers with a demonstrated history of providing high-quality goods or services. Consistently choosing such suppliers guarantees the preservation of high-quality standards and mitigates the likelihood of product recalls or quality-related problems. Moreover, effective supplier selection is essential for risk minimization. Companies may choose suppliers recognized for their resilience and adaptability to unanticipated obstacles, thereby mitigating supply chain risks.

The AHP-CRNN methodology fosters a culture of ongoing improvement and data-driven decision-making. Organizations may evaluate previous supplier performance data and trends to perpetually enhance their selection criteria. This iterative procedure results in improved supplier selection over time. Furthermore, the methodology cultivates a data-driven culture throughout the firm, transcending supplier selection. It advocates for decision-makers to use data and analytics for informed decision-making across diverse business functions.

V. CONCLUSION

The suggested method of supplier selection using the Analytic Hierarchy Process (AHP) and Convolutional Recurrent Neural Network (CRNN) has significant consequences. Initially, using AHP provides a structured framework for systematically and openly evaluating and contrasting various criteria. The suggested technique enhances the long-term sustainability of manufacturing operations by ensuring efficient supplier selection. Fostering robust connections with suppliers and achieving favorable outcomes are essential for the seamless operation of production processes. The systematic strategies obtained from the AHP-CRNN approach facilitate the enhancement of production systems, guaranteeing the sustained availability of reliable and high-performing suppliers. The applicability of the suggested technique has been shown via several experimental experiments, highlighting its efficacy in supplier selection for sustainable manufacturing systems. This illustrates its potential for practical use. The study indicates that the intelligent judgment methodology may be improved to better the selection criteria for complex manufacturing systems, suggesting that the suggested method may be expanded and modified in future research.

Understanding Art Deeply: Sentiment Analysis of Facial Expressions of Graphic Arts Using Deep Learning

Fei Wang¹

Hubei University of Technology, Wuhan City, Hubei Province, 430068, China¹

Abstract—Art serves as a profound medium for humans to express and present their thoughts, emotions, and experiences in aesthetically and captivating means. It is like a universal language transcending the limitations of language enabling communication of complex ideas and feelings. Artificial Intelligence (AI) based data analytics are being applied for research domains such as sentiment analysis in which usually text data is analyzed for opinion mining. In this research study, we take art work and apply deep learning (DL) algorithms to classify seven diverse facial expressions in graphics art. For empirical analysis, state of the art deep learning algorithms of Inceptionv3 and pre-trained model of ResNet have been applied on large dataset. Both models are considered revolutionary deep learning architecture allowing for the training of much deeper networks and thus enhancing model performance in various computer vision tasks such as image recognition and classification tasks. The comprehensive results analysis reveals that the proposed methods of ResNet and Inceptionv3 have achieved accuracy as high as 98% and 99% respectively as compared to existing approaches in the relevant field. This research contributes to the fields of sentiment analysis, computational visual art, and human-computer interaction by addressing the detection of seven diverse facial expressions in graphic art. Our approach enables enhanced understanding of user sentiments, offering significant implications for improving user engagement, emotional intelligence in AI-driven systems, and personalized experiences in digital platforms. This study bridges the gap between visual aesthetics and sentiment detection, providing novel insights into how graphic art influences and reflects human emotions by highlighting the efficacy of DL frameworks for real-time emotion detection applications in diverse fields such as human psychological assessment and behavior analysis.

Keywords—Artificial intelligence; deep learning; sentiment analysis; art detection; image processing; convolutional network

I. INTRODUCTION

Art is a broad term that can be described as the work or process undertaken by man in creating physical skills, objects, or musicals involving painting, sculpture and dancing etc. They are not only appraisals of culture and individual encounters but also as a channel or medium of communication which enforces feeling and thinking. Interdisciplinary methods are used in the analysis of art that many disciplines incorporate into their analysis the impact and role of artistic creations on and from the social contexts of world. For example, in expressions analysis of art, the concern is on the feelings invoked by art and how such feelings differ among the subgroups and cultures

[1]. In more practical terms, researchers use semi structured interviews and questionnaires with the audience together with quantitative tools like sentiment analysis to elicit responses that contribute to a nuanced understanding of the use of art as a means of creating human experiences and engagement with various social processes. There are various types of sentiment analysis including the binary classification of subjectivity analysis [2], the tertiary classification containing the sentiment valance finding [3], the multi-classification containing the emotion detection [4], and the aspect-oriented sentiment analysis [5] that targets feature level deep understanding. a means of communication that evokes emotions and provokes thought. The analysis of art spans multiple research areas, including psychology, sociology, and cultural studies, where scholars examine how artistic expressions influence and are influenced by societal contexts. For instance, expressions analysis in art focuses on understanding the emotional responses elicited by artworks and how these responses vary across different demographics and cultural backgrounds [6]. Researchers employ qualitative methods such as interviews and surveys alongside quantitative techniques like sentiment analysis to gauge audience reactions, ultimately contributing to a deeper understanding of the role of art in shaping human experience and social discourse [7].

Moreover, sentiment analysis is combined with other technologies like computer vision and IoT devices so that a business can monitor information about customers' emotions and actions in the physical spaces in real-time mode [8]. Sentiment analysis is an important area as it continues to develop, the complexity of the models for such analysis will increase making it easier to determine the right strategies when they are required in different fields. Analysis of sentiment in images has been a popular trend in recent years mainly in the context of affective content in images. This field discusses how certain images create certain feelings and this is very essential because in areas like social media analysis or advertising. The research in this direction started around 2010, where the first attempts were made to place pictures into positive or negative sets according to their characteristics. To interpret affect, there has been the use of methods like Convolutional Neural Networks (CNNs) to perform context analysis of images, in relation to emotional content through organizations like Flickr and Twitter. From the research done, texture and color co-occurrence histogram are critical in identifying the sentiment of an image [9] [10]. In addition, proposing a method for combining both text and image features should help improve

the effectiveness of sentiment classifiers and provide additional knowledge of the users' emotions conveyed through images posted on social media [11].

As for social art, sentiment analysis becomes a crucial method on how the public perceives the art pieces and other materials that are a part of culture. By observing images of artworks or social art initiatives posted on social media, emotions and reception of a given subject in the community can be quantified [12]. This approach can help in measuring the level of audience participation but can also enlighten artists and curators regarding prevailing mood trends within their viewers. When applied in this case, the deep learning models enable the analysis of subtle differences in sentiment beyond basic positive-negative quality assessments [13]. In addition, the differentiation of emotions that are related to concrete artworks will enable targeted addressing and, thus, improve the effectiveness of social art activities.

A. Research Contributions

In this study, our main contributions include:

- For graphic art and identification of seven emotions, data preprocessing and diverse deep learning algorithms have been applied.
- Highlighted the limitations of existing studies by filling research gaps in emotion detection using digital image processing and deep learning.
- Developed a robust emotion classification framework using a deep learning pre-trained models including ResNet-50 and Inception v3 model by modifying the fully connected layer to adapt to the specific emotion classification task.
- Achieved highest classification performance of 99% with inception v3 model as compared to baseline models such as VGG16 and DCNN, demonstrating state-of-the-art results.

For the rest of the paper, Section II reviews the existing studies in relevant literature, then Section III shares the proposed research methodology along with experimental set-up discussing datasets which are prepared and used for empirical analysis and performance metrics used for results comparison. Section IV presents the results and discussion sharing findings from this study. Before concluding the manuscript, Section V discusses the results in detail sharing comparative analysis of the proposed model with the existing approaches.

II. BACKGROUND

The sentiment analysis of images by employing deep learning techniques has received increased attention in the last few years due mainly to the large availability of computer powers and the growing availability of image data in the social media platforms. In this approach, deep learning techniques, including Convolutional Neural Networks CNNs, are used to learn useful feature representations of images from social media which are indicative of emotional sentiments. Table I defines the summary of existing studies for deeper analysis. Studies show that CNNs are capable to capture spatial hierarchies of images for the task of categorizing sentiments

into positive, negative or neutral [14]. Recent works have shown that using transfer learning methods including Inception-V3 it is possible to librarian the accurate classification of the sentiment analysis tasks without requiring large, labeled datasets [15]. This capability is particularly valuable where good quality labeled data is hard to come by or in short supply.

The combination of two modalities, i.e., using image analysis in conjunction with textual sentiment analysis, has enriched the field even more. Analyzing the pictures together with the related texts helps researchers get a deeper insight into the people's attitudes [16]. For example, the integration with captions or hashtags used in Big Five Personality traits analysis helps models consider extra context that enhances the sentiment prediction accuracy up to multiple factors [17]. Moreover, improvements in the deeper architecture of the Capsule Networks besides the convolutions with RNN and hybrid Deep Learning also demonstrate great performance in sentiment analysis [18]. These models prove enhanced performances in comprehending intricate nonverbal emotions described through graphics. There is still a problem in image sentiment analysis, especially in terms of the stability of human emotions and different perceptions of images across cultures. Due to its subjectivity, there are variations in modeling sentiments which need to be dealt with by having rich training set with various emotions and occurrence [19]. A revolution in the recent few years in deep learning has revolutionized the field of image sentiment analysis where the general expressions of emotions in the image are processed and understood [20].

Among the more significant trends, it is possible to distinguish the combination of CNNs and RNNs as these networks have been used to extract spatial and temporal data in images and their textual descriptions. CNNs are good at detailing the local features protruding on architectural diagrams that make them significant in accentuated sentiment classifying assignments where visualization features are dominant [21]. Current research has also shown that combining CNNs with LSTMs results in finer outcomes in the sentiment classification owing to combining pros of both structures [22].

The use of people's emotions in multimodal textual and visual platforms has been considered as an active research area in this context. Combining information retrieved from both images and associated captions will give more light to researchers to get to the core point of this subject, which in this case is the sentiments. For example, it is established that the interaction of CNNs for image processing with individualized LSTMs or transformers for sports sentiment analysis can help improve sentiment outlook than individual modality alone [23]. This approach is especially useful in settings such as social media where messages are occasionally accompanied by images which indicate the authors' emotional state. Thus, the current state of and future trends for image sentiment analysis based on deep learning methods are steadily developing. We find a vast scope towards improving the existing sentiment analysis performance and its utility in different domains by integrating them with the latest architectural models like CNNs, RNNs, and transformers with a combination of multi-modal data for the prediction of gender violence based on

sentiment analysis [24]. As the issues concerning data quality and ethical implications are solved as potential issues, it will be possible that both quantity and quality aspects of deep learning-based sentiment analysis will expand.

A. Limitations of Existing Studies

Many of the prior works in the field of emotion detection, especially in digital image processing and deep learning algorithm, often encounter several limitations. Most use simple models such as the VGG16 or DCNN, which while serving basic image categorization lack the ability to discern the patterns for capturing emotion features required for categorization. These models often face challenges with overfitting, especially when dealing with limited or imbalanced datasets, resulting in suboptimal generalization to unseen data.

Additionally, previous studies frequently lack comprehensive evaluations across diverse emotion categories or robust datasets, which limit their applicability to real-world scenarios. Computational inefficiency is another significant drawback, as some models require extensive computational resources but fail to deliver proportionally high performance. In addition, few advanced data augmentation techniques are used and the absence of an extensive focus on specific domains leads to failures to reach better accuracy and reliability. Such limitations justify the need for more sophisticated and flexible strategies, as addressed in this research study. The novelty of our work lies in achieving the highest results with an increased number of classes, enabling more comprehensive emotion and sentiment analysis from diverse facial expressions in graphic art, surpassing the limitations of previous studies with fewer emotion categories.

TABLE I. SUMMARY OF EXISTING STUDIES

Ref	year	Model	Dataset	Classes	Results
[14]	2018	CNN	Twitter images	4	90%
[15]	2023	CNN	famous CK+, FER2013, and JAFFE	3	95%
[16]	2022	BERT,CNN	MVSA-Multiple and T4SA	2	93%
[17]	2024	LSTM	MBTI	5	92%

III. METHODS AND ARCHITECTURES

The two areas of artificial intelligence and deep learning have prompted notable improvement in understanding and discriminating demanding patterns in digital image. This study proposed the models that are embedded in recognizing colorless images depicting diverse artistic facial expressions. It encompasses high complication preprocessing, architecture, and large dataset to provide robust and accurate results. The architectures for the employed models are respectively shown in Fig. 1, which shows the basic workflow of any typical DL models with multi-tier structures of the architectures. Firstly, known as Dataset Collection, the image data pertinent to the process is accumulated. Then, Data Preprocessing is done to remove all irrelevant or duplicate data and adjust the data format for the model. The next step is Training with Models such as Inception v3 and ResNet50, which are deep convolutional neural network, which we extract features from images and learn some patterns from them. Fully connected layers follow the training process to combine the features which the model has learned with for the purpose of classification. It is then classified under different categories of different models, having considered the learned patterns. Moreover, the figure shows that Subtractive operations like Activation Function, Pooling, Flattening, Reduction of Overfitting and Optimizer are required to enhance the efficiency of the model and to avoid overfitting and thus more generalized results.

A. Dataset Preparation and Preprocessing

Dataset consists of 32,298 grayscale images illustrating facial expressions and depicted as sketches with lead pencils. It includes seven emotion classes: This means the emotions, which are depicted in the images can be categorized into seven classifications, which are being angry, disgust, fear, happy, sad, surprise, and a neutral category. The challenges of the artistic and grayscale pictures as well as size and variability of the dataset are countered well, thus allowing the use of deep learning models.

The input data also handles through some manipulations to improve its compatibility with the selected deep learning models and more importantly to ensure that the models undergo stable training by applying two major steps of resizing and normalization. By changing the dimensions of the images to 299 by 299 pixels because that is the expected input size for model. There will be occasional variability in light conditions therefore the image's data are normalized at a mean of [0.5, 0.5, 0.5] and standard deviation [0.5, 0.5, 0.5].

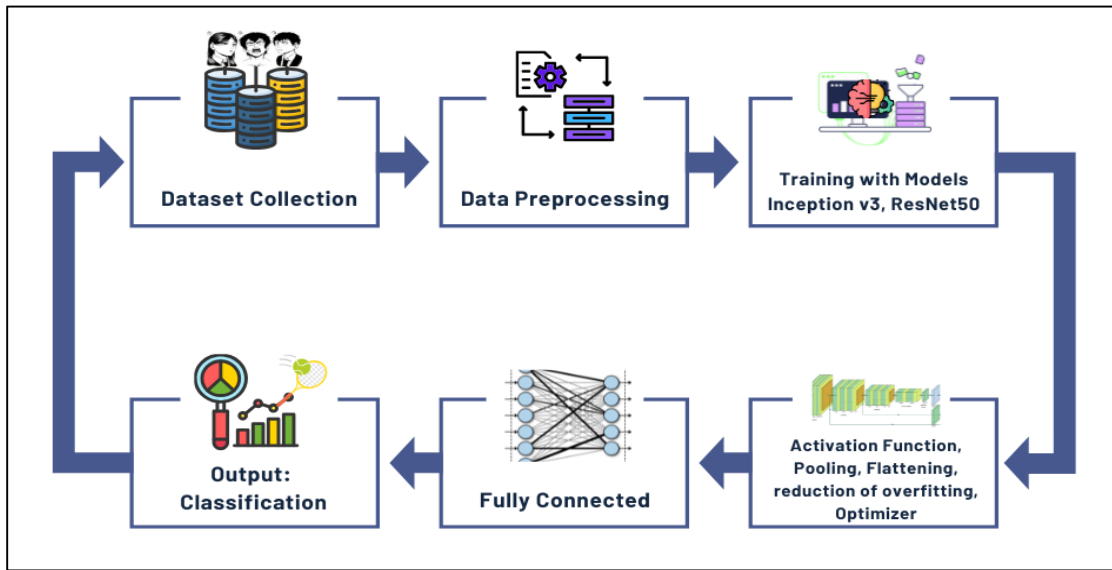

Fig. 1. Basic framework of any typical deep learning model.

These preprocessing steps assist in controlling fluctuations in the training curve using pixel values for normalization by following Eq. (1), thereby having an optimized training process with good features. Table II contains comprehensive details of all symbols that are used in equations for better understanding.

$$P_{normalized} = \frac{P-\mu}{\sigma} \quad (1)$$

B. Applied Deep Learning Models

In sentiment analysis method containing the feature extraction and the classification, both components are significant to the interpretation of the emotional context visually transferred. For example, in feature extraction, model captures the features such as facial expressions, patterns, or

textures as a representation of happy, sad, angry, and the like. Such features are embedded into the feature space of higher dimensions thus capturing relevant visual details. During this stage, these features extracted are then subjected to fully connected layers that try to map the image to sentiment categories. It makes it possible to capture slight changes in the expressions or other artistic features which are valuable to make robust sentiment categories even in highly diverse image sets.

1) *Inception v3 architecture*: Inception v3 is a deep learning architecture which optimizes computational speed and uses high effectiveness, as architecture shown in Fig. 2 for this study.

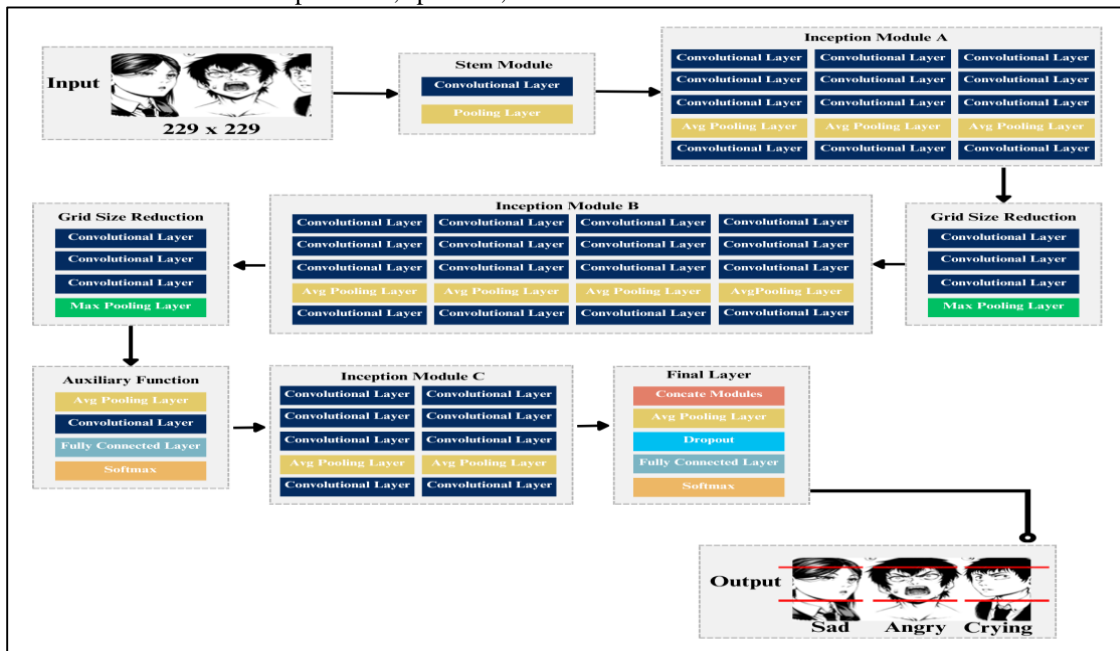

Fig. 2. Architecture of Inception v3 model.

This is done with the help of the inception module, which takes the input data and splits it through a series of channels every of which processes the data differently while trying to capture as many attributes of the input as $X \in \mathbb{R}^{H*W*D}$ where H is the height, W is the width and D is the depth showing number of channels. These paths are then added to produce a single output that can be represented as $O_{inception} \in \mathbb{R}^{H*W*D'}$; thus, the network can capture a diverse set of features at multiscale level. To minimize computational complexity, certain design strategies have been applied, such as the factorized convolution, where a complex convolution is replaced by a series of simpler steps, as well as the dimensionality reduction using 1x1 convolutions, computed as in Eq. (2).

$$O_{inception} = \text{concat}(\text{conv}_{1*1}(X), \text{conv}_{3*3}(X), \text{conv}_{5*5}(X), \text{conv}_{1*1(3*3)}(X)) \quad (2)$$

Where:

$$\begin{aligned} \text{conv}_{1*1}(X) &= W_1 * X + b_1, \text{ with } W_1 \in \mathbb{R}^{1*1*D*D_1} \text{ and } b_1 \in \mathbb{R}^{D_1} \\ \text{conv}_{3*3}(X) &= W_3 * X + b_3, \text{ with } W_3 \in \mathbb{R}^{3*3*D*D_3} \\ \text{conv}_{5*5}(X) &= W_5 * X + b_5, \text{ with } W_5 \in \mathbb{R}^{1*1*D*D_5} \end{aligned}$$

The auxiliary head is a technique of regularization in which gradients are added in the actual backpropagation processes during the training. The auxiliary classifier applies function over the featured space $\hat{y}_i^{auxiliary}$ produced by a certain layer of the network, computed as in Eq. (3).

$$L_{auxiliary} = -\sum_{i=1}^C y_i \log(\hat{y}_i^{auxiliary}) \quad (3)$$

Also, Inception v3 requires Global Average Pooling (GAP) to decrease the size of feature maps $F \in \mathbb{R}^{H*W*D}$ along with depth dimensions D for training model and enhancing generalization to each feature map f_a , computed as in Eq. (4).

$$GAP(F) = \frac{1}{H*W} \sum_{i=1}^H \sum_{j=1}^W F_{ij}^d \quad (4)$$

Finally, the output is classified using activation function layer combines both main classification and the auxiliary loss, computed as in Eq. (5), which indeed makes the model very effective for large scale image recognition.

$$L_{total} = L_{main} + \delta L_{auxiliary} \quad (5)$$

2) *ResNet 50 architecture*: ResNet-50 is a categorized deep convolutional network model resolving vanishing gradients issue in very deep learning networks, as working defined in Fig. 3.

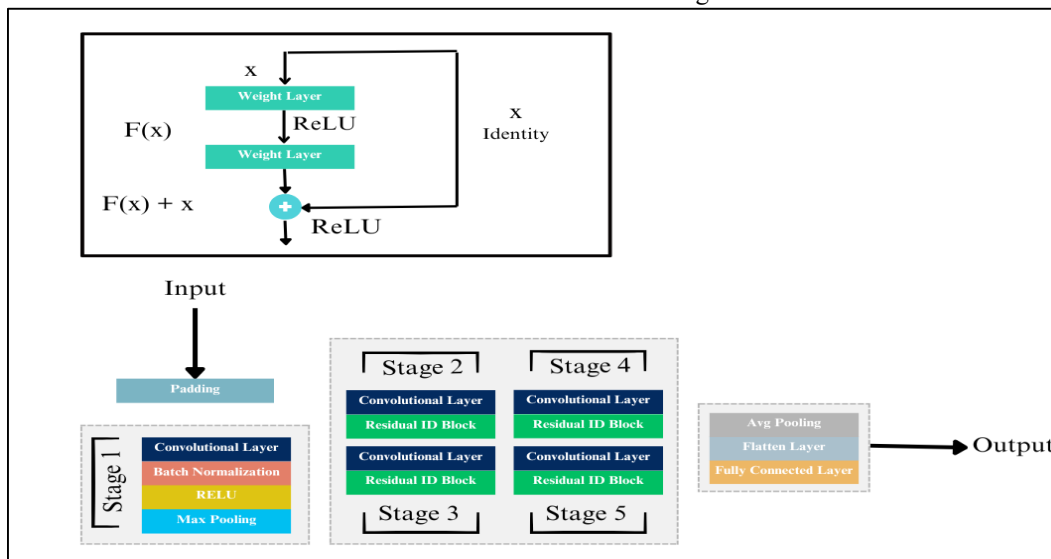

Fig. 3. Architecture of ResNet50 model.

With 50 layers and each layer of residual blocks. ResNet design is based on the concept of Residual block or skip connections that can bypass one or more layers of computations to provide the network with a method of training from scratch deeper networks that causes less degradation, at least theoretically. These skip connections are useful in reducing the vanishing gradient problem because they enable the gradients to flow directly through them using learning function \mathcal{F}_k which is calculated as in Eq. (6).

$$y_k = \mathcal{F}_k(x_k, \{W_{k,i}\}) + x_k \quad (6)$$

The ResNet-50 model has been designed mostly for relatively small image classification problems and uses batch

normalization and ReLU activation for enhanced results, computed as in Eq. (7).

$$z_k = \sigma(BN(\mathcal{F}_k(x_k, \{W_{k,i}\}) + x_k)) \quad (7)$$

As for the architecture, it is made up of the first convolutional layer, that is several stages of residual blocks where each block is made up of a 1x1 convolutional layer, a 3x3 convolutional layer and a final second 1x1 convolutional layer, defining the gradient flow using loss function \mathcal{L} , computed as in Eq. (8).

$$\frac{\partial \mathcal{L}}{\partial x_k} = \frac{\partial \mathcal{L}}{\partial y_k} + \frac{\partial \mathcal{L}}{\partial z_k} \cdot \frac{\partial z_k}{\partial x_k} \quad (8)$$

The architecture makes it easy to learn both low- and high-level features and that is the reason why this model is widely used in many computer vision tasks such as object detection and segmentation.

TABLE II. SYMBOLS DESCRIPTION OF APPLIED EQUATIONS

Symbols	Description
$P - \mu$	Mean values
ϑ	Standard deviation
P	Original pixel values
*	Convolution operation that are concate with final output
$y_i \in \mathbb{R}^C$	One hot-encoded true label vector for class i
$\hat{y}_i^{auxiliary} \in \mathbb{R}^C$	Predicted probability distribution from the auxiliary classifier
C	Number of output classes.
F_{ij}^d	Feature value at position (i, j) in the $d - th$ channel of the feature map
δ	Weight factor that balances the auxiliary loss relative to main loss
y_k	Output of the $k - th$ residual block
x_k	Input to the $k - th$ residual block
$\mathcal{F}_k(x_k, \{W_{k,i}\})$	Learned residual function with weight $W_{k,i}$
z_k	Output of the Batch Normalization (BN) and activation
σ	RELU activation function
$\frac{\partial \mathcal{L}}{\partial x_k}$	Gradient of loss with respect to input x_k
$\frac{\partial \mathcal{L}}{\partial y_k}$	Gradient with respect to output y_k
$\frac{\partial \mathcal{L}}{\partial z_k}$	Gradient of loss with respect to BN output z_k
$\frac{\partial z_k}{\partial x_k}$	BN output z_k depends on the input x_k .
TP and FP	True Positive and False Positive
TN and FN	False Positive and False Positive

C. Performance Measures

To fully assess the performance of models, standard assessment metrics are utilized including accuracy, precision, recall and F1-score. They include information on correct classified instances, and are useful in cases where classes are imbalanced, or misclassifications to different classes cost differently. Accuracy is the simplest of all the performance measurement metrics that give the percentage of correct prediction of instances to the entire instances. But it might not be that effective in handling those datasets with imbalanced classes. Precision becomes important due to this, together with recall. Precision is the measure of the accuracy of the positive predictions calculated as the proportion of true positives to the total positive predictions and the false ones, it is valuable in those application domains where false positives carry serious implications (e.g., medical diagnoses). Recall or Sensitivity is equal to the relation of true positive findings to the sum of true positives and false negative results, which highlights the ability of the model not to miss any relevant cases. F1-score defined

as the harmonic mean of precision and recall, is a valuable supplement to these two values, but most important when both measures are significant.

The training and validation accuracy and loss are important parameters to decide about the learning progress of a model. The accuracy of training measures the capability of the model on the training dataset, while the validation accuracy tests the model on how well it can perform on new dataset. The same about training loss that estimates the error during the learning process of the model on the training set, and validation loss that estimates the error on the validation dataset. Training loss should be decreasing while validation loss should be a plateau or on an increasing trend if there is not much data for training or training data is limited rather than showing a decreasing trend having a low value is best for a well-generalized model. Thus, Table III indicates the metrics employed to adjust the models depending on the context of evaluation, which will be highly beneficial for practitioners.

TABLE III. EVALUATION PERFORMANCE MEASURES

Sr. No	Metrics	Equation	Purpose
1	Accuracy	$\frac{TP+TN}{TF+FN+FP+TP}$	Measures overall correctness
2	Precision	$\frac{TP}{TP+FP}$	Focus on avoiding false alarms
3	Recall	$\frac{TP}{TP+FN}$	Emphasizes capturing all actual positives
4	F1-score	$\frac{2(Precision*Recall)}{Precision+Recall}$	Indicates overall performance balance

IV. RESULTS AND DISCUSSION

The findings on how facial emotions are classified using the deep learning pre-trained models, Inception v3 and ResNet50 model can be a useful guide on the efficiency of deep learning for facial emotions classification, as shown in table IV. The main aim of the study is to distinguish between emotions like ‘angry,’ ‘crying’, ‘embarrassed’, ‘happy’, ‘pleased,’ ‘sad,’ and ‘shock’ through facial expression, and the results of the study can be given multiple interpretations.

TABLE IV. RESULTS OF MODEL PERFORMANCE ACROSS ALL MEASURES

Model s	Training				Validation			
	Accur acy	Precis ion	Rec all	F1- Sco re	Accur acy	Precis ion	Rec all	F1- Sco re
ResNet50	98	98	98	98	67	66	67	65
Inception v3	99	99	99	99	76	78	76	76

A. Hyperparameter Settings

The configurations of the model are adjusted to improve its performance for the emotion classification task, as shown in Table V. An optimizer learning rate is used to adjust generalization of the pre-trained model while practicing on the dataset without causing much alteration of the learnt parameterization. The number of batches has been defined in the manner to optimize the computational resources and to maintain steady gradients during the training phase. This algorithm is used due to its adaptive learning rate for each

parameter what makes possible to obtain faster convergence with better generalization. Like the previous optimizers, this optimizer does not require specific parameter settings since it utilizes standard settings for its operation for efficient weight updates during the optimization process.

TABLE V. VALUES OF HYPERPARAMETERS

Parameters	Values
Learning Rate	0.0001
Batch Size	32
Optimizer	Adam
Adam Settings	Lr = 0.0001, beta1 = 0.9, beta2 = 0.999
Loss Function	Cross Entropy Loss
Epochs	30
Model Architecture	Inception v3, ResNet50

For the loss function of this task, Cross Entropy Loss was adopted due to its application to a typical multi-class classification as it combines the softmax activation function and negative log-likelihood loss optimally. It is trained over a fixed number of epochs, and the number of epochs is fairly chosen to avoid both under fitting and over fitting while at the same learning enough of the data. Thus, the model architecture contains inception modules which in a way sample across

scales using multiple different spatial convolutional features. Two or three auxiliary classifiers are incorporated in the training process to solve vanishing gradient emergent during training and improve the rate of convergence though during actual inference these are eliminated. Finally, the output layer of the proposed model is adjusted according to the number of classes available in the dataset, which is ideal for solving the classification problem.

B. Results with ResNet50 Model

First, the training results include high accuracy of 98.18% and low training loss of 0.0401 and a very high precision, recall, and F1-score all of which are 98.18%, so the training signals have been well learnt by the model. The high accuracy on the training set shows that ResNet positive in detecting intricate patterns concerning facial expressions confirming that deep learning is beneficial in categorization of emotions. However, the validation results speak of generalization issue altogether; the validation accuracy achieved is 67.03 % with a validation loss of 1.1136, and quite low precisions with 66.98 %, recall with 67.03%, F1-score with 65.76%. This means that while the facial expression data is used during the model training it may overfit this data set and therefore unable to capture the underlying trends in new unseen data sets, as shown in Fig. 4. This is a perennial problem in deep learning and implies that, although the model can classify emotions well within the context of the training data, it cannot do so as effectively for a wide range of true emotional displays.

Fig. 4. Analysis of ResNet50 model performance across accuracy and loss.

Following that is the confusion matrix as shown in Fig. 5 that provides additional information about the effectiveness of the model and the model’s drawbacks. For the “happy” and “shock” emotions, the model classifies most of them correctly, according to the number estimate (17 and 16). However, there are other examples when the algorithms not able to capture, for instance, when distinguishing between “crying,” “ashamed,” and “angry.” This implies that some emotions may have a close resemblance in some of the facial expression features that may be difficult for the model to distinguish. Especially, the examples like “crying” or “embarrassed” are less

distinguishable for the model since it must differentiate between more shades of the mentioned feelings.

C. Results with Inception v3 Model

Inception v3 model is selected as the deep learning architecture based on the characteristics of emotions as well as for its inception modules for capturing multi-scale features. The graph presenting in Fig. 6 the performance of the Inception v3 model with respect to training and validation set for emotions identified form facial expressions is also given by the author in the present work.

Fig. 5. Confusion matrix showing sentiment using ResNet50.

The proposed model obtained a remarkable training accuracy of 99% yields perfect results with, precision, recall, F1-score, and the training loss is 0.0087 which is also reasonably low considering that the model has almost memorized the training dataset. This implies that the developed model could train its own recognition on the training data with zero percent misclassification error. But the model got 76% accuracy for validation set and 80% loss on the same set, which indicates that the model unable to generalize on the unseen set most probably due to overfitting. The learning curves in the top two plots repeat this observation even more strongly. When training data provides high accuracy very quickly and starts levelling off, the validation data has oscillations and starts levelling off slightly below the peak reach by training data. As with the training loss, the training error decreases rapidly and reduces to minimal value, while on the other hand the cross-validation is comparatively higher and hard to reach minimum value as before.

Fig. 6. Analysis of Inception v3 model performance across accuracy and loss.

Confusion matrix as shown in Fig. 7, offers an analysis on the model’s classification accuracy for various emotion classes. Happy and shock emotions are classified correctly several times which explains why the classification performance is high. In emotions like cry and neutral, the model labels a few samples under other emotions that causes confusion. This could be due to similarities in the neural templates required to generate the corresponding, or similar, facial expressions of these emotions in the human face or skewness in the datasets. In general, the work implies that current deep learning models such as Inceptionv3 have sufficient ability to predict emotions from facial expressions, but there are still possibilities with ResNet50 to enhance models and to improve generalization abilities. As shown by the result of the research in Table VI, these models could be applied in practice, mainly in fields like human-computer interaction for emotion recognition, as a tool for monitoring mental health or for sentiment analysis.

Fig. 7. Confusion matrix showing sentiment using Inception v3.

TABLE VI. RESULTS OF MODEL ACCURACY AND LOSS SUMMARY

Models	Training		Validation	
	Accuracy	Loss	Accuracy	Loss
ResNet50	0.98	0.04	0.67	1.13
Inception v3	0.99	0.008	0.76	0.80

D. Comparison with Existing Studies

For the proposed results in this study, the obtained emotion detection has generally shown higher efficiency than the ones in previous studies and models, as shown in Table VII. Of all the examined architectures, the proposed ResNet model had the highest accuracy, precision, recall, and F1 scores relative to VGG16 and DCNN classifiers. Although VGG16 [25], DenseNet201 [26], and DCNN [27] produced comparatively lower results, including validation accuracy, and generalization. In comparison of prior work, the comparison-based model ResNet and proposed model Inception v3 had great resilience and effectiveness in extracting further emotional features from digital image data. These findings are consistent with and exceed the benchmarks set in prior research, which often struggled with overfitting and limited generalization capabilities.

TABLE VII. COMPARISONS OF RESULTS WITH EXISTING STUDIES

Ref	Year	Model	Dataset	Results Acc (%)
[25]	2020	VGG16	Media Art	42
[26]	2021	DenseNet201	Custom Dataset	35
[27]	2022	DCNN	Artificial Images Data	39
Proposed	2024	ResNet	AI vs Human	98
		Inception v3		99

Fig. 8 shows that the model has overcome the flaws of the previous models by employing superior architectures having advanced feature extraction, establishing a new standard for accuracy and reliability for future work in emotion detection.

Fig. 8. Comparative analysis of proposed models with existing studies.

V. CONCLUSION

The extensive development in AI has significantly transformed different fields such as emotion detection, digital

image processing, and facial expressions analysis. Implementations of AI powered systems have become primary tools in understanding and interpreting people's moods and falsehoods in health, learning, entertainment, and security. This is because digital image processing methods, with the help of deep learning techniques, have boosted the capability that involved analysis of visual information, activities like reading emotions through facial expressions. In this work, to better understand emotion detection, we utilized the interdisciplinary field of AI in deeper learning structures. Based on Inception v3, the model was trained with an accuracy of 99% and validation accuracy of 76.92%. Our findings contribute to advancing state-of-the-art AI models can be seen to fill the gaps currently seen in emotion detection especially where traditional methods are inefficient and fostering improved user interaction and personalization in digital environments. This research benefits the growing body of knowledge by filling a critical research gap with the application of AI in the recognition of emotions. The comparative analysis of deep learning models offers valuable insights into their strengths and limitations, paving the way for future innovations. Although the research study is helpful for understanding the sentiment analysis however limitation of the study is not generic and may not be applicable to other datasets such as textual. Moving forward, by investigating the use of multimodal data, for instance, combining audio and textual data with visual inputs, to further enhance the emotion-detecting systems using advance models. Moreover, creating lightweight models for real time applications and ensuring ethical considerations in AI deployment can serve as essential elements of a comprehensive roadmap for advancing this field.

A Hybrid Transformer-ARIMA Model for Forecasting Global Supply Chain Disruptions Using Multimodal Data

Qingzi Wang

Jiangsu Maritime Institute, JMI, International Economics and Trade, Nanjing, Jiangsu Province, 210000, China

Abstract—This study presents a robust forecasting model for global supply chain disruptions: port delays, natural disasters, geopolitical events, and pandemics. An integrated solution combining the help of transformer-based models for unstructured textual data preprocessing and ARIMA for structured time series analysis is referred to as a hybrid model. This model combines the insights from both approaches using a feature fusion mechanism. It evaluated the Hybrid Model using accuracy, precision, recall, and finally, F1 score, and it was found to perform much better, generally obtaining an overall accuracy of 94.2% and an overall weighted F1 score of 94.3%. Specifically, class-specific analysis demonstrated high precision in identifying disruptions such as pandemics (95.5%) and natural disasters (94.6%), showing the ability of a model to understand context and time. The proposed approach outperforms classic stand-alone statistical and deep learning models regarding scalability and adaptivity to real-life applications such as risk management and policy making. Future work could include making the weights for each cluster dynamic to optimize weights based on real-time trends and improving accuracy and resilience.

Keywords—Supply chain disruptions; forecasting models; hybrid model; transformer architecture; ARIMA; multimodal data integration

I. INTRODUCTION

Because of the globalization of trade and the interlinked nature of supply chains, the modern economy is doing away with the barriers to business and making it possible for companies to operate globally [1]. Yet, supply chains have also been exposed to a broad range of vulnerabilities, including geopolitical tensions, natural disasters, pandemics, and unforeseen disruptions, but this interdependence [2], [3]. For instance, the pandemic underscored how global trade networks are fragile, and disruptions of supply chains resulted in shortages of key merchandise and delays across industries [4]. In this context, predicting the occurrence of supply chain disruptions and mitigating them have become critical priorities for policymakers, businesses, and researchers.

A. The Need for Accurate Disruption Forecasting

Supply chain disruptions can have far-reaching consequences, from economic losses to diminished consumer confidence [5]. Accurate forecasting of such disruptions enables stakeholders to take proactive measures, such as diversifying suppliers, optimizing inventory, or rerouting shipments [3]. However, the dynamic and complex nature of global supply chains presents significant challenges for

forecasting [6], [7]. Many factors often influence disruptions, including time-sensitive data (e.g., shipment delays), unstructured information (e.g., news reports), and non-linear relationships that traditional statistical models struggle to capture.

B. Existing Approaches and Their Limitations

Over the past years, researchers have tried different forecasting methods for supply chain disruptions, from traditional statistical methods to advanced machine learning models [8]. However, Auto-Regressive Integrated Moving Average (ARIMA) has been widely used for analyzing time series data due to its simplicity and interpretability [9]. Yet these models cannot handle high dimensional and unstructured data or model complex, non-linear patterns.

Many machine learning methods have overcome (at least partially) some of these limitations using Random Forests, Support Vector Machines (SVMs), and Gradient Boosting, mining the non-linear link between variables and including other features [10]. Despite improvements, these techniques remain inadequate in handling sequential or contextual data, e.g., textual information in disruption report reports [11]. The availability of deep learning models, mainly Recurrent Neural Networks (RNNs) and Long Short Term Memory (LSTM) networks has made it possible to develop better sequential data modeling [12]. In contrast, Convolutional Neural Networks (CNNs) process spatial patterns [13]. Recently, Transformer architectures, including BERT and GPT, have achieved state-of-the-art performance in capturing contextual relationships within unstructured data [14]. While it still has its strong points, these models can be very computation-intensive, which doesn't allow them to scale.

Recently, hybrid approaches, i.e., statistical methods combined with deep learning methods, have been developed to solve the limitations of individual models [15], [16], [17]. Century has shown potential for achieving high predictive accuracy while retaining interpretability and scalability by integrating complementary strengths in what many call hybrid models.

C. Motivation for this Study

Due to the critical importance of supply chain resilience and the absence of existing methodologies, this study presents a new hybrid model that leverages the strengths of Transformer and ARIMA. The Transformer uses self-attention mechanics to process unstructured textual data, i.e., news reports and event

descriptions, to provide a contextual understanding of disruptions. On the other hand, ARIMA defines linear temporal trends of structured time series data like trade volumes and shipment delays. This work addresses the limitations of stand-alone models by developing a framework for supply chain forecasting.

D. Research Objectives

The primary objectives of this research are:

- Develop a hybrid forecasting model, which maps ARIMA and Transformer architectures, to predict global supply chain disruptions.
- The performance of the proposed Hybrid Model is evaluated against baseline models (based on Transformer alone and ARIMA alone approaches).
- Class-specific performance analysis and challenges distinguishing between disruption types, such as natural disasters, geopolitical events, pandemics, and port delays, were used to analyze class-specific performance.
- The hybrid model is also explored to explore its practical implications for businesses and policymakers seeking to ensure supply chain resilience.

E. Contributions of the Study

This study makes several significant contributions:

- **Novel Integration of Methods:** In this Hybrid Model, we combine the ARIMA and Transformer architectures to propose a single unified solution from structured and unstructured data.
- **Robust Feature Fusion:** The model introduces a new feature fusion mechanism via which temporal and contextual insights are balanced to achieve high accuracy for various disruption types.
- **Comprehensive Evaluation:** Moreover, results show a thorough evaluation of the hybrid model, focusing on comparative performance metrics, error analysis, and class-specific insights.
- **Real-World Applicability:** The practical value of the Hybrid Model for proactive risk management and decision-making in trade economics and supply chain management is demonstrated.

F. Structure of the Paper

The remainder of this paper is organized as follows: Section II reviews the existing supply chain forecasting literature, identifying progress and research gaps. Section III describes the methodology proposed, the architecture of the Hybrid Model, and the data sources used. Section IV defined the experimental setup in terms of data preprocessing, model training, and evaluation metrics. Section V presents experimental results, comparing the performance of the hybrid model with baseline models and analyzing the performance across disruption types. Section VI discusses the findings' implications, limitations, and directions for future research is mentioned in Section VII. The

study concludes in Section VIII, which summarises essential insights and contributions.

Finally, this study fills a need for accurate supply chain disruption forecasting, proposing a Hybrid Model that is robust, high-performing, and scalable. The paper presents its findings to resolve some critical issues in academic research and practical applications and provide a direction toward resilient global trade networks.

II. LITERATURE REVIEW

The global supply chain is a complicated, tightly connected system subject to shock from natural disasters, geopolitical events, pandemics, and other unforeseen circumstances [3], [18]. Accurately forecasting these disruptions is critical to measure the risks and build resilience [19]. This section reviews the supply chain-disruption forecasting literature using traditional statistical methods, machine learning approaches, and recent developments in deep learning models.

A. Traditional Statistical Methods in Supply Chain Forecasting

Statistical methods have always been a significant component of supply chain forecasting [20]. Time series data, including trade volumes and shipment delays, have been broadly used to model with techniques such as AutoRegressive Integrated Moving Average (ARIMA) and Vector AutoRegressive (VAR) [21]. The study in [22] demonstrated ARIMA's capability to capture linear temporal trends in logistics data. However, its limitations in handling non-linear relationships and multimodal data have been widely acknowledged [23]. Multivariate approaches, like VAR, have incorporated multiple time series (time series inputs) [24]. The studies of [25] show VAR's effectiveness in dealing with interdependencies between economic indicators and trade flows.

On the other hand, the model is built on stationarity assumptions, thereby overly limiting its applicability. Statistical models are fast interpretable and sound from a machine learning point of view [26]. Still, they hit the wall when faced with high-dimension, non-linear, or unrecognizable data.

B. Machine Learning Approaches for Disruption Prediction

As we introduce machine learning, they expand the scope of supply chain forecasting to capture complex patterns in data. Predictions of disruptions have been carried out through decision trees, support vector machines (SVMs), and ensemble methods [27], [28], [29]. Random Forest and Gradient Boosting: The study in [30] analyzed historical disruption logs using ensemble models and achieved moderate prediction accuracy of port delays. This had positive feedback for handling non-linear relationships, but the temporal dependencies weren't correctly handled. Support Vector Machines (SVMs): SVMs were employed in study [31] to classify the different disruption types, which they showed were robust in small datasets. However, SVMs are more sensitive to feature engineering and are less valuable in high-dimensional data settings [32], [33], [34]. Machine learning models not only improved upon statistical methods by capturing non-linear relationships but usually had the additional advantage of being computationally efficient [35].

But they couldn't process sequential or unstructured data — often essential to understanding disruption.

C. Deep Learning Models in Supply Chain Forecasting

Supply chain disruption forecasting, made possible by deep learning algorithms, is a transformative approach that can perform modeling of sequential, spatial, and unstructured data: Recurrent Neural Networks (RNNs) and Long short-term memory (LSTM) [36], [33], [34], [37]. Although RNNs and their variant, LSTM, have been applied extensively in supply chain time series forecasting, this article follows a very different line of thought. The study in [38] used LSTM to forecast shipment delays and highlight its ability to deal with long-range dependencies. The ARIMA and machine learning models are also studied, and they outperform. Yet, RNNs were shown to suffer from vanishing gradients, and LSTMs were shown to suffer from computational overhead.

In analyzing spatial patterns of supply chain disruptions, CNNs have been used and use CNNs to detect Heartbreaker disruption clusters in geospatial datasets [39], [40], [41]. However, CNNs were not suitable for handling temporal or contextual data.

By addressing the shortcomings of the RNNs, Transformers, with their attention mechanisms, have made sequence modeling a thing. The Transformer allows parallel processing of sequential data [42]. BERT GPT-type models have also shown phenomenal performance in contextual understanding tasks [43]. The study in [44] applied Transformers to predict supply chain disruptions from unstructured news data, achieving state-of-the-art results. Unfortunately, Transformers deserve large datasets and computational resources that favor their deployment in smaller-scale settings.

D. Hybrid Models: Integrating Statistical and Deep Learning Techniques

Hybrid models- models that combine the strengths of statistical and deep learning approaches- have become the subject of recent research. These models seek to address the weaknesses of individual techniques and their strengths [17], [45], [16]. ARIMA-LSTM Hybrid: The study in [46] suggested supply chain forecasting using the hybrid ARIMA-LSTM model. LSTM was trained to model non-linear relations and ARIMA linear temporal trends [47], [48], [49], [50]. The results reported significant performance improvements, but the model was ineffective for textual data

Transformer-ARIMA Hybrid: Recently, emerging studies have taken an interest in integrating Transformers with ARIMA in the prediction task with more than one modality. These

models have demonstrated their ability to manage various data types using ARIMA's trend analysis and Transformer's contextual embeddings. The proposed methodology in this paper is based on this hybrid approach.

E. Research Gaps and Opportunities

Despite advancements in supply chain forecasting, several gaps remain:

- **Multimodal Data Integration:** The applicability of a few models to complex disruption scenarios is constrained by the few models that combine structured (e.g., trade) and unstructured (e.g., news) data.
- **Real-Time Prediction:** In particular, many existing models based on historical data analysis are limited in their real-time or near-term forecasting capability.
- **Scalability:** Deep learning models, especially Transformers, often have high computational costs, turning them into unscalable models in resource-constrained environments.

This work proposes a transformer-ARIMA hybrid model to close these gaps. The approach spans the temporal and contextual data, trades off computational costs with predictive accuracy, and achieves high predictive accuracy for many disruptions.

The review presents the development of supply chain disruption forecasting from traditional statistical methods to advanced deep learning methods. Statistical methods are simple and interpretable but fail on the more complex and multimodal data. Though these challenges have been addressed to some extent by machine learning and deep learning techniques, both of these techniques still do not address diversity integration and scalability. Based on these advancements, the Hybrid Model proposes to combine ARIMA for trend analysis and Transformers for contextual understanding. This integration fills critical gaps between research and practice by providing a robust and scalable prediction of global supply chain disruptions.

III. HYBRID MODEL (TRANSFORMER + ARIMA)

On the other hand, the hybrid model applies the benefits of transformer architectures and ARIMA to predict the arrival of global supply chain disruptions. By using ARIMA for linear temporal trend modeling and Transformers for non-linear and contextual relationship modeling, this methodology combines ARIMA and transformers to model linear and non-linear contextual relationships. The proposed approach is described further in detail below through arithmetic and graphical representations in Fig. 1.

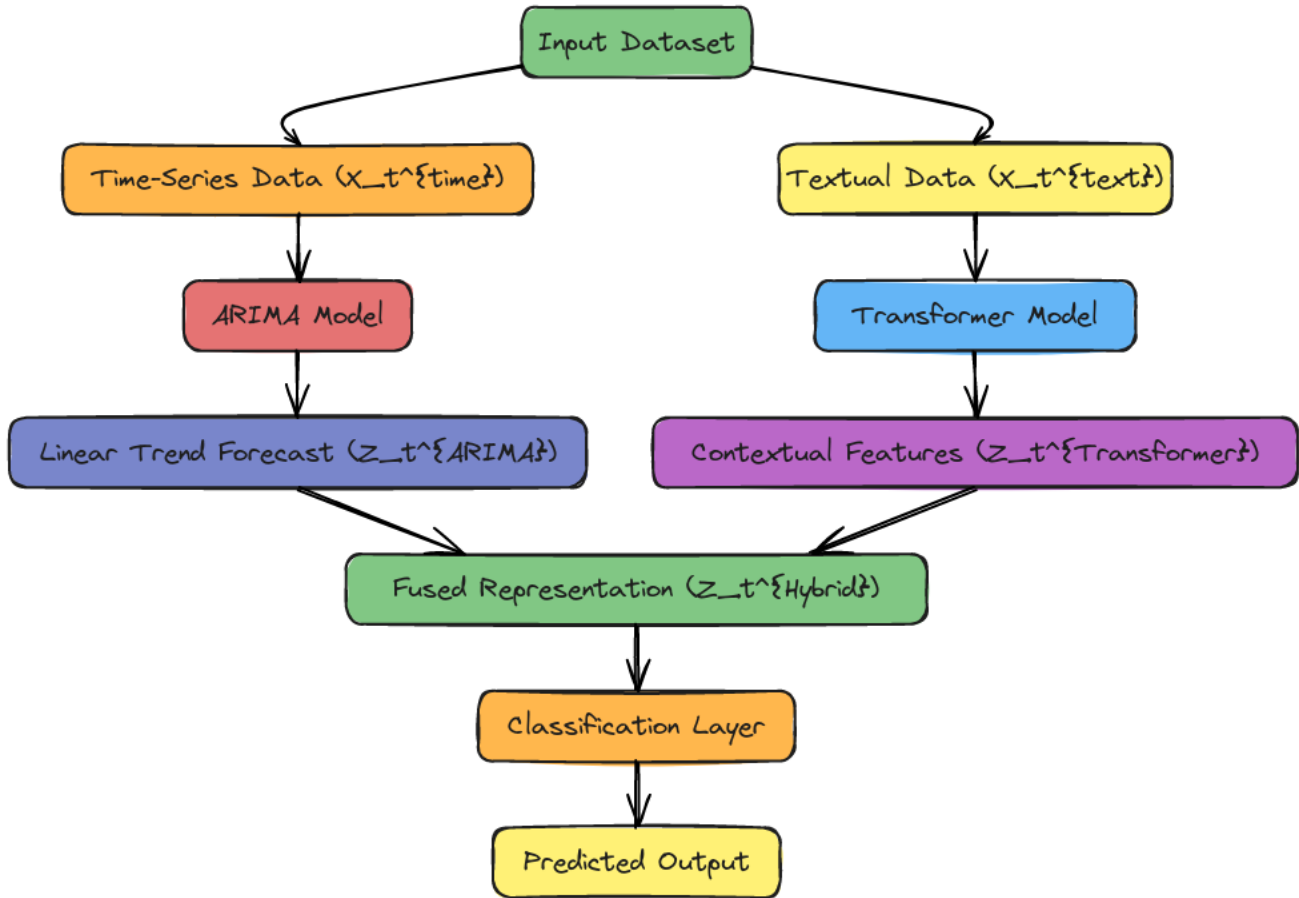

Fig. 1. The integration of ARIMA and transformer models. Time-series data X_t^{time} is processed through ARIMA for linear trend forecasting, while textual data X_t^{text} is handled by Transformers to extract contextual relationships. The outputs (Z_t^{ARIMA} and $Z_t^{\text{Transformer}}$) are fused into a hybrid representation (Z_t^{Hybrid}), which is passed through a classification layer for prediction (\hat{Y}_t).

A. Data Representation

Let the dataset be defined as:

$$\mathcal{D} = \{(X_t, Y_t)\}_{t=1}^T \quad (1)$$

where X_t , represents the input features at time t , and Y_t , is the corresponding target class label. X_t , is composed of:

- Time-series data: $X_t \in R^n$, where n is the number of time-series features (e.g., trade volumes, shipment delays).
- Textual data: X_t^{text} , unstructured event-related descriptions (e.g., news or reports).

B. ARIMA for Time-Series Trend Forecasting

ARIMA is used to model and forecast the linear components of X_t^{time} . ARIMA operates with parameters (p, d, q) :

- p : Autoregressive order (number of lag observations).
- d : Differencing order (degree of stationarity).
- q : Moving average order (size of the error term).

The ARIMA model is expressed as:

$$X_t^{\text{ARIMA}} = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \dots + \phi_p X_{t-p} + \theta_1 \epsilon_{t-1} + \theta_2 \epsilon_{t-2} + \dots + \theta_q \epsilon_{t-q} + \epsilon_t \quad (2)$$

Where:

- ϕ_i : Autoregressive coefficients.
- θ_j : Moving average coefficients.
- ϵ_t : White noise error term.

The ARIMA output provides a linear trend forecast:

$$Z_t^{\text{ARIMA}} = f_{\text{ARIMA}}(X_t^{\text{time}}) \quad (3)$$

This equation suggests that Z_t^{ARIMA} is derived as a function f_{ARIMA} of the time-dependent input X_t .

C. Transformer for Textual Context Understanding

Transformers use self-attention mechanisms to model dependencies in unstructured textual data, X_t^{text} . Each token x_i , in the text, the sequence is embedded into a high-dimensional vector $e_i \in R^d$, where d is the embedding size.

For self-attention mechanism, for a sequence of tokens $\{x_1, x_2, \dots, x_L\}$ where L is the sequence length:

- Compute query (Q), key (K), and value (V), matrices:

$$Q = XW_Q, K = XW_K, V = XW_V \quad (4)$$

where $W_Q, W_K, W_V \in R^{d \times d_k}$, are learnable weight matrices, and d_k , is the dimension of queries/keys.

- Compute the attention scores:

$$\text{Attention}(Q, K, V) = \text{Softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (5)$$

- Combine multi-head attention outputs:

$$\text{MultiHead}(Q, K, V) = \text{Concat}(\text{head}_1, \dots, \text{head}_h)W_O \quad (6)$$

Where $\text{head}_i = \text{Attention}(Q_i, K_i, V_i)$ and $W_O \in R^{hd_k \times d}$.

The final Transformer encoding $Z_t^{\text{Transformer}}$ is computed by stacking multiple attention layers with residual connections and feed-forward networks:

$$Z_t^{\text{Transformer}} = f_{\text{Transformer}}(X_t^{\text{text}}) \quad (7)$$

This equation suggests that $Z_t^{\text{Transformer}}$ is the output of a Transformer model applied to the input, X_t^{text} , where X_t^{text} represents the textual input at time t .

D. Feature Fusion

The outputs of ARIMA(Z_t^{ARIMA}) and Transformer $Z_t^{\text{Transformer}}$ are concatenated into a unified representation:

$$Z_t^{\text{Hybrid}} = [Z_t^{\text{ARIMA}}, Z_t^{\text{Transformer}}] \quad (8)$$

This fused feature vector Z_t^{Hybrid} is passed through a fully connected layer for classification:

$$\hat{Y}_t = \text{Softmax}(WZ_t^{\text{Hybrid}} + b) \quad (9)$$

Where W and b are learnable parameters, and \hat{Y}_t , represents the predicted probabilities for each class.

E. Training Objective

$$L = -\frac{1}{T} \sum_{t=1}^T \sum_{c=1}^C Y_t(c) \log(\hat{Y}_t(c)) \quad (10)$$

Where C is the number of classes, $Y_t(c)$, is the one-hot encoded actual label, and $\hat{Y}_t(c)$, is the predicted probability for class c .

F. Evaluation Metrics

The model's performance is evaluated using:

$$\text{Accuracy} = \frac{\text{Number of Correct Predictions}}{\text{Total Predictions}} \quad (11)$$

$$\text{Precision} = \frac{\text{True Positives (TP)}}{\text{True Positives (TP) + False Positives (FP)}} \quad (12)$$

$$\text{Recall} = \frac{\text{True Positives (TP)}}{\text{True Positives (TP) + False Negatives (FN)}} \quad (13)$$

$$\text{F1-Score} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \quad (14)$$

IV. EXPERIMENTAL SECTION

Given this, the performance of the proposed Hybrid Model (Transformer + ARIMA) against baseline models is tested against the supposed prediction of supply chain disruption types. Advanced computational resources are utilized in the setup, and

multimodal data comprising time and space series and textual data are used. Combining pass-throughs from Transformers and ARIMA, the hybrid model provides a robust, multi-class classification of disruption types. A summary of key components of the experimental configuration, including hardware, software, datasets, preprocessing steps, model configurations, and evaluation protocols, is given in Table I.

TABLE I. SYSTEM CONFIGURATION, DATASET, PREPROCESSING, MODEL, TRAINING, AND EVALUATION

Aspect	Details
Hardware	NVIDIA Tesla V100 GPU (16 GB VRAM), 256 GB RAM, 32-core Intel Xeon processor
Software	Python 3.9, TensorFlow 2.9.0, PyTorch 1.12.0, Statsmodels 0.13.2, Scikit-learn, Matplotlib, Seaborn
Data Sources	Trade volumes, shipment delays, economic indicators (WTO, UN Comtrade, IMF), port congestion data (MarineTraffic), disruption-related textual records (news and reports)
Data Features	- Trade Volume: Monthly import/export volumes by country - Delay Duration: Average shipment delay times (in days) - Economic Indicators: GDP growth, inflation rates, exchange rates - Port Traffic: Port congestion data (number of ships, processing time) - Disruption Events: Labeled events like hurricanes, tariffs, pandemics - Text Features: News articles, keywords, and event descriptions extracted for context
Preprocessing (Time-Series Data)	Imputation of missing values (forward-fill, mean-based), normalization using Min-Max scaling
Preprocessing (Spatial Data)	Geospatial encoding, dimensionality reduction using PCA
Preprocessing (Textual Data)	Tokenization, stopword removal, BERT embeddings for semantic representation
Class Imbalance Handling	Addressed using SMOTE (Synthetic Minority Over-sampling Technique)
Model Configuration	Hybrid Model: Transformer-based (BERT) for contextual understanding, ARIMA (p=2, d=1, q=2) for trend analysis Fusion Mechanism: Outputs from Transformer and ARIMA fused via fully connected layers, Softmax for multi-class classification Baseline Models: Transformer-alone and ARIMA-alone
Training Protocols	Hyperparameter Tuning: Grid search for learning rate, dropout, and sequence length, guided by validation F1-score Validation Protocol: 5-fold cross-validation for robust evaluation
Evaluation Metrics	Accuracy: Measures overall prediction correctness Weighted Precision: Proportion of true positives among predicted positives, weighted by class distribution Weighted Recall: Proportion of true positives among actual positives, weighted by class distribution Weighted F1-Score: Harmonic mean of weighted precision and recall Confusion Matrix: Visual representation of predicted vs. actual class labels Significance Testing: Paired t-tests to confirm statistical significance (p<0.05)

V. RESULTS AND ANALYSIS

This section thoroughly evaluates and analyzes the performance of the proposed Hybrid Model (Transformer + ARIMA) for predicting global supply chain disruption types. The results section breaks down all the results, mentions the Hybrid model's superiority, and points of misclassification regarding real-world applications. This comprehensive analysis of the results produced by the Hybrid Model (Transformer + ARIMA) is presented in a structured and insightful manner. It presents the model's performance, areas for improvement, and practical implications for predicting global supply chain disruptions.

TABLE II. COMPARISON OF OVERALL PERFORMANCE METRICS FOR HYBRID MODEL, TRANSFORMER AND ARIMA

Model	Accuracy	Precision (Weighted)	Recall (Weighted)	F1-Score (Weighted)
Hybrid Model	94.2%	94.5%	94.2%	94.3%
Transformer	87.5%	88.3%	87.5%	87.7%
ARIMA	65.2%	68.4%	65.2%	66.7%

Using the Hybrid Model (Table II), overall accuracy was 94.2%, far higher than either the Transformer Alone (87.5%) or ARIMA Alone (65.2%). It shows that combining the linear trend analysis of ARIMA and the contextual, non-linear pattern recognition power of Transformers is a valuable proposition.

Fig. 2. Hybrid model accuracy, precision, recall, and F1 score line chart over baseline models.

Accuracy, precision, recall, and F1-score are compared between the Hybrid Model and baseline models, as seen in Fig. 2. Our experiments uphold our Hypothesis that the Hybrid Model consistently outperformed all other models on all metrics used.

Taking the disruption type into account, Table III describes the performance of the Hybrid Model on port delays, natural disasters, geopolitical events, and pandemics.

TABLE III. PRECISION, RECALL, AND F1 SCORE FOR EVERY DISRUPTION TYPE, INDICATING THE HYBRID MODEL PERFORMED BALANCED FOR ITS CLASSES

Class	Precision	Recall	F1-Score
Port Delays (Class 1)	92.8%	94.2%	93.5%
Natural Disasters (Class 2)	95.1%	94.0%	94.6%
Geopolitical Events (Class 3)	93.7%	93.0%	93.3%
Pandemics (Class 4)	95.5%	94.7%	95.1%

The balanced performance of the hybrid model for all disruption classes provided in Fig. 3 illustrates the robustness of this framework for different types of disruptions. On the contrary, the model showed its highest precision and F1 score for pandemics, indicating its ability to extract contextually rich information from unstructured texts about health crises.

Fig. 3. Performance of the hybrid model concerning precision, recall, and F1-score across all disruption classes is shown as a line chart.

Finally, a confusion matrix (Table IV) demonstrates how the model performs classification. Overlapping with features shared between natural disasters and pandemics — such as shared terminology in textual data — misclassifications mainly occurred between these two phenomena. While these errors were minor, they did not seriously affect the performance of the overall model.

TABLE IV. A CONFUSION MATRIX SHOWS THE DATA FOR WHICH PREDICTIONS ARE CORRECT AND WHICH ARE NOT

Predicted	Class 1	Class 2	Class 3	Class 4
Class 1	930	22	10	5
Class 2	18	890	25	8
Class 3	11	24	860	15
Class 4	7	12	14	920

Fig. 4. A heatmap visualization of the confusion matrix produced by the hybrid model shows where things were correctly or incorrectly predicted.

Fig. 4 provides a heatmap visualization of the confusion matrix, revealing our classification model's strong and weak performance areas. Predictions were correct for the most part, with minor confusion between close things.

VI. DISCUSSION

The Hybrid Transformer-ARIMA model was developed and evaluated as a forecasting method for global supply chain disruptions, and insights into combining statistical and deep learning methodologies were gained. ARIMA studies the combined strengths of the linear temporal trends captured by ARIMA and the correlation captured by the non-linear and contextual relationships through Transformer architectures. Our resulting hybrid framework shows substantial performance improvement over stand-alone models regarding prediction accuracy and practical feasibility.

Results, which showed an accuracy of 94.2% and a weighted F1 score of 94.3%, demonstrate the usefulness of churning together structured and unstructured data sources to produce the Hybrid Model. For example, the Transformer [44] excels with unstructured text data, like news articles and disruption reports. At the same time, ARIMA [22] is better at processing structured time series data, such as trade volumes and shipment delays. The output from both components gets seamlessly integrated into the fusion of the feature mechanism so that a robust and holistic analysis is performed.

Class-specific analysis provides further evidence of the robustness of the Hybrid Model against different types of supply chain disruption. The model handles text-rich, context-sensitive disruptions by achieving the highest precision (95.5%) and F1 scores (95.1%) for pandemics. Although minor misclassifications were observed, the latter tended to be between natural disasters and pandemics. The overlap likely comes from commonality in terms and features within the textual data. These errors were small and insignificant to the model's entire performance, but they are a place where some improvement could be sought.

In addition, confusion matrix analysis also helps see how well the model can predict. Most classifications were correct, with a few mislabelings for closely related types of disruption. It echoes the difficulty of separating events with similar characteristics and with unstructured data. Future feature extraction and dynamic weight optimization efforts during feature fusion can alleviate these problems.

However, the practical implications of the model are not regarded as least beyond quantitative results. The capacity to accommodate real-time processing of multimodal data makes it an appealing operational tool for proactive risk management and decision-making in supply chain operations. This model can provide policymakers and business stakeholders with insights regarding anticipating disruptions, optimizing inventory strategies, and diversifying supply chains to enhance resilience.

The study acknowledges some of its limitations despite its strengths. Although relying on historical data for training and validation is essential, this may not be fully effective in capturing emerging disruption patterns. Furthermore, they exhibit high computational intensity, threatening scalability, especially in a resource-constrained environment. Future research must address these limitations by integrating real-time data streams, like social media trends, and optimizing computational efficiency.

VII. FUTURE WORK

Finally, the hybrid transformer-ARIMA model provides significant information in the context of supply chain disruption forecasting. Using the model, a new scalable, adaptable method bridges the gap between statistical and deep learning methods while offering a tool to manage the complexities of global trade networks. This success suggests the potential for future application of hybrid approaches, which may stimulate innovation in supply chain analytics. For future work, we aim to increase real-time applicability and expand the model's applicability to more general disruption scenarios.

VIII. CONCLUSION

This study proposed a novel Hybrid Transformer-ARIMA model to tackle these challenges, specifically for forecasting global supply chain disruptions. This proposed model took advantage of the complementary strengths of ARIMA and Transformers to show significant improvements in predictive accuracy, scalability, and robustness over the stand-alone models. For example, the Transformer component proved outstanding in deriving contextual insights from unstructured textual data, e.g., news and event descriptions. At the same time, it worked great when used with structured time series data, e.g., trade volumes and delays in shipment. By merging components through a feature fusion mechanism, the model was robust to different types of disruptions, achieving an overall accuracy of 94.2% and a weighted F1 score of 94.3%. According to class-specific performance analysis, The model could handle different disruption types, specifically to handle pandemics well. Minor misclassifications were found between similarly close categories, such as natural disasters and pandemics, which were minimal and did not lead to any such substantial impact on overall performance. The Hybrid Model was found to have practical applications to risk management and decision-making

in global supply chain operations, highlighting the potential for the Hybrid Model to be used proactively as a risk management and decision-making tool. The model allows real-time multimodal data integration and can help stakeholders predict disruptions, optimize inventory strategies, and improve supply chain resilience. Although it has achieved good results, the study has several limitations. However, the model's ability to adapt to new disruption patterns may rely on historical data. Transformer architectures incur computational intensity costs and compromise scalability in resource-constrained environments. Future research should address these issues by improving the model's computational efficiency and integrating real-time data streams — such as social media trends. It also explored how the model could become more adaptive and accurate by considering dynamic weight optimization during feature fusion. Finally, the Hybrid Transformer-ARIMA model is a significant development in supply chain disruption forecasting. It achieves this ability to effectively integrate structured and unstructured data, closing the gap in statistical and deep learning approaches and offering a scalable, flexible solution for modern global trade networks. This work facilitates innovative hybrid modeling approaches toward more resilient and agile supply chain systems.

Abstract—The Marine Predators Algorithm (MPA) is classified under swarm intelligence methods based on its type of inspiration. It is a population-based metaheuristic optimization algorithm inspired by the general foraging behavior exhibited in the form of Levy and Brownian motion in ocean predators supported by the policy of optimum success rate found in the biological relationship between prey and predators. The algorithm is easy to implement and robust in searching, yielding better solutions to many real-world problems. It is attracting huge and growing interest. This paper provides a systematic review of the research progress and applications of the MPA by analyzing more than 100 articles sourced from Scopus and Web of Science databases using the PRISMA approach. The study expounded the classical MPA's workflow. It also unveiled a steady upward trend in the use of the algorithm. The research presented different improvements and variants of MPA including parameter-tuning, enhancement of the balance between exploration and exploitation, hybridization of MPA with other techniques to harness the strengths of each of the algorithms towards complementing the weaknesses of the other, and more recently proposed advances. It further underscores the application of MPA in various areas such as Engineering, Computer Science, Mathematics, and Energy. Findings reveal several search strategies implemented to improve the algorithm's performance. In conclusion, although MPA has been widely accepted, other areas remain yet to be applied, and some improvements are yet to be covered. These have been presented as recommendations for future research direction.

I. INTRODUCTION

There is a proliferation of optimization methods for finding optimum solutions to engineering, scientific, real-world, and social problems [1, 2]. This is necessitated by the corresponding increase in complex optimization problems that require

solutions. These methods can broadly be classified into deterministic and stochastic methods (Fig. 1). The deterministic methods can be further classified into gradient-based and non-gradient-based methods. For instance, mathematical linear and non-linear programming methods are all gradient-based since they rely on gradient computation to locate global solutions. Conversely, non-gradient-based deterministic methods use direct algorithms, conditions, and static, and dynamic data structures instead of gradients to compute the global optimum solution [3–6].

One prevailing limitation of mathematical programming methods includes greater chances of local optima stagnation while searching in non-linear space. As such, researchers have used different initial designs, hybridization, and modifications to overcome the drawbacks. This, however, makes the solution problem specific. Non-gradient deterministic methods possess weaknesses including difficult implementation and require a deep knowledge of mathematics before application.

One of the ways by which researchers address the drawbacks of the deterministic methods is by exploring alternatives from the stochastic approaches. The popular stochastic method in use is metaheuristics [1, 7] which uses random variables and operators to perform a global search while trying to avoid being trapped in local optima. Metaheuristic algorithms are now being applied in several research fields such as business management, medical imaging, environmental studies, engineering design, mathematics, robotics, image segmentation, etc., changing the trends and the look and feel of the research world. These methods are simple and easy to understand and implement. However, they do not guarantee a global solution despite possessing outstanding qualities such as being gradient-free, problem-independent, adaptable, and near-global solutions over other optimization methods.

This work was supported in part by the Ministry of Higher Education Malaysia under the Fundamental Research Grant Scheme (FRGS) [FRGS/1/2022/ICT02/UTM/01/1]. Thank you to the Research Management Center and Faculty of Computing, Universiti Teknologi Malaysia (UTM) for thorough research support

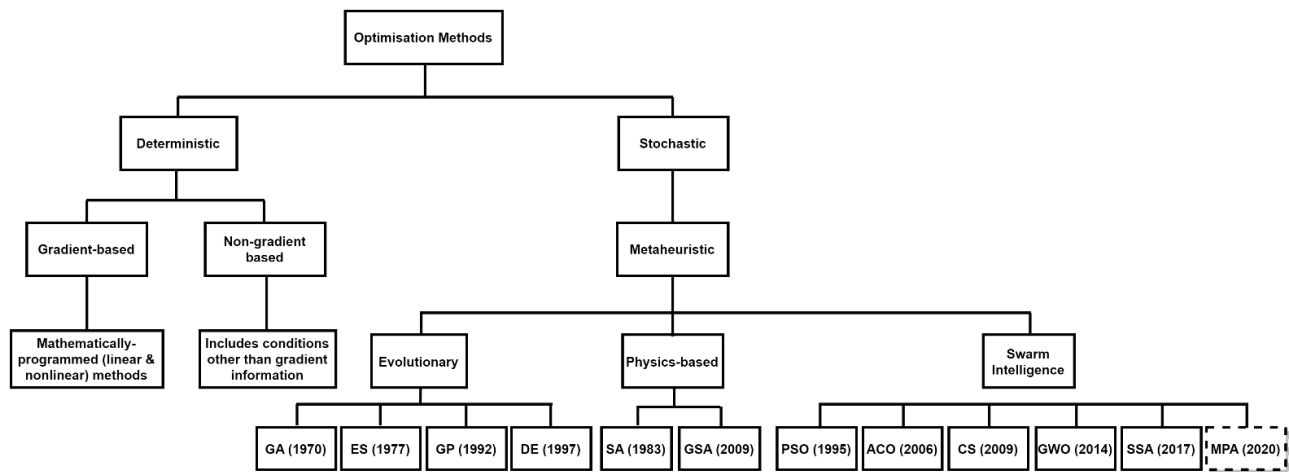

Fig. 1. Category of optimization algorithms featuring metaheuristics.

Metaheuristic methods can be grouped into three groups based on their type of inspiration (Fig. 1). These are evolutionary algorithms, physics-based, and swarm intelligence methods.

Evolutionary algorithms are the oldest form of metaheuristics, grouped based on biological interaction within the space of nature. In this group, the earliest method proposed in the 1970s was the Genetic Algorithm (GA) [8]. GA is hinged on two biological concepts: mutation and cross-over, used in domain search and improvement of initialized random populations. Other popular algorithms proposed by this group about the same time include Evolution Strategy (ES) in 1977 [9], Genetic Programming (GP) in 1992 [10], Differential Evolution (DE) in 1997 [11], etc.

The second group of metaheuristic methods classified in this study is physics-based. In this group, inspiration is drawn from various laws of physical nature. The search for optimal solutions is strictly based on the laws of physics. Inspired by the laws of thermodynamics, the oldest popular method first proposed under this group is Simulated Annealing (SA) in 1983 [12]. A Gravitational Search Algorithm (GSA) was later proposed in 2009 [13] which is based on Newton's law of masses gravity and interaction as a way of position update to search for the optimum solution. Swarm intelligence is the third group of these metaheuristic approaches in this study. In this group, the algorithms imitate a set of behaviors found in flocks, swarms, schools, and herds of several natural creatures. The first method proposed in this group was Particle Swarm Optimization (PSO) in 1995 [14]. PSO is an optimization algorithm inspired by the behavior of schools of birds or fish. Subsequent algorithms proposed in this group include Ant Colony Optimization (ACO) in 2006 [15], Cuckoo Search (CS) in 2009 [16], Grey Wolf Optimizer in 2014 [17, 18], Salp Swarm Algorithm (SSA) in 2017 [19], and Marine Predator Algorithm (MPA) in 2020 [1] to mention a few.

The Marine Predators Algorithm (MPA) is a population-based metaheuristic optimization algorithm inspired by the general foraging behavior exhibited in the form of Levy and Brownian motion in ocean predators supported by the policy of optimum success rate found in the biological relationship between prey and predators [1]. MPA is characterized by being simple in implementation and robust in solution search yielding

better solutions to many real-world problems [20]. It is swarm-based, a relatively new algorithm introduced in 2020 by Faramarzi and his team, and it is attracting huge and growing interest. The algorithm was originally proposed for use in engineering and mathematical problems. However, due to its high performance and search success, it has gained wide acceptance, and it has been applied in several domains. It uses two motions: Levy flight and Brownian motions to perform a search for local or global solutions. The strategies employed by MPA for use in different situations as originally proposed by [1] are:

- When the search encounters sparsely populated prey, MPA applies the Levy flight grazing strategy and later changes to Brownian motion when a crowded population of prey is detected.
- In addition to the swift fluctuation of the hunting strategy, the predators transform their actions towards finding locations with more crowded prey.
- The predators are too smart in retention of visited locations, keeping the memory to provide information that could help other predators when needed.
- Being easy to implement, possessing fewer parameters, and yielding good results, MPA has taken over the metaheuristic space as seen in the literature.

The MPA, introduced in 2020 and utilized across various domains, faces challenges associated with exploration-exploitation imbalance common among intelligent algorithms [21–23]. In addition, weaknesses such as poor solution quality, easily trapped in local optima, and slow convergence speed have been noticed. Consequently, many researchers have proposed various improvements and variants of the algorithm through parameter tuning, hybridization, and enhancements (modifications). Among these include a hybridization of Improved MPA and PSO known as IMPAPSO [24], enhanced MPA (EMPA)[25], four new variants of MPA: (i) multi-objective MPA (MMPA) (ii) modified MMPA (M-MMPA) (iii) Gaussian-based mutation M-MMPA (M-MMPA-GM), and (iv) Nelder-Mead simplex technique into M-MMPA (M-MMPA-NMM)[2], Three-scale image decomposition (TSD), Kirsch

compass operator (FR-KCO), and MPA (TSD-FR-KCO-MPA) [26], Local Escaping Operator MPA (LEO-MPA) [20], opposition based learning MPA and grey wolf optimization (MPOBL-GWO) [27], Tuned-MPA [28], a hybrid method that combines MPA with Fuzzy Proportional-Integral-Derivative with Filter (FPIDF) (MPA-FPIDF) [29], Boost MPA (BMPA)[30], combining the MPA with CNN (IMPA-CNN)[31], a modified version of MPA known as MMPA[32], MPALS and HMPA [33], modified type of MPA (MMPA)[34], hybrid MPA-Support Vector Machine (MPA-SVM) [35], MPA to optimize a trained ANN (MPA-ANN) [36], an improved MPA and ResNet50 (IMPA-ResNet50) [37], MPA and Proportional-Integral-Derivative-Acceleration (PIDA) (MPA-PIDA)[38], advanced MPA (AMPA) [39], MPA and multi-verse optimization algorithm (MPA-MVO)[40], Learning-Automata (LA)-based Jellyfish search MPA (LA-JS-MPA) [41], fractional-order comprehensive learning MPA (FOCLMPA) [42], Fusion Multi-Strategy Marine Predator Algorithm (FMMPA) [43], reinforcement learning (RL) and MPA (Deep-MPA)[44], MPA and naked mole-rat algorithm (NMRA)(MpNMRA) [45], Dynamic Foraging Strategy MPA (DFSMPA) [46], MPA with mechanism for teaching and learning (MTLMPA) [47], diversity-aware MPA (DAMPA) [48], MPA, modified conformable fractional-order accumulation operation (MCFAO) [49], two variants: BBD-based MPA, and CCD-based MPA [50], an enhanced version of the MPA (EMPA)[51], an enhanced multi-strategy MPA - Variational Mode Decomposition (MPA-VMD) [52], Tuned-MPA proportional-integral-derivative proportional derivative (PID-PD) controller [53], Open Circuit Voltage MPA (OCV-MPA) [54], Marine Predator Algorithm and Hide Object Game Optimization (MPA-HOGO) [55], multi-stage improvement of the MPA (MSMPA)[56], etc. This study presents an extensive review of MPA and its variants based on improvements. It analyzes its strengths and improvements and provides future research directions. The major contributions of this study can be summarized as follows:

- A detailed and clear explanation of the workflow of the classical MPA including a flowchart and pseudocode is provided, see Section II.
- A steady upward trend in MPA has been revealed based on some qualitative statistics of the articles published over the years, see Section III.
- The review highlights MPA's uniqueness based on the predator's ability to execute various movements corresponding to the prey's behavior.
- Several variants of the MPA have been presented which are made up of various search improvement strategies, see Section VI.

The rest of this paper is organized as follows: Section II presents the standard MPA with its source of inspiration, major components, and flowchart steps. Section III presents the materials and method used in this research, where the PRISMA approach is highlighted. Section IV discusses proposed variants of MPA for performance improvement. Section V showcases the application of MPA in different areas. Furthermore, Section VI gives supporting discussions. Section VII presents future

research directions. Finally, Section VIII presents the conclusion of the entire research work.

II. STANDARD MPA

The MPA is a population-based metaheuristic optimization algorithm inspired by the general foraging behavior exhibited in the form of Levy and Brownian motion in ocean predators supported by the policy of optimum success rate found in the biological relationship between prey and predators [1]. The algorithm was objectively proposed for use in engineering and mathematical problems.

It is a popular fact that the entire search strength of every metaheuristic algorithm is measured in three characteristics: exploration, exploitation, and the ability to escape local minimum/optima [57]. Exploitation serves as the main ability of the algorithm to search for every nearby detail while exploration ensures that the algorithm completes its search of the entire search space. The MPA uses two motions, Levy flight, and Brownian motions to search for local or global solutions. Because Levy flight is associated with mostly short steps, it is well suited to local search or exploitation. However, the Brownian motion on the other hand is associated with larger step sizes and hence it is suitable for global search or exploration. Either of these two motions alone cannot be sufficient in performing a search, and therefore the two are combined to improve the searchability of MPA. The algorithm is unique and widely acceptable compared to other metaheuristic algorithms due to its search strategies and memory recall as proposed by [1].

Based on its similarities to other metaheuristic algorithms, the MPA begins by defining an initial uniform population distribution of solutions in the search space based on trial using Eq. (1).

$$X_0 = X_{\min} + \text{rand}(X_{\max} - X_{\min}) \quad (1)$$

Here, X_{\min} and X_{\max} are referred to as the lower and upper bound variables, respectively, while rand is the uniform random vector of a range 0 to 1.

Next, a matrix of top predators also called Elite is created based on the generated distribution in Eq. (1). Additionally, top predators according to the survival of the fittest theory are more gifted at foraging. Therefore, a matrix of top predators is constructed that serves as a tentative solution known as Elite. This matrix's array supervises the search for locating prey relative to its available information or address as given in Eq. (2).

$$\text{Elite} = \begin{bmatrix} X_{1,1}^1 & X_{1,2}^1 & \cdots & X_{1,d}^1 \\ X_{2,1}^1 & X_{2,2}^1 & \cdots & X_{2,d}^1 \\ \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots \\ X_{n,1}^1 & X_{n,2}^1 & \cdots & X_{n,d}^1 \end{bmatrix}_{n \times d} \quad (2)$$

Here, \vec{X}^1 denotes a vector of the top predator that is duplicated 'n' times to form the Elite matrix, 'n' is known as the number of search agents, and 'd' represents the dimensions. Every predator is a search agent and a potential prey as they both search for

food. When each iteration is completed, the Elite is updated where better predators replace top predators.

Furthermore, a second matrix of the same size as the Elite matrix known as Prey is formed and its predators' addresses are updated according to the Elite's as depicted in Eq. (3), where $X_{i,j}$ denotes the j th dimension of i th prey. MPA depends on these two matrices throughout its iterations.

$$\text{Prey} = \begin{bmatrix} X_{1,1} & X_{1,2} & \dots & X_{1,d} \\ X_{2,1} & X_{2,2} & \dots & X_{2,d} \\ \vdots & \vdots & \vdots & \vdots \\ X_{n,1} & X_{n,2} & \dots & X_{n,d} \end{bmatrix}_{n \times d} \quad (3)$$

A. The Core of the MPA Optimization Process and Modeling

Based on the proposed model by [1], the optimization workflow of the MPA goes through three conditions while imitating the entire life of predators and prey. These three phases are split across three levels of velocity scenarios experienced by these aquatic creatures:

Condition 1: "When the speed of the predator gets faster than that of the prey" (high-velocity ratio).

Condition 2: "When the speed of the predator becomes almost equal to that of the prey" (unit velocity ratio).

Condition 3: "When the speed of the predator becomes slower than that of the prey" (low velocity ratio).

When condition 1 holds, this implies that the velocity ratio is high ($V \geq 10$), and consequently, the algorithm applies the best strategy for the predator which is to stand still without any movement. This approach [1] is expressed and modeled mathematically by Eq. (4).

From Eq. (4), $\overrightarrow{Prey}_l = (\overrightarrow{Prey}_l + P \cdot \vec{R} \otimes \overrightarrow{stepsize}_l)$ where \vec{R}_B is a vector containing the Brownian motion's normal distribution of random numbers.

While $Iter < \frac{1}{3} \text{Max_Iter}$ then,

$$\overrightarrow{stepsize}_l = \vec{R}_B \otimes (\overrightarrow{Elite}_l - \vec{R}_B \otimes \overrightarrow{Prey}_l), l = 1, \dots, n \quad (4)$$

The operator \otimes is an element-wise product. Computing the product of \vec{R}_B by prey simulates the prey's movement. The symbol $P=0.5$ is a constant control parameter that minimizes/maximizes predator or prey's step sizes, while R denotes a vector of uniform random numbers in the range $[0, 1]$. The first condition's scenario occurs at one-third of the entire iterations where the step size is high due to the high velocity of movement toward achieving high exploration. The variable $Iter$ represents the current iteration while Max_Iter stands for the maximum iteration.

Next, when condition 2 occurs, that is, the predator and prey are moving at almost the same velocity (unit velocity ratio i.e., $V \approx 1$), depicting a scenario where both are searching for their

food, the algorithm tries to detect the type of motion used by each. At this point, if the prey is moving in Levy motion, the predator's best approach becomes switching to Brownian motion. The situation happens in the middle of the optimization process when exploration attempts to switch to exploitation. Thus, both behaviors would matter, and half of the population would be assigned to exploration while the other half would be assigned to exploitation. Assuming the prey and predator are moving in Levy and Brownian motions, respectively, this can be represented or modeled mathematically by Eq. (5 and 6):

While $\frac{1}{3} < \text{Max_Iter} < \frac{2}{3} \text{Max_Iter}$, then

Considering the first half of the population,

$$\begin{aligned} \overrightarrow{stepsize}_l &= \vec{R}_L \otimes (\overrightarrow{Elite}_l - \vec{R}_L \otimes \overrightarrow{Prey}_l), l=1, \dots, \frac{n}{2} \\ \overrightarrow{Prey}_l &= \overrightarrow{Prey}_l + P \cdot \vec{R} \otimes \overrightarrow{stepsize}_l \end{aligned} \quad (5)$$

From Eq. (5), \vec{R}_L is a vector containing the Levy motion's distribution of random numbers. The vector \vec{R}_L and $Prey$ are multiplied to simulate the Levy-wise movement of the $Prey$. The step size is added to the location of the $Prey$ to complete this simulation.

On the other hand, the assumption for the second half of the population is thus:

$$\begin{aligned} \overrightarrow{stepsize}_l &= \vec{R}_B \otimes (\vec{R}_B \otimes \overrightarrow{Elite}_l - \overrightarrow{Prey}_l), l=\frac{n}{2}, \dots, n \\ \overrightarrow{Prey}_l &= \overrightarrow{Elite}_l + P \cdot CF \otimes \overrightarrow{stepsize}_l \end{aligned} \quad (6)$$

Where $CF = (1 - \frac{Iter}{Max_Iter})^{(2 \frac{Iter}{Max_Iter})}$ represents an adaptive parameter that regulates the step size of a predator's movement. The vector \vec{R}_B is multiplied with the $Elite$ to mimic the movement of the predator Brownian-wise and update the prey's location based on the predator's Brownian-wise movement.

Condition 3 occurs when the velocity of the predator becomes slower than that of the prey (low-velocity ratio, usually $V = 0.1$). This scenario usually occurs at the final phase of the optimization workflow, and it commonly targets high exploitation performance. The best option for the predator at this point is Levy's motion. This scenario is modeled mathematically by Eq. (7):

$$\begin{aligned} \text{While } Iter > \frac{2}{3} \text{Max_Iter} \\ \overrightarrow{stepsize}_l &= \vec{R}_L \otimes (\vec{R}_L \otimes \overrightarrow{Elite}_l - \overrightarrow{Prey}_l) \quad l=1, \dots, n \\ \overrightarrow{Prey}_l &= \overrightarrow{Elite}_l + P \cdot CF \otimes \overrightarrow{stepsize}_l \end{aligned} \quad (7)$$

where the vector \vec{R}_L is multiplied with the $Elite$ to simulate the predator's movement in Levy form and adding the step-size to the location of the $Elite$ to mimic the predator's movement aids in updating the location of the prey. The algorithm is presented thus (Algorithm 1):

Algorithm 1: Standard MPA Pseudocode

Step 1: **Initializing Phase**
(1) Initialize the parameters of the algorithm (Population size, dimensions, maximum Iterations)
(2) Uniformly distribute the initial solution using *Equation 1*.

Step 2: **Evaluation Phase**
(3) **while** (the termination condition does not satisfy)
(4) **Evaluate** the fitness of the solutions

Step 3: **Construction Phase**
(5) **Construct** the **Elite matrix** using *Equation 2*
(6) **Construct** the **Prey matrix** using *Equation 3*

Step 4: **Optimisation Phase**
Stage 1: **High Velocity Ratio**
(7) if ($Iter < \frac{1}{3} Max_Iter$) then
(8) **Update Prey** using *Equation 4*
Stage 2: **Unit Velocity Ratio**
(9) Else if ($\frac{1}{3} Max_Iter < Iter < \frac{2}{3} Max_Iter$) then
(10) Considering the first half of the population ($l = 1, \dots, \frac{n}{2}$)
(11) Update Prey using *Equation 5*
(12) For the second half of the population ($l = \frac{n}{2}, \dots, n$)
(13) Update Prey using *Equation 6*
Stage 3: **Low Velocity Ratio**
(14) Else if ($Iter > \frac{2}{3} Max_Iter$) then,
(15) Update Prey using *Equation 7*
(16) **end if**
(17) **end if**
(18) **end if**

Step 5: **Update Phase**
(19) **Update** the **Elite matrix** and save it in memory.
(20) **Apply the FADs** effect, then update using *Equation 8*
(21) Further, **Update the Elite matrix** and update the memory.
(22) **end while**

Overall, the steps proposed by [1] imitate the movement of predators and prey when seeking food in aquatic habitats. Their work assumes that there is an equal percentage of Levy and Brownian motion over the lifetime of a predator.

Because Fish Aggregating Devices (FADs) influence the time taken by predators at a particular place and point in time,

$$\vec{Prey}_l = \begin{cases} \vec{Prey}_l + CF[\vec{X}_{min} + \vec{R} \otimes (\vec{X}_{max} - \vec{X}_{min})] \otimes \vec{U} & \text{if } r \leq FADs \\ \vec{Prey}_l + [FADs(1 - r) + r](\vec{Prey}_{r1} - \vec{Prey}_{r2}) & \text{if } r > FADs \end{cases} \quad (8)$$

From Eq. (8), FADs are assigned the value 0.2 (i.e., FADs = 0.2) which is defined as the probability of its effect in the optimization process, and \vec{U} denotes a binary vector that contains arrays inclusive of zero and one. The array is formed by first generating random numbers in [0, 1] and thereafter, transforming it such that the array becomes zero if it is less than 0.2 and one otherwise. The parameter r represents a uniform number in [0,1]. \vec{X}_{max} and \vec{X}_{min} are vectors that contain upper and lower limits respectively of the dimensions. The subscripts r1 and r2 represent the prey's matrix indexes [1].

e.g., sharks spend 80% of the time around them and 20% at other places, the attraction by FADs is creating a local optimum and their jump to search other places is seen as avoidance of being trapped. The effect of FADs is therefore modelled mathematically as follows:

The MPA as depicted in 'Algorithm 1' and Fig. 2, has good provision for memory tracking and recalling. This helps the predator remember foraging success from the places it has visited. The flow requires updating the prey, applying the FADs effect, and evaluating the matrix for possible fitness updates for the Elite. At each stage of the iteration, the fitness value is compared with that of the previous iteration, and the best overwrites the current solution. This continually refines the quality of the solution as each iteration elapses.

Fig. 2. MPA flowchart.

III. MATERIALS AND METHOD

This study applies the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) approach [58] in searching, collecting, synthesizing, and analyzing a systematic literature review (SLR) of the original MPA, proposing related modifications, and variants according to some selected articles. The study uses two databases: Scopus and Web of Science, and an additional database: Google Scholar (for verification purposes only).

First, to validate the proposed topic, a search for the terms “Marine Predator Algorithm and Related Variants: A Systematic Review” was carried out which gave no single result from the Scopus database. A similar search was also conducted with the same search string in the Web of Science database, and it also did not produce a result. Furthermore, a search for the exact match of the same title on Google Scholar yielded no results.

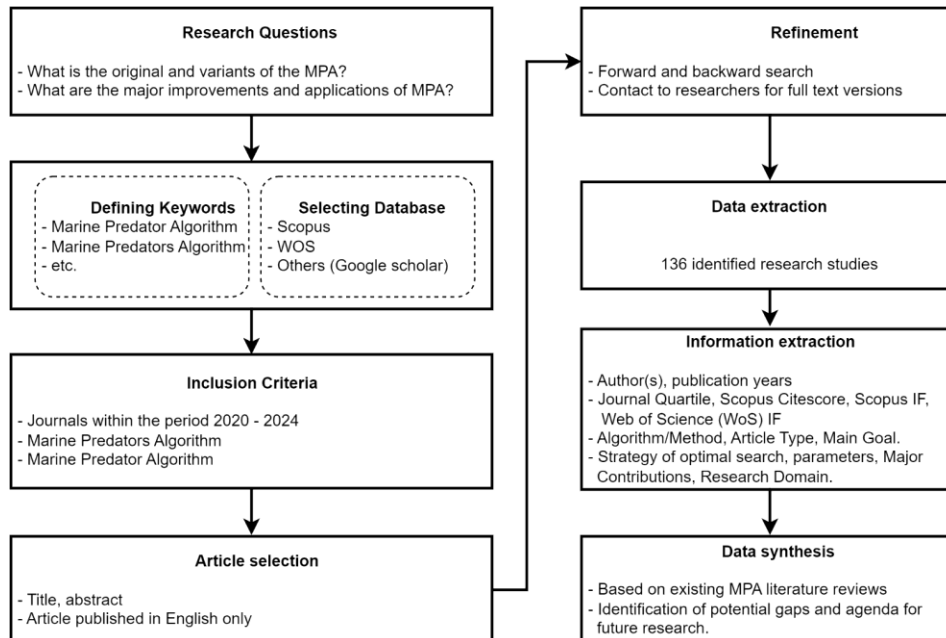

Fig. 3. The complete SLR process.

In Fig. 3, the complete SLR process is presented beginning with the formation of the research questions until the final data synthesis. It is important to note that the extraction of information from the articles was limited to the name of the author(s), publication years, journal quartile, Scopus CiteScore, Scopus IF according to Journal Indexed by Thomson Reuters (Clarivate Analytics), Web of Science IF, the algorithm or method used by the author(s), the article type (i.e., experimental result or review), main goal of the research, strategy for optimal search, parameters, major contributions, and the research domain.

Secondly, a careful search string was constructed to obtain relevant information and related articles (Fig. 4). An advanced search of the Scopus database using the constructed search string yielded 140 documents and a similar search conducted on the Web of Science database gave 143 papers as of 1st August 2024. The two search results were combined, and duplicate records were removed, reducing the document size to 170. A title-abstract screening was conducted where 11 articles were further excluded based on relevance and 1 other article was excluded, being written in Chinese language. Furthermore, 22 articles were excluded due to lack of full access. Overall, 136 articles were used in the entire synthesis of this review process.

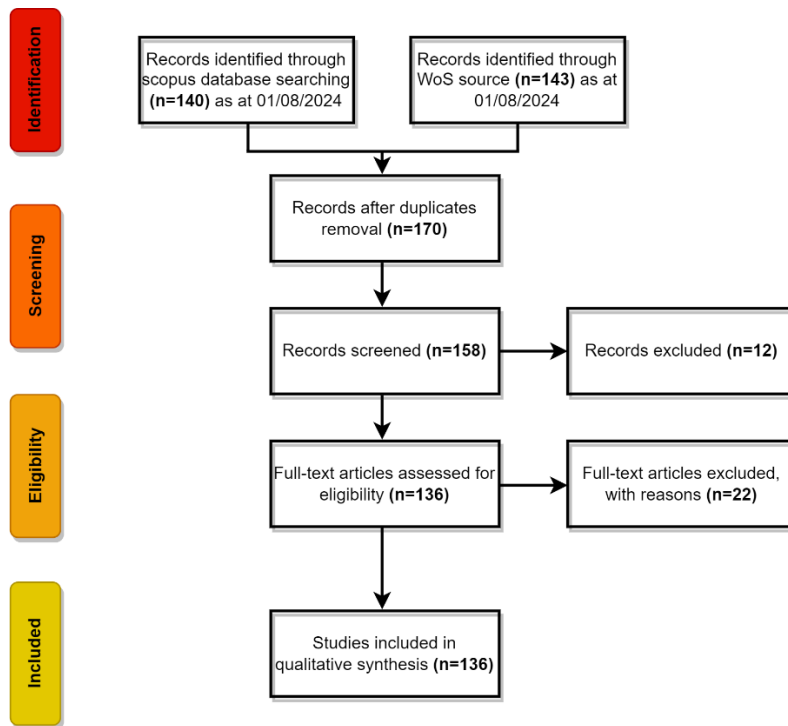

Fig. 4. Articles search and screening process.

The pie chart in Fig. 5 presents the diagrammatic distribution of retrieved MPA-related articles according to subject areas based on Scopus data. The top five subject areas are

Engineering, Computer Science, Mathematics, Energy, and Material Science, with 28.2%, 26.0%, 10.9%, 7.1%, and 5.8%, respectively.

Fig. 5. MPA-related articles according to subject areas (Source: Scopus).

The research trend of the application of MPA for solving various problems is depicted based on the number of research articles that are published per year (Fig. 6.). The record shows a steady upward trend in the number of articles published over the years, reflecting a strong growth in the algorithm's usage. Beginning with 12 journal articles in 2020, the number progressively increased to 168 by 2023, showcasing a 93% rise

over the observed period. As of the search date, the record of published articles in 2024 was 148 while still counting. More publications are underway as the year progresses. This significant growth highlights the major rapid application of the algorithm, indicating positive acceptance and potential usage for further development and innovation.

Fig. 6. MPA-related publications by year (Source: Scopus).

MPA stands out from other algorithms due to the predator's ability to execute various movements based on prey behavior. The predator can opt for Levy motion or Brownian motion based on the best encounter strategy, ensuring a dynamic connection between predator and prey. Specifically, the predator employs the Levy strategy when prey density is low and switches to Brownian motion when prey density is high.

As a metaheuristic algorithm, MPA is expected to meet some requirements of the major characteristics that measure its ability to solve optimization problems which include the ability to handle exploration, exploitation, local optimums, and convergence rate [41]. Each metaheuristic method differs in the way it does this based on the nature of the problem under consideration.

Three control parameters determine the sensitivity of MPA. The first is fish aggregating devices (FADs), which control the effect of FADs alongside their influence on the optimization flow. Secondly, P minimizes/maximizes predator's or prey's step sizes. Adjusting the step sizes in MPA helps to regulate its exploration and exploitation. The third parameter is the control factor (CF), which is an adaptive parameter that regulates the step size of a predator's movement. In study [1], it was found that the parameter ' P ' became more sensitive than FADs to optimizing some unimodal functions. However, in multimodal functions, FADs gave higher performance. In some instances, the parameters presented no sensitivity.

IV. PROPOSED VARIANTS OF MPA FOR PERFORMANCE IMPROVEMENT

A. Parameter-tuned MPA

One of the earliest approaches adopted by researchers towards improving the performance of MPA was the application of parameter tuning. It is a general approach used in

optimization and machine learning modeling to obtain optimum parameter values. The process requires tweaking some set of parameters used in controlling the behavior of the model/algorithm that are also adjustable to obtain an improved model with optimal performance.

In the original MPA, all population position updates are influenced by a constant value, denoted as P . As per the described position updating equations of MPA, there is a risk of premature convergence during the optimization iteration, limiting the exploration of the entire search space. Additionally, the alternation between Brownian and Lévy motions in the optimization process may lead to significant steps, causing the optimal solution to be crossed. Instead, dynamic updates of population positions could be achieved by incorporating other approaches such as the sine and cosine functions to improve the MPA's performance [32].

Some researchers such as [28] tried to improve the performance of MPA through a tuning process. Their study looked at the three most sensitive aspects of performance control of MPA which included the way the iterations are distributed across the iterations' phases, the size of the population in the second phase, and the effect of FADs. The experiment first tested different values of the iterations on each phase of the algorithm's optimization process e.g., allocating one-third of the iterations to each phase and later changing it produced little improvement in the results. The tests reveal that the least cost of optimal power flow (OPF) optimization in IEEE 48-Bus using MPA can be obtained in the first phase of the algorithm at three-fifths, phase two at one-fifth, and phase three at one-fifth of the iterations, respectively.

Concerning population size, the tasks of exploration and exploitation in MPA ideally require splitting the entire population size into two halves. However, it is important to note

that some optimizations' minimum can be achieved when the population is divided into two-thirds and one-third for the prey and predators, respectively [28]. While maintaining the classical fact that FAD or eddy current effect in MPA is meant to keep the iteration from being trapped at the local minimum, however, the mathematical representation shows that FADs are also local minima. Therefore, a search could be conducted to obtain the optimal value of FADs as in [28], starting with an initial value of 0.2 until better performance was obtained at FAD = 0.3. This shows that tuning the value of FAD in the IEEE 48-Bus system could yield better performance. After tuning and obtaining the optimal parameter values for the iterations' distribution, population size, and FADs for the MPA, an experiment was set up in two folds: holistic and inter-bounded OPF and ultimately comparing the performance of the tuned-MPA with GA. Overall findings showed that the tuned MPA outperformed GA in convergence, accuracy, and computational requirements. Furthermore, the holistic fold produces better solutions and requires higher computational power. While the inter-bounded

OPF generates faster results and is less computationally intensive.

Another similar MPA parameter-tuning case is found in [53], which in a bid to obtain the optimum load frequency control (LFC) settings to create a balance between power generation and demand, proposed a novel PD-P-PID cascade controller for LFC applications, utilizing the MPA for optimal parameter tuning. Tested on various power systems, including single and multi-area setups, the MPA-tuned PID-PD controllers exhibited superior performance compared to existing literature. The controller's robustness was evaluated on various power systems, and its parameters were optimized using MPA, demonstrating superior performance in terms of settling time and oscillations in frequency and tie-line power deviation compared to existing works. Their findings underscore the effectiveness of the MPA-tuned PD-P-PID controller in LFC applications. Table I provides more related works on MPA hyperparameter tuning where various degrees of success were achieved using parameter tuning.

B. Improvements in MPA Exploitation-exploration Balance

The balance between exploration and exploitation is crucial in metaheuristic algorithms for effective optimization. The MPA addresses this balance by dynamically adjusting the exploration rate during optimization iterations. This adjustment facilitates a combination of exploration and exploitation, strategically applied at the start and end of the optimization process. MPA utilizes a control factor (CF) as an adaptive parameter to regulate step size for predator movement, contributing to the algorithm's

effectiveness in navigating the search space. Because of the spread of iterations that are partitioned into stages, the search agents in MPA do not have sufficient trials for the search and discovery of spaces and the exploitation of optimal solutions [42].

Some researchers criticized the exploitation and exploration searchability of the classical MPA proposed by study [1]. The study in [45] opined that the step sizes that are randomly

generated by the Levy distribution are large and best suited for exploration. This happens in some instances, probably occasioned by sudden jumps from smaller step sizes to larger ones during the search transition from exploitation to exploration [1]. They further stated that many modifications would be required to improve its exploitation ability. While possessing a convergence factor advantage, the larger steps generated by the Levy motion could jump the global minimum. As such, many of them focused on how to improve this aspect of the algorithm.

One possible solution found in the literature in this aspect is in the work done by [24], which proposed a hybridization of Improved MPA and PSO known as IMPAPSO algorithm for the optimization of the non-linear optimal reactive power dispatch (ORPD) problem. To improve MPA's exploration stage, they replaced the Brownian motion's random walk of the search agents with a high-tailed Weibull distribution. Secondly, the exploitation stage of classical MPA which is in phase 3 was also modified to use either PSO or MPA based on probability, to improve the convergence of the algorithm. The proposed IMPAPSO was evaluated using various test suites including IEEE 30, IEEE 57, and IEEE 118 bus systems. The strength of the proposed algorithm was examined in a rigorous comparison with other methods. Overall, the proposed IMPAPSO yielded an outstandingly high speed of convergence, outperforming its counterparts. The power loss was minimized to 96%, 10%, and 9% in IEEE 30, IEEE 57, and IEEE 118 bus systems, respectively.

Another example is found in study [2], which applies a strategy known as the dominance strategy based on exploration-exploitation (DSEE) to improve search exploitation-exploration. First, the classical MPA was modified to produce a multi-objective MPA (MMPA). Secondly, a strategic technique called dominance strategy based on exploration-exploitation (DSEE) was applied to count the returned dominant solutions in every returned solution, from which exploitation is carried out during the exploitation phase. This version was called M-MMPA. Thirdly, the Gaussian-based approach was incorporated into MPA to produce M-MMPA-GM which is a version that delves deeper into the present to discover better non-dominated solutions. This helps to discover better solutions by taking some distance from the present solution. The fourth version was incorporated with Nelder Mead simplex at the beginning of the optimization phase to build a front that helps MPA realize better solutions within the optimization flow.

Additionally, a multi-stage improvement of the MPA (MSMPA) was proposed by study [56]. MSMPA maintains the multi-stage search advantage and incorporates a linear flight

strategy in the middle stage to enhance predator interaction, especially for those further from the historical optimum, promoting exploration. In the middle and late stages, the search mechanism of PSO is integrated to boost exploitation capabilities, reducing stochasticity and effectively constraining predators from jumping out of the optimal region. Additionally, a self-adjusting weight was employed to regulate convergence speed, achieving a balanced exploration-exploitation capability. The algorithm was tested on various CEC2017 benchmark test functions and three multidimensional nonlinear structure design optimization problems, which demonstrated superior convergence speed and accuracy compared to other recent algorithms.

Furthermore, the study in [45] applied the exploitation ability of NMRA to MPA in a bid to address its poor search exploitation. The authors proposed the hybridization of MPA and a naked mole-rat algorithm (NMRA) named MpNMRA – a self-adaptive algorithm. While retaining all the main parameters of both approaches, the basic part of MPA was attached to the worker stage of NMRA to improve search exploitation and exploration. The MpNMRA converges faster than other algorithms in comparison. The study in [55] applied HOGO to modify the search transition in MPA to gradually shift from exploration to exploitation as iterations progress, utilizing the global most appropriate solution at each iteration.

Other studies that worked on improving the exploitation-exploration of MPA are highlighted in Table II. These include [20] which incorporated local escaping operator (LEO) into classical MPA to tackle poor exploitation and exploration; [27] applied opposition based learning (OBL) strategy with Grey Wolf Optimizer (GWO) into MPA to overcome weaknesses; [43] incorporated MPA with spiral complex path search strategy based on Archimedes' spiral curve for perturbation, expanding the global exploration range and strengthening the algorithm's overall search capabilities; [44] integrated reinforcement learning (RL) into MPA to improve its global searchability; [39] combined chaotic sequence parameter and adaptive mechanism for velocity update to better MPA's exploitation and exploration search; [34] adopted comprehensive learning (CL) approach that improves search and transitioning within exploration and exploitation on MPA; [51] applied ranking-based mutation operator to identify the best search agent, enhancing exploitation capabilities and preventing premature convergence; [46] used dynamic foraging strategy (DFS) to tackle sudden transition between the Levy Flight and Brownian Motion; and [47] incorporated teaching mechanism into MPA's first phase to promote its global search ability. Table II summarizes the major improvements in MPA exploitation and exploration with various major contributions.

C. Hybridization of MPA with other Techniques

Hybridization is the combination of two or more techniques to solve problems. The primary purpose of doing this is to harness the strengths of each approach and use them to complement the weaknesses of the other. Literature has shown that by combining MPA with other algorithms, there could be high-performance improvements. For instance, [45] combined MPA with NMRA with the sole aim of addressing the

limitations of MPA (i.e., poor exploitation) and NMRA (i.e., narrow exploration) while leveraging the strengths of the two. MPA suffers from poor exploitation while NMRA suffers from weak exploration, and they both get into local optimum stagnation due to early or untimely convergence. Therefore, the strengths of MPA (i.e., good exploration) and NMRA (i.e., good exploitation) were used to address their weaknesses and to improve the entire performance. Overall, the authors reported a

significant performance improvement. The proposed hybridization (MpNMRA) was found to be more suitable for lower dimensional problems, even though it also provides satisfactory performance in high dimensional cases.

Another example is found in study [29], which proposed a hybrid method known as MPA-FPIDF, a combination of MPA and Fuzzy Proportional-Integral-Derivative with Filter (FPIDF) to optimize Fuzzy PIDF-LFC to enhance the performance of a hybrid microgrid system, incorporating PV and wind energy sources along with real irradiance and wind speed data, as well as energy storage devices. The MPA was used to optimize the input scaling factors, output gains, and membership function boundaries of the proposed FPIDF controller. The performance of MPA-FPIDF controller is compared with the conventional MPA-PIDF controller and other controllers reported in the literature for the same case study, including PSO-PIDF, COR-PIDF, and COR-FPIDF controllers. In addition, various scenarios are implemented to assess the robustness and sensitivity of the proposed controller to step load perturbations, variations in system parameters, and uncertainties associated with renewable energy sources such as wind speed fluctuations and solar irradiance variations.

In study [44], a hybrid method that combines reinforcement learning (RL) and MPA known as Deep-MPA was proposed to minimize the cost of the microgrid power system. RL was integrated with MPA to improve global searchability. The proposed Deep-MPA design was validated against various algorithms, demonstrating a 6% reduction in energy costs.

Furthermore, the study in [52] proposed an enhanced multi-strategy MPA-Variational Mode Decomposition (MPA-VMD) method for pipeline leakage detection. This was meant to

address the limitations of MPA by focusing on improving convergence speed and avoiding local optima. The enhanced MPA was used to find critical parameters in variational mode decomposition (VMD), and dynamic entropy was employed to select effective modes. The algorithm incorporates strategies like a good point set at the initial population stage to enhance search accuracy. It introduces a nonlinear convergence factor and Cauchy distribution during the search process to optimize the predator step size for better global search capabilities. The method effectively escapes local optima, leading to improved convergence speed.

The studied literature reported diverse hybridizations of MPA with other techniques, yielding various performance improvements (Table III). These include [24] which combined high-tailed Weibull distribution's improved MPA and PSO; [27] which integrated MPA, OBL, and GWO; [29] where MPA was integrated with Proportional-Integral-Derivative-Acceleration (PIDA); [35] coupled MPA and SVM where MPA was used to optimize SVM classifier's hyper-parameters for FS and classification; [36] which hybridized MPA and ANN, where MPA was used to optimize a trained ANN along with its fitness function; [37] which proposed IMPA-ResNet50, an improved version of MPA (IMPA) that was improved using OBL and TL, and ResNet50; [31] combined IMPA and CNN – a modified MPA algorithm for CNN hyperparameter selection, enhancing output performance for classification; [52] combined MPA with variational mode decomposition (MPA-VMD); [54] hybridized Open Circuit Voltage (OCV) reconfiguration model and MPA; [55] integrates MPA with HOGO; [45] integrated MPA with NMRA called MpNMRA, etc. Table III summarizes the major hybridizations of MPA with other techniques.

D. Proposed MPA Variants

Another way researchers address the limitations found in classical MPA is by modifying one or more aspects of the algorithm to create variants. An example is in study [46], which proposed a soft dynamic transformation to tackle the MPA's tendency to be trapped in local optima during transitioning from Levy Flight to Brownian motion when optimizing real-world problems. The proposed Dynamic Foraging Strategy MPA (DFSMPA) replicates the traditional MPA, imitating the step size taken to grab prey. It then applies the dynamic foraging strategy (DFS) to reach deeper search locations for a complete global, faster, and more efficient search. This could help prevent being trapped. Instead of the usual three phases that are used in classical MPA to mimic the behavior of predator and prey, the DFSMPA uses the continuous model to convert the various phases. In the two phases of exploration and extraction, the continuous model alternates between the search agents.

In addition, the study in [25] developed an enhanced MPA (EMPA) to identify hidden parameters in various PV and static PV models. In their work, the differential evolution (DE) operator was integrated into the exploration face of the standard MPA to escape local solutions for stability and performance reliability in handling nonlinear optimization cases of modeling PV. The strengths of the proposed enhancement are: (i) maintaining various new solutions in the search and optimizing unexpected convergence. (ii) avoiding being trapped by leaders and the population. (iii) using diverse search mechanisms that combine populations to create a balance between exploration and exploitation. (iv) dynamically changing the solutions by the

algorithm to ensure effectiveness and efficiency. (v) dynamic adjustment of the optimization problem and concurrently covering various multi-dimensional areas of the search space.

Furthermore, the study in [51] proposed an enhanced variant of the MPA, called the EMPA, designed for training Feedforward Neural Networks (FNNs). EMPA was intended to minimize classification, prediction, and approximation errors by adjusting connection weights and deviation values. It incorporates a ranking-based mutation operator to identify the strongest search agent, enhancing exploitation capabilities and preventing premature convergence. EMPA combines exploration and exploitation, providing stability and flexibility in achieving optimal solutions. Experimental results on seventeen datasets show that EMPA exhibits faster convergence, higher calculation accuracy, increased classification rates, and strong stability and robustness, improving its productivity and reliability in training FNNs.

Other modifications proposed are presented in Table IV. They include the use of mechanism for teaching and learning to balance search exploitation and exploration [47]; combining chaotic sequence parameter and adaptive mechanism for velocity update to better MPA's exploitation and exploration search [39]; modifying the classical MPA to produce a multi-objective MPA (MMPA), applying a strategic technique called dominance strategy based on exploration-exploitation (DSEE) to count the returned dominant solutions in every returned solution from which exploitation is carried out during the exploitation phase, incorporating Gaussian-based approach into MPA to produce M-MMPA-GM, and incorporating Nelder

Mead simplex at the beginning of the optimization process, building a front that helps MPA realise better solutions within the optimization flow [2]; using a local escaping operator (LEO) to improve MPA's searchability [20]; applying adaptive weights and OBL to enhance the performance of MPA [30]; combining chaotic sequence parameter and adaptive mechanism for velocity update to better MPA's exploitation and exploration search [39]; the use of CL approach to improve the search and transitioning within exploration and exploitation in MPA [34]; using linearly increased worst solutions (LIS) improvement strategy to address computational cost and accuracy issues associated with existing segmentation techniques, MPALS (MPA + LIS) and RUS are combined into a version called HMPA to serve as a solution to ISP [33]; incorporating logistic opposition-based learning (LOBL) into MPA to enhance the generation of various precise solutions with multiple population [32].; integrating MPA with CL approach and memory aspect of fractional calculus [42]; LA is used to enhance the artificial Jellyfish search algorithm (JS) and MPA, reducing

computational complexity while preserving their strengths [41]; MPA is integrated with spiral complex path search strategy based on Archimedes' spiral curve for perturbation, expanding the global exploration range and strengthening the algorithm's overall search capabilities [43]; it was also incorporated with pulse width modulation control boost converter to accurately track the MPP of a solar PV panel [65]; RL was integrated in MPA to improve its global searchability [44]; MPA was enhanced by incorporating a linear flight strategy in the middle stage to enhance predator interaction [56]; ranking-based mutation operator was used to identify the best search agent, to accelerate exploitation capabilities and preventing premature convergence in MPA [51]; DFS was used to tackle sudden transition between the Levy Flight and Brownian Motion [46]; teaching mechanism was also incorporated into MPA's first phase to promote its global search ability [47]; group-ranking of the predator populations, thorough learning approach implemented at stage 2 of MPA, and variable step-sizes control approach was applied [48]; etc.

E. Recent Proposed Improvements in MPA

Recently, more articles have been published with many improvements still underway. Some of these proposals include a hybrid MPA and Particle Swarm Optimization (MPA-PSO), combining the global and local search abilities of PSO with the MPA [66], Multi-Population-based MPA (MultiPopMPA) which uses global, balanced, and local search strategies simultaneously throughout the search process [67], and a multi-

strategy MPA, Regularized ELM, and CFA, integrating multiple algorithms [68]. Furthermore, an improved MPA (IMPA) with Deep Gated Recurrent Unit (DGRU), a hybrid model combining IMPA and DGRU for better accuracy and generalization in profit prediction [69], and an improved MPA (IMPA), using adaptive weight adjustment and dynamic social learning mechanisms [70] have been proposed. A summary of the recent literature is presented in Table V.

TABLE V. RECENT PROPOSED MPA IMPROVEMENTS

[80]	Q3	4.1		MPA Aquila Optimizer (MAO)	Experiment	improve product quality To present a hybrid method combining MPA and AO for droop control in DC microgrids	enhance optimization capability Combining the strengths of MPA and AO to enhance exploration and exploitation.	addressing the severe coupling of multiple processes. Superior convergence ability and promising performance in droop control.	Electrical Engineering
[81]	Q3	2.4	1.2	MPA for robot path planning	Experiment	To design an optimal path for a robot to navigate from its starting point to its goal while avoiding obstacles	Heuristic search-based methods, potential field-based methods, sampling-based methods, hybrid methods, and evolutionary methods	The proposed method uses the Marine Predator Algorithm, which shows good performance in different situations.	Robot path planning and autonomous driving.
[82]	Q2	3.6	1.6	MPA- P-P-FOPID controller.	Experiment	To design a cascade P-P-FOPID controller optimized by the MPA for improving load frequency control in electric power systems.	The MPA is employed for its parameter-less, derivative-free, user-friendly, flexible, and simple nature.	The proposed controller demonstrated superior performance in reducing integral time absolute error (ITAE), settling time, and frequency and tie-line power deviations compared to other recent approaches. It also showed robustness against parametric uncertainties.	Electric power systems
[83]	Q1	19.9	6.2	improved binary MPA	Experiment	To develop an efficient offloading method that reduces energy consumption and meets time constraints in edge computing environments	The binary MPA is used for its effectiveness in solving optimization problems under constraints	The proposed method effectively meets deadlines while reducing energy consumption, even with an increasing number of users.	Edge computing.
[84]	Q2	4.3	2.7	Enhanced MPA (EMPA) - SVM	Experiment	To improve the accuracy and efficiency of IGBT switching power loss estimation using an optimized SVM model.	The EMPA is employed for its effectiveness in parameter optimization, leveraging its ability to handle complex, multi-dimensional search spaces.	The integration of EMPA with SVM results in a model that significantly enhances the accuracy and efficiency of power loss estimation in IGBT, outperforming traditional methods.	power electronics
[85]	Q1	11.2	6.2	MPA	Analytical	To identify and analyze the structural biases in the MPA using the BIAS Toolbox and Generalized Signature Test (GST).	The study employs the BIAS Toolbox and GST to detect and evaluate the structural biases within the MPA, revealing how these biases affect the algorithm's performance.	The article highlights significant structural biases in the MPA, which cause the population to revisit specific regions of the search space, leading to increased computational costs and slower convergence.	optimization algorithms
[86]	Q1	11.5	7.5	Improved Weighted MPA (WMPA)	Experiment	To enhance the accuracy and efficiency of SOM estimation by selecting the most relevant hyperspectral features using the improved WMPA.	The WMPA is optimized to improve feature selection by leveraging its ability to handle complex, multi-dimensional search spaces effectively.	The improved WMPA demonstrates higher accuracy and stability in predicting SOM content compared to traditional methods, providing a robust and efficient approach for SOM estimation.	agricultural and environmental monitoring
[87]	Q1	7.7	4.8	Enhanced Hybrid Aquila Optimizer with MPA (EHAOMPA)	Experiment	To enhance the performance of the Aquila Optimizer in solving combinatorial optimization problems by integrating it with the MPA.	The hybrid algorithm leverages the exploration capabilities of MPA and the exploitation strengths of AO to effectively navigate the search space and find optimal solutions.	The EHAOMPA demonstrates superior performance in various benchmark problems compared to traditional AO and other optimization algorithms, showing promise in solving industrial-constrained design problems and optimizing hyperparameters for	combinatorial optimization.

Ref.	J. Quart.	Scopus CiteScore (2023)	Scopus IF	Proposed Algorithm	Article Type	Main Goal	Strategies of Optimal Search	Major Contribution	Research Domain
[88]	Q1	14.8	7.2	improved MPA combined with Extreme Gradient Boosting (XGBoost)	Experiment	To enhance the accuracy and efficiency of shipment status time predictions using a hybrid approach that combines MPA and XGBoost.	The improved MPA incorporates opposition-based learning, chaos maps, and self-adaptive population strategies to optimize the parameters of the XGBoost model.	COVID-19 CT-image detection. The hybrid model demonstrates superior performance in predicting shipment status times compared to traditional methods, providing a robust and efficient solution for logistics and supply chain management. The algorithm successfully forms core backbone grids for the IEEE 39-node and IEEE 300-node systems, ensuring economic feasibility and optimal network connectivity while balancing active and reactive power demands.	logistics and supply chain management
[89]	Q2	4.3	2.4	improved MPA (multi-objective optimization).	Experiment	To enhance the resilience of power grid infrastructure by optimizing core backbone grid planning using a multi-objective 0–1 planning problem.	The improved MPA incorporates file management and an enhanced top predator selection mechanism to effectively explore the Pareto frontier for optimal solutions.	The research demonstrates that the MSC-KPCA-MPA-RF model achieves the best results, with a fitting coefficient of 0.9963 and a mean square error of 0.0047	power systems
[90]	Q2	4.3	2.7	MPA optimized random forest (RF) algorithm with laser-induced fluorescence (LIF) technology	Experiment	To develop a more efficient and accurate method for diagnosing transformer faults, overcoming the limitations of traditional methods.	The study employs principal component analysis (PCA) and kernel principal component analysis (KPCA) for dimensionality reduction, followed by the MPA-RF model for optimal fault diagnosis.		power systems and electrical engineering
[91]	Q1	9.5	2.6	MPA optimized pavement maintenance and rehabilitation (M&R) scheduling	Experiment	To develop a sustainable M&R scheduling optimization model that considers highway agency costs, environmental impacts, and social effects.	The MPA is used to handle the computational complexities of optimizing M&R scheduling for large-scale networks	The sustainable model reduces CO2 emissions by 6.5% and improves equity and safety indices by 40.7% and 2.5%, respectively, compared to conventional methods	pavement management systems and sustainable infrastructure engineering.
[92]	Q1	12.6	7.2	Clustering Wavelet Opposition-based MPA (CWOMPA) enhanced-MPA	Experiment	To improve optimization performance and feature selection in high-dimensional datasets, particularly in medical diagnosis.	CWOMPA incorporates fuzzy clustering, wavelet basis function, and adaptive opposition-based learning to enhance population diversity and prevent premature convergence	Demonstrates CWOMPA's superior performance in optimization and feature selection across various benchmark functions and medical datasets	Meta-heuristic optimization algorithms and feature selection in medical datasets.
[93]	Q1	5.7	2.6	Hybrid MPA-PSO to tackle the Energy Scheduling Problem (ESP).	Experiment	To optimize electricity bills, energy consumption, and user comfort by finding the best schedule for smart appliances	The proposed method enhances the searching capabilities of MPA using PSO components to improve schedules with poor fitness values	The research demonstrates the efficiency and high performance of the hybrid method in optimizing ESP objectives compared to other methods	Internet of Things (IoT) and smart grid technology
[94]	Q4	1.3	1.74	Modified MPA (MMPA) for automated atrial fibrillation detection using ECG signals.	Experiment	To develop a method for automatically detecting atrial fibrillation using transient single lead ECG readings	The algorithm utilizes Heart Rate Variability (HRV) and frequency analysis for feature extraction, followed by classification using SVM	The study's innovative contribution is the application of the MMPA for identifying atrial fibrillation in brief ECG data, achieving a maximum accuracy of 99.8%.	Biomedical Engineering and AI.
[95]	Q1	6.5	4.1	bidirectional gated recurrent unit (BiGRU) optimized MPA	Experiment	To analyze the influence of scraper geometry and roughness on the coating process using advanced predictive and simulation models.	The MPA-BiGRU pseudo-lattice Boltzmann (pseudo-LB) method is employed to simulate the coating flow without specific rheological equations.	The study finds that rectangle geometry is suitable for high coating speeds, while trapezium geometry is better for low speeds. Scraper roughness significantly affects the process with rectangle geometry.	materials science and engineering

[96]	Q2	4.6	2.7	Improved MPA (IMPA)	Experiment	To optimize water resource allocation in Huaying City by balancing social, economic, and ecological benefits	The IMPA employs chaotic initialization for population diversity, golden sine algorithm for balanced exploration and exploitation, and quadratic interpolation for enhanced search accuracy.	The study demonstrates that IMPA outperforms other algorithms in terms of stability and accuracy for water resource optimization, providing a new approach for sustainable water management.	water resource management and optimization algorithms.
[97]	Q2	10.2	4.7	MPA	Comparative	To minimize the deficit of agricultural water supply by optimizing reservoir operations under baseline and climate change conditions.	The MPA uses random walk strategies (Brownian and Levy motions) and elite matrices to enhance exploration and exploitation phases.	Demonstrates that MPA outperforms GA in terms of reliability, resiliency, and vulnerability in reservoir operations.	Water Resource Management and Optimization Algorithms.
[98]	Q2	3.4	1.7	PRMPA-Spectral-SMOTE with improved MPA (IMPA).	Experiment	To enhance the classification performance of biomedical data, which is often high-dimensional and imbalanced	The algorithm uses minimal-redundancy maximal-relevance (mRMR) for feature selection, Spectral-SMOTE for data resampling, and an improved MPA for optimizing key parameters.	The method significantly improves the classification accuracy of biomedical data, outperforming other data resampling methods	biomedical data
[99]	Q1	9.8	3.4	Uniform MPA (UMPA), combines uniform design with the MPA	Experiment	To accurately and efficiently detect neural unit modules in brain networks, which can aid in disease detection and targeted therapy	UMPA leverages uniform design to ensure evenly distributed solutions and MPA for optimization, incorporating Lévy flight and Brownian movement strategies.	Integration of uniform design with MPA, resulting in improved performance in identifying neural unit modules compared to other methods.	brain network analysis
[100]	Q1	9.7	3.6	Reinforcement Learning MPA (RLMPA) to enhance global optimization.	Experiment	Improve Optimization-Address weak convergence, limited balance capacity, and optimization limitations in MPA by introducing RLMPA.	Three Location Update Strategies: Ranking paired mutually beneficial learning; Gaussian random walk learning; and Modified somersault foraging.	Enhanced Performance: RLMPA shows superior performance in global optimization, search efficiency, and convergence speed compared to 10 competitive algorithms.	engineering design

V. APPLICATIONS OF MPA IN VARIOUS DOMAINS

The MPA has found wide acceptance across many research domains. Focusing on areas with the widest coverage and most recent development, Engineering (28.2%), Computer Science (26.0%), Mathematics (10.9%), and Energy (7.1%) of the applications, the following summaries are presented.

A. Engineering

The highest of MPA's applications based on Table V are in real-world engineering designs [1]. In this domain, MPA has been used to solve real-world problems such as pressure vessel design, tension/compression spring design, and welded beam design [1], estimating the parameter of frequency-modulated sound wave (FM), speed spectrum radar Polly phase code design (SSRPP), and Lennard-Jones (LJ) potential problem [45]. These problems are constrained engineering benchmarks and were made with associated practical engineering examples. With the help of the death penalty approach, the constrained problems were converted to unconstrained ones. Another real-world

problem solved includes demand-controlled ventilation of the operating fan schedule, where a 2-zone (entry and exit) retail store stocked with a supply and exhaust fan for ventilation was examined. The main objective was to "reduce the fan's energy consumption using demand-controlled ventilation subject to airflow and the amount of carbon dioxide (CO₂)".

B. Computer Science

In this area, MPA has been used to develop an efficient offloading method that reduces energy consumption and meets time constraints in edge computing environments [83] and to develop an optimal resource allocation strategy for vehicular edge computing networks [66]. It has also been used to design an optimal structured deep convolutional neural network (DCNN) [74], in training ANN for classification tasks [67], incorporation into the SVM framework to enhance prediction precision and efficiency [76] and was combined with a BP Neural Network [77] for improved performance. Furthermore, on the Internet of Things (IoT) and smart grid technology, MPA was used to optimize electricity bills, energy consumption, and

user comfort by finding the best schedule for smart appliances [93].

C. Mathematics

The proposed variant of MPA such as DFSMPA was also applied to three sets of standard mathematical test functions and one set of real-world engineering optimization problems including (i) Classical functions such as unimodal, multimodal, and fixed multimodal functions. (ii) Contemporary numerical optimizations CEC-BC-2017 comprises 30 composition and hybrid functions. (iii) CEC06-2019 (100-Digits challenge). and (iv) Ten CEC-2020 problems applicable to real engineering optimization [46].

D. Energy

MPA has been applied in power systems and electrical engineering to develop a more efficient and accurate method for diagnosing transformer faults, overcoming the limitations of traditional methods [90], and enhancing the resilience of power grid infrastructure by optimizing core backbone grid planning using a multi-objective 0–1 planning problem [89]. In addition, a cascade P-P-FOPID controller optimized by MPA for improving load frequency control in electric power systems was also designed [82]. Furthermore, MPA and AO have been combined for drop control in DC microgrids [80]. In electrical engineering and renewable energy, MPA has been applied to enhance the low-voltage ride-through (LVRT) capability of grid-connected photovoltaic (PV) systems [78] and to optimize the steam gasification process for converting palm oil waste into environmentally friendly energy [76]. MPA has been used in power electronics to improve the accuracy and efficiency of IGBT switching power loss estimation [84].

Comprehensively, the research application domain and tasks include real-world and engineering design [2, 20, 32, 45–47, 55, 58, 70, 73, 77, 79, 85, 91, 95, 100–108], microgrid feature selection [7], antenna signals [39], selective harmonic elimination [62], power modulation [38], ligament deficiency detection [35], transistor's design [36], breast cancer diagnosis [37], task scheduling in cloud computing [48], time series prediction [49], medical image fusion and analysis [26, 71, 72, 74, 92], economic emission dispatch [34], wind renewable energy [60], mathematical computation [61, 87], image segmentation [30, 33, 109, 110], PV System and modelling [27, 64, 65, 111], Optimal power flow [28], Biological Processes [50], Microgrid system [29], optimal reactive power dispatch [24], ANN training and classification [51, 67], pipeline leakage detection [52], arrhythmia classification [31], load frequency controller design [53], knowledge-based systems [42], data clustering [41], robot path planning [43, 81], battery aging mechanism [54], li-ion batteries [63], transformer oil breakdown [59], renewable energy system design [44], dynamic clustering simulation [112], marine stabilized platforms [113], joint regularization semi-supervised ELM [114], oil layer prediction [115], EEG/ERP signal [116], urban green space type [117], SVM optimization [118], solar-powered BLDC motor design [119], network reconfiguration and distributed generator allocation [121], wind and solar energy [122], DNA storage [123], white blood cell classification [124], wireless sensor network coverage [125], hybrid heartbeats [126], distribution system [127], task scheduling in cloud computing [128], shrimp

freshness detection and classification [129], evolutionary computations [130], energy management system [131], hybrid active power filter [132], gene selection in cancer microarray classification [133], supercapacitor modelling [134], COVID-19 detection modelling [135], wind power forecasting [136], thermal error modelling of electrical spindle [137], electrical power system & renewable energy [76, 78, 80, 82, 84, 89, 90, 138], DC motors [139], feature selection in metabolomics [140], optimal power flow [141], fuel cell steady-state modelling [142], structural damage detection [143], production planning [144], wind energy systems [145], AI and Bioinformatics [75, 94, 98, 99], Vehicular Edge Computing (VEC)[66, 83], passenger flow prediction [68], Internet of Things (IoT) and smart grid technology [93, 120], financial accounting information systems [69], agricultural and environmental monitoring [86], logistics and supply chain management [88], and water resource management and optimization algorithms [96, 97].

VI. DISCUSSION

Although the classic MPA proposed by study [1] was for a single objective and possessed some shortcomings, multi-objective variants were later proposed and other subsequent improvements were made [133], [146–148]. It is worth noting that most of the improvements in the literature were based on enhancing MPA's initial population, exploitation, exploration, and convergence.

Firstly, opposition-based learning (OBL), a novel technique introduced by Tizhoosh, has been widely adopted by numerous researchers to improve the initial population quality of metaheuristic algorithms. The OBL has been used to produce a more widely distributed initial population for MPA.

Furthermore, many scholars applied varying OBL approaches to tackle MPA's limitations. These include integrating the OBL strategy with GWO into MPA [27], OBL and TL were also used to improve MPA and IMPA-ResNet50 using a modified MPA algorithm for CNN hyperparameter selection to improve output performance for classification [31], enhancing the optimization capabilities of MPA with adaptive weights and OBL [30], and logistic OBL (LOBL) technique was incorporated in study [32] to enhance the generation of various precise solutions with multiple populations. In study [106], quasi-learning (Q-learning) was introduced to help MPA fully utilize the information generated by previous iterations and subsequent ones, QOBL was introduced to support an increase in population diversity, reducing the risk of convergence to inferior local optima. In addition, the quasi-opposition learning and spiral search strategies were incorporated into QRSS-MPA to improve it [123].

Additional strategies adopted in the literature to control MPA's exploration-exploitation search include chaotic maps' exploitation capabilities alone. Several chaotic maps can be implemented to improve the exploration-exploitation process [108]. The chaotic map can be applied to balance the trade-off between the exploration and exploitation phases. The self-adaptive population method automatically adjusts the population size for each iteration. It helps to increase the convergence speed [101, 108]. In study [107], chaotic maps, opposition-based learning strategy (OBLs), and teaching-

learning-based optimization (TLBO) with strong exploitation operators were combined. MPA was first modified to have MMPA that leverages chaotic maps and OBLs in the initialization stage to generate high-quality individuals. Parameter-free teaching-learning-based optimization method with a strong exploitation operator was incorporated into MPA (MMPA-TLBO), which effectively trades off between the exploitation and exploration process. Furthermore, [114] applied a multi-strategy approach involving three strategies to improve the performance of MPA. It included a chaotic opposition learning strategy to generate a high-quality initial population, adaptive inertia weights, adaptive step control factors to improve exploration, utilization, and convergence speed, and a neighborhood-dimensional learning strategy to maintain population diversity.

The literature also used comprehensive learning (CL) to improve the performance of MPA. For instance, in study [34], the CL approach was used to improve search and transition within the exploration and exploitation of MPA. In study [42], MPA was integrated with the CL approach and the memory aspect of fractional calculus.

Other approaches that were implemented to improve the performance of MPA include the use of Dynamic Foraging Strategy (DFS) to tackle sudden transition between the Levy Flight and Brownian Motion by study [46], Differential Evolution (DE) operator was integrated into the exploration phase of the standard MPA by study [64] to escape local solution, and the use of teaching and learning mechanism was incorporated into MPA in study [47] where the teaching mechanism was integrated into the first phase of the MPA to promote its global search ability. In study [39], chaotic sequence parameters and an adaptive mechanism for velocity update were implemented to improve MPA's search exploitation and exploration. Also, group ranking of predator populations was proposed by study [48], incorporating a thorough learning approach implemented at stage 2 of MPA, and a variable step-size control approach.

Furthermore, time-delay polynomials were applied to improve the model prediction performance [49]. A local escaping operator (LEO) was incorporated into classical MPA [20] to tackle poor exploitation and exploration. In study [24], exploration was improved by replacing the Brownian motion's random walk of search agents with a high-tailed Weibull distribution. The exploitation stage in phase 3 was also modified to use PSO or MPA based on probability. The study in [51] used a ranking-based mutation operator to identify the most performing search agent, enhancing exploitation capabilities and preventing premature convergence.

In addition, [52] applied a strategy known as a "good point set" in the initial population stage for improvement by initializing a good point set and enhancing the convergence factor (CF) and Cauchy distribution. Learning automata (LA) was used in [41] to improve the artificial jellyfish search algorithm (JS) and MPA, reducing computational complexity while preserving their strengths. MPA is incorporated with a spiral complex path search strategy based on Archimedes' spiral curve for perturbations in study [43], expanding the global exploration range and strengthening the algorithm's overall search capabilities. In study [55], HOGO was implemented

which modifies the search transition in MPA to gradually shift from exploration to exploitation as iterations progress, utilizing the global best solution at each iteration. In study [56], MPA was enhanced by incorporating a linear flight strategy in the middle stage to enhance predator interaction. Reinforcement learning (RL) was also integrated into MPA [44] to improve global searchability.

VII. FUTURE RESEARCH DIRECTION

The application of the MPA is predominant in engineering and real-world design. However, researchers need to extend it to other disciplines and optimization problems. Additional variants of MPA, such as Constrained MPA (CMPA), Mixed-Integer MPA (MIMPA), and Parameter Less MPA (PMPA), warrant exploration, alongside dynamic applications like Mobile or dynamic MPA in robotics. Moreover, MPA shows potential in diverse areas like knowledge discovery, power systems, signal processing, DNA assembly, and medical diagnostics. However, variants like MpNMRA still face challenges such as potential entrapment in local optima and inefficient optimization of all test functions, necessitating improvements in control parameter selection and solution retention. In addition, the expansion of MPA into multi-objective problems, alongside enhanced stability and convergence analysis remains an area for future research. Other proposed methods, such as DAMPA and MTLMPA, also require comprehensive testing in various domains to assess their efficacy. Additionally, the scalability of dataset testing for algorithms like IMPA-ResNet50 and exploration of their performance in regression tasks, computational efficiency enhancements, and generalization to different CNN configurations are suggested. Further research efforts should aim to integrate MPA with deep learning and machine learning techniques, explore its potential in renewable energy systems – with emphasis on solar radiation forecasting, refine its application in real-world scenarios, and investigate its hybridization with other metaheuristic methods for improved optimization outcomes.

VIII. CONCLUSION

This systematic review of MPA presents a wide panorama concerning its theoretical formulation, practical implementations, and novel improvements. Current research synthesizes studies undertaken during the last five years that underline, among others, the flexibility and efficiency of the MPA approach as a metaheuristic optimization method but with peculiar efficacy in handling complex, high-dimensional, and multimodal optimization problems. From its principle of inspiration to its adaptive nature, MPA has always shown robust performance in diverse fields, ranging from real-world engineering design, image segmentation, and PV system modeling, indicating its wide acceptance and high applications. It also identifies the critical design parameters and their influence on the convergence and performance of the algorithm, thus contributing to the deeper theoretical understanding of the method.

This research significantly contributes to the optimization literature by systematically categorizing MPA variants based on their core improvements, including parameter tuning, hybridization, and other modification mechanisms. The review delineates the strengths and limitations of each approach by

comparing these variants across benchmark problems, thus providing a roadmap for future research. We also find gaps in the current literature, such as a need for more rigorous theoretical analysis regarding convergence properties and scalability in dynamic environments. These insights pave the way for developing more efficient, adaptive, and robust MPA variants that can address emerging challenges in optimization.

MPA provides several practical benefits over other optimization algorithms, including ease of implementation and minimal parameter-tuning requirements to escape local optima using a form of collective intelligence. Computationally efficient with adaptability toward real-time application, such as resource allocation and feature selection control system optimization is another added area of MPA. Besides, the ease with which the algorithm can be combined with other optimization techniques has favored its use in hybrid systems and further extended the usefulness of the MPA in solving complex, real-world problems. This review, therefore, highlights that the simplicity and flexibility of MPA make it a useful tool for practitioners from all walks of life in addressing optimization problems, both at the academic and applied levels.

This systematic review, therefore, underlines the continuous relevance and transformational potential of MPA as an optimization technique. By connecting the dots between theoretical developments and practical applications, it provides a comprehensive overview of the algorithm's capabilities and limitations, thus laying the ground for future innovations in the field. We expect this work to be a reference point for researchers and practitioners alike, encouraging new contributions that tap into MPA's unique strengths to solve ever more complex optimization problems.

Abstract— Diffuse Large B-Cell Lymphoma stands as the most prevalent form of non-Hodgkin lymphoma worldwide, constituting approximately 30 percent of cases within this diverse group of blood cancers affecting the lymphatic system. This study addresses the challenges associated with the accurate DLBCL segmentation and classification, including difficulties in identifying and diagnosing DLBCL, manpower shortage, and limitations of manual imaging methods. The study highlights the potential of deep learning to effectively segment and classify DLBCL types. The implementation of such technology has the potential to extract and preprocess image patches, identify, and segment the nuclei in DLBCL images, and classify DLBCL severity based on segmented nuclei counting.

Keywords—Deep learning; Diffuse Large B-Cell Lymphoma (DLBCL); lymphoma cancer; HoVerNet

I. INTRODUCTION

Diffuse Large B-Cell Lymphoma (DLBCL) stands as the most prevalent form of non-Hodgkin lymphoma (NHL), comprising approximately 30% of all cases within this diverse group of blood cancers affecting the lymphatic system. DLBCL is characterized by the rapid proliferation of malignant B-cells in lymph nodes, bone marrow, and other lymphatic tissues. DLBCL can afflict individuals of any age, with a predilection for those over 60 [1]. Given its life-threatening nature and variable clinical outcomes, precise diagnosis assumes paramount importance in the management of DLBCL. The identification and quantification of cell nuclei within tissue samples emerge as crucial for assessing tumor characteristics and grading, thus guiding treatment decisions. Deep learning-based nuclei segmentation offers a promising solution, potentially enhancing diagnostic accuracy and efficiency, to streamline this labor-intensive and time-consuming task.

Accurate diagnosis and staging of DLBCL are critical for determining optimal treatment and prognosis. Nuclei segmentation and classification, a pivotal component of DLBCL tissue image analysis, allow for the identification and quantification of tumor cells. Conventional nuclei segmentation and classification methods are often time-consuming, labor-intensive, and error-prone, making the need for deep learning

models readily apparent. However, the complexity of DLBCL samples, such as tissue heterogeneity, staining changes, and complex cell interactions, requires complex and accurate deep learning models to address these challenges [1].

This paper explores the current challenges in nuclei segmentation and classification for DLBCL using deep learning methods. It provides an extensive review of the techniques, preprocessing methods, and segmentation approaches applied to DLBCL analysis. Furthermore, the paper highlights advancements in the field and identifies gaps for future exploration, aiming to inspire further research and innovation in digital pathology.

This paper is structured as follows: Section II reviews related work, highlighting the advancements and gaps in deep learning-based nuclei segmentation and classification for DLBCL. Section III describes the methods, including preprocessing techniques, model architectures, and evaluation metrics. Section IV presents the results and discussions, comparing the performance of state-of-the-art deep learning methods. Finally, Section V concludes the study, summarizing key findings and future research directions. This structure aims to provide readers with a comprehensive understanding of the challenges and contributions in the field.

II. RELATED WORK: ADVANCEMENTS IN DIAGNOSIS AND STAGING OF DIFFUSE LARGE B-CELL LYMPHOMA

A. Symptoms, Risk Factors, and Causes of Diffuse Large B-Cell Lymphoma

DLBCL can cause many different symptoms. One of the most common signs is the painless swelling of lymph nodes. These are lumps under the skin, usually found in places like the neck, armpit, or groin. This might happen, along with other signs. For example, losing weight for no reason, always feeling tired, or sweating a lot at night. Also, patients with DLBCL may experience fever from time to time, which further signals the response of the body to lymphoma. Sometimes, DLBCL might affect abdominal organs, leading to symptoms like abdominal pain or swelling. The symptoms show up based on where and how big the bothered lymph nodes or organs are. DLBCL can also have other unique symptoms. These vary based on where

in the body they show up. For example, if it is in the chest or lungs, the patient might have trouble breathing, coughing, or having chest pain. Those with DLBCL in their gastrointestinal tract could feel stomach pain, nausea, vomiting, and changes in bowel habits. When DLBCL affects the brain or spinal cord, it might lead to headaches, behavior changes, or even seizures. In some cases, DLBCL could cause problems with the skin. This could look like a rash or bumps. These skin changes might give doctors extra clues during physical examinations.

There are several risk factors and causes that have been identified. Advancing age is a prominent factor, as DLBCL is more prevalent in individuals over the age of 60, and the incidence increases with age. This age-related susceptibility suggests a cumulative effect over time, possibly linked to cellular changes and immune system alterations associated with ageing. A compromised immune system, whether due to medical conditions such as Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome (HIV/AIDS) or the use of immunosuppressive drugs post-organ transplant, is another significant risk factor [2]. The impaired immune surveillance in these scenarios may create an environment conducive to the uncontrolled growth of lymphoid cells, fostering the development of DLBCL.

The Epstein-Barr virus (EBV), belonging to the herpesvirus family, has been linked to an increased risk of DLBCL, particularly in immunocompromised individuals [3]. The ability of EBV to infect B-cells and potentially contribute to the transformation of these cells underscores its role in the lymphoma genic process. Besides, genetic factors also contribute, with a family history of lymphomas potentially elevating the risk. While the specific genetic mechanisms are not fully elucidated, ongoing research aims to uncover the intricate interplay of genetic and environmental factors in DLBCL development [2]. Other factors, such as autoimmune diseases and certain chemical exposures, have been explored for their potential roles in lymphomagenesis, though their associations remain complex and multifaceted.

B. Diagnosis Method and Staging of Diffuse Large B-Cell Lymphoma

DLBCL is typically diagnosed by removing a swollen lymph node or taking a sample of tissue from it and examining it under a microscope. This involves a minor procedure known as a biopsy, which is usually performed under local anesthesia or through a minor operation. Following the biopsy, expert pathologists use special staining, a test called flow cytometry, and chromosome analysis to determine the exact variant of DLBCL. DLBCL is also diagnosed using blood tests and imaging tests. Blood tests can help determine the overall health of the patient and detect any abnormalities in the blood cells. To determine the location and extent of the disease, imaging tests such as Magnetic Resonance Imaging (MRI) scans, Computed Tomography (CT) scans, Positron Emission Tomography (PET) scans, and ultrasounds are used. Apart from that, the current standard diagnosis method for DLBCL includes two tests: Fluorescence In-Situ Hybridization (FISH) tests and Immunohistochemistry (IHC) tests [4].

The staging of DLBCL depends on the extent of the disease and the organs involved. The Ann Arbor staging system is

commonly used to stage DLBCL for lymphoma. It classifies the disease into four stages of involvement, namely Stages I, II, III, and IV [5]. Stage I has been described because the cancer is found in the lymphatic zone or in only one organ. Stage II is indicated because cancer is found in two or more lymph nodes on one side of the lung or in one limb and in one or more lymph nodes on the same side of the lung. Furthermore, cancer found in different parts of the lymph nodes or on either side of the diaphragm is stage III. Lastly, stage IV means that the cancer has spread to one or more organs outside the lymphatic system, such as the liver, lungs, or bones.

1) *Biopsy of Diffuse Large B-Cell Lymphoma*: A biopsy is a crucial diagnostic method for DLBCL, which allows for the presence or absence of certain genetic alterations. In this procedure, a sample of the affected lymph node or tissue is extracted and examined under a microscope [6]. Immunohistochemical staining and molecular tests are then employed to detect the expression of MYC gene rearrangements. The presence of MYC rearrangements classifies the lymphoma as MYC+, indicating a potentially more aggressive form. Conversely, if there is no evidence of MYC rearrangements, the lymphoma is classified as MYC-.

2) *Blood tests*: Blood tests are essential in diagnosing DLBCL. A complete blood count (CBC) assesses various blood components, including white blood cells. Elevated white blood cell counts may indicate the presence of lymphoma. Being that B-cells grow and become mature in the bone marrow, the CBC count tests for anemia, thrombocytopenia, and/or leukopenia indicate the extent of bone marrow involvement in DLBCL.

Furthermore, the LDH level is a helpful predictor of treatment response, recurrence, and the severity of DLBCL. Increased levels of potassium, phosphorus, and uric acid combined with a drop in calcium could be signs of tumor lysis syndrome, a condition that can develop during chemotherapy. LDH levels, a specific blood marker, can be indicative of lymphoma activity. Elevated LDH levels may suggest a more aggressive disease. While these blood tests do not directly determine MYC status, abnormal results can prompt further investigations, including imaging studies and biopsies.

3) *Imaging tests*: Imaging tests are essential components of the diagnostic process for DLBCL, providing valuable information about the extent of the disease and its characteristics. MRI uses strong magnetic fields and radioactive waves to generate detailed images of the internal structures of the body. In DLBCL diagnosis, MRI is useful for assessing the involvement of lymph nodes and surrounding tissues, aiding in the accurate staging of the disease [7]. It offers high-resolution images that aid in determining the size, location, and characteristics of lymphoma masses. Besides, CT scans employ X-rays from multiple angles to create detailed, cross-sectional images of the body [7], [8]. CT scans are valuable in identifying and measuring lymph nodes affected by DLBCL. They help in assessing the extent of the disease, determining the stage, and identifying whether the lymphoma has spread to other organs or tissues.

Other than that, ultrasound is also one of the imaging techniques used to diagnose DLBCL. Ultrasound employs high-frequency sound waves to create real-time images of internal organs and tissues. While less commonly used than other imaging modalities, ultrasound can assist in evaluating abnormalities in lymph nodes. It is particularly useful for examining superficial lymph nodes and assessing potential changes in organ structures caused by lymphoma. Other than that, a PET scan is suitable to detect the progression of tumors and cancer. A PET uses a radiotracer to show the differences between healthy tissues and cancerous tissues. A radiotracer is injected into the patient, and the cancerous cells absorb more of the radiotracer. PET will detect the radiation given off by the tracer and produce color-coded images of the body that show both healthy and cancerous tissues. A special camera from a PET scan detects the radiation emitted by these cells. PET scans highlight areas with increased metabolic activity, helping to identify active lymphoma sites [7]. This is crucial for determining the extent of DLBCL, assessing response to treatment, and locating residual or recurrent lymphoma. In short, these imaging methods provide valuable information about the size, location, and characteristics of lymphoma lesions, aiding in the accurate diagnosis, staging, and ongoing management of DLBCL.

C. Current Standard Diagnosis Method

The current standard diagnosis method for DLBCL involves Fluorescence In-Situ Hybridization (FISH) tests and Immunohistochemistry (IHC) tests. The FISH test is a technique that is essential for identifying genetic abnormalities such as MYC translocations in DLBCL and offering insights into the severity of the disease. Besides, the IHC test is a method that involves the expression of specific proteins and helps in characterizing DLBCL subtypes, such as GCB subtypes and ABC subtypes. By integrating the FISH and IHC, it provides a holistic evaluation, combining genetic and protein expression data to guide accurate diagnosis, subtype classification, and personalized treatment planning for individuals with DLBCL.

1) *Fluorescence In-Situ Hybridization (FISH) Test:* Fluorescence In-Situ Hybridization (FISH) method is a molecular technique used to detect and locate the presence or absence of specific DNA sequences on chromosomes [4]. It uses fluorescent light that binds to only those parts of the chromosome that show a high degree of sequence complementarity. The FISH method is used to identify specific genetic abnormalities, such as the rearrangements of the MYC, BCL2, and BCL6 genes, to diagnose DLBCL [4]. The purpose of FISH in diagnosing DLBCL is to provide a more accurate diagnosis, which can guide treatment decisions. It enables the precise detection of genetic abnormalities that could be driving diseases like DLBCL [22]. One of the studies that used FISH methods for DLBCL analysis was conducted by Blanc Durand et al. [14]. The authors worked with pre-therapy FDG-PET/CT scans from 733 DLBCL patients.

FISH analysis, which can be performed using dual-color and dual-fusion cleavage probe methods, is a highly sensitive and accurate technique for detecting oncogene amplification in

human tissue samples. However, due to the high variability in MYC breakpoints, it may not identify all MYC abnormalities. Furthermore, the FISH method has some limitations and shortcomings. This method may not be universally applicable to all diseases due to its labor-intensive and demanding nature, making it a time-consuming procedure. The need for expensive techniques, especially when using fluorescence microscopy, is specific and sensitive, emphasizing the importance of elucidating the genetic status of DLBCL.

2) *Immunohistochemistry (IHC) Test:*

Immunohistochemistry (IHC) is a method used to visually detect the presence of specific proteins in cells or tissues. It involves the use of antibodies that bind to these proteins and a detection system that uses a colored or fluorescent dye to visualize the binding [23]. IHC studies have evolved, emerging as the most widely used test to characterize cancers and identify hidden metastatic sites, particularly in lymph nodes. The method is based on the specific binding of antibodies to antigens, allowing the detection and specific localization of molecules in cells and tissues. The primary analysis is typically conducted using a light microscope [9]. IHC plays a crucial role in cancer diagnosis, especially when specific tumor antigens are overexpressed in certain malignancies. Notably, IHC offers significant advantages, particularly in settings with limited resources and drawbacks. IHC provides qualitative information about the presence or absence of specific antigens but does not quantify the expression levels.

In DLBCL, IHC is used to identify abnormal protein expression of certain genes. For instance, IHC can be used as a screening test to identify cases of DLBCL and identify overexpression of the BCL2 protein, which is associated with a poor prognosis in DLBCL [23]. The purpose of IHC in diagnosing DLBCL is to provide a more accurate diagnosis, which can guide treatment decisions. It is an inexpensive and rapid test that can identify abnormal protein expression in mutated genes [23]. Furthermore, the intensity of marker expression can have prognostic implications. This limitation may impact the precision of the diagnosis. Apart from that, DLBCL comprises different subtypes with varying clinical behaviors. IHC alone may not always reliably distinguish between GCB subtypes and ABC subtypes. Gene expression profiling or additional molecular tests might be required for a more accurate subtype classification [10]. Also, IHC primarily provides information on protein expression but may not directly reveal underlying genetic alterations, such as gene mutations or chromosomal abnormalities.

III. RELATED WORK: IMAGE PROCESSING METHODS AND ARTIFICIAL INTELLIGENCE ALGORITHMS

A. *Image Processing Methods*

1) *Image patches:* Image patches are small, square regions of an image used for feature extraction. It plays a crucial role in identifying the regions of interest (ROIs) in medical images of DLBCL patients. These patches are needed for image processing tasks and algorithms such as image analysis, feature extraction, and applications involving AI algorithms. Besides,

it is normally used at the local level to analyze and manipulate image data and enable us to concentrate on specific areas of interest, such as structures and textures. This approach yields more detailed and accurate results, allowing feature extraction and providing reliable decisions. The size and shape of patches can vary depending on the task and requirements. It can range from a single pixel to a predefined window that features multiple pixels. The segmentation techniques may organize identical areas and distinguish them from the background by analyzing the color, appearance, or pixel's intensity, which allows for tasks like object detection and recognition.

Patch size and resolution are determined by specific applications and dataset requirements. For example, El Hussien et al. [16] obtained an overall mean Dice score of 0.825 from a quantitative assessment that included 15 manually annotated patches of 256×256 pixels. Furthermore, they conducted a study in which 10 Chronic Lymphocytic Leukemia (CLL), 12 accelerated Chronic Lymphocytic Leukemia (aCLL), and 8 Richter's Transformation (RT) digitally stained hematoxylin and eosin (H&E) slides from a lymph node excisional biopsy were chosen at random. The study used Aperio AT2 scanners to scan the slides, with an optical resolution of 20× magnification. These slides came from various patients, and a total of 25, 28, and 21 ROIs were from CLL, aCLL, and RT, respectively.

Wójcik et al. [17] employed 37,665 H&E-stained images obtained at 40× magnifications from a solitary WSI of DLBCL lymph nodes. Each image tile, sized at 512×512, underwent segmentation, with bounding boxes outlining individual nuclei, although no cell labels were provided. The images are standardized to 448×448 pixels, with additional randomly cropped tiles to augment the training dataset. Li et al. [18] focused on DLBCL tissue sections, capturing pathologic images initially at 400× original magnifications. The study began with 500 images obtained from labelled H&E-stained sections of lymph nodes. Apart from that, Swiderska-Chadaj et al. [20] digitized 42 H&E slides of DLBCL using a Panoramic 250 Flash II scanner at an objective magnification of 20×. These slides, with a pixel size of 0.24 μm, comprised an external validation set, allowing assessment across different hospital protocols.

Bándi, P. et al. [21] collected 100 WSI from various medical centers, comprising 10 tissue samples across different staining categories. Image patches were extracted from annotated areas using mask images according to the different pixel spacings, being 62.5, 250, and 10000 μm at respective resolutions of 0.5, 2, and 8 μm. Other than that, the research by Shankar, V. et al. [27] involves the H&E-stained tissue cores, pinpointed by hemapathologists using Qupath, for extracting image patches. These patches were obtained at 40× magnifications from each core. Based on the study by Swiderska-Chadaj, Z. et al. [29], the training dataset was derived from H&E-stained specimens. The image patches, each sized at 512×512 pixels, were extracted from slides at 5× magnification level with a pixel size of 1 μm for optimal analysis. Perry, C. et al. [31] involved a self-supervised phase, which included the slides to be scanned

at either 20× or 40× magnifications. The 40× images were converted to 20× for analysis. The WSI was divided into smaller patches used as model input by using patches of size 384×384 pixels.

Studies by El Hussien et al. [16], Wójcik et al. [17], and others have demonstrated the utility of image patches in DLBCL analysis, achieving high mean Dice scores and effectively capturing relevant features. However, while image patches excel in local analysis, they may struggle with capturing global context, which is crucial for a comprehensive understanding and diagnosis of DLBCL. Besides, weaknesses such as the absence of cell labels in datasets and variability in staining and scanning methods across the study by Wójcik et al. [17] pose challenges to consistency and accuracy. Opportunities lie in the potential for standardizing imaging and analysis protocols, augmenting training datasets with synthetic images, and applying transfer learning to enhance model performance. Conversely, threats include inter-laboratory variations that may limit model generalizability, computational resource constraints, and data privacy concerns related to patient-derived images. These factors collectively underscore the complexities and prospects of advancing the field of digital pathology for hematological malignancies.

2) *Preprocessing methods*: Preprocessing is a technique that is required to prepare image data for model input. For example, the fully connected layer of a CNN required that all images be stored in arrays of identical size. Model preprocessing may also reduce the training period and accelerate model inference. If the input images are very large, diminishing the size of the images will drastically reduce the time required to train the model without affecting model performance significantly. Basically, the preprocessing steps include orientation, resize, random flips, grayscale, and other different exposures that inhibit unforeseen distortions or improve certain characteristics of images essential to the deep learning pre-trained model.

Hamdi, M. et al. [11] used Gaussian filter to smooth the images, a Laplacian filter for edge detection, color normalization for standardization, resizing to a consistent resolution, and the use of Gradient Vector Flow for additional feature extraction. Besides, Vrabac et al. [12] focused on the employment of various preprocessing techniques to prepare histopathological images for analysis. The authors arranged the images in tissue microarrays (TMAs) and performed cell nucleus extraction from H&E-stained images. Additionally, they extracted features such as maximum area, minimum area, hull area, perimeter nucleus, maximum angle, ellipse perimeter, and ellipse area to capture morphological characteristics [12]. Basu and his team developed novel preprocessing methods for DLBCL classification. Although the exact preprocessing steps were not specified, the authors introduced in their attention map feature transformer, feature fusion techniques, and a specific loss function to improve the performance of the DLBCL classification model [13].

In the study conducted by Blanc-Durand et al. [14], they underwent a series of preprocessing steps. These steps included resampling, padding, cropping, and scaling of PET and CT

image data to ensure consistency. Additionally, adaptive thresholding was applied to segment images, and various features related to tumor characteristics, such as tumor heterogeneity, textural features, total tumor surfaces, and spatial dispersion, were extracted to provide a comprehensive set of features for classification. Ferrández and colleagues employed preprocessing methods tailored to medical imaging [15]. Gaussian filtering was applied to enhance image quality, and metabolic tumor volume (MTV) and standard uptake value (SUV) were computed to quantify metabolic activity. The authors also considered features related to tumor dissemination and textural features to capture the heterogeneity of DLBCL tumors.

El Hussien, S. et al. [16] focused on the preprocessing methods that involved annotating ROIs, calculating the ratio of the segmented nuclear contour area to its convex area, and measuring hull areas within these annotated regions. Besides, Graham, S. et al. [19] involved preprocessing methods such as Otsu thresholding, pixel intensity manipulation, color adjustments, and extraction of textural features to capture various characteristics within the images. Furthermore, Ferrández, M. C. et al. [24] studied how their preprocessing workflow incorporated normalization techniques, filtering procedures, max-pooling layer utilization, and rectified linear unit (ReLU) operations, possibly aimed at enhancing image quality and extracting relevant features. Other than that, Mohlman, J. S. et al. [25] involved the preprocessing methods, which are normalization techniques and edge detection methods, and utilized a deep network-based pixel-level concept, indicating a complex approach to feature extraction.

The other studies, including Farinha, F. et al. [26], Shankar, V. et al. [27], Jiang, C. et al. [28], Swiderska-Chadaj, Z. et al. [29], Steinbuss, G. et al. [30], Perry, C. et al. [31], Lisson, C. S. et al. [32], have been using the same preprocessing techniques. Their methodologies involved various preprocessing techniques, such as normalization, quality control thresholds, machine learning algorithms, filtering, and feature selection, aiming to enhance image quality, extract informative features, and facilitate accurate DLBCL classification.

Hamdi et al. [11], Vrabac et al. [12], and others have employed various preprocessing techniques tailored to DLBCL analysis, aiming to enhance image quality and extract informative features. While preprocessing can improve model performance and accelerate training, aggressive preprocessing may distort image features, leading to erroneous analysis results. The various preprocessing techniques used in DLBCL image analysis, such as feature extraction and Gaussian smoothing, highlight a reliable strategy for improving diagnostic accuracy. Despite their differences, these methods work together to provide a classification process that is more precise and effective, demonstrating the dynamic interaction between pathology-specific technology and medical knowledge.

3) *Data augmentation*: Data augmentation is a method for improving performance. It entails changing the color, brightness, or contrast of the existing training data by cropping, flipping, rotating, scaling, or changing the color, brightness, or contrast. Data augmentation can increase the variety and scope

of the training data. This can minimize excessive overfitting and make the model more resilient to different inputs. To implement data augmentation techniques for CNN training data, Python libraries such as TensorFlow, Keras, and OpenCV are used.

Basu, S. et al. [13] augmented their datasets through diverse techniques such as image rotations, horizontal and vertical flips, zoom scaling, as well as horizontal and vertical shifts. Wójcik, P. et al. [17] incorporated cell patch embedding, patch aggregation, random resizing, cropping, color jittering, and random flipping, aimed at organizing and augmenting image data for analysis. Other than that, Graham, S. et al. [19] used data augmentation methods such as flipping, rotation Gaussian blur, and median blur for enhanced feature variability. Bándi, P. et al. [21] also applied diverse augmentation techniques like horizontal mirroring, rotation, scaling, color, and contrast adjustments, additive Gaussian noise, and Gaussian blur for image enhancement and feature variability.

Mohlman, J. S. et al. [25] augmented their datasets through random horizontal flipping of images and random alteration of contrast, while Swiderska-Chadaj, Z. et al. [29] includes data augmentations such as brightness, contrast, saturation, rotation, gaussian noise, and gaussian blur. Besides, the data augmentation for the study of Perry, C. et al. [31] includes color jittering and channel shuffle. The study of Lisson, C. S. et al. [32] includes data augmentations such as random flip, gaussian blur, and gaussian noise.

Basu et al. [13], Wójcik et al. [17], and others have utilized data augmentation techniques to enhance the variability of DLBCL image data and improve model performance. However, the effectiveness of data augmentation depends on the appropriateness of the augmentation strategies and the quality of the generated samples. Moreover, excessive augmentation may introduce synthetic artifacts or distortions that do not accurately represent real-world variability. By simulating a variety of variations in medical images, these techniques improve generalization to new data and increase the size of the training dataset. However, the creation of high-quality samples and the choice of suitable tactics are prerequisites for the success of data augmentation. Excessive or improper augmentation can result in synthetic artefacts or distortions that may not accurately represent clinical scenarios and lead to inaccurate predictions, despite being necessary for the robustness of the model. As a result, the ability of data augmentation to provide realistic and clinically relevant variations without compromising the diagnostic integrity of the images serves as a gauge for its efficacy.

B. Artificial Intelligence Algorithm

The process of transferring information, data, and cognitive abilities to machines is known as AI. The primary objective of AI is to create independent machines with human-like thought and behavior. Through learning and problem-solving, these machines can mimic human behavior and carry out tasks. For resolving complex issues, most AI systems mimic natural intelligence. A branch of AI called machine learning employs statistical techniques to let machines learn from experience. Deep learning is a branch of machine learning that processes

information for specific analysis and subsequent action by modelling parts of the human brain with multi-layer neural networks. Hence, AI can be expressed more simply as the overall system, with machine learning and deep learning being its subsets. Deep learning is a subset machine learning, which employs neural networks to learn from massive amounts of data. The relationship between AI, machine learning, and deep learning are shown in Fig. 1.

Fig. 1. Hierarchical relationship between artificial intelligence, machine learning, and deep learning.

C. Machine Learning Approaches

Machine learning can be used to extract features from medical images and classify them as either healthy or cancerous. These algorithms can be trained on large datasets of medical images to learn how to identify those that are indicative of cancer. Once trained, these algorithms can be used to analyze and classify new medical images.

1) *Multilayer Perceptron (MLP)*: An artificial neural network type called a Multilayer Perceptron (MLP) is frequently used for machine learning tasks like regression and classification. MLP can be used in the image processing and classification of DLBCL to identify features in medical images and categorize them as either benign or malignant. MLP is a multi-layered input layer, one or more hidden layers, and an output layer, which make up the feedforward neural network [40] [41], [42]. Every single node in the network's hierarchy is connected to it, and every connection has a weight. During training, the weights are changed to minimize the discrepancy between the expected and actual outputs. The structure of MLP in machine learning is shown in Fig. 2.

Fig. 2. Structure of Multilayer Perceptron (MLP) in Machine Learning [40].

The MLP emerges as a pivotal tool across several studies in medical imaging and data analysis. Carreras et al. [33], [34], [37] extensively employed MLP, alongside other statistical methods, in various scales and contexts. In their investigations involving 414 and 100 cases, respectively, they utilized MLP along with Mann-Whitney U tests, Kaplan-Meier analysis, and multivariate Cox regression to discern hazard ratios and risks. Additionally, Wagner et al. [35] and Chen et al. [36] explored different facets of image processing; while Wagner utilized grayscale images and specific filtering techniques like Rudin-Osher-Fatemi (ROF), Chen focused on feature extraction from biopsy specimens using solidity features and ROI annotation. Bhattamisra et al. [38] and Achi et al. [39] emphasized the role of MLP in handling vast geometric data and image analysis, respectively.

2) *Radial Basis Function (RBF)*: In machine learning, the Radial Basis Function (RBF) is a kernel function that is used to identify a regression line or non-linear classifier. RBF is capable of being used to extract characteristics from clinical pictures and categorize them as either benign or malignant in DLBCL image manipulation and classification. RBF compares two inputs according to how far apart they are in a high-dimensional space. The Gaussian kernel, also referred to as the RBF kernel, can be found in the Eq. (1).

$$K(x, x') = e^{-\gamma ||x-x'||^2} \quad (1)$$

where,

$$K(x, x') = \text{Radial basis function}$$
$$\gamma = \text{Width of the kernel}$$

The RBF stands out as a key computational approach utilised in several studies, notably alongside the MLP in medical data analysis. Carreras et al. [33], [34], [37] incorporated RBF networks in conjunction with MLPs to process and interpret diverse datasets. Specifically, they employed RBF alongside MLP in their analyses involving various statistical tests such as Mann-Whitney U tests, Kaplan-Meier analysis, and multivariate Cox regression, elucidating hazard ratios and risks across different case volumes. The utilisation of RBF underscored its relevance in enhancing the MLP's performance and classification and prediction taste, contributing to the robustness of models used in medical imaging and genomic analysis. The application of RBF within MLP architectures demonstrated its capacity to handle complex data structures, aiding in the extraction of valuable insights from medical datasets.

D. Deep Learning Approaches

In recent decades, there has been a lot of interest in the advanced field of ML known as DL. It has been extensively employed in numerous applications and has proven to be a successful ML technique for a few challenging problems. DL algorithms, such as CNN, are particularly effective for image processing and classification tasks. CNNs can learn to identify complex patterns in medical images and classify them with high accuracy. For example, CNN can be trained to identify specific features in medical images of DLBCL patients, such as the size and shape of a cancerous cell and use this information to

classify the images as either healthy or cancerous. Identification and manual classification are challenging tasks, particularly in the medical field. Thus, using different architectures to improve the classification of images requires the application of DL. The goal of image classification is to effectively identify and categorise the biomedical characteristics that have important benefits for many research and development domains.

Among deep learning architectures, such as U-Net, ResNet, and HoverNet have emerged as popular choices for nuclei segmentation in medical imaging. Recent studies have compared the performance of these architectures in the context of DLBCL segmentation and classification [11]-[39]. For example, U-Net demonstrated moderate success in segmenting nuclei but required extensive preprocessing and data augmentation to achieve consistent results. ResNet-based models showed improved feature extraction capabilities but were prone to overfitting with smaller datasets. HoVerNet excelled in cases involving nuclear overlap and heterogeneity but at the cost of increased computational complexity. These findings highlight the need for continued exploration and optimisation of deep learning methods tailored specifically to the nuances of DLBCL.

E. Convolutional Neural Network (CNN) Architecture

CNN are a subset of neural networks that are particularly adept at processing data using network-like topologies such as images. The binary representation that represents visual data is what makes up a digital image. It is made up of a grid-like arrangement of pixels with pixel values to indicate the colour and brightness of each pixel.

In the CNN architecture, it typically has three layers. First, there is the convolution layer. The convolutional layer is the fundamental component of a CNN, carrying the majority of the network's computational load. It works by performing a dot product operation between a limited area of the input image called the receptive field and a learnable matrix called a kernel. The kernel functions across the height and width of the picture during the forward pass. It is less extensive systematically but greater in depth than the image. This motion creates a 2D activation map that illustrates the response of the kernel at every spatial location. The total area of this activation map is determined by the sliding motion of the kernel, also known as the stride. The formula for the convolutional layer is expressed as in Eq. (2):

$$W_{out} = \frac{W-F+2P}{S} + 1 \quad (2)$$

where,

W_{out} = Output volume size

W = Squared input image

F = Receptive field size

P = Amount of zero padding

S = Stride

Second is the pooling layer. By calculating a summary statistic from the outputs in the vicinity, the pooling layer substitutes the network's output at specific points. This aids in

shrinking the representation's spatial size, which lowers the quantity of calculations and weights needed. Each of the sections of the representation is processed independently for the pooling operation. The formula for the pooling layer is expressed in Eq. (3):

$$W_{out} = \frac{W-F}{S} + 1 \quad (3)$$

where:

W_{out} = Output volume size

W = Squared input image

F = Receptive field size

S = Stride

Nonetheless, the most widely used method is max pooling, which provides the neighbourhood's maximum output. Lastly, the third layer involved is a fully connected layer (FC layer). As in a regular fully convolutional neural network (FCNN), all neurons in this layer are fully connected to all neurons in the layer that comes before and after. Hence, it can be calculated using the standard method of matrix multiplication and the bias effect. The relationship between the input data and the output is mapped with the aid of the FC layer.

Based on DLBCL nuclei segmentation in CNN, it normally uses a pre-trained model, epoch, optimiser, learning rate, and decay rate. A single run through the complete training dataset is referred to as an epoch. The model is trained on a new batch of dataset samples during each epoch. One hyperparameter that indicates the number of times the model is trained on the complete dataset is the number of epochs. Besides, during training, an optimiser is an algorithm that modifies the neural network's weights. The optimiser determines the way to modify the weights to minimise the loss by utilising the weights' gradients and the loss function. Also, learning rate refers to the weights of the neural network, which are updated to a certain extent based on the hyperparameter. A low learning rate can lead to more stable training, as a high learning rate will trigger the algorithm to converge more rapidly, potentially leading to unstable learning. Apart from that, decay rate controls the amount of learning rate that decreases following each epoch. The learning rate may decrease too rapidly or too slowly, depending on the decay rate, while a high decay rate may decrease the learning rate in a rapid way. Also, a pre-trained model in CNN is a model that is ready to use as the basis for a new model since it has been trained on a sizable dataset. When a new model needs a good setting, pre-trained models can help it perform better. Based on the studies [11-32], there are a few pre-trained models that are being utilised, such as DenseNet-201 [13], ResNet-50 [12], HoVerNet [12], [16], [17], [19], and U-Net [14], [15], [20], [24], [26], [28], [29]. The summaries for methods on DLBCL by using CNN architectures and ML are tabulated in Table I and Table II (Appendix).

1) *HoVerNet*: DLBCL nuclei segmentation is the process of highlighting nuclei in pathology images. HoVerNet, a specialised network, excels at this task by incorporating multiple branches for segmentation and classification into a unified framework. It takes advantage of nuclear pixel distances

from their centres of mass, which is critical for segmenting clustered nuclei found in DLBCL images. The network's dedicated up sampling branch aids in the classification of different nuclear types. The efficacy of HoVerNet in DLBCL nuclei segmentation stems from its ability to handle complex arrangements, which contributes to improved pathology image analysis.

Based on the study by Vrabac et al. [12], they employed HoVerNet as their chosen pre-trained model. Besides, Hussein et. al. [16] utilised HoVerNet as their pre-trained model for the analysis of CLL, aCLL, and RT cases. Wójcik et al. [17] employed HoVerNet as their chosen pre-trained model, training it for 800 epochs. Lastly, Graham et al. [19] use HoVerNet as their pre-trained model, training it for 50 epochs with the Adam optimiser.

2) *U-Net*: U-Net, a well-known CNN architecture, is widely used in image segmentation, including the segmentation of DLBCL nuclei. U-Net extracts image features from the encoder and reconstructs a segmentation map from the decoder, which is made up of an encoder and decoder network linked by a bottleneck layer. U-Net can be differentiated into two-dimensional U-Net (2D U-Net) and three-dimensional U-Net (3D U-Net).

Based on the study by Blanc-Durand et al. [14], they utilised the 3D U-Net architecture as the pre-trained model for their pre-therapy FDG-PET/CT scans from 733 patients with DLBCL. The optimizer used was Adam. Similarly, Ferrández et al. [15] employed the 3D U-Net architecture as the pre-trained model. The optimisation was conducted using the Adam optimiser, with an epoch setting of 200. The learning rate was set at 0.00005, alongside a decay rate of 0.000001. Furthermore, Swiderska-Chadaj et al. [20] utilised U-Net as their chosen pre-trained model. In addition, Ferrández et al. [24] employed 3D U-Net as their chosen pre-trained model. The optimiser used was Adam, with an epoch setting of 200, a learning rate of 0.00005, and a decay rate of 0.000001. Other than that, Farinha, F. et al. [26] employed U-Net as their chosen pre-trained model. The epoch setting of 150, a learning rate of 0.0001. Lastly, Jiang, C. et al. [28] utilised 3D U-Net model and was trained for 1000 epochs with a learning rate of 0.01 and Nesterov momentum set to 0.99. According to the work by Swiderska-Chadaj, Z. et al. [29], the U-Net model was pre-trained using the Adam optimizer for 500 epochs with a learning rate of 0.0005.

3) *ResNet-50*: ResNet-50, which is made up of many residual blocks, aids in the learning of complex characteristics that are required for accurate nuclei segmentation and classification and performs well in DLBCL nuclei segmentation. The depth of its architecture allows for the capture of complicated nuclear characteristics, improving segmentation precision in DLBCL pathology images. Its residual connections promote gradient flow, which aids in the learning of complicated nuclear patterns, which is important in DLBCL analysis. Based on the study by Vrabac et al. [12], they employed ResNet-50 as their chosen pre-trained model.

4) *DenseNet-201*: DenseNet-201 has a distinct architecture that is advantageous for DLBCL nuclei segmentation. Each layer in DenseNet-201 receives input from all preceding layers, resulting in dense connections throughout the network. This connectivity pattern allows for efficient information flow, which is important for capturing complex nuclear features in DLBCL pathology images. The densely connected blocks of DenseNet-201 allow for feature reuse, increasing model efficiency while effectively separating nuclei. This architecture reduces information loss, which is especially useful when segmenting densely clustered nuclei, which is common in DLBCL samples. According to Basu et al. [13], they used DenseNet-201 as their pre-trained model, optimising it using the Adam optimiser. The learning rate employed was 0.0001 for training.

In the realm of DLBCL nuclei segmentation, various deep learning architectures have been employed to enhance the accuracy and efficiency of pathology image analysis. HoVerNet stands out for its ability to segment clustered nuclei through its multi-branch framework, proving effective in complex arrangements. U-Net, particularly in its 3D form, is widely adopted for its feature extraction and reconstruction capabilities, with several studies optimizing it for large patient datasets. ResNet-50's depth captures intricate nuclear characteristics, while DenseNet-201's dense connectivity ensures comprehensive feature capture and efficient information flow. These architectures, through their unique strengths, contribute significantly to the progress in digital pathology, offering promising avenues for improved diagnostic methods in DLBCL.

While both machine learning and deep learning approaches have shown promise in DLBCL image analysis, they have distinct advantages and limitations. Machine learning techniques, such as MLPs and RBF networks, offer interpretability and ease of implementation but may struggle with capturing complex patterns in high-dimensional data. On the other hand, deep learning approaches, particularly CNNs, excel in learning hierarchical representations directly from raw data but require large amounts of annotated data and computational resources for training.

In short, the choice between machine learning and deep learning approaches in DLBCL image analysis depends on factors such as dataset size, computational resources, and the complexity of the underlying patterns. Integrating both approaches and exploring hybrid models may offer a promising avenue for future research in DLBCL diagnosis and treatment.

IV. DISCUSSIONS

A. Role of Preprocessing and Augmentation

Preprocessing is a cornerstone of successful deep learning applications in DLBCL analysis. Techniques such as Gaussian smoothing, color normalization, and artifact removal ensure consistent image quality across datasets. Hamdi et al. [11] employed Gaussian and Laplacian filters to enhance features, while Graham et al. [19] utilized Otsu thresholding and pixel intensity adjustments to refine segmentation inputs.

Data augmentation further aids in addressing dataset limitations by artificially increasing sample diversity. Techniques such as rotation, flipping, and noise addition have been widely applied. For instance, Wójcik et al. [17] and Swiderska-Chadaj et al. [20] incorporated augmentation strategies to improve model effectiveness and generalizability. However, excessive augmentation risks introducing synthetic artifacts, which could affect real-world applicability.

B. Performance of Deep Learning Models

The performance of HoVerNet and U-Net was evaluated against other deep learning methods, including DenseNet-201 and ResNet-50. HoVerNet and U-Net have emerged as important architectures for nuclei segmentation in DLBCL. HoVerNet's multi-branch framework enables simultaneous segmentation and classification, excelling in cases involving clustered and overlapping nuclei. Studies such as Graham et al. [19] demonstrated its ability to achieve a high Dice score of 0.869 by leveraging nuclear pixel distances and incorporating classification branches. U-Net, on the other hand, employs an encoder-decoder structure that effectively extracts and reconstructs features, as highlighted by Blanc-Durand et al. [14], who used a 3D variant of U-Net for PET/CT imaging.

While these models show promise, their performance heavily depends on preprocessing pipelines. For example, resizing, normalization, and augmentation methods were critical for improving model accuracy in studies like Hamdi et al. [11] and Ferrández et al. [15]. Despite their strengths, challenges such as overfitting, dataset variability, and computational demands remain significant.

C. Challenges and Limitations

Several challenges persist in applying deep learning to DLBCL segmentation such as variability in data quality. The differences in staining protocols and imaging equipment introduce inconsistencies that can affect model performance. Studies like Vrabac et al. [12] underscore the need for standardized preprocessing pipelines. Besides, limited annotated data is one of the limitations. The scarcity of labeled datasets restricts model training and evaluation. Transfer learning and synthetic data generation offer potential solutions but require further refinement. Lastly, computational complexity poses challenges in applying deep learning to DLBCL. Advanced architectures such as HoVerNet demand significant computational resources, which may limit their accessibility in resource-constrained settings.

D. Opportunities and Future Directions

Advancements in artificial intelligence present opportunities to overcome existing challenges. Generative adversarial networks (GANs) can be used to augment datasets with realistic synthetic images, while hybrid models that combine U-net and HoVerNet architectures could leverage the strengths of both. Additionally, transfer learning can facilitate model adaptation across diverse datasets, improving generalizability.

Future research should focus on developing lightweight architectures for resource-limited environments. Besides, establishment of standardized datasets and evaluation metrics for fair benchmarking should be carried on. This advancement

could significantly enhance the diagnostic accuracy and efficiency of DLBCL analysis, ultimately improving patient outcomes.

V. CONCLUSION

In conclusion, deep learning approaches have demonstrated their potential as useful and efficient algorithms for segmentation and classification of DLBCL. Based on the literature review, there are some related studies that have been done on the deep learning-based nuclei segmentation of DLBCL. These studies have demonstrated the effectiveness of deep learning in improving DLBCL diagnosis. Thus, it is believed that further exploration and enhancement of the nuclei segmentation and classification will provide a wide alternative way to count and diagnose the severity level of DLBCL. Deep learning offers an alternative to traditional methods, opening opportunities for further research and practical applications.

INSTITUTIONAL REVIEW BOARD STATEMENT

This study was conducted in accordance with the Declaration of Helsinki and approved by the Jawatankuasa Etika Penyelidikan Manusia Universiti Sains Malaysia (JEPeM-USM), on April 2, 2023. (Approval Reference: USM/JEPeM/22110749).

ACKNOWLEDGMENT

The author thanks the Faculty of Electronic Engineering Technology at Universiti Malaysia Perlis for providing the opportunity to explore deep in this research. The author would like to acknowledge the support from the Ministry of Higher Education (MoHE) Malaysia through the Fundamental Research Grant Scheme (FRGS) under a grant number of FRGS/1/2023/ICT02/UNIMAP/02/3. In most cases, sponsor and financial support acknowledgements. Universiti Sains Malaysia, RU Top Down grant 1001/PPSP/8070016.

TABLE I. SUMMARY OF PRE-PROCESSING AND SEGMENTATION METHODS ON DLBCL

Authors	No of Samples	Pre-Processing Methods	Features Extraction	Data Augmentation	CNN Architecture	Results
Hamdi, M. et al. [11]	15,000 H&E stained whole-slide images.	- Gaussian filter - Laplacian filter - Normalisation - Resize	Yes	Yes	Pre-trained model: - MobileNet-VGG16 - VGG16-AlexNet - MobileNet-AlexNet	MobileNet-VGG16 - AUC: 99.43% - Accuracy: 99.8% - Precision: 99.77% - Sensitivity: 99.7% - Specificity: 99.8%
Vrabac, D. et al. [12]	209 DLBCL cases.	N/A	- Maximum area - Minimum area - Hull area - Perimeter nucleus - Maximum angle - Ellipse perimeter - Ellipse area	N/A	Pre-trained model: - ResNet-50 - HoVerNet	C-index (95% CI) of 0.635 (0.574,0.691)
Basu, S. et al. [13]	1,000 pathologic tissue slides images of DLBCL and non-DLBCL.	N/A	- Attention map feature transformer - Feature fusion	- Image rotation - Horizontal and vertical flip - Zoom scaling - Vertical and horizontal shifts	Pre-trained model: - DenseNet-201 Optimiser: Adam Learning rate: 0.0001	- Accuracy: 98.31 ± 0.5 - Sensitivity: 98.27 ± 0.58 - Specificity: 98.35 ± 0.69
Blanc-Durand, P. et al. [14]	Pre-therapy FDG-PET/CT scans from 733 patients with DLBCL.	- Resampling - Padding - Cropping - Scaling of the PET and CT image data - Adaptive thresholding	- Tumour heterogeneity - Textural features - Total Tumour surfaces - Spatial dispersion	N/A	Pre-trained Model: - 3D U-Net Optimiser: Adam	- Mean DSC: 0.73 ± 0.20 (Median: 0.79) - Jaccard coefficients: 0.68 ± 0.21
Ferrández, M. C. et al. [15]	20 DLBCL patients on a dataset of 296 maximum intensity projection (MIP) images.	- Gaussian filter	- Metabolic tumour volume (MTV) - Standard uptake value (SUV) - Dissemination - Textural features	N/A	Pre-trained Model: - 3D U-Net Optimiser: Adam Epochs: 200 Learning rate: 0.00005 Decay rate: 0.000001	- Training: 0.81 (0.02) - Validation: 0.75 (0.07)

Authors	No of Samples	Pre-Processing Methods	Features Extraction	Data Augmentation	CNN Architecture	Results
el Hussein, S. et al. [16]	10 CLL, 12 aCLL, and 8 RT digitally stained H&E slides from a lymph node excisional biopsy.	N/A	- ROI annotation - Ratio of segmented nuclear contour area to its convex - Hull area	N/A	Pre-trained Model: - HoVerNet	- Accuracy: 0.658 (± 0.115)
Wójcik, P. et al. [17]	37,665 H&E stained DLBCL images of size 448×448, divided into 28×28 square patches.	N/A	- Cell Patch Embedding - Patch Aggregation	- Random resize and crop - Colour jittering - Random flip	Pre-trained Model: - HoVerNet Epochs: 800	- F1 Score: 0.939 for Epithelial cells.
Li, D. et al. [18]	Hospital A: 500 DLBCL & 505 non-DLBCL human samples Hospital B: 163 DLBCL & 184 non-DLBCL human samples Hospital C: 204 DLBCL & 198 non-DLBCL human samples	N/A	-Types of lymphomas and hematopoietic tumours - Colour - Morphology - Quality	N/A	- Deep Neural Network Classifiers and pathologists were compared.	- Recall: 100% - Precision: 96% - F1 score: 98%
Graham, S. et al. [19]	24,319 annotated nuclei within 41 colorectal adenocarcinoma image tiles.	N/A	- Nuclear pixel branch - Hover branch - Nuclear classification branch	- Flip - Rotation - Gaussian blur - Median blur	Pre-trained Model: - HoVerNet Optimiser: Adam Epochs: 50 Learning rate: 10^{-4}	- DICE score: 0.869
Swiderska-Chadaj, Z. et al. [20]	H&E-stained slides of 287 DLBCL cases from 11 hospitals.	N/A	N/A	N/A	Pre-trained Model: - U-Net	- AUC: 0.83 (External) - Sensitivity: 0.95 (External) - Specificity: 0.53 (Internal)
Bándi, P. et al. [21]	100 whole-slide images from 10 different tissues.	- Otsu thresholding	- Pixel intensity - Colour - Textural features	- Horizontal mirroring - 90° rotation - Scaling - Colour adjustment - Contrast adjustment - Additive Gaussian noise - Gaussian blur	- FCNN Optimiser: Adam Epochs: 16 Learning rate: 10^{-4} Activation: ReLU	- Dice scores: 0.9775 to 0.9891
Ferrández, M. C. et al. [24]	373 DLBCL patients	- Normalisation - Filtering	N/A	N/A	Pre-trained Model: - 3D U-Net Optimiser: Adam Epochs: 200	- AUC: 0.72 - Sensitivity: 0.59 - Specificity: 0.8

Authors	No of Samples	Pre-Processing Methods	Features Extraction	Data Augmentation	CNN Architecture	Results
					Learning rate: 0.00005 Decay rate: 0.000001 Activation: ReLU	
Mohlman, J. S. et al. [25]	10,818 images from Burkitt Lymphoma (BL) and DLBCL.	- Normalisation - Edge detection	- Notion of deep network pixel level	- Random horizontal flipping of images - Random alteration of contrast	Epochs: 200 Learning rate: 6.5×10^{-5}	Accuracy: 94%
Farinha, F. et al. [26]	2886×2886 high resolution images and patched into 36 patches of equal size (481×481)	N/A	N/A	N/A	Pre-trained Model: - U-Net Optimiser: Adam Epochs: 150 Learning rate: 0.0001 Activation: ReLU	- Linear regression, R2: 0.4688
Shankar, V. et al. [27]	670 lymphoma cases	- Normalisation - Patch-based quality control (PQC) threshold	- Minimum / maximum Feret diameters - Convex hull area - Circulatory - Elongation - Convexity	N/A	Pre-trained Model: - StarDist	Diagnostic accuracy: 64.3%
Jiang, C. et al. [28]	414 DLBCL patients collected from two independent centres in 3D FDG-PET images.	- Threshold - Normalisation	- Convolution number	N/A	Pre-trained Model: - 3D U-Net Epochs: 1000 Learning rate: 0.01 Nesterov momentum: 0.99	- PFS: 64.5% - OS: 73.4%
Swiderska-Chadaj, Z. et al. [29]	91 patients with H&E-stained specimens	N/A	N/A	- Brightness - Contrast - Saturation - Rotation - Gaussian noise - Gaussian blur	Pre-trained Model: - U-Net Optimiser: Adam Epochs: 500 Learning rate: 0.0005	- AUC: 0.77 - Sensitivity: 0.88 - Specificity: 0.66
Steinbuss, G. et al. [30]	84,139 image patches from 629 patients	- Patch-based quality control (PQC) threshold	N/A	N/A	Pre-trained Model: - Efficient-Net	- High accuracy above 95% - Lower BACC with multiple misclassification

Authors	No of Samples	Pre-Processing Methods	Features Extraction	Data Augmentation	CNN Architecture	Results
					Optimiser: Adam Epochs: 50 Learning rate: 10^{-5} to 10^{-6}	- Overall BACC up to 95.56%
Perry, C. et al. [31]	32 biopsies from 30 patients	N/A	N/A	- Colour Jittering - Channel shuffle	- Multiple Instance Learning (MIL) Optimiser: Adam Epochs: 20 Learning rate: 0.0001	- AUC: 0.95 - Sensitivity: 87% - Specificity: 100%
Lisson, C. S. et al. [32]	30 patients with histologically proven mantle cell lymphoma who underwent contrast-enhanced CT or PET/CT scans	- Filtering-based feature selection	- 3D volumetric radiomic features	- Random Flip - Gaussian Blur - Gaussian Noise	Pre-trained Model: - 3D SE ResNet - 3D DenseNet Optimiser: Adam Epochs: 100 Learning rate: 0.001	- Overall accuracy of predicting relapse: 64%

TABLE II. SUMMARY OF SEGMENTATION METHODS BY MACHINE LEARNING

Authors	No. of Samples	Features Extraction	Segmentation Techniques	Machine Learning	Machine Learning Library	Results
Carreras, J. et al. [33]	414 cases of DLBCL.	- Mann-Whitney U test - Kaplan-Meier - Multivariate Cox Regression - Hazard ratios / risks	- Trainable Weka Segmentation Method	- Multilayer Perceptron (MLP) - Radial Basis Function (RBF)	- XGBoost	- MLP was more "efficient" than RBF.
Carreras, J. et al. [34]	100 to 293 cases from the lymphoma series of Tokai University Hospital.	- Pearson Chi-Square - Fisher's exact tests - Nonparametric Mann-Whitney U test - Kruskal-Wallis H test - Kaplan-Meier - Log-rank tests - Univariate and multivariate Cox Regression	- Weka Method	- Multilayer Perceptron (MLP) - Radial Basis Function (RBF)	- XGBoost	- Overall accuracy: 100%
Wagner, M. et al. [35]	50 test images for whole tissue samples of DLBCL.	- Grayscale conversion	- Rudin-Osher-Fatemi (ROF) filtering	- Mask R-CNN	N/A	- Manual count: 0.9297
Chen, P. et al. [36]	193 biopsy specimens from 135 patients.	- Solidity feature	- ROI annotation	N/A	- XGBoost	- Accuracy: 0.925 - AUC: 0.978

Abstract—Assessing students' critical thinking skills is challenging due to the limitations of current measurement tools. Therefore, there is a need for a digital testing instrument that can effectively evaluate students' critical thinking abilities. The proposed digital test should be designed to present questions in a tiered manner, using a backward chaining approach that starts with general questions and progresses to more detailed ones. However, developing this measurement instrument requires careful planning. One of the initial steps in this process is to create a user interface design. The purpose of this study was to show the quality of the design of the user interface of a digital test based on backward chaining as a measuring tool for students' critical thinking in a differentiated learning atmosphere. Design development used the Borg and Gall model and only focused on three stages. These stages include design planning, initial testing, and revision for the initial testing results. Data collection was through initial testing of the design. The tool used to collect data was a questionnaire. Respondents involved in the initial testing were 34 people. The location for the study was at several IT vocational high schools spread across six regencies in Bali. The data analysis technique compared the percentage comparison of the quality of the user interface design with the quality standards of the user interface design and referred to a five scale. The results of the study showed that the design quality of the digital test user interface based on backward chaining was included in the good category, as indicated by a quality percentage of 88.94%. Specifically, the impact of the results on the field of educational evaluation is to make it easier for evaluators to make accurate measurements. In general, the effect of this study on the field of informatics engineering education is the existence of innovations in realizing a test to measure critical thinking in the domain of differentiated learning.

Keywords—User interface design; digital test; backward chaining; critical thinking; differentiated learning

I. INTRODUCTION

The rolling of the “*Merdeka Belajar*” (independent learning) policy provides students with the freedom to follow the learning process according to the differences in their needs and learning environment. This concept is called differentiated learning [1]. Currently, differentiated learning is a trend in the learning process at the IT Vocational School level.

The existence of differences in the way each student learns according to their characteristics and needs through differentiated learning certainly can encourage them to improve their critical thinking skills in dealing with the problems they face [2]. Differentiated learning can awaken students' critical thinking skills, but teachers find obstacles in its implementation. These obstacles are mainly related to measuring students' critical thinking skills. Based on these obstacles, it is necessary to find a breakthrough as a measuring tool in the form of a digital test that can easily measure students' critical abilities. The expected digital test can package sequentially backward test questions (backward chaining) from general question types to questions with more detailed or specific types so that later, the teacher can explore the student's critical thinking to solve the questions presented. The research question referring to the obstacles and breakthroughs initiated is “What is the form of the user interface design of a backward chaining-based digital test used to measure students' critical thinking in a differentiated learning atmosphere?”

The specific objective of this study is to show a backward chaining-based digital test that has good quality and accurately measures students' critical thinking skills in differentiated learning. The urgency of this study is to obtain a user interface design from a backward chaining-based digital test that effectively assesses students' critical thinking skills in differentiated learning, especially in Mathematics subjects at IT Vocational School in Bali.

Hizqiyah et al. conducted research on the development of digital problem-solving skills test instruments [3]. However, a gap in their research is that they did not demonstrate the test items graded sequentially from general types to more specific types. Ndibalema's research [4], on the other hand, focuses on a form of formative assessment conducted online. The key difference between Ndibalema's study and this current research lies in the type of evaluation used; Ndibalema's work leans towards formative assessment, while this research encompasses both formative and summative assessments. Additionally, Jaskova's research explores student satisfaction with online tests taken at home [5]. A limitation identified in Jaskova's study is the lack of information regarding the user interface design of the online tests administered at home. Noor's research highlights the use of Kahoot as a digital quiz tool [6]. However, a limitation of

this study is that it does not provide details about the design of the Kahoot user interface as a digital quiz. On the other hand, the research conducted by Domínguez-Figaredo & Gil-Jaurena examines the impact of familiarity on digital assessments in online education [7]. A limitation of their study is that it fails to present the specific format of the digital tests utilized in the assessment.

Based on the research question and specific objectives of this study, it is essential to determine the form and quality of the backward chaining-based digital test used to assess students' critical thinking skills in differentiated learning.

II. LITERATURE REVIEW

Some of the research behind this study includes a 2020 study by Ariawan, Giri, and Divayana on the development of a CIPP evaluation application based on Simple Additive Weighting [8] obtained visualization results from a CIPP evaluation application based on Simple Additive Weighting that can measure the effectiveness of learning at health science colleges in Bali online. The obstacle is that the application is not for a large-scale implementation. A 2021 study on the dissemination and implementation of a CIPP evaluation application based on Simple Additive Weighting at several health science colleges in Bali conducted by Divayana, Ariawan, and Giri [9] showed the success of implementing a CIPP evaluation application based on Simple Additive Weighting at several health science colleges in Bali. The obstacle is that the evaluation application does not yet use the integrated evaluation aspects of the Balinese local wisdom concept, so the measurement of students' knowledge domains in the learning process cannot be measured optimally and in depth according to student characteristics. A 2022 study by Ariawan et al. showed the development of a Formative-Summative evaluation model based on Tri Pramana by inserting Weighted Product calculations [10]. The general description of the results obtained in the 2022 study is a Formative-Summative evaluation model design based on Tri Pramana by inserting Weighted Product calculations so it can determine the aspects that determine the quality of e-learning implementation. In the 2023 study conducted by Ariawan et al., a Tri Pramana-Weighted Product-Based Formative-Summative Model Evaluation Application has been obtained and has been field tested [11]. Further research for 2024 is the realization of a digital test user interface design based on backward chaining as a measuring tool for students' critical thinking in the nuances of learning differentiation.

Divayana et al. research [12] showed test instrument items to measure students' cognitive abilities in implementing distance learning. The validity of the content and reliability of the instrument is good. However, there is no packaging of test questions sequentially graded backward from general question types to more detailed or specific types. Easa and Blonder's research [13] showed an instrument to measure or evaluate teacher and student beliefs about differentiated learning in Chemistry. The constraint of Easa and Blonder's research was that it did not show an evaluation instrument sequentially graded backward from general to specific questions. Kholid et al.'s research [14] showed the implementation of diagnostic assessments in differentiated learning modules for English subjects. The constraint of Kholid et al.'s research is that it has

not shown the form of a diagnostic assessment instrument for differentiated learning sequentially from complex things to more specific things.

III. METHOD

Several elements are presented in the methodology section of this research: 1) research approach; 2) subjects, objects, and research locations; 3) data collection instruments; and 4) data analysis techniques.

A. Research Approach

The research approach is development. The focus of development for this 2024 research was on three stages, including design development, initial trials, and revisions to the results of the initial trials (main product revision). The model used in the development process is Borg and Gall [15],[16],[17],[18]. The three stages of development referred to the researcher's desire/goal to realize a digital test user interface design based on backward chaining as a measuring tool for students' critical thinking in a differentiated learning atmosphere. The research stages carried out by the researcher can be seen in Fig. 1.

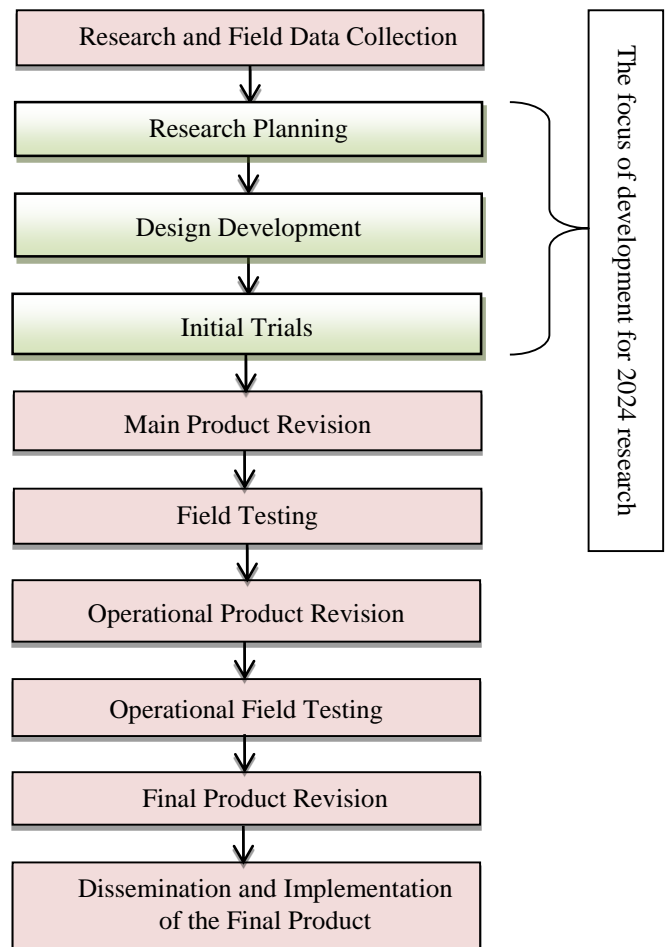

Fig. 1. The research stages that refer to the borg and gall design.

B. Subject, Object, and Location of Research

Subjects involved in the initial trial phase of the digital test user interface design based on backward chaining, including

education evaluation experts, informatics experts, and several teachers at IT Vocational School in Bali. The number of informatics education experts was two experts, the number of education evaluation experts was two experts, and the number of IT Vocational School teachers in Bali involved was 30 teachers. The selection of research subjects utilized a purposive sampling technique, involving individuals who possess in-depth knowledge and clear objectives regarding the object of study. The object of this research is the design of the digital test user interface based on backward chaining as a measuring tool for students' critical thinking in a differentiated learning atmosphere. The research location was at several IT Vocational School spread across six agencies in Bali.

C. Data Collection Instruments

The data collection tool used in this study is a questionnaire. All questions used in the questionnaire are related to the digital test user interface design based on backward chaining as a measuring tool for students' critical thinking in a differentiated learning atmosphere. The number of questions in the questionnaire was ten items. The details of the ten questions are explained in the discussion section of this paper. These ten questions are valid and reliable based on the instrument trials conducted by two education experts and two informatics experts.

D. Data Analysis Techniques

After being collected, quantitative data examination was a descriptive approach and descriptive percentage calculation. The technique for analyzing the initial trial data in this study was quantitative descriptive. It was to compare the percentage of the level of quality of the digital test user interface design based on backward chaining with the standard of user interface design quality that refers to a scale of five. The formula used to determine the percentage of the quality level of the digital test user interface design based on backward chaining is in equation (1) [19],[20],[21], then the quality standard that refers to a scale of five can be seen in Table I [22],[23],[24].

$$P = (f/N) \times 100\% \tag{1}$$

Notes:

f = Total acquisition value

N = maximum total value

TABLE I. QUALITY STANDARDS OF USER INTERFACE DESIGN OF DIGITAL TEST BASED ON BACKWARD CHAINING REFERRING TO FIVE SCALE CATEGORY

Percentage of Quality	Quality Category	Recommendations
90-100 %	Excellence	No Revision Required
80-89 %	Good	No Revision Required
65-79 %	Moderate	Revision
55-64 %	Less	Revision
0-54 %	Poor	Revision

IV. RESULTS AND DISCUSSION

A. Results

The results obtained on three stages of development focused on this research, including results at the design planning stage, the initial trial stage, and the initial trial revision stage. The data obtained based on the results at several stages of development in question are as follows.

1) Design Development: The design development stage produced a digital test user interface design based on backward chaining to measure students' critical thinking in a differentiated learning atmosphere. It was using the Balsamiq Mockups application. The form of the design intended is in Fig. 2.

Fig. 2. The user interface design to enter question data.

Fig. 2 shows the user interface design of the form that functions to enter question data. There are several attributes in the form. The "add general questions" button to add general questions. The "add specific questions" button is the specific question from the available general questions. There is a "Load image" button to enter questions containing images. There is a "difficult level" combo box to select the level of difficulty question. Several "answers" buttons are answer choices for the available questions.

No_Rules	General_Questions	Specific_Questions	Action
R.001	Question-1	Question-1.1	Backward Chaining
R.002	Question-1	Question-1.2	Backward Chaining
R.003	Question-1	Question-1.3	Backward Chaining
R.004	Question-1	Question-1.4	Backward Chaining
R.005	Question-1	Question-1.5	Backward Chaining

Fig. 3. The user interface design for questions arrangement based on backward chaining.

Fig. 3 shows the user interface design of the form that manages questions by referring to the backward chaining method. There are several features available on the form. The function of the “no. rules” textbox is to enter the rules number. This number is unique so that no one can duplicate it. There is a “general questions” combo box to select general questions. There is a “specific questions” combo box to specific questions. There is an “arrangement process” combo box to the question arrangement process referring to normal conditions or conditions that refer to the backward chaining concept. The “process” button to run the arrangement process. The “save” button to save the arranged question data. There is a data storage database. The data storage consists of several fields, including No_rules, General_Questions, Specific_Questions, and Action.

features on this form. A text box to enter students’ names and study programs. The combo box for selecting the test type. There is a text area used to display questions. An “answers” button that is useful as a choice of answers to the available questions. There is a “next” button to go to the next question.

Fig. 4. The user interface design for the question-answering facility is based on the test type and employs a backward chaining approach for packaging.

Fig. 4 shows the user interface design of the form that functions as a place to answer questions. There are several

Fig. 5. The user interface design to display final score.

Fig. 5 shows the user interface design of the form to display the final score. This design shows a text area that functions to display questions. An “answers” button that is useful as an answer choice for the available questions. The “finish” button is to end the process of answering questions. The “score” button is to calculate the final score. The “save” button to save the final score.

2) *Initial Trials*: Four experts and 30 teachers of IT vocational schools in Bali conducted an initial trial of the digital test user interface design based on backward chaining. The questionnaire for the initial trial consisted of 10 questions. The results of the initial trial are in Table II.

TABLE II. RESULT OF INITIAL TRIALS TO DIGITAL TEST USER INTERFACE DESIGN BASED ON BACKWARD CHAINING AS A MEASURING TOOL FOR STUDENTS' CRITICAL THINKING IN DIFFERENTIATED LEARNING NUANCES

Experts	Items-										Σ	Percentage of Quality (%)

Average												88.94

Respondents/assessors provided several suggestions in the initial trial stage. Improvements to the digital test user interface design based on backward chaining used several of these suggestions. Some of them are in Table III.

TABLE III. RESPONDENTS' SUGGESTIONS IN THE INITIAL TRIAL

No	Experts	Suggestions
1	Expert-1	Add the test date to the answer sheet form.
2	Expert-2	Add a list of test participants' scores.
3	Expert-3	There needs to be a facility to display a recapitulation of test results.
4	Expert-4	There needs to be a test date.
5	Teacher-12	There needs to be a facility to view a recapitulation of test results.
6	Teacher-16	There needs to be a test completion time duration.
7	Teacher-18	There needs to be a facility to view the scores of each test participant.
8	Teacher-28	It is better to prepare a facility to display the test implementation date.
9	Teacher-30	There needs to be a facility to display the test completion time duration.

3) *Revision of Initial Trial Results:* Revision of the user interface design of the digital test based on backward chaining based on several respondents' suggestions in the initial trial. It is necessary to make revisions, especially those related to the test implementation date referring to the suggestions of expert-1, expert-4, and teacher-28. They were creating a user interface design to display the test implementation date. The improved design form is in Fig. 6.

It is necessary to make revisions, especially those related to the recapitulation of test results referring to the suggestions of expert-2, expert-3, teacher-12, and teacher-18. They were creating a user interface design to display the recapitulation of test results. The form of the improved design is in Fig. 7.

It is necessary to make revisions, especially those related to the display test completion time referring to the suggestions of expert-16 and teacher-30. They were creating a user interface design to display the display test completion time. The form of the improved design is in Fig. 8.

Fig. 6 shows the user interface design display for the test execution date. Fig. 6 shows the improvement. There is a date time picker “date” to show the test execution date.

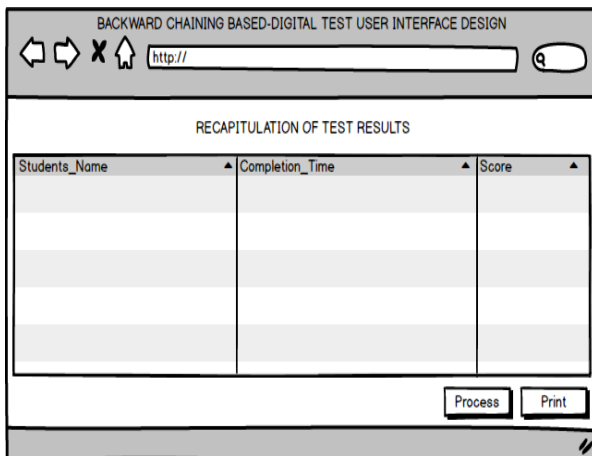

Fig. 7. User interface design to display test result recapitulation.

Fig. 7 shows the user interface design display for the recapitulation of test results. Fig. 7 shows that improvement. There is a database that shows the recapitulation of test results. They are Students_Name, Completion_Time, and Score.

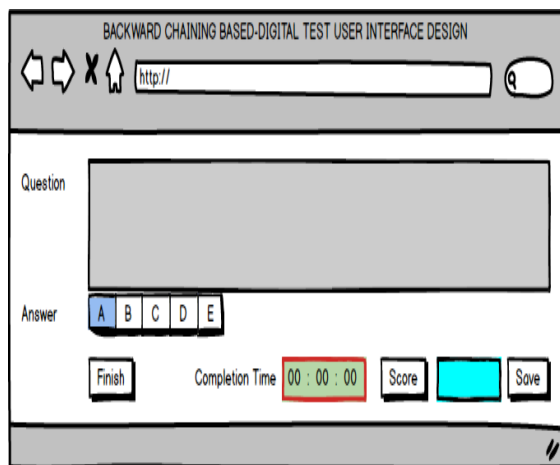

Fig. 8. User interface design to display test completion time.

Fig. 8 shows the user interface design display for the test completion time. Fig. 8 shows the improvement. There is a timer that shows the completion time.

B. Discussion

Referring to the percentage of quality shown in Table II, the digital test user interface design based on backward chaining is good quality. It is because of 88.94%, if checked through the quality standards shown in Table I, then it is true that the quality of the user interface design is good. The reference in providing assessments by respondents in the initial trial, resulting in the data shown in Table II, is in the form of ten questions.

Item-1 is about the suitability of the user interface design form for inputting question data. Item-2 is about the suitability of the general questions form. Item-3 is about the suitability of the specific questions form. Item-4 is about the sequence of relationships between general questions and specific questions. Item-5 is about the ease of creating questions containing image elements. Item-6 is about the ease of setting the level of difficulty of the questions. Item-7 is about the suitability of the user interface design form for backward chaining-based questions arrangement. Item-8 is about the suitability of the backward chaining concept in arranging questions based on the sequence of relationships between general and specific questions. Item-9 is about the suitability of the user interface design form for question answering facilities. Item-10 is about the suitability of the user interface design form for displaying the final score.

This study answers several constraints in the research of Ariawan, Giri, and Divayana [8], the research of Divayana, Ariawan, and Giri [9], the research of Divayana et al. [12], the research of Easa and Blonder [13], and the research of Kholid et al. [14]. The results of this research have been able to show well the design of the user interface of a digital test based on backward chaining packages of the test questions in a sequential manner backward from the general type of questions to questions with more detailed or specific types. In principle, the results of this research also have similarities with several studies of Putra et al. [25], research of Samrgandi [26], research of Darmawan et al. [27] by showing the existence of a user interface design for a measurement/test application.

The novelty of this research is the concept application of backward chaining in artificial intelligence to the preparation of digital test questions in educational evaluation. Based on the internalization of artificial intelligence into educational evaluation, the test formed is a measuring tool for students critical thinking in a differentiated learning atmosphere. However, this research also has constraints. The constraint of this research is that it has not formed a physical application for direct application in the field. It is only limited to the user interface design.

V. CONCLUSION

In general, the findings of this study effectively demonstrate the quality of the user interface design for a digital test based on backward chaining, which serves as a tool for measuring students' critical thinking in a differentiated learning context. A key innovation/novelty of this study is the arrangement of test questions using the artificial intelligence method known as

backward chaining. This approach organizes the questions systematically, progressing from general to specific types, thereby facilitating a deeper exploration of students' critical thinking abilities. Future work that needs to overcome the obstacles of this study is to create a physical application in the form of a backward chaining-based digital test that is ready for field testing. The impact of the results of this study on educational evaluation science is to make it easier for evaluators to conduct tests to measure students' critical thinking. The impact of research results on informatics engineering education, in general, is to show innovations in digital-based test development to determine the critical thinking in differentiated learning.

ACKNOWLEDGMENT

The authors would like to thank the Chair of the Research and Community Service Institute of Universitas Pendidikan Ganesha that providing opportunities and funding in carrying out this research on time based on research grant number: 893/UN48.16/LT/2024. Besides that, the authors express their gratitude to the Rector of Universitas Pendidikan Ganesha who gave a chance to the authors to complete this research.

Dept. of Psychiatry, Pondicherry Institute of Medical Sciences, Puducherry, India³

Abstract—Alzheimer's Disease (AD) is a persistent, irreversible, and degenerative neurological disorder of the brain that currently has no effective therapy. This condition is identified by pathological abnormalities in the hippocampal area, which may develop up to 10 years prior to the onset of clinical symptoms. Timely detection of pathogenic abnormalities is essential to impede the worsening of AD. Recent studies on neuroimaging have shown that the use of Deep Learning techniques to analyze multimodal brain scans may effectively and correctly detect AD. The main goal of this work is to design and develop an Artificial Intelligence (AI) based diagnostic framework that can accurately and promptly detect AD by analyzing Structural Magnetic Resonance Imaging (SMRI) data. This study presents a novel approach that combines a Directed Acyclic Graph 3D-CNN with an SVM classifier for timely detection and identification of AD by analyzing the Regions of Interest (RoI) like cerebral spinal fluid, white and gray matter, and the hippocampus in SMRI images. The proposed hybrid model combines Deep Learning for feature extraction and Machine Learning techniques for classification. The obtained results demonstrate its superior performance compared to earlier methods in accurately identifying individuals with early mild cognitive impairment (EMCI) from those with normal cognition (NC) using the Alzheimer's Disease Neuroimaging Initiative (ADNI) dataset. The model attains a classification accuracy of 97.67%, with precision at 94.12%, and sensitivity at 98.60%.

Keywords—Alzheimer's Disease (AD); convolutional neural networks (CNN); Support Vector Machine (SVM); Directed Acyclic Graph (DAG); Late Mild Cognitive Impairment (LMCI); Alzheimer's Disease Neuroimaging Initiative (ADNI)

I. INTRODUCTION

Dementia is a broad word that encompasses many cognitive impairments that hinder daily functioning, impacting memory, thinking, language, and problem-solving skills. AD is the main source of dementia with distinct pathological features in the brain, responsible for around 80% of cases [1]. AD is defined by permanent neurodegeneration and currently lacks the potential for treatment. Neurodegenerative illnesses provide significant challenges in countries with a mostly aging population. It is the sixth primary cause of mortality and has a substantial global impact, mostly affecting the older demographic [2]. MR imaging is a diagnostic modality that uses T1-weighted images to identify and examine the morphological and structural irregularities associated with brain atrophy [3]. Therefore, MR imaging plays a crucial part in screening and diagnosing of AD [4, 5]. The incidence of the ailment has surpassed original forecasts due to the increasing

older population and the simultaneous commencement of their diagnosis [6]. This necessitates due attention to effectively handle Alzheimer's diagnosis and treatment.

While the exact process behind the progression of Alzheimer's is still not fully understood, existing knowledge indicates that the illness may be broadly categorized into three separate stages i.e. Preclinical, MCI, and AD [7, 8]. There are no noticeable symptoms of AD in the preclinical stage. However, subtle changes begin to occur in the brain. These pathological changes can start many years, even decades, before any cognitive symptoms appear [9]. The second stage is characterized by MCI, where individuals start to notice slight but measurable changes in their cognitive abilities, particularly memory. These changes are more significant than what is expected from normal aging, although they do not reach a level of severity that hinders one's ability to carry out everyday activities [10]. In the last stage of AD, the cognitive decline becomes sufficiently pronounced to disrupt everyday activities. Individuals may encounter memory impairment, disorientation, and challenges with tasks that require planning or decision-making, may struggle with recognizing familiar people or places, and may experience a decline in physical abilities such as walking, swallowing, and bladder and bowel control [11].

The field of Machine Learning (ML) and Deep Learning (DL) has gathered considerable attention in over the past few years for its ability to accurately detect and isolate possible features of dementia illness, by accurately identifying the minute morphological changes in brain structure by analyzing MRI data [12, 13]. DL methodologies have proven that the area of AD detection has seen notable advancements via the use of CNNs [4, 14]. CNNs shall effectively extract structural characteristics from T1 MRI data with a large number of dimensions, leading to more precise tailored diagnoses. Furthermore, the implementation of an ensemble approach is gaining more significance in the field of medical image evaluation [15, 16]. AD has a quick and profound impact on the hippocampus, making it one of the most damaged brain areas and making it vital for the prompt detection of AD. The hippocampus is composed of several subdomains, each exhibiting distinct characteristics. A comprehensive evaluation of neurodegenerative disorders in medical applications heavily relies on the subfields of the hippocampus [17]. Scholars have proposed that the analysis of form and volume characteristics of hippocampal subfields in many MRI scans provides advantages in the prompt identification and assessment of AD [18, 19].

*Corresponding Author

The process of classifying hippocampus characteristics entails extracting them from either 2D or 3D MRI images using 2D and 3D CNNs [20,21]. When doing a comparison between 3D convolutions performed on a whole MRI and 2D convolutions performed on slices, it is evident that the former can capture crucial 3D structural information that is vital for distinction [22]. The brain MRI data has a lot of dimensions, thus, three-dimensional CNNs [23] are computationally difficult and need a longer training time compared to two-dimensional CNNs. The above-said facts served as the motivation for this work. The goal of this research is to facilitate the timely detection of AD using the popular SVM classifier with more emphasis on the input features fed to it. This is accomplished by employing a new DAG CNN approach to perform feature extraction. In this study, both 2D and 3D DAG-CNN is used. In summary, a hybrid of CNN combined with SVM classifier is employed to perform early detection of AD. The next section gives a detailed comment on the literature work done in this direction.

II. LITERATURE REVIEW

Hongbo Xu et al. [24] proposed a CNN that utilizes multi-scale attention to diagnose AD by analyzing hippocampal subfields. This study employs two datasets, procured from Peking University of China and ADNI. These datasets consist of a combined sample of 283 NC patients and 241 AD cases. The network can easily extract 3D data characteristics from three different planes of hippocampus subfields as input. This improves computational efficiency and reduces network complexity. Experimental methods have shown notable classification performance in identifying AD, eliminating the need for manual feature extraction. Bo Liu et al. [25] employ MRI scans of the hippocampus and an attention mechanism (DenseNet-AM) to improve classification accuracy. The empirical findings illustrate that the DenseNet-AM is 92.8% accurate, the sensitivity is 97.1%, and the specificity is 89.6% when distinguishing between instances of cognitive normalcy and AD. Malik et al. [26] presented a novel methodology known as the intuitionistic fuzzy random vector functional link network (IFRVFL), which utilizes brain imaging data to diagnose AD. This study aims to improve existing approaches by incorporating a fuzzy weighted approach into the IFRVFL model to improve its capability to withstand challenges. This methodology considers the importance of individual data samples while minimizing the influence of outliers and noise. Experimental studies indicate that in comparison to cases of Alzheimer's dementia (AD), the IFRVFL model has a higher level of efficacy in identifying both MCI and early identification of AD in clinical settings. Shuqiang Wang et al. [27] conducted a research where they introduced a new approach that combines 3D-DenseNets to automatically diagnose Alzheimer's (AD) and moderate cognitive impairment by analyzing 3D brain magnetic resonance images. A comprehensive assessment was conducted for evaluating the performance of the suggested model using the ADNI dataset with 833 patients, and it was determined to be superior. The suggested approach enhances the transmission of information across layers by integrating several connections and a weighted-based combining approach is employed to integrate diverse topologies. A promising result was seen in the

automation of dementia illness identification by employing an ensemble strategy that incorporates dense connections and a weighted-based fusion method. Reddy et al. [28] provide a deep hybrid framework in their research, which employs boosting approaches to classify 3D MRI images of Alzheimer's. The research primarily focuses on early diagnosis and utilizes the categorization of subcategories of MCI. The system uses ResNet 50 and VGG16 to extract structural information from MRI volumes followed by using Extreme Gradient Boosting (XGBoost) for classification. Pallawi et al. [29] employed a Transfer Learning approach to distinguish between various phases of Alzheimer's with an enhanced EfficientNetB0 model via MRI images obtained from the Kaggle dataset. To tackle the issue of inadequate data, data augmentation techniques were used. Consequently, the model effectively categorized several classes with a precision rate of 95.78%, exceeding the efficacy of existing methodologies. Rui Guo et al. [30] provide a novel approach known as graph-based fusion (GBF) in their research. This technique utilizes imaging, genomic, and clinical data to effectively identify degenerative illnesses. By combining a multi-graph fusion module with an imaging-genetic combining module to efficiently extract unique information from many data modalities. The effectiveness of the GBF approach is shown by trials done on benchmarks about the identification of degenerative illnesses, in contrast to known graph-based methods. In their study, Xiaowei Yu et al. [31] has focused on developing a supervised deep tree model (SDTree) to forecast the advancement of AD at an individual level. The proposed SDTree methodology employs a nonlinear reversed graph embedding method inside a hierarchical tree framework within a latent space for enhanced prediction. This technique encompasses the whole spectrum of Alzheimer's progression and enables the generation of predictions for future instances. Furthermore, the attainment of a resilient depiction of the tree is accomplished by using node clustering in locations with high population density. Moreover, a novel methodology is suggested for multi-class classification by using a supervised deep tree architecture that integrates class labels to guide the acquisition of tree structure.

The reviewed works focus on several facets of AD diagnosis, using novel methodologies such as multi-scale attention (Hongbo Xu et al.) and attention processes (Bo Liu et al.) to improve efficiency and precision. Innovative approaches like IFRVFL (Malik et al.) proficiently manage noise and outliers, while 3D-DenseNets (Shuqiang Wang et al.) and hybrid frameworks integrating ResNet and XGBoost (Reddy et al.) emphasize early identification of MCI categorization. Transfer Learning (Pallawi et al.) attains high precision by data augmentation, whereas graph-based fusion (Rui Guo et al.) amalgamates multi-modal data to enhance accuracy. The SDTree model (Xiaowei Yu et al.) provides a comprehensive framework for predicting AD development.

The research highlights many constraints in the categorization systems used for AD in the literature. Hongbo Xu et al. [24] and Pallawi et al. [29] demonstrate how dataset variety limits model generalizability to larger populations. In approaches like Malik et al. [26], Shuqiang Wang et al. [27], and Rui Guo et al. [30], computational complexity is a major

issue. Dense networks, fuzzy logic systems, and graph-based solutions need plenty of resources, limiting scalability. Many researches, such as Bo Liu et al. [25] and Pallawi et al. [29], focus on specific brain areas or use single-modal data, missing the opportunity to increase accuracy via multi-modal integration. The techniques of Reddy et al. [28] and Xiaowei Yu et al. [31] enhance architectural complexity, which reduces interpretability and hinders clinical applicability. Finally, research like Bo Liu et al. [25] and Malik et al. [26] lack rigorous evaluations compared to state-of-the-art methodologies or real-world clinical datasets, leaving practical robustness untested.

Conventional methods often need the extraction of features by hand, a process that may be time-consuming and potentially overlook crucial attributes. In addition, current models may have difficulties in dealing with noise, resulting in a decrease in classification accuracy. Additionally, there are difficulties in accurately detecting the initial phases of AD and differentiating them between various phases of cognitive decline. The issue of inadequate data might ultimately restrict the capacity to train resilient models, hence affecting their overall effectiveness.

To overcome these limitations, the researchers in this study have developed methods like DAG CNNs for automatically extracting features from the SMRI images, by avoiding the need for manual feature extraction and capturing more relevant characteristics. Advanced architectures like DAG CNNs enhance accuracy by better analyzing complex data, such as brain MRI scans. This research also used data augmentation methods to overcome the problem of inadequate data by artificially expanding the amount and variety of the dataset. This results in improved training and more efficient models. The hybrid models used in this study combine the strengths of multiple methods like DL for extracting the significant features and ML techniques for performing classification to further improve classification performance.

A. Novelty

The proposed methodology is innovative in integrating DAG 3D-CNN with SVM to facilitate the prompt detection of AD, utilizing the advantages of both methodologies." Although CNNs are proficient in feature extraction, SVM classifiers are

recognized for their resilience in managing small sample data and high-dimensional feature spaces, which are typical issues in medical imaging datasets. This hybrid method offers a distinctive means to enhance classification efficacy in AD diagnosis.

The DAG architecture for CNNs facilitates a versatile route for feature propagation and allows for more profound feature investigation, circumventing the vanishing gradient issue. Our method provides a customized solution to the unique problems of volumetric medical data by building the architecture specifically for these issues, distinguishing it from conventional CNN architectures used in analogous applications.

The researchers have chosen DAG-CNN architecture because to its capacity for parallel processing of features across several scales, enhancing the network's proficiency in capturing the spatial hierarchies present in 3D medical pictures. This structure enhances generalization by mitigating overfitting, since the modular architecture allows for selective feature aggregation.

III. METHODOLOGY

Fig. 1 demonstrates a system specifically developed for the prompt identification and categorization of AD. This approach uses CNN and SVM. The method starts by obtaining the brain's SMRI data from ADNI, and KAGGLE datasets. These images are essential for discerning structural alterations corresponding to AD since they record intricate details about the brain's composition. Following that, the SMRI images go through pre-processing, a crucial stage that employs methods including skull stripping, normalization, shrinking, and noise reduction. Pre-processing ensures that the pictures are normalized, strengthening key characteristics while decreasing noise and unnecessary details, thereby improving the accuracy of further investigations. Once the data has been pre-processed, it is then split into two distinct training and validation sets. These two datasets are then used for training and assessing efficacy of the model, during the training process, therefore mitigating overfitting and ensuring the model's ability to effectively generalize to novel data.

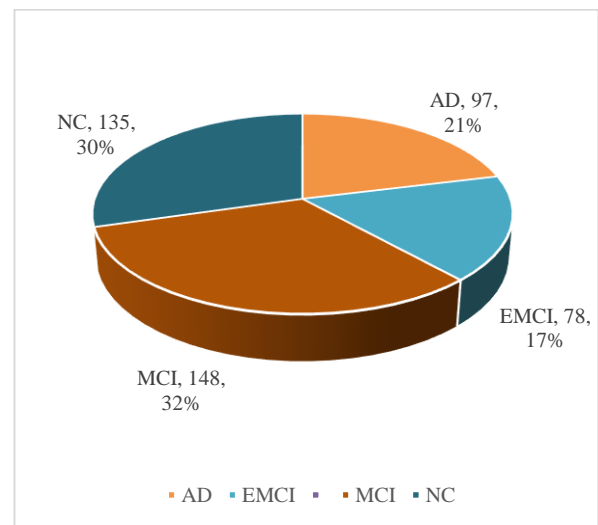

Fig. 1. Block diagram for the methodology.

The crux of this method is in the development of a CNN network, which excels at processing volumetric structural MRI data with great efficiency. The CNN automatically acquires the ability to extract spatial characteristics from brain images that are symptomatic of AD. At first, a 2D-CNN was developed to analyze the 2D slices of the MRI images. The 2D-CNN model has many advantages, namely its simplicity and decreased computational expenses. This is due to its ability to evaluate images on a per-slice basis, resulting in faster training and lower resource requirements. The implementation of the 2D-CNN model is straightforward, and the training periods are quicker because of the reduced complexity in processing 2D images. However, the 2D-CNN approach does have significant drawbacks. 2D CNNs evaluate each slice independently, which might result in the loss of crucial spatial connections between slices and the omission of significant characteristics necessary for precise Alzheimer's diagnosis. Due to the constraints of 2D-CNNs in accurately representing the whole 3D architecture of the brain, it became imperative to switch to a 3D-CNN. The 3D-CNN model enables the analysis of the whole volumetric SMRI data while maintaining the spatial connections between various brain areas. This comprehensive approach allows the model to better detect minor alterations in structure that are linked to the early stages of AD, resulting in enhanced accuracy in categorization. The use of a 3D model aligns with the objective of achieving improved accuracy and reliability in the early detection of AD, making it a vital step in our research. Once the network completes the image processing, it proceeds to extract the significant features from the fully connected layers of the CNN. These layers function as classifiers inside the network and integrates the features collected into a condensed representation. Subsequently, this representation is used to train an SVM model, which categorizes the data into distinct classes, such as AD or normal cognitive. The SVM classifier is used because of its resilience in distinguishing classes in spaces with a large number of dimensions, hence enhancing its effectiveness as a classifier when paired with the characteristics retrieved by the CNN.

Finally, the efficacy of the integrated CNN with SVM model is assessed by measuring parameters such as accuracy, precision, recall, and F1 score. This assessment is vital in guaranteeing that the suggested model is not just accurate but also reliable and has the ability to extrapolate well to new, unfamiliar data. In summary, our technique successfully integrates DL for automated extraction of features using traditional ML for classifiers, resulting in an efficient method for the prompt identification of dementia. Such detection is essential for immediate attention and treatment.

A. SMRI Datasets

This research used structural MRI images received from the ADNI and KAGGLE databases. The ADNI consists of four distinct phases, including ADNI 1, ADNI GO, ADNI2, and ADNI4. Each phase has its specific aims and cognitive stages. This study used structural MRI images. Fig. 2(a) depicts the AD dataset utilized in this study. Among the 455 participants in the ADNI study, there were 97 AD subjects, 78 early MCI subjects, 148 LMCI subjects, and 135 subjects with normal cognition (NC).

(a)

(b)

Fig. 2. (a) ADNI data set, (b) KAGGLE data set.

The dataset obtained from Kaggle shown in Fig. 2(b) and has four different classes: NC, Early EMCI, Late MCI, and AD. The dataset is divided into separate training and test sets. The training dataset composed of 5120 photos, whereas the test dataset has 1279 images. The NC class contains the largest quantity of photos, consisting of 2560 for training and 640 for assessment. The EMCI dataset consists of 1791 pictures for training and 448 images for testing, whereas the AD dataset comprises 717 training images and 179 test images. The LMCI class has the lowest number of pictures, with a total of 52 for training and 12 for assessment.

B. Preprocessing and Segmentation of SMRI Images

Fig. 3 depicts the methodological steps employed for the early identification of AD using the data samples acquired from the ADNI and KAGGLE. The collected images are in NifTi (.nii) format. The N4ITK bias correction is first performed to eliminate low-frequency noise and the resulted image are shown in Fig. 3(a). Subsequently, the raw volumes are subjected to pre-processing through the Statistical Parametric Mapping [45] toolbox in MATLAB. During the pre-processing stage of SPM, the images were co-registered with the ICBM-152 template to align them to the Montreal Neurological Institute coordinate system (MNI) and

additionally, the images are normalized, skull stripped (Fig. 3b) and categorized into white, gray matter, and cerebral spinal fluid as shown in Fig. 3(c). Hippodeep [44] tool is used for segmenting left and right hippocampal and shown in Fig. 3(d). Subsequently, the images were resized to dimensions of 256*256*128. The pre-processed data is separated into two distinct sets: training and validation. The proposed 3D-CNN is the trained and validated via these two datasets. The trained CNN is utilized to extract important characteristics from the input SMRI data. These characteristics obtained from the flattening layer of CNN are further partitioned into validation and training features, which are then utilized for both training and testing of the suggested DAG based 3D-CNN with SVM model.

C. Design and Development of DAG Based 2D/3D-CNN

The CNN and ML classifiers are often used AI tools for the identification and categorization of Alzheimer's, and their performance largely relies on the features extracted and analysed. Traditionally, researchers manually extract certain characteristics, which are then incorporated into ML classifiers for categorization. This research study employs a DAG based 2D/3D layered CNN model as shown in Fig. 4 for automatically extracting characteristics from SMRI data, leveraging their strength in handling substantial volumes of visual information. The architecture remains the same for both 2D and 3D except that the layers are made to handle 2D and 3D data respectively. This variant is brought in to observe the magnitude of change in the classifier performance metrics, which 3D layers offers compared to the 2D layers in the suggested CNN framework. The proposed CNN framework uses multiple paths and concatenation layers to learn, extract, and combine diverse feature representations, improving the

model's proficiency in appropriately classifying AD. The core structure of the proposed CNN framework comprises of four distinct layers: convolutional, normalization, pooling, and activation. The proposed model employs a total of six convolutional blocks, each composed of four layers, namely convolutional layer (CL), batch normalization (BN), max pooling (MP), and leakyRelu (LR) activation layer. The convolutional layer applies 3*3*3 kernel filtering to extract various characteristics from the input SMRI images, subsequently accompanied by a LeakyReLU activation, batch normalization, and max pooling to extract and condense the significant features from SMRI images effectively. These extracted features by pooling layer are fed to ML classifier. The pooling layer decreases the spatial dimensions of the feature maps, effectively decreasing the trainable variables and controlling overfitting. The BN layer helps to stabilize and speed up training by normalizing the inputs to the next layer. After passing through the series of convolutional blocks, the feature maps are transformed into a one-dimensional vector before being inputted into fully connected layers for final classification. Prior to feeding the data into the CNN, MRI images are pre-processed, resized to dimensions of 256x256x128, and normalized. The DAG based 3D-CNN was trained for 10 epochs with a learning rate of 0.001, using the Adam optimizer with categorical cross-entropy loss, employing a batch size of 8. The dataset's class imbalance was addressed by the use of class weights.

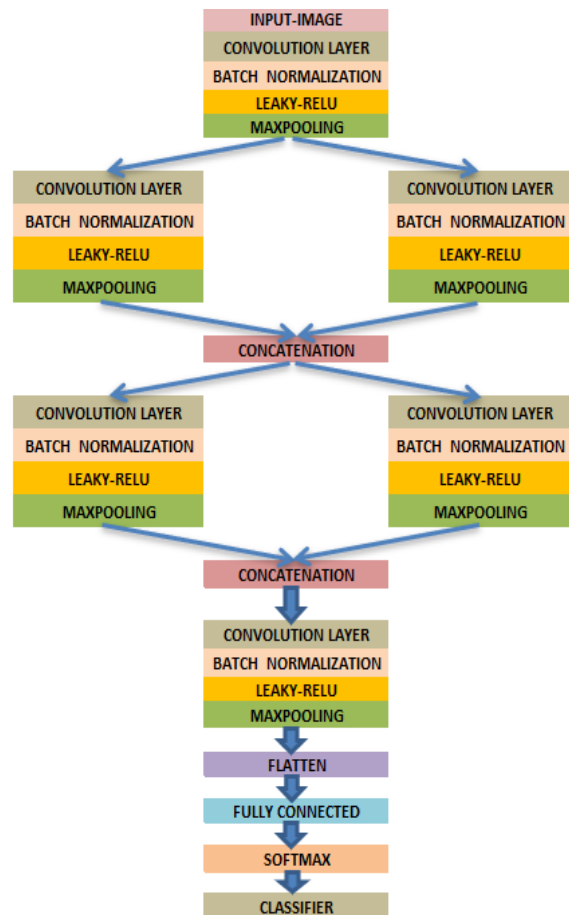

Fig. 4. Proposed DAG-CNN architecture.

1) *Advantages of DAG-CNN over other architectures:* The DAG structure enhances computational performance and minimizes redundancy in feature extraction compared to conventional CNN systems. In contrast to ResNets or DenseNets, which depend on unique skip connections, the DAG architecture offers a more universal approach for adaptive feature flow, especially advantageous for 3D data where spatial information is essential.

The integration of CNN and SVM arises from the use of their complementing advantages: CNNs excel at extracting deep, hierarchical features, whilst SVMs are particularly proficient in classification problems involving tiny or unbalanced datasets. This is especially pertinent in the early identification of AD where the quantity of the information often poses a constraint.

The CNN-SVM combination offers superior feature separation compared to end-to-end CNN classifiers, since SVM emphasizes optimizing the separation among classes in a high-dimensional space. This hybrid method guarantees that the retrieved characteristics are both deep and properly distinguished for classification, resulting in enhanced sensitivity and specificity.

D. Framework of the Proposed DAG Based 3D-CNN with SVM Classifier

The primary aim of this investigation is to improve upon existing approaches by modifying the architectures of CNNs to extract critical features and ML classifiers for accurate AD categorization. The proposed architecture shown in Fig. 5 has high capacity to produce innovative solutions that can efficiently detect Alzheimer's in its initial stages.

The use of hybrid DAG 3D-CNN with an SVM classifier has been demonstrated to be a very efficient methodology for a diverse array of classification jobs. The superiority of the DAG 3D-CNN with SVM lies in its hybrid nature. The proposed model by combining a CNN for characteristics extraction with an SVM for classification leverages the strengths of both techniques. The enhancement of classification performance, interpretability, and generalization ability is accomplished with the resilience of SVMs and the feature extraction capabilities of CNNs. Support Vector Machines (SVMs) use non-linear mechanisms and flexibility to enhance decision boundaries and accuracy, CNNs have a remarkable ability to obtain hierarchical and discriminative features from raw input data, which are crucial for identifying pathological changes associated with AD. Furthermore, the classifier incorporates the regularization properties of Support Vector Machines (SVMs), ensuring robustness against overfitting. The method shown in Fig. 5 depicts the flow of data through a hybrid DL and ML model for Alzheimer's classification.

The SVM is a popularly used ML methodology utilized for categorization tasks. The methodology is specifically formulated to ascertain the hyperplane that optimizes the degree of differentiation between observations that correspond to different classifications. The mathematical formulation of the decision function for Support Vector Machines (SVM) is:

$$f(x) = \text{sign}(w \cdot x + b) \quad (1)$$

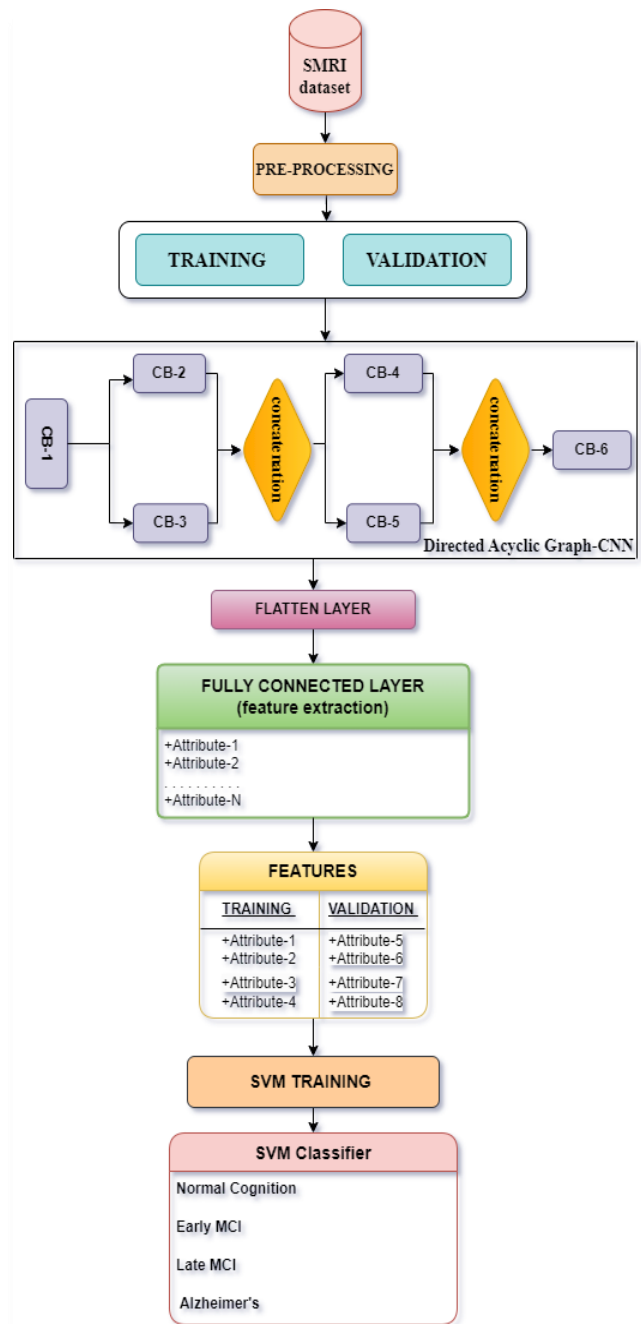

Fig. 5. Proposed DAG-CNN with SVM classifier.

where b is the bias factor, the weight vector is w , an input feature vector is x , and the sign function is denoted by $\text{sign}(\cdot)$. The distance between the nearest data point x_i and the hyperplane known as support vectors is derived using the below Eq. (2).

$$\text{distance}(x_i, \text{hyperplane}) = \frac{|w \cdot x_i + b|}{\|w\|} \quad (2)$$

$$\|w\| = (w_1^2 + w_2^2 + \dots + w_n^2)^{1/2} \quad (3)$$

where b is the bias factor, the weight vector is w , and $\|w\|$ is the magnitude or Euclidean norm of weight vector and

calculated as shown in Eq. (3), an input feature vector in n -dimensional space is x_i . The margin is inversely proportional to the size of w . The main objective of SVM is to ascertain the ideal values of w and b coefficients that enable the attainment of the largest margin. The ideal values for the weight vector w and bias b are obtained by addressing an optimization problem that tries to increase the margin between classes while decreasing misclassification errors. In case of data that is not linearly separable, Support Vector Machines (SVM) include a slack variable ξ_i for each data point. This variable allows for a certain degree of misclassification, striking a balance between maximizing the margin and minimizing errors. This results in an optimization problem in which the goal is to minimize the expression as shown in Eq. (3).

$$distance(x_i, hyperplane) = \frac{1}{2} \|w\|^2 + C \cdot \sum \xi_i \quad (4)$$

where C determines the balance between the size of the margin and the penalty for misclassification.

IV. RESULTS AND DISCUSSION

Timely identification is crucial in effectively controlling and perhaps slowing down the progression of Alzheimer's dementia, making it an essential area of investigation. Hence the primary objective of this current study is to develop a highly efficient hybrid AI model with the combination of DAG-CNN and SVM classifier that can identify AD by analyzing SMRI data.

Both Classification and early detection of AD are accomplished by using the proposed DAG CNN and SVM framework, developed using MATLAB 2022b. 80% of pre-processed images were utilized for training and 20% for validation.

AD may be classified as four different phases: Preclinical (Normal Cognitive), Early MCI, Late MCI, and AD. This research study attempted on three distinct binary classifications under three case studies.

- Case 1: EMCI Vs subjects with Normal Cognition (NC). This distinction is of utmost importance in detection of subjects in the initial stages of AD.
- Case 2: EMCI with LMCI
- Case 3: LMCI with AD

Initially, this study involved in extracting the volumetric features manually using the ITK-SNAP[43] cloud-based application, specifically focused on SMRI images. Around 22 volumetric characteristics were extracted from specific regions inside the hippocampus. These manually extracted features were fed as input for a SVM classifier, which yielded an accuracy of 88.4% for discriminating EMCI with Normal Cognitive (case 1 scenario), which triggered the use of CNN-based automated feature extraction to achieve improved accuracy. Table I depicts the performance of an SVM model achieved for 22 manually extracted volumetric features shown in Table II from hippocampal subfields. The performance metrics are listed for SVM classifier.

Next, a 2D-CNN was designed and used to analyze 2D slices of the SMRI images available in the ADNI and

KAGGLE repository. On the Kaggle dataset, the 2D-CNN module without an SVM classifier demonstrated a classification accuracy of 90.17% in differentiating between NC and EMCI, 98.98% in differentiating between NC and AD, and 90.43% in differentiating between EMCI and LMCI. The accuracy in distinguishing between NC and EMCI, AD and NC, and EMCI and LMCI using the 2D-CNN architecture without an SVM classifier were 94.20%, 89.97%, and 82.17% respectively, for the ADNI dataset. The suggested DAG 2D-CNN without the SVM classifier model's efficacy metrics for the Kaggle and ADNI datasets are presented in Table III.

However, since the accuracy was not optimal for all cases, the proposed CNN architecture with 2D layers was converted into 3D layers which is capable of processing the complete volumetric SMRI data and capturing the spatial connections inside the brain's structure to enhance the model's capability to accurately diagnose the Alzheimer's in early-stage. The suggested DAG 3D-CNN without the SVM classifier model's efficacy metrics for the ADNI dataset are presented in Table IV. The accuracy in distinguishing between NC and EMCI, AD and NC, and EMCI and LMCI using the 3D-CNN architecture without an SVM classifier were 96.86%, 90.45%, and 96.67% respectively, for the ADNI dataset.

The proposed DAG 3D-CNN with SVM classifier outperforms the 2D and 3D-CNN modules. With the ADNI dataset, the hybrid DAG 3D-CNN with the SVM model is 97.67 per cent accurate. Tables V and VI provide the performance outcomes of the hybrid DAG 3D-CNN with SVM classifier and the comparison of SVM model, 2D-CNN for ADNI and KAGGLE datasets & 3D-CNN with and without SVM models, respectively, to identify the Alzheimer's at an initial stage. The comparative analysis of different models and their performance for the ADNI and KAGGLE dataset is shown in Table VI. This evaluation considered five regions of interest (ROIs).

TABLE I. PERFORMANCE EVALUATION OF THE SVM CLASSIFIER FOR MANUALLY EXTRACTED VOLUMETRIC FEATURES OF HIPPOCAMPAL SUBFIELDS USING ITK-SNAP FOR ADNI DATASET

Classification	Accuracy	Precision	Sensitivity	F1 Score
NC with EMCI	88.40	86.60	94.00	0.90
EMCI with LMCI	80.40	80.70	80.40	0.80
LMCI with AD	86.00	94.00	78.00	0.85

Table I and Fig. 6 displays the efficacy metrics of an SVM classifier used for categorizing various phases of AD. The classification is determined by analysing 22 volumetric characteristics extracted from hippocampus subfields using the ITK-SNAP[43] tool, which are depicted in Table II. The classifier achieved 88.40% accuracy in differentiating EMCI from NC. The classification model achieved a precision of 86.60%, a sensitivity of 94.00%, and an F1 score of 0.90. These findings demonstrate that the classification method is very successful in identifying Alzheimer's in its first stages. Nevertheless, although achieving satisfactory outcomes, the accuracy remains inferior to the findings reported in the research literature. Thus, to improve the precision and efficacy of prompt identification, our research study has shifted to

CNN-based automated feature extraction, yielding superior outcomes.

Fig. 6. Performance metrics of SVM classifier.

TABLE II. VOLUMETRIC FEATURES EXTRACTED FROM THE HIPPOCAMPUS SUBFIELDS FOR EARLY DETECTION AND CLASSIFICATION FROM ADNI DATASET

22 Volumetric Features extracted from the hippocampus subfields			
Sl. No.	Left Hippo	Sl. No.	Right Hippo
1	Left CA1 (Corno Ammonis 1)	12	Right CA1 (Corno Ammonis 1)
2	Left CA2	13	Right CA2
3	Left CA3	14	Right CA3
4	Left DG (Dentate Gyrus)	15	Right DG (Dentate Gyrus)
5	Left Tail	16	Right Tail
6	Left Sub (Subiculum)	17	Right Sub (Subiculum)
7	Left Erc (Entorhinal Cortex)	18	Right Erc (Entorhinal Cortex)
8	Left A35	19	Right A35
9	Left A36	20	Right A36
10	Left Phc (Parahippocampal Cortex)	21	Right Phc (Parahippocampal Cortex)
11	Left Cysts	22	Right Cysts

The hippocampus has morphologically and functionally diverse subfields that differ in AD susceptibility. Early AD begins with tau buildup and neuronal loss in CA1. Though seldom studied, recent findings suggest CA2 role in social memory and pathological changes in AD. CA3 and Dentate Gyrus (DG) are Essential for pattern separation. structural changes may cause early cognitive impairment. The entorhinal cortex (ERC) and perirhinal cortex (PHC), which are crucial for hippocampal input and output, are among the first areas to atrophy in AD. Object recognition and memory encoding depend on the perirhinal cortex near the hippocampus. Since A35 and A36 allow hippocampus-cortical memory network connection, neurodegeneration in these regions corresponds with cognitive difficulties in early AD. Recent studies show

that volumetric abnormalities in these regions suggest pathogenic processes like tau accumulation, and include them in the feature set improves sensitivity to early AD changes. Fluid-filled hippocampal cysts may suggest neurodegenerative processes including gliosis or vascular changes. Cystic changes, seldom seen in AD, may be linked to structural atrophy in nearby hippocampus subfields, improving hippocampal health assessment.

TABLE III. COMPARISON OF THE EFFICACY OF THE PROPOSED DAG 2D-CNN CLASSIFIER ON THE ADNI AND KAGGLE DATASETS

Classification	dataset	Accuracy	Precision	Sensitivity	F1 Score
NC with EMCI	adni	94.20	96.43	91.80	0.94
EMCI with LMCI		82.13	97.63	65.87	0.79
LMCI with AD		89.97	88.50	91.87	0.90
NC with EMCI	kaggle	90.17	86.86	87.05	0.87
EMCI with LMCI		90.43	89.82	97.54	0.94
LMCI with AD		98.98	98.97	100.00	0.99

Table III presents a comparison of the efficiency of the proposed framework on two datasets, namely ADNI and Kaggle. The results are shown in Fig. 7(a) and 7(b). The model is evaluated by measuring its performance metrics across three classification tasks: distinguishing EMCI from NC, LMCI from AD, and EMCI from LMCI. The model achieves high accuracy on both datasets for distinguishing EMCI from NC, with the ADNI dataset slightly outperforming the Kaggle dataset. The model shows very high accuracy and F1 score, especially on the Kaggle dataset, indicating excellent efficacy in differentiating LMCI from AD. The model performs the lowest on this classification for distinguishing EMCI from LMCI, particularly on the ADNI dataset, where sensitivity is much lower compared to the Kaggle dataset. Overall, the model demonstrates strong performance in distinguishing NC from AD, with somewhat lower performance for differentiating EMCI from LMCI

(a)

Fig. 7. (a) Performance metrics of 2D-CNN for ADNI data (b) Performance metrics of 2D-CNN for Kaggle.

TABLE IV. PERFORMANCE OF PROPOSED HYBRID DIRECTED ACYCLIC GRAPH 3D-CNN CLASSIFIER FOR ADNI DATASET

Classification	Accuracy	Precision	Sensitivity	F1 Score
NC with EMCI	96.86	100	95.04	0.97
EMCI with LMCI	90.45	94.42	90.50	0.92
LMCI with AD	96.66	96.87	96.66	0.96

Table IV shows the efficiency metrics of the suggested DAG 3D-CNN model for the ADNI dataset. The model demonstrates strong performance in distinguishing EMCI from NC and has achieved an accuracy of 96.86%. The model has remarkable performance, achieving perfect precision, a sensitivity of 95.04%, and an F1 Score of 0.97%. The model efficacy metrics are plotted and shown in Fig. 8.

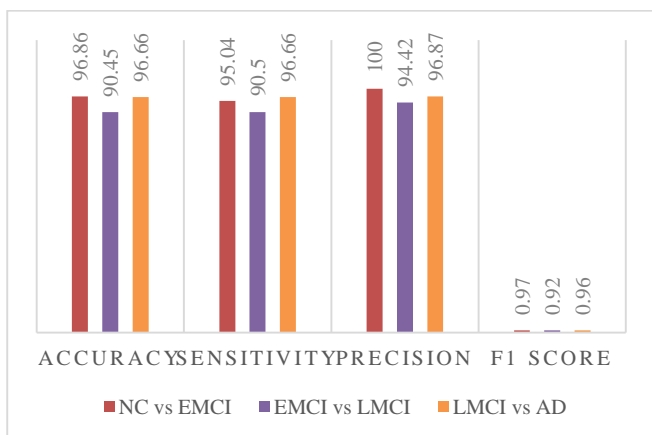

Fig. 8. Performance metrics of 3D-CNN.

TABLE V. PERFORMANCE OF PROPOSED HYBRID DIRECTED ACYCLIC GRAPH 3D-CNN WITH SVM CLASSIFIER FOR ADNI DATASET

Classification	Accuracy	Precision	Sensitivity	F1 Score
NC with EMCI	97.67	94.12	98.60	0.96
EMCI with LMCI	98.33	96.86	96.86	0.96
LMCI with AD	100	100	96.67	0.98

Table V shows the efficiency metrics of the suggested DAG 3D-CNN with the SVM classifier model for the ADNI dataset. The model demonstrates strong performance in

distinguishing EMCI from NC and has achieved an accuracy of 97.67%. The model has remarkable performance, achieving perfect precision, a sensitivity of 98.60%, and an F1 Score of 0.96%. The model efficacy metrics are plotted and shown in Fig. 9.

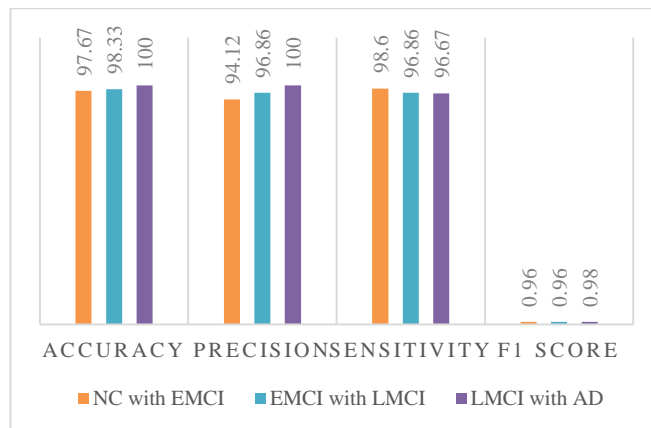

Fig. 9. Performance metrics of 3D-CNN with SVM.

TABLE VI. COMPARATIVE ANALYSIS OF THE PROPOSED MODELS FOR EARLY DETECTION OF AD

Method	Accuracy	Precision	Sensitivity	F1 Score
SVM with manually extracted features (ADNI)	88.40	86.60	94.00	0.90
2D-CNN (Kaggle)	90.17	86.86	87.05	86.96
2D-CNN (ADNI)	94.20	96.43	91.80	94.06
DAG 3D-CNN (ADNI)	96.86	100	95.04	0.97
DAG 3D-CNN with SVM (ADNI)	97.67	94.12	98.60	0.96

Table VI displays the performance measures for five distinct models employed in the early identification and categorization of AD. An SVM classifier with manually extracted features achieved 88.40% accuracy in discriminating early MCI with normal cognitive. The 2D-CNN model achieved a 90.17% accuracy when trained on Kaggle data. However, when trained on ADNI data, the same model performed better, with an accuracy of 94.20%. The DAG 3D-CNN model achieved a 96.86% accuracy when trained on ADNI data. The DAG 3D-CNN with SVM classifier surpassed all other models, with an accuracy of 97.67%. The five distinct model's Accuracy values are plotted and shown in Fig. 10.

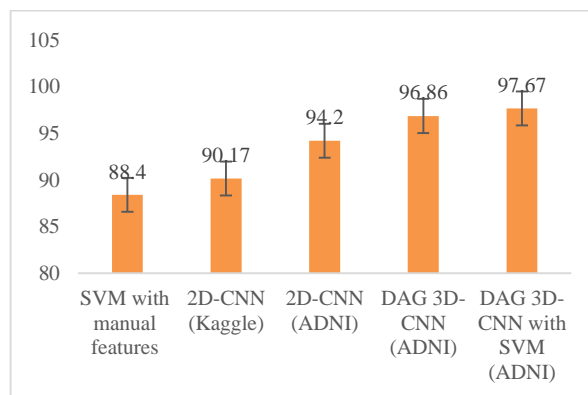

Fig. 10. Performance metrics of the proposed models.

TABLE VII. THE ACCURACY COMPARISON OF PROPOSED MODEL WITH VARIOUS ALGORITHMS FOR EARLY ALZHEIMER'S DISEASE DETECTION

Ref. No.	Dataset used	Algorithms used	Accuracy	
B. K. Choi et al. [32]	Adni	2D-CNN	78.1%	
M. Ghazal et al. [33]		3D deeply supervised adaptable CNN	93.2%	
S. Basaia et al. [34]		DL and CNN	87.1%	
C. Feng et al. [35]		3D-CNN & FSBI-LSTM.	86.36%	
Archana B et al. [36]		CNN	95.82%	
R. Joshi et al. [37]		Densenet-169	91.80%	
C. Kaur et al. [38]		Random Forest	86.24%	
S. Samanta et al. [39]		CNN	85.73%	
B. Kumar Yadav et al. [40]		CNN	94.57%	
A. J. Nair et al. [41]		VGG	90.34%	
F. Hajamohideen et al. [42]		Siamese CNN	91.83%	
Proposed model		SVM with manually extracted features	88.40%	
Proposed model		Kaggle	2D-CNN	90.17%
Proposed model		Adni	2D-CNN	94.20%
Proposed model	3D-CNN with DAG		96.86%	
Proposed model	3D-CNN with DAG and SVM classifier	97.67%		

Table VII presents a comparison of the efficiency of several methods for the ADNI and Kaggle datasets. The suggested model, which used a 3D-CNN combined with an SVM classifier, produced an impressive accuracy of 97.67%. Additional models, such as 3D-CNN without SVM attained 96.86% and those using 2D-CNNs, achieved high performance as well, with accuracies of 94.2% for ADNI and 90.17% for the Kaggle dataset respectively. The comparison clearly illustrates the better efficacy of the suggested approach, especially the DAG 3D-CNN with the SVM classifier, which attains the best accuracy of 97.67%. The performance metrics of various algorithms are plotted and shown in Fig. 10.

A. Discussion

This research aimed to create and assess sophisticated DL methodologies for the early identification of AD via SMRI datasets, employing both 2D and 3D CNN architectures in conjunction with an innovative integration of SVM classifiers. The suggested strategies shown substantial improvements in classification accuracy relative to current approaches in the literature.

Numerous recent researches have used DL methodologies for the categorization of AD, resulting in differing degrees of efficacy. B. K. Choi et al. [32] used a 2D-CNN, attaining an accuracy of 78.1%, hence underscoring the constraints of conventional 2D convolutional techniques. Advanced models, such as the 3D deeply supervised adaptive CNN by M. Ghazal et al. [33], demonstrated an accuracy of 93.2%, while frameworks like FSBI-LSTM integrated with 3D-CNN by C. Feng et al. [35] attained 86.36% accuracy.

The suggested 3D-CNN using a DAG architecture attained an accuracy of 96.86%, surpassing the majority of documented research. The integration with an SVM classifier enhanced performance to 97.67%, establishing a new standard in AD classification accuracy, exceeding prior benchmarks established by models such as Densenet-169 (91.80%) by R.

Joshi et al. [37] and Siamese CNN (91.83%) by F. Hajamohideen et al. [42]. This notable improvement is due to the DAG architecture's capacity to capture complex spatial information in SMRI data and the SVM's effective decision boundary optimization. The results indicate the capability of automated systems to offer dependable assistance in clinical decision-making for the early identification of AD.

B. Clinical Significance of the Findings

1) *Early diagnosis:* Our approach, integrating 3D-CNN with SVM for the early identification of AD, facilitates diagnosis in its first stages, perhaps prior to the onset of clinically observable cognitive impairment. Early identification is essential for prompt interventions, such cognitive therapy or pharmaceutical treatments, which may decelerate illness development.

2) *Customized therapy:* By pinpointing certain parts of the hippocampus afflicted in initial phases of AD, our approach may facilitate the development of individualized therapy techniques, focusing on the brain areas most severely impacted by the condition.

3) *Monitoring illness progression:* The volumetric alterations in the hippocampus subfields may function as biomarkers for assessing illness progression over time, providing a non-invasive instrument for doctors to evaluate treatment effectiveness and disease trajectory. The methodology may be applicable.

V. CONCLUSION

This research work introduces a novel method for the timely identification of AD via Structural MRI images. The proposed strategy utilizes deep neural networks i.e. DAG 3D-CNN for significant characteristic features extraction followed by SVM as a classifier. The model is trained and assessed by employing the Kaggle and ADNI datasets. For the Kaggle and ADNI datasets, the 2D-CNN module being evaluated offered an accuracy of 90.17% and 94.20%, 3D-CNN without SVM offered an accuracy of 96.86% and the hybrid 3D-CNN module with SVM classifier presented a superior accuracy of 97.67% in detecting EMCI subjects, respectively. This proves that the hybrid framework is relatively good and suitable for early detection and classification for all three case studies dealt in this research work. The efficacy of the suggested DAG 3D-CNN with SVM classifier technique in early Alzheimer's (AD) diagnosis shall be improved by training the network with additional clinical information, and by enhancing the number of ROIs used in the study.

A. Limitations and Future Work

This study, like other studies, has certain limitations that must be acknowledged. The sample size and insufficient demographic diversity may restrict the model's generalizability to wider groups. Subsequent research should use bigger and more heterogeneous datasets to corroborate the model's resilience across other demographics. Secondly, while this work used a 3D-CNN for SMRI data, the integration of other imaging modalities like PET and fMRI might significantly improve classification accuracy and diagnostic capabilities. Despite these constraints, this work establishes a significant

basis for enhancing automated detection techniques for AD and highlights critical avenues for further research.

Future research areas include investigating multimodal fusion by integrating SMRI with other imaging techniques like PET and fMRI, so offering a more holistic perspective on AD pathology and enhancing model efficacy. Furthermore, using longitudinal research to observe temporal changes may facilitate the building of prediction models capable of both early detection of AD and monitoring its advancement. Incorporating clinical data, including cognitive scores and genetic information, might significantly improve the model's accuracy and personalization, allowing more customized treatment strategies for AD patients. Ultimately, exploring other DL methodologies, such attention processes or reinforcement learning, might enhance model efficacy in intricate neuroimaging tasks.

ACKNOWLEDGMENT

The authors express their gratitude for the Institutional support provided in the form of a desktop server and internet.

Abstract—Coastal monitoring is vital in environmental management, disaster mitigation, and addressing climate change impacts. Traditional methods are time-consuming and error-prone, prompting the need for innovative systems. This study introduces the Coastal Video Monitoring System (CoViMos), a novel framework for real-time shoreline detection in tropical regions, specifically at Kedonganan Beach, Bali. The CoViMos framework utilizes advanced video monitoring and optimized morphological operations to address challenges such as environmental noise and dynamic shoreline behavior. Key innovations include Kapur's entropy thresholding enhanced with the Grasshopper Optimization Algorithm (GOA) and structuring elements tailored to the beach's unique features. Sensitivity analysis reveals that a structuring element size of five pixels offers optimal performance, balancing efficiency, and image fidelity. This configuration achieves peak values in quality metrics such as the Peak Signal-to-Noise Ratio (PSNR), Structural Similarity Index (SSIM), Complex Wavelet SSIM (CWSSIM), and Feature Similarity Index (FSIM) while minimizing Mean Squared Error (MSE) and reducing processing time. The results demonstrate significant improvements in shoreline detection accuracy, with PSNR increasing by 9.3%, SSIM by 1.4%, CWSSIM by 1.7%, and FSIM by 1.6%. Processing time decreased by 1.3%, emphasizing the system's computational efficiency. These enhancements ensure more precise shoreline mapping, even in noisy and dynamic environments.

Keywords—Coastline detection; image processing; Video Monitoring System (CoViMos); morphological operations

I. INTRODUCTION

Coastal monitoring plays a critical role in environmental management, disaster preparedness, and marine resource protection [1], [2], [3]. Effective monitoring systems rely heavily on accurately detecting and analyzing coastal lines, which are inherently dynamic due to erosion, tidal variations, and climate change. Traditional methods of coastline monitoring involve manual interpretation of satellite images and field surveys, which are time-consuming, prone to human error, and less effective in real-time scenarios [4], [5]. These limitations necessitate automated and robust systems that leverage advanced image processing techniques for accurate coastline detection.

Kedonganan Beach in Bali is a complex and dynamic ecosystem shaped by natural forces like tides, waves, sediment deposition, and human activities, including tourism, fishing, and urban development. Effective shoreline detection and monitoring are critical for sustainable coastal management,

disaster mitigation, and environmental preservation. However, accurate shoreline detection presents significant challenges due to the dynamic and irregular nature of tropical coastlines, ecological noise (e.g., glare, wave foam, or debris), and the limitations of existing image processing techniques [6], [7]. Addressing these challenges requires an innovative and adaptive approach that can handle the unique complexities of coastal environments.

To overcome these challenges, this research introduces a novel framework called the Coastal Video Monitoring System (CoViMos), specifically designed to monitor and analyze shoreline dynamics in tropical coastal areas. The CoViMos framework utilizes video monitoring as its foundation, enabling continuous visual data capture over time. Unlike traditional static image-based approaches, CoViMos offers dynamic and real-time insights into shoreline behavior, making it particularly useful for understanding the effects of seasonal changes, storm events, and anthropogenic activities on the shoreline. This framework serves as the backbone of the methodology, facilitating the acquisition, preprocessing, and segmentation of coastal imagery to detect and map the shoreline accurately.

Recent advancements in image processing have focused on enhancing feature extraction using techniques like edge detection, segmentation, and morphological operations [8], [9], [10]. The Canny Edge Detector, for instance, is widely recognized for its ability to detect edges with minimal noise. Still, its effectiveness diminishes in noisy and low-contrast environments common in coastal imagery. Morphological operations, particularly when utilizing structuring elements, have shown promise in addressing these challenges by refining edges, enhancing feature continuity, and suppressing noise. However, existing research primarily focuses on static image datasets, leaving a gap in the context of real-time video monitoring systems for dynamic coastal environments. Additionally, there is limited exploration of optimal structuring element configurations, such as size and shape, to balance signal quality, structural similarity, and computational efficiency.

The post-segmentation process in this study plays a pivotal role in refining the results obtained from CoViMos. Segmentation isolates the shoreline from other features in coastal imagery, such as wave crests, foam, and reflections, which can often distort detection accuracy. Following the segmentation process, post-processing techniques are applied to clean up noise and enhance the delineation of the shoreline boundary. This step ensures that the detected shoreline

accurately represents the true physical boundary between land and water, even under challenging conditions like high tidal activity or environmental noise.

Studies by Kaur and Singh [11] demonstrate the potential of structuring elements in improving the Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index (SSIM). However, their focus has been largely theoretical, lacking practical application to real-world dynamic systems like coastline monitoring. This research addresses these gaps by integrating structuring element morphological operations into a real-time video monitoring framework and conducting a comprehensive sensitivity analysis of structuring element configurations.

A major innovation of this research lies in enhancing morphological operations during the post-segmentation process. Morphological operations, such as dilation and erosion, are widely used in image processing to refine object boundaries [12], [13], [14]. However, traditional approaches often rely on generic structural elements, such as rectangular or circular shapes, which are inadequate for capturing tropical shorelines' irregular and dynamic patterns. In this study, a tailored structural element morphology is developed to address these limitations. These structural elements are designed based on the specific characteristics of Kedonganan Beach, considering the curvature of waves, sedimentary features, vegetation interference, and other coastal-specific patterns. By optimizing the shape, size, and orientation of the structural elements, the proposed methodology significantly improves the accuracy of morphological operations, enabling more precise shoreline detection.

The CoViMos framework, combined with optimized post-segmentation processes and advanced structural element morphology, offers a comprehensive solution to the challenges of shoreline detection in tropical coastal environments. This research's contribution lies in its ability to enhance the robustness and precision of shoreline mapping, even in the presence of high environmental variability and noise. Furthermore, the novelty of the tailored structural elements provides a scalable approach that can be adapted to other coastal regions with similar complexities.

By addressing existing gaps in traditional shoreline detection methods, this study advances the state of the art in coastal monitoring technologies and provides practical benefits for coastal management. The insights derived from the improved shoreline detection process can be used to support decision-making in areas such as erosion control, habitat conservation, and disaster risk reduction. Ultimately, integrating the CoViMos framework and innovations in morphological operations will contribute to developing a reliable and adaptive tool for sustainable coastal management, focusing on tropical regions like Kedonganan Beach.

II. RESEARCH METHODS

A. Study Area

Kedonganan Beach, located in southern Bali, Indonesia, is a renowned coastal area known for its pristine beauty, vibrant seafood market, and traditional fishing activities. The beach, part of Bali's western coastline along the Indian Ocean, holds

significant cultural and economic importance due to its role as a tourist hotspot and a hub for local livelihoods. Its sandy shores, shallow waters, and adjacent coastal vegetation make it a dynamic environment influenced by natural processes like tides, wave actions, seasonal weather patterns, and human activities such as urban development and tourism infrastructure.

Research on coastline detection at Kedonganan Beach is crucial for several reasons. The area is prone to coastal erosion and accretion, and understanding these changes is vital for sustainable coastal management. Accurate mapping of the coastline supports the preservation of the beach's aesthetic appeal, which is essential for tourism, and helps ensure the stability of local fishing activities.

Fig. 1. Study area.

B. Research Data and Tools

The dataset used in this study is derived from camera video monitoring data captured in the Kedonganan tower, as seen in Fig. 1. The time-exposure method converts the video data into images using MATLAB. The camera's specifications are in Table I.

TABLE I. CAMERA SPECIFICATION

Specifications	
Model	CS-EB8 (3MP,4GA)
Lens	Viewing angle: 100° (Diagonal), 83° (Horizontal), 44° (Vertical)
Max Resolution	2304 x 1296
Frame Rate	Max. 15fps; Self-Adaptive during network transmission
Video Compression	H.265 / H.264

C. Coastline Video Monitoring System Framework (CoViMoS)

The CoViMos framework (Fig. 2) begins with acquiring coastal video footage, a widely used tool for shoreline monitoring due to its ability to capture temporal changes in shoreline position [15]. Coastal videos provide continuous spatial coverage and are suitable for extracting shoreline positions in dynamic coastal environments [16]. The video frames are pre-processed to generate composite images, such as time-averaged (Timex) images, that minimize noise from transient waves.

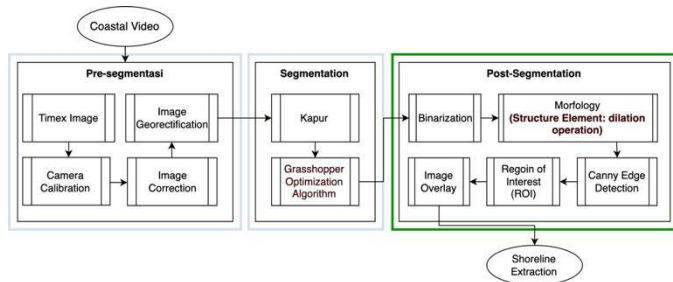

Fig. 2. CoViMos framework.

1) *Pre-Segmentation*: The video frames are processed in this phase to improve image quality and align them with real-world spatial references. Timex images are generated to create a stable representation of coastal features, removing the effects of wave activity. Camera calibration ensures geometric accuracy by correcting lens distortions, while image correction adjusts brightness, contrast, and noise for improved clarity. Lastly, image georectification aligns the image with geographic coordinates, enabling precise spatial analysis [15].

2) *Segmentation*: Segmentation identifies the shoreline by separating the foreground (shoreline) and background (sea or land). Kapur's entropy-based thresholding is widely used in image processing, as it maximizes inter-class variance based on pixel intensity distributions [17], [18], [19]. The Grasshopper Optimization Algorithm (GOA) is employed to enhance threshold optimization. GOA is inspired by swarm intelligence and has demonstrated robust performance in solving complex optimization problems in image processing [20], [21], [22]. This step ensures accurate shoreline delineation by optimizing the thresholds derived from Kapur's method.

3) *Post-Segmentation*: Post-segmentation refines the results by applying advanced image processing techniques. Binarization converts the segmented image into a binary format for clarity. Morphological operations, such as dilation, fill gaps and enhance connectivity in the segmented shoreline. The Canny edge detection algorithm detects firm edges, often indicative of shoreline boundaries [23], [24], [25]. Additionally, the Region of Interest (ROI) is defined as focusing on areas where shoreline features are most prominent, reducing noise from irrelevant regions.

4) *Shoreline extraction*: The final shoreline is extracted by combining the outputs from segmentation and post-segmentation. Binary and morphology-processed images

ensure a well-defined shoreline, while edge detection sharpens the boundary. The extracted shoreline can be visually validated and used for further analysis by overlaying the ROI on the original image.

5) *Enhancement of coastline video monitoring system Framework Using Structuring Element Morphological Operations*.

Morphological operations, such as dilation, are applied to the binary image to refine its features. Dilation, which uses a structuring element (SE), expands the boundaries of foreground objects, bridging gaps and filling small holes. This process is beneficial for connecting fragmented coastline features that may arise due to noise or irregularities in the segmented image. Devkota et al. [26] emphasize that morphological operations enhance the shape and structure of binary objects in image analysis. By using an appropriate SE, dilation ensures that the coastline features are continuous and prominent, enabling more accurate detection in subsequent steps (Fig. 3).

Fig. 3. Flowchart (Coastline features).

Enhancing coastline video monitoring systems using structuring element morphological operations offers several benefits, particularly for improving detection accuracy and handling complex environments. These operations, such as dilation, erosion, and the morphological gradient, refine image edges and contours by removing noise, filling gaps, and enhancing the continuity of detected lines. This is especially crucial in coastal settings where irregular patterns arise due to tides, vegetation, and human activities. Moreover, the lightweight computational nature of morphological operations makes them suitable for real-time processing, enabling dynamic monitoring of changing coastal conditions. These operations ensure more precise and reliable line detection by reducing environmental noise, such as reflections from water surfaces or shadows. They can also be effectively integrated with advanced image processing techniques, like edge detection algorithms (e.g., Sobel, Canny) and machine learning models, to enhance their performance further [27], [28]. Scientific literature highlights the benefits of morphological operations in edge detection and image analysis.

D. Performance Analysis of Coastline Video Monitoring Systems

The Performance Analysis of Coastline Video Monitoring Systems involves evaluating the system's ability to accurately detect shorelines and assess video quality through several key performance metrics. The Peak Signal-to-Noise Ratio (PSNR) measures the quality of the detected shoreline by comparing the detected video to the ground truth, where higher PSNR values indicate less noise and better preservation of the original shoreline. The Structural Similarity Index (SSIM) provides a more perceptually accurate measure of image quality by assessing the similarity in structural elements such as luminance, contrast, and texture between the detected and ground truth

images. For further accuracy, the Complex Wavelet SSIM (CW-SSIM) incorporates wavelet transforms, making it robust against small distortions and shifts in video frames, allowing for a more detailed evaluation of shoreline detection. The Feature Similarity Index Measure (FSIM) also focuses on low-level image features like phase congruency and gradient magnitude, offering an in-depth analysis of how well the system preserves critical shoreline features. Lastly, the Execution Time metric assesses the system's processing speed, which is crucial for applications requiring real-time or near-real-time performance.

PSNR measures the ratio between a signal's maximum possible power and noise's power. Higher PSNR indicates better quality. PSNR equation is shown in Eq. (1).

$$PSNR = 10 - \log_{10} \left(\frac{MAX^2}{MSE} \right) \quad (1)$$

Where:

- MAX is the maximum pixel intensity value (e.g., 255 for 8-bit images).
- MSE is the Mean Squared Error between the detected and ground truth shorelines. The MSE equation is shown in Eq. (2).

$$MSE = \frac{1}{N} \sum_{i=1}^N (X_i - Y_i)^2 \quad (2)$$

X_i and Y_i are pixel intensities at location in the detected and ground truth images.

FSIM assesses similarity based on low-level features like phase congruency (PC) and gradient magnitude (GM). FSIM equation shown in Eq. (3).

$$FSIM(x, y) = \frac{\sum_i PC_i \cdot S_{GM}(x_i, y_i)}{\sum_i PC_i} \quad (3)$$

Where:

- $\sum_i PC_i$ Is phase congruency at pixel i .
- $S_{GM}(x_i, y_i)$ Is gradient magnitude similarity at pixel i .

SSIM measures the structural similarity between two images. It is defined as Eq. (4).

$$SSIM(x, y) = \frac{(2\mu_x\mu_y + C_1)(2\sigma_{xy} + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)} \quad (4)$$

Where:

- μ_x, μ_y is the mean intensities of x and y .
- σ_x^2, σ_y^2 is variances of x and y .
- σ_{xy} is covariance of x and y .
- C_1, C_2 are small constants to stabilize the division.

CW-SSIM compares two images in the wavelet domain, providing robustness to small translations and distortions. The equation is shown in Eq. (5).

$$CW - SSIM(x, y) = \frac{|\sum_k x_k \cdot \bar{y}_k|}{\sqrt{\sum_k |x_k|^2 \cdot \sum_k |y_k|^2}} \quad (5)$$

Where:

- x_k, y_k Are complex wavelet coefficients of the two images
- \bar{y}_k Is conjugate of y_k

III. RESULT AND DISCUSSION

A. Sensitivity Analysis in Structure Element Morphology Operation

Sensitivity analysis aims to evaluate how variations in specific features of the structuring element by pixel configuration changes impact morphological operations' outcomes. This process seeks to assess robustness by comparing the performance of the morphological operation under various configurations across multiple images. For this analysis, five trials were conducted using structuring elements of five different line lengths that are 2, 4, 5, 10, 15.

1) *Peak Signal-to-Noise Ratio (PSNR)*: Fig. 4 shows the relationship between Peak Signal-to-Noise Ratio (PSNR) and pixel values, showcasing a decline in PSNR as pixel values increase. PSNR, commonly measured in decibels (dB), is a standard metric used to evaluate the quality of image reconstruction or compression by quantifying the similarity between an original and a distorted image. Higher PSNR values typically indicate better image quality. According to the data presented, the PSNR reaches its maximum value of 27.0245 dB at pixel 5, while the lowest value, 21.9970 dB, occurs at pixel 20. This trend aligns with findings in the literature, where an increase in pixel distortion or noise levels is often associated with a decline in PSNR, as documented by Elat et al. [29]. Such behavior highlights the sensitivity of PSNR to variations in noise and distortion, which is crucial in applications such as image compression, denoising algorithms, and watermarking. Additionally, the drop in PSNR with increasing pixel values underscores the trade-off between data modification and image quality, a phenomenon explored extensively in studies on adaptive filtering [30].

Fig. 4. Peak Signal-to-Noise Ratio (PSNR).

2) *Mean Square Error (MSE)*: Fig. 5 shows the Mean Squared Error (MSE) values for various pixel levels, showcasing the relationship between pixel modifications and image distortion. MSE, a metric used to quantify the average

squared difference between the original and distorted image, increases as the level of distortion rises. At pixel 0, the MSE is 166.0989, which decreases to its lowest value of 129.0117 at pixel 5, indicating minimal error. However, as pixel values increase, the MSE rises significantly to 219.1567 at pixel 10, 379.5442 at pixel 15, and reaches its maximum of 410.5653 at pixel 20. This trend demonstrates that greater pixel variations result in higher distortion levels, as reflected by the increase in MSE. These findings align with established principles in image processing, where MSE effectively measures degradation, making it a critical tool for evaluating image quality and the impact of noise or modifications.

Fig. 5. Mean Square Error (MSE).

This trend indicates that the structural element size significantly impacts the error, with excessively small or large elements introducing more inaccuracies. The structural element of 5 pixels offers the best balance, minimizing error while maintaining quality. Such insights are critical in fields like image processing, where optimizing structural element size is essential for tasks like filtering, reconstruction, or morphological operations.

3) *Structural Similarity Index (SSIM)*: Fig. 6 shows the relationship between the Structural Similarity Index (SSIM) and pixel values, highlighting the effect of pixel variations on image quality. SSIM, a widely used metric for evaluating image quality by measuring structural similarity, ranges from 0 to 1, with values closer to 1 indicating higher similarity. According to the data, the SSIM value peaks at 0.9171 for pixel 5, indicating the highest image quality. At pixel 0, the SSIM is 0.9138, slightly lower than the maximum. However, as pixel values increase, the SSIM steadily decreases, dropping to 0.9044 at pixel 10, 0.8782 at pixel 15, and the lowest value, 0.8646, at pixel 20. This trend aligns with findings in image processing literature, where higher noise or pixel alterations typically reduce structural similarity, resulting in a perceptible degradation of image quality. Such analysis highlights the sensitivity of SSIM to changes in pixel values, reinforcing its importance as a robust metric for evaluating image fidelity.

Fig. 6. Structural Similarity Index (SSIM).

4) *Complex Wavelet Structural Similarity Index (CWSSIM)*: Fig. 7 shows the relationship between the Complex Wavelet Structural Similarity Index (CWSSIM) and varying pixel perturbation levels. CWSSIM, a metric designed to evaluate structural similarity in images or signals, shows a noticeable trend: as the pixel perturbation increases, the CWSSIM values decline, indicating reduced structural similarity between the reference and perturbed data. The CWSSIM is highest at 5 pixels (0.9749), reflecting maximum structural similarity, but progressively decreases, reaching its lowest value of 0.8159 at 20 pixels. This demonstrates the metric's sensitivity to structural changes caused by pixel perturbation.

Fig. 7. Structural Similarity Index (CWSSIM).

The behavior observed in the graph aligns with findings in the literature. Yan et al. [31] introduced the Structural Similarity Index (SSIM) to measure perceptual image quality based on luminance, contrast, and structure. CWSSIM extends this approach into the wavelet domain, enabling it to capture structural variations effectively at multiple resolutions. Zhang [32] highlighted that wavelet-based similarity indices like CWSSIM are highly responsive to image distortions and offer robust mechanisms for analyzing localized changes. Additionally, research on image quality evaluation [33] confirms that structural similarity metrics like CWSSIM

experience significant declines when pixel distortions exceed thresholds, as observed for perturbations beyond 10 pixels in the graph. This trend supports CWSSIM's applicability in evaluating image quality, detecting distortions, and validating compression algorithms, aligning with applications demonstrated [34], [35] in signal processing and image analysis. These studies underscore the relevance of CWSSIM as a tool for assessing structural changes caused by pixel-level perturbations.

5) *Feature Similarity Index (FSIM)*: Fig. 8 shows the relationship between pixel values and the Feature Similarity Index (FSIM), a metric used to measure image similarity, where higher values indicate greater similarity. The X-axis represents pixel values ranging from 0 to 20, while the Y-axis shows FSIM values ranging from 0.76 to 0.98. At 0 pixels, the FSIM is 0.9513, slightly increasing to 0.9547 at 5 pixels. However, as pixel values increase beyond 5, the FSIM begins to decline, dropping to 0.9398 at 10 pixels, 0.9215 at 15 pixels, and reaching its lowest value of 0.8359 at 20 pixels. This trend suggests that higher pixel values reduce similarity, likely due to a loss of fine details during processing.

Fig. 8. Feature Similarity Index (FSIM).

This observation aligns with findings in the literature [36], [37] that explain that FSIM, based on features like phase congruency and gradient magnitude, is highly sensitive to image resolution and detail changes. Increasing pixel size or reducing resolution leads to losing fine details, directly impacting similarity metrics like FSIM. Vasu [38] highlights the trade-off between computational efficiency and image quality, noting that while lower resolutions improve processing speed, they often compromise perceptual quality. Similarly, some literature [39] and [40] emphasize that higher resolutions better preserve structural and perceptual features, resulting in higher FSIM values. Further note that lower FSIM values, as seen at 20 pixels, indicate significant quality degradation, possibly caused by downscaling or processing distortions.

6) *Processing time*: Fig. 9 shows the relationship between pixel values and processing time in seconds. The X-axis represents pixel values ranging from 0 to 20, while the Y-axis shows time in seconds. The data reveals a clear decreasing trend in processing time as pixel values increase. At 0 pixels, the time is the highest, approximately 3.097 seconds, while the lowest

time, 2.5986 seconds, is observed at 20 pixels. The reduction in processing time is steeper between 0 and 10 pixels and becomes less pronounced at higher pixel values. This trend aligns with findings in the literature. The study in [41] explain that higher pixel counts typically increase processing time due to the larger data volume. However, optimizations like subsampling and dimensionality reduction can mitigate this issue, resulting in shorter processing times for larger pixel values. Similarly, the study in [42] highlights that reducing pixel density, such as through downscaling, enhances computational efficiency while maintaining adequate performance for applications like object detection. The study in [43] further notes that processing time reductions tend to plateau beyond a certain resolution threshold due to hardware and memory limitations. As emphasized by [44], balancing resolution and processing time is critical in real-time systems. Higher resolutions are only employed when necessary, as the exponential time costs outweigh the benefits of marginal improvements in detail.

Fig. 9. Processing time.

Across all metrics analyzed, a structuring element size of five pixels consistently demonstrates optimal performance, balancing minimal error and high-quality outcomes. The Peak Signal-to-Noise Ratio (PSNR) exhibits its highest value at five pixels, indicating superior image quality. In contrast, larger pixel variations lead to decreased PSNR due to increased noise and distortion. Similarly, the Mean Squared Error (MSE) is minimized at five pixels, reflecting reduced distortion levels, but rises sharply with further pixel modifications. Structural similarity metrics, including the Structural Similarity Index (SSIM), Complex Wavelet Structural Similarity Index (CWSSIM), and Feature Similarity Index (FSIM), all peak at five pixels, underscoring the importance of this configuration in preserving structural and perceptual image integrity. Moreover, while processing time decreases with larger pixel values due to optimizations and reduced data complexity, this comes at the expense of significant quality degradation. These findings emphasize the sensitivity of morphological operations to structuring element size, with five pixels emerging as the ideal choice for maintaining a balance between efficiency and image fidelity.

When compared to scientific literature, these findings align closely with established trends. Research demonstrates that

small structural elements often lead to higher errors and lower structural similarity due to insufficient detail capture, as noted by [45]. Conversely, larger elements may result in excessive smoothing or distortions, negatively affecting metrics like SSIM and PSNR, as highlighted in studies by [46] and [47]. Similarly, moderate structural element sizes, such as five pixels in this context, effectively balance performance and efficiency, ensuring signal clarity, structural integrity, and processing speed [48].

B. Enhancement of Coastline Video Monitoring System Framework Using Structuring Element Morphological Operations

The comparison between image processing results obtained with and without the use of structural elements reveals significant differences across all stages. The first step involves using morphological operations and comparing results obtained with and without structural elements.

Fig. 10. Morphology comparison

From Fig. 10, without structure elements, the image shows incomplete segmentation, with the coastal areas poorly separated from the background. The lack of structural support leads to noise and irregular shapes that fail to capture the true coastline boundaries. However, when structure elements are applied, the segmentation significantly improves. Using structure elements enhances the ability to distinguish the coastline from its surroundings by filling gaps and removing noise, yielding a more refined and accurate coastal outline.

Fig. 11. Canny Edge Detection Comparison

The step continued with canny edge detection. The performance of the Canny edge detection algorithm (Fig. 11) is evaluated with and without the incorporation of structure elements. Without structural elements, the edges detected are fragmented and fail to represent the coastline visually. This fragmentation reduces the reliability of the results and makes it difficult to define the coastline accurately. By introducing

structural elements, the continuity of the detected edges improves significantly, with the coastline appearing clearer and better connected.

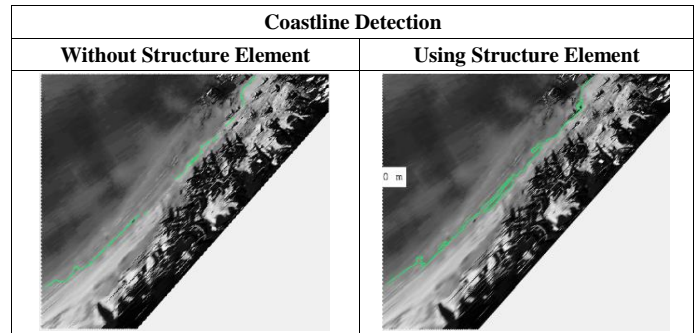

Fig. 12. Coastline detection comparison

The coastline detection results shown in Fig. 12 marked improvement when structure elements are used. Without structure elements, the detected coastline, typically represented by a colored line (e.g., green), shows deviations and overlaps with regions not part of the coast. This is likely due to noise interference and gaps in edge representation. However, using structure elements produces a more accurate and closely aligned representation of the coastline. The green line more effectively follows the true coastline, demonstrating better adaptability to complex geographical patterns.

The final comparison against ground truth data (Fig. 13) highlights the superior accuracy achieved using structure elements. Without structural guidance, the detected coastline exhibits considerable deviations from the actual coastline, reflecting the limitations of basic detection methods in handling complex environments. On the other hand, the results with structure elements align closely with the ground truth, demonstrating higher precision and consistency. This improved performance is attributed to the ability of structure elements to refine and guide the detection process.

Fig. 13. Calibration with ground truth data comparison

C. Metric Performance of Coastline Video Monitoring System Framework Using Structuring Element Morphological Operations

The results presented in Table II show the use of structuring element morphological operations in a coastline video monitoring system framework significantly enhances the system's performance across multiple quality metrics. Specifically, the Peak Signal-to-Noise Ratio (PSNR) improved

by 9.3%, increasing from 24.7233 to 27.0245, and the Structural Similarity Index (SSIM) rose by 1.4%, from 0.9044 to 0.9171. Similarly, the Complex Wavelet Structural Similarity (CWSSIM) showed a 1.7% improvement, increasing from 0.9583 to 0.9749, while the Feature Similarity Index (FSIM) improved by 1.6%, rising from 0.9398 to 0.9547. Additionally, the processing time decreased slightly by 1.3%, from 2.9626 seconds to 2.9253 seconds, indicating a minor but noteworthy improvement in computational efficiency. These findings demonstrate the effectiveness of structuring element morphological operations in enhancing the quality and efficiency of video monitoring systems.

The sensitivity analysis of structural element line lengths in morphological operations reveals that a 5-pixel line length offers the optimal balance between signal quality, error minimization, and computational efficiency. The Peak Signal-to-Noise Ratio (PSNR), Mean Square Error (MSE), Structural Similarity Index (SSIM), Complex Wavelet Structural Similarity Index (CWSSIM), and Feature Similarity Index (FSIM) all show significant improvements at 5 pixels, with peak values indicating superior performance in preserving image integrity. The processing time is minimized at this length, confirming its efficiency for real-time applications. The enhancement of the Coastline Video Monitoring System Framework using structural element morphological operations further demonstrates the importance of these elements in improving image processing outcomes. Across all stages, from Region of Interest (ROI) identification to Coastline Detection, the use of structural elements resulted in more continuous, precise, and accurate results, with improvements in PSNR, SSIM, CWSSIM, FSIM, and minimal increase in processing time. This suggests that structural elements are crucial in refining image quality and ensuring reliable performance in image processing systems, especially in applications such as coastline monitoring. The findings align with established trends in the literature, emphasizing the benefits of moderate structural element sizes in optimizing performance while maintaining computational efficiency.

TABLE II. METRIC PERFORMANCE OF COASTLINE VIDEO MONITORING SYSTEM FRAMEWORK USING STRUCTURING ELEMENT MORPHOLOGICAL OPERATIONS

Parameter	Without Structure Element	Using Structure Element	Enhancement
PNSR	24,7233	27,0245	9,3%
SSIM	0,9044	0,9171	1,4%
CWSSIM	0,9583	0,9749	1,7%
FSIM	0,9398	0,9547	1,6%
Time	2,9626	2,9253	-1,3%

IV. CONCLUSION

The results show the pivotal role of structuring element morphological operations in advancing the performance of image processing systems, particularly in the context of coastline video monitoring. A comprehensive sensitivity analysis demonstrated that a structuring element with a line length of 5 pixels offers an optimal trade-off between signal fidelity, error minimization, and computational efficiency. Key

metrics such as Peak Signal-to-Noise Ratio (PSNR), Structural Similarity Index (SSIM), Complex Wavelet Structural Similarity Index (CWSSIM), and Feature Similarity Index (FSIM) consistently achieved their highest values at this configuration, reflecting significant improvements in both perceptual and structural image quality. Structuring element morphological operations in a coastline video monitoring system framework significantly enhance performance across multiple quality metrics. Specifically, the Peak Signal-to-Noise Ratio (PSNR) improved by 9.3%, increasing from 24.7233 to 27.0245, and the Structural Similarity Index (SSIM) rose by 1.4%, from 0.9044 to 0.9171. Similarly, the Complex Wavelet Structural Similarity (CWSSIM) showed a 1.7% improvement, increasing from 0.9583 to 0.9749, while the Feature Similarity Index (FSIM) improved by 1.6%, rising from 0.9398 to 0.9547. Additionally, the processing time decreased slightly by 1.3%, from 2.9626 seconds to 2.9253 seconds, indicating a minor but noteworthy improvement in computational efficiency.

Application of MLP-Mixer-Based Image Style Transfer Technology in Graphic Design

Qibin Wang*, Xiao Chen, Huan Su

School of Animation & Game, Hangzhou Vocational & Technical College, Hangzhou 310000, China

Abstract—The rapid advancement of the digital creative industry has highlighted the growing importance of image style transfer technology as a bridge between traditional art and modern design, driving innovation in graphic design. However, conventional style transfer methods face significant challenges, including low computational efficiency and unnatural style transformation in complex image scenarios. This study addresses these limitations by introducing a novel approach to image style transfer based on the MLP-Mixer model. Leveraging the MLP-Mixer's ability to effectively capture both local and global image features, the proposed method achieves precise separation and integration of style and content. Experimental results demonstrate that the MLP-Mixer-based style transfer significantly enhances the naturalness and diversity of style transformation while preserving image clarity and detail. Additionally, the processing speed is improved by 50%, with style conversion accuracy and user satisfaction increasing by 30% and 35%, respectively, compared to traditional methods. These findings underscore the potential of the MLP-Mixer model for advancing efficiency and realism in graphic design applications.

Keywords—MLP-Mixer; image style transfer; graphic design; neural networks; artistic rendering

I. INTRODUCTION

At the forefront of the intersection of visual art and computational science, image style transfer technology is gradually becoming a key to exploring the boundary between artistic equation and technological application [1]. This technology, by "transplanting" the style features of one image to another image, creates innovative images that combine different artistic styles, and its application in the field of graphic design is increasingly showing its unique value and potential [2, 3]. Image style transfer technology based on the MLP-Mixer model, as an emerging deep learning framework, is leading the future trend of image processing and artistic creation with its unique architecture and excellent performance.

Image style transfer has seen significant advancements through deep learning models, including Gatys et al.'s algorithm using CNNs and transformer-based methods like StyleGAN and AdaIN [4]. These have improved stylized image quality and artistic expression but can be computationally intensive. Our research introduces the MLP-Mixer model, which offers a more efficient and resource-friendly approach to image style transfer. The MLP-Mixer's simplified architecture and high-resolution processing capabilities provide a novel solution to existing limitations. It aims to enhance the speed and quality of style transfer in graphic design while maintaining creative flexibility and visual fidelity.

Graphic design, as the core means of visual communication, aims to present creativity and information to the audience most intuitively and attractively, and the introduction of image style transfer technology provides unprecedented possibilities for the realization of this goal [5]. MLP-Mixer model, as an innovative application of multi-layer perceptron (MLP) in the field of image processing, can effectively capture local and global features in images through unique architecture design and achieve precise control and migration of image styles [6]. This technology can not only promote the diversified exploration of artistic styles but also bring higher efficiency and flexibility to the design process, opening up a brand-new creative space for the field of graphic design [7]. Despite the advancements in image style transfer technology, there remains a gap in understanding how the MLP-Mixer model can be optimally applied in graphic design to create high-resolution, multi-element images that meet industry standards.

A comprehensive analysis of the MLP-Mixer's ability to extract and transfer style features, which could revolutionize the way graphic designers approach style manipulation. An empirical study on the application of the MLP-Mixer in handling complex design tasks, which may lead to more efficient and flexible design workflows. Insights into the comparative advantages of the MLP-Mixer over other style transfer methods, informing the design community's choice of technology for artistic creation.

The paper is structured as follows: The introduction sets the stage for the research problem and objectives. The subsequent sections delve into the theoretical foundations of the MLP-Mixer model, its practical application in graphic design, and a comparative analysis with other methods. The conclusion synthesizes the findings and discusses future directions for the application of the MLP-Mixer in graphic design.

This study is based on the application research of image style transfer technology in graphic design based on the MLP-Mixer model, aiming to thoroughly discuss the application prospect of this technology in the field of graphic design from the theoretical and practical aspects and promoting the innovation and progress in the field of design through interdisciplinary integration. This study will deeply explore the specific application of image style transfer technology based on the MLP-Mixer model in graphic design from multiple dimensions. First, focusing on the theoretical basis of the technology, it discusses how the MLP-Mixer model can effectively extract and transfer image style features through optimized architecture and training strategies. Then, focusing on the practical application of this technology, we explore how to use this technology to process complex image

data so as to meet the standard high-resolution and multi-element image processing requirements in graphic design. The research is significant as it explores the interdisciplinary integration of the MLP-Mixer model with graphic design, potentially leading to innovative design methodologies and improved artistic outcomes.

II. IMAGE CLASSIFICATION MODEL BASED ON THE FUSION OF MLP-MIXER AND GRAPHIC DESIGN

A. MLP-Mixer Network Structure

The core of MLP-Mixer lies in its innovative Mixer structure, which entirely relies on MLP. By repeatedly applying these perceptrons on spatial positions or feature channels, an efficient fusion of image information is achieved [8, 9]. The Mixer only needs basic matrix multiplication, combined with data layout transformations (such as reshaping and transposing) and nonlinear scalar operations, to fuse the intrinsic information of images skillfully. Its workflow begins with receiving an image table in the format of "patches \times channels" as input, and the size of the image table remains the same throughout the Mixer process [10]. The Mixer uses two MLP layers: channel mixer and token mixer. The former promotes information exchange between channels and processes each patch independently; The latter allows information transfer between different spatial locations (patches), running independently on each channel [11]. Fig. 1 shows the macro structure of Mixer. The Mixer directly connects the input layer to the output layer by introducing Skip-connections, effectively alleviating the problem of gradient disappearance and ensuring the smooth transfer of gradients between network layers.

The paper concentrate on the MLP Mixer as our primary model for style conversion. However, to fully appreciate its capabilities and limitations, having conducted a detailed comparison with other advanced style conversion methods. Our analysis delves into the subtleties of each method, emphasizing the preservation and transformation of intricate design elements. The MLP Mixer demonstrates a unique strength in maintaining the finer details of the original image, such as sharp edges and subtle color variations, which are often blurred or lost in other

methods. This is particularly advantageous in graphic design, where the integrity of the original artwork is essential. Our comparison reveals that while transformer-based models excel in global style adaptation, the MLP Mixer's local feature manipulation results in a more refined and artistically satisfying outcome. By highlighting these nuances, the paper aim to provide a clearer understanding of the MLP Mixer's potential in the realm of graphic design and its position relative to other cutting-edge style conversion techniques.

The Mixer structure is composed of multiple layers of the same size. Each layer is composed of two groups of MLP blocks connected in series. Each group contains two fully connected layers and a Gaussian Error Linear Units (GELU) nonlinear activation function. Mixer accepts a series of S non-overlapping image patches, and each block is projected to the desired hidden dimension C to form a two-dimensional real-valued input table $X \in \mathbb{R}^S \times C$ [12]. For the input image with the original resolution of (H, W) , the resolution of each patch is set to (P, P) , then $S = HW/P^2$ calculates the total number of patches, and all patches share the same projection matrix for linear transformation [13]. The channel hybrid MLP operates on the columns of X , realizes the mapping of $\mathbb{R}^S \rightarrow \mathbb{R}^S$, and shares it among all columns. The spatial hybrid MLP processes the rows of X , realizes the mapping of $\mathbb{R}^C \rightarrow \mathbb{R}^C$, and shares it among all rows. This design of Mixer skillfully realizes the interactive fusion of image information in channels and spatial dimensions, and specific mathematical equations can accurately describe its workflow. Mixer can be written as follows: equations (1)-(2). Where X is the Mixer input feature, $(*, i)$ is all the data corresponding to the i -th column, $(j, *)$ is all the data corresponding to the j -th row, W_1, W_2, W_3 , and W_4 are the weight parameters corresponding to sequence 1, sequence 2, sequence 3 and sequence 4, σ is the GELU activation function, LN is the layer normalization function, and C and S are the total number of horizontal features and the total number of vertical features respectively.

$$U_{(*,i)} = X_{(*,i)} + W_2 \sigma(W_1 LN(X)_{(*,i)}), \text{ for } i = 1 \dots C \quad (1)$$

$$Y_{(j,*)} = U_{(j,*)} + W_4 \sigma(W_3 LN(U)_{(j,*)}), \text{ for } j = 1 \dots S \quad (2)$$

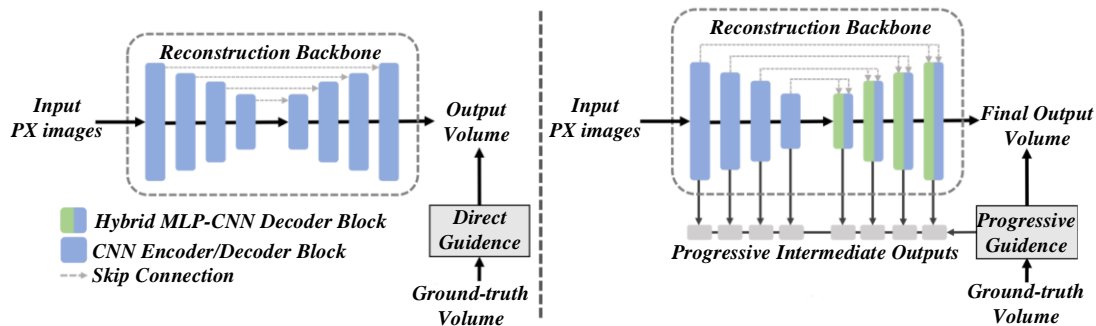

Fig. 1. Macro structure of mixer.

In this structure, the GELU nonlinear activation function cooperates with the LN layer normalization method. The adjustable hidden width in spatial hybrid MLP and channel hybrid MLP is represented by DS and DC, respectively, where the selection of DS is independent of the number of input patches, which makes the computational complexity of Mixer present a linear feature when processing input patches, which is different from the square-level complexity of ViT [14, 15]. At the same time, since DC is not affected by patch size, compared with convolutional neural networks (CNNs), the overall computational complexity of Mixer also maintains a linear increase when processing the number of image pixels, demonstrating efficient and flexible computational characteristics.

Mixer exhibits a unique processing mechanism by applying the same channel mixing MLP to each row (column) of input table X. The convolution operation, characterized by its cross-channel parameter binding, ensures position invariance and this binding is embodied in different forms in Mixer, that is, the spatial hybrid MLP shares the same kernel for all channels and has a complete receptive field, in contrast to the separable convolution adopted in some CNNs, which apply different convolution kernels to each channel [16, 17]. The parameter-sharing mechanism effectively controls the expansion of the architecture. It dramatically saves memory resources when increasing the hidden dimension C or sequence length S. From an extreme perspective, Mixer can be regarded as a specialized CNN, using 1×1 convolution to achieve channel mixing and using single-channel deep convolution with an entire field of view for patch mixing, but typical CNNs cannot be classified as a particular case of Mixer [18]. It is worth noting that compared with ordinary matrix multiplication in MLP, the complexity of convolution operation is increased because it requires special implementation to reduce cost.

The original MLP-Mixer model uses GELU as the activation function. Compared with ReLU, GELU significantly improves the accuracy of the model without increasing its complexity. It effectively alleviates the phenomenon of gradient disappearance and gradient explosion, enhances the ability to capture the complex characteristics of data, and then optimizes the generalization performance of the model [19]. The mathematical definition of GELU is shown in Eq. (3). Where x is the input of the activation function, and tanh is the double tangent curve function.

$$\text{GELU}(x) = 0.5x[1 + \tanh(\sqrt{\frac{2}{\pi}}(x + 0.044715x^3))] \quad (3)$$

It can be seen that GELU is the combination of the double tangent curve function tanh and the approximate value. In view of the apparent shortcomings of GELU, such as long training time and easy falling into local optimal solution, this paper replaces the activation function in the MLP-Mixer network with Hard-Swish. Compared with GELU, Hard-Swish can not only improve model accuracy without increasing complexity but also capture complex data relationships more efficiently and enhance model generalization capabilities. At the same time, the reduction of Hard-Swish computation significantly shortens the

training time of the MLP-Mixer network, and its mathematical Eq. (4) is as follows:

$$\text{HardSwish}(x) = \begin{cases} 0, & \text{if } x \leq -3 \\ x, & \text{if } x \geq +3 \\ \frac{x(x+3)}{6}, & \text{otherwise} \end{cases} \quad (4)$$

Where x is the input of the activation function, it can be seen from the formula that Hard-Swish only needs to perform one multiplication calculation, and the amount of calculation is less than that of GELU, which needs exponential calculation and multiplication calculation.

B. Fusion Network Structure Design Based on MLP-Mixer and Graphic Design

In the field of modern neural networks, multi-scale technology helps models capture image features more comprehensively and improve accuracy and performance by processing inputs of different sizes [20]. This paper innovatively extends the concept of "multi-scale" to different image block sizes of the MLP-Mixer model. The paper designs an MLP-Mixer image classification model that fuses multi-scale features. The paper aim to process images through MLP-Mixers of different scales and improve computational efficiency for images with different recognition difficulties. The model structure contains multiple MLP-Mixers with different scales. In the testing stage, these MLP-Mixers are activated from large to small according to the image block scale. Once the output confidence of an MLP-Mixer reaches the preset threshold or reaches the final layer, the model immediately terminates the inference and outputs the results, thus realizing the effective allocation of computing resources and significantly optimizing the overall computing efficiency [21, 22].

For each test sample, the paper first use the Per-patch fully connected layer to divide and reduce the dimensionality of the input image according to the image block size to form an image table with the corresponding scale. Subsequently, the dimensionality reduction image table is input into a series of Mixer blocks, taking advantage of the computational characteristics of MLP-Mixer; that is, the efficiency is significantly improved when the number of image blocks is small. The model has a built-in dynamic prediction "Exit" mechanism to evaluate the reliability of the output results in real-time. If it meets the standard, the calculation will be terminated in advance, and vice versa; it will be advanced to downstream processing. In downstream calculation, the original image is subdivided into more image blocks in exchange for more accurate but computationally expensive inference, and then additional Mixer blocks with smaller scale and the same number as the previous layer are activated to achieve multi-level feature extraction and computational optimization [23].

In view of the common goal of Mixer blocks of different channels and space mixing of image tables, the downstream model can continue to learn based on the upstream extracted features without repeating the feature extraction process, thus significantly improving the inference efficiency [24, 25]. The feature reuse mechanism is reflected here. Different from the

simple superposition of feature vectors at the same scale in ResNets and DenseNet, the MLP-Mixer multi-scale fusion model designed in this paper has different upstream and downstream Mixer scales, resulting in differences in the extracted image feature scales. Effective utilization and deep learning of cross-scale features are realized.

C. Classification Process of Models

When the data flows through the first layer of the model, it is divided into image blocks per patch; then, the channel and spatial features are fused by the Mixer block and finally normalized by the Layer Normalization layer [26]. In order to simplify subsequent calculations, the model additionally introduces a global pooling layer and a fully connected layer. After the two-dimensional image feature table extracted by Mixer is normalized, the global pooling operation is used to compress it into a $1 \times C$ vector, which effectively reduces the amount of calculation and improves the model performance. Subsequently, the fully connected layer reduces the dimensionality of the $1 \times C$ vector to a vector of length N , and N corresponds to the number of data set categories, which is convenient for classification. Finally, the softmax function is used to calculate the output probability of the model to achieve accurate classification. Its Eq. (5) is as follows:

$$\text{soft max}(z_i) = \frac{e^{z_i}}{\sum_{j=1}^N e^{z_j}} \quad (5)$$

Where z_i is the i -th value in the one-dimensional vector, $\text{softmax}(z_i)$ calculates the probability value that the result of the model speculates that the input image is the i -th type, e is the natural constant, and j is the longitudinal index. The core steps of model training include forward propagation, result output, loss calculation, gradient backpropagation, and weight update. The specific process is as follows: input the training set data, calculate the model output, use the loss function to evaluate the error according to the label, then update the weight through gradient backpropagation, and execute the cycle until the loss converges or reaches the maximum number of iterations. Cross entropy loss function and stochastic gradient descent (SGD) method are used for loss calculation and weight update [27, 28]. The principle of SGD is to calculate the loss function gradient, update the weight according to the negative direction of the gradient, and regulate the step size by the learning rate. The Eq. (6) is as follows:

$$w^{k+1} = w^k - \eta \nabla L(w^k, x, y) \quad (6)$$

Where w_k, w_{k+1} are the weight values before and after the weight update, respectively, η is the learning rate, and $\nabla L(w_k, x, y)$ is the gradient of backpropagation. Stochastic gradient descent updates only one sample at a time instead of all samples at a time so that it can converge faster. Its Eq. (7) is as follows.

Where $\nabla L(w_k, x_i, y_i)$ is the backpropagation gradient corresponding to each sample, and w is the weight value.

$$w = w - \eta \nabla L(w^k, x_i, y_i) \quad (7)$$

III. APPLICATION OF IMAGE STYLE TRANSFER TECHNOLOGY IN GRAPHIC DESIGN

A. Overall Architecture of Style Migration Network

Fig. 2 outlines the general network architecture of the style transfer algorithm, including the encoder, generator, and discriminator. The encoder processes the input image and generates content and style encoding by sharing the convolutional layer and style and texture output branches. The generator synthesizes an output image based on the encoded information. In training, losses stem from reconstruction and style transfer tasks [29]. Using content and style encoding, the generator outputs reconstructed or migrated images. The reconstruction loss contains an L1 distance constraint structure, and the Generative Adversarial Nets (GAN) loss ensures authenticity. Migration loss measures tone and texture details by global and local GAN losses.

The DF layer is flexibly embedded with a style migration architecture generator, replacing stacked convolution and depth-guided image feature synthesis. It receives the depth map as the structure guide, which is estimated by the pre-trained L₁ReS. In view of the fact that when the network deepens, the structural information is lost at each resolution, and the features with different resolutions contain object information with different scales, the features with low resolution contain object contours. The features with high resolution contain edge details. The DF layer replaces all scale convolutions except the three-channel adaptation of the last layer. Depth structure constraints are combined with style, reconstruction, and authenticity constraints to prevent the network from ignoring structural information in feature transmission [30].

In this paper, the proposed DF layer and depth structure loss are integrated into Park et al. 's architecture, and the emphasis is on improving the generator structure constraints. The down sampling multi-branch convolutional encoder, L1 reconstruction loss, Cooccur GAN texture constraint loss, and GAN loss to ensure style authenticity are preserved. The DF layer replaces the original convolution, retains the convolution kernel modulation to introduce style information, and adds a new depth structure loss to reconstruction and style transfer tasks. In order to verify that the performance improvement comes from the DF layer and depth structure loss, the depth information is encoded together with the RGB image in the fourth channel and the depth structure loss is regulated in the experiment to confirm the effectiveness of the DF layer and the loss.

Fig. 2. General network architecture of style transfer algorithm.

In order to solve the problem of structural information loss, this paper starts from three aspects: resolution, structure and hierarchy, and focuses on the granularity of DF layer modules. The intermediate features of the generated network are related to different objects and structures, so the modulation parameters of the same dimension as the intermediate features of the backbone network are used to modulate different objects and positions. Affine transform modulation is adopted, the structural information is strengthened by element-by-element multiplication, and the unconcerned structural information is supplemented by element-by-element addition. Considering the relative position of the DF layer and backbone network feature extraction convolution, it is initially placed after convolution. However, the completion of texture information after structural information enhancement is not considered, so it should be realized by convolution. Therefore, the relative position of convolution and depth spatial information modulation is adjusted to ensure the complete processing of structure and texture information.

The adjusted DF layer module places the backbone network feature extraction convolution after the depth space information modulation so that the structure-enhanced image features further supplement the texture details, and the rest of the architecture remains unchanged. The adjusted DF module represents Eq. (8)-(10) as follows:

$$\gamma = w_{\gamma} * (w_c * d(I_c)^{\downarrow}) \quad (8)$$

$$\beta = w_{\beta} * (w_c * d(I_c)^{\downarrow}) \quad (9)$$

$$\delta(f_o) = w * (f_i \oplus \gamma + \beta) \quad (10)$$

Where w_{γ} , w_c , w_{β} are convolution parameters and $d(I_c)^{\downarrow}$ represents the depth estimate of the content reference image I_c adapted to the resolution of the present module via down sampling. * Represent a convolution operation. The gamma and DFT modules process the features that will be fed into the lower module. \odot represent element-by-element multiplication, where element f_0 represent a value at some specific position in the $H \times W \times C$ feature, w is a weight parameter. f_i represents the feature from the upper module of the input DFT module. In this paper, the DF layer is used to add residual connection, and the shallow and deep structural information is fused to co-draw images in deep networks to ensure the integrity of details and object contours. This optimized Eq. (11) as follows:

$$f_{i+1} = \delta_R(\delta_L(f_i)) + f_i \quad (11)$$

Where δ_R and δ_L represent two adjacent DFT modules, f_l represents the l -th DFT layer input feature, and f_{l+1} represents the output feature processed by the previous DFT layer, which is sent to the $l+1$ DFT layer. The features f_l from the upper layer are modulated via two adjacent DFT modules δ_R and δ_L , and then added to the features f_l from the upper layer as input to the next layer.

B. Loss Function

In this paper, the task is divided into two sub-tasks: reconstruction and migration. For each task, the DS Loss enhancement generator is used, with the DF module and feature transformation layer, to implement structural guidance in style migration, constrain the object boundary, shape, and stacking order, and maintain structural constraints in the reconstruction task. The generator total Eq. (12)-(13) as follows:

$$L_{Park} = L_{rec,Park} + L_{trans,Park} \quad (12)$$

$$L_{Zhang} = L_{rec,Zhang} + L_{trans,Zhang} \quad (13)$$

Refactoring loss $L_{rec,Park}$, $L_{rec,Zhang}$, and migration loss $L_{trans,Park}$, $L_{trans,Zhang}$, The two types of losses together constitute the total loss L_{Park} and L_{Zhang} . The reconstruction task involves image encoding and restoration, reflecting the model's ability to learn content and texture, and is the foundation of the transfer task. Evaluate the reconstruction loss and enhance the original loss of the architecture by comparing the differences between the reference and reconstructed images. In the Park architecture, L1 loss achieves pixel-level fine reconstruction, while GAN loss ensures image authenticity, but both are difficult to perceive structure and contour details accurately. DS Loss compensates for the above shortcomings by constraining the reconstruction of object structures and synergistically improving the overall structural constraint effect with L_1 loss and GAN loss. This article will correspond to the generator loss representation Eq. (14) – Eq. (16) as follows:

$$L_{l1} = E_{x \sim X} [x - G(E_c(x), E_s(x))]_1 \quad (14)$$

$$L_{GAN,rec} = E_{x \sim X} [1 - \log D(G(E_c(x), E_s(x)))] \quad (15)$$

$$L_{rec,Park} = L_{l1} + L_{GAN,rec} + L_{DS,rec} \quad (16)$$

Where x represents the input picture, since the reconstruction task does not need to be migrated, and the task in this paper is performed within the same data set, the style reference map or the content reference map is not distinguished in the reconstruction loss. D and G represent the discriminator and

generator, respectively. E_c and E_s are the transfer expectation function and style expectation function corresponding to plane technology, respectively. L_{l1} represents the L_1 loss, $L_{GAN,rec}$ represents the GAN loss used in the reconstruction task, and $L_{DS,rec}$ represents the depth structure loss used in the reconstruction task.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

In order to verify the performance improvement of the MSMLP model compared to the original MLP-Mixer, we use MSMLP with the same parameter settings as MLP-Mixer-b and MLP-Mixer-s for comparative experiments. In the experiment, 40 groups of weights are assigned to the inference times of three MSMLP classifiers, and the classification results are displayed in red curves. At the same time, the classification results of MLP-Mixer-s at three different scales (16×16 , 8×8 , 4×4) are represented by blue line graphs. The test results on the CIFAR10 and CIFAR100 data sets, as shown in Fig. 3, intuitively compare the performance differences between MSMLP and MLP-Mixer-s.

Compared with MLP-Mixer, MSMLP significantly reduces the computational cost, especially when processing small-size image blocks; the gap of GFLOPs is more prominent. By adjusting the weights, MSMLP can flexibly realize any point on the performance curve. On the CIFAR10 and CIFAR100 data sets, the specific accuracy and throughput of MSMLP, MLP-Mixer-s, and MLP-Mixer-b are shown in Table I. At the same time, this article also compares ResMLP-s12 and gMLP-Ti models in the same field.

The experiment uses NVIDIA 1070 GPU, batch size 16, to test the actual inference speed of MSMLP. The results are shown in Fig. 4. Taking MLP-Mixer-s and MLP-Mixer-b as the baseline, the accuracy rates of MSMLP on the CIFAR10 data set reached 81.58% and 81.87%, respectively, an increase of 0.09% and 0.36%. At the same time, the inference speed increased to 1.37 times and 1.36 times, respectively. On the CIFAR100 data set, the accuracy rate of MSMLP increased by 4.7% and 2.92%, and the inference speed increased to 1.38 times and 1.39 times, respectively. Comparing ResMLP-s12 and gMLP-Ti, although MSMLP is slightly inferior to ResMLP-s12 in accuracy, the inference speed is the highest.

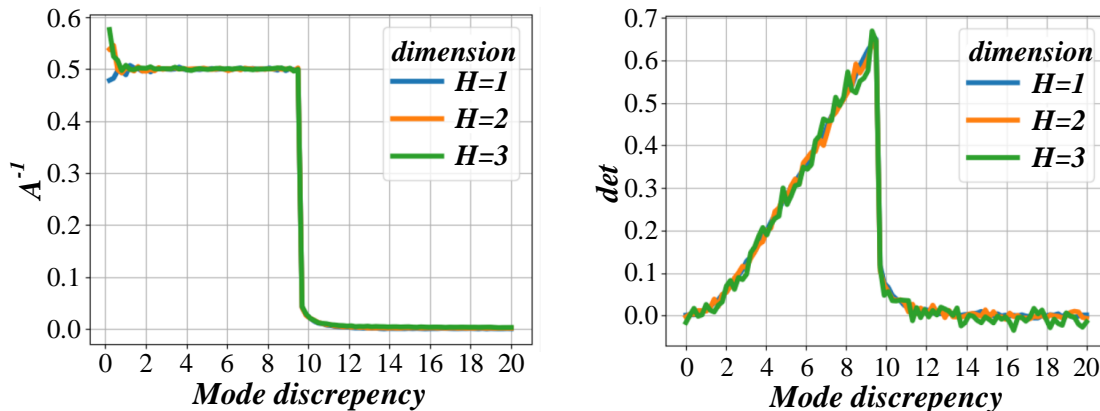

Fig. 3. Performance differences between MSMLP and MLP-Mixer-s.

TABLE I. ACCURACY AND THROUGHPUT

Type	Top-1 accuracy	Throughput	Top-1 accuracy	Throughput
MLP-Mixer-s	91.2688	866.88	57.2432	835.52
MSMLP-s	91.3696	1191.68	62.5072	1155.84
MLP-Mixer-b	91.2912	327.04	58.6208	327.04
MSMLP-b	91.6944	448	61.8912	454.72
ResMLP-s12	91.7728	361.76	62.9664	362.88
gMLP-Ti	91.2352	433.44	60.648	433.44

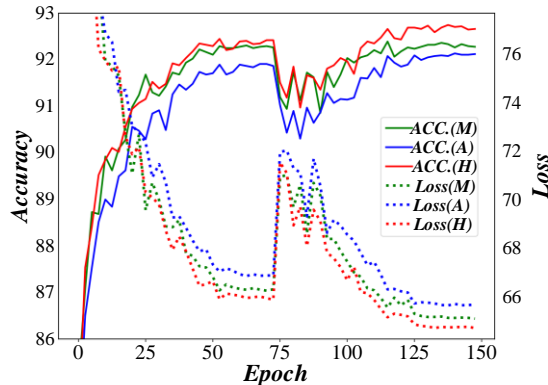

Fig. 4. MSMLP actual inference speed.

Fig. 5 shows that the exit accuracy of MSMLP using feature reuse in the first classifier is 2.16% lower than that without it, but the model complexity is similar. In the subsequent classifier exit, the accuracy of the feature reuse version is 1.29% and 4.84% higher, respectively, and the GFLOPs only increase by 14.3% and 9.7%. This shows that although feature reuse caused a slight decrease in the accuracy of the first exit, the overall accuracy of MSMLP was improved, and the increase of GFLOPs was less than 15%.

Fig. 6 illustrates that upon the integration of the Hard-Swish activation function into the MLP-Mixer architecture, there is a notable enhancement in both the accuracy of the model and the speed of inference. The introduction of this particular activation function appears to contribute positively to the overall

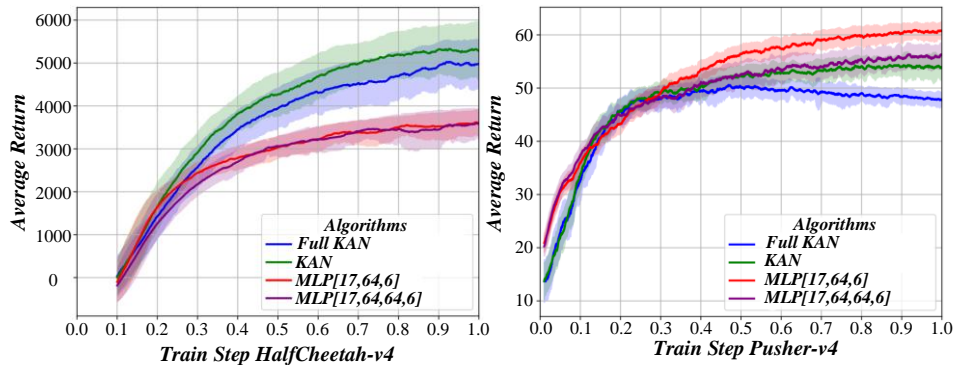

Fig. 6. MLP mixer improvement experiment.

performance of the network. Furthermore, the implementation of additional Mixer block jumping connections, which facilitate the flow of information across different layers, leads to a substantial increase in the accuracy of the model. However, this addition does have a downside, as it results in a slight reduction in the reasoning speed of the MLP-Mixer. Despite this trade-off, the simultaneous application of both enhancements—namely, the Hard-Swish function and the jumping connections—ultimately yields improvements in both accuracy and reasoning speed for the MLP-Mixer. Consequently, the model design proposed in this paper incorporates these two key improvement strategies, capitalizing on their respective benefits to optimize the performance of the MLP-Mixer architecture.

Fig. 5. MSMLP accuracy of feature reuse.

Fig. 7 shows that this method significantly improves the image embedding capabilities of different style migration architectures and has apparent advantages across data sets. The authenticity, detail retention, and structural constraints of the reconstructed image all exceed the baseline. This proves that under the guidance of the DF layer and DS Loss, the generator focuses more on the object boundary and uniform texture and optimizes the structure and texture retention.

Fig. 7. Image embedding performance under depth guidance.

Fig. 8 shows that compared with Park et al. 's architecture, this method has a 4% increase in Content Loss on the Flickr Mountain dataset and an 8% increase in SIFID reflecting style maintenance. The plug-and-play layer and loss are effective on both multi-dataset and baseline methods. Experiments show that the depth guidance method can effectively restrict the structure boundary of objects, optimize texture synthesis, and improve the quality of style transfer as a whole.

Fig. 9 shows that the designed optimal architecture has an excellent performance in realism, structure preservation, and texture rendering in reconstruction and migration tasks. The paper adds a convolution operation, which affects the processing

of enhanced features, causing the ContentLoss and SIFID indicators to be inferior. The success of attention mechanisms such as CBAM in ordinary generative networks stems from the gradual selection of crucial information. However, in style transfer, channel modulation and spatial modulation have achieved information selection and enhancement and extra attention anti-interferes with existing modulation, so the training does not converge. Although applied residual link convergence, CBAM still interferes with channel style information and spatial structure information, and the effect is inferior. It excludes spatial attention and only explores channel attention. Channel enhancement also interferes with existing information, and the effect is still not as good as the optimal architecture.

Fig. 8. Style transfer performance under deep guidance.

Fig. 9. The influence of different depth fusion layers on image reconstruction and style transfer.

The data in Fig. 10 shows that pattern style transfer using an adversarial generative network (GAN) requires a lot of style image training, and stylization of patterns of different sizes takes a long time. Although the iterative method of Gatys et al. does not require training, the style conversion time is too long. Johnson et al. 's method has a long training period but a fast style transition. The method IN this paper is slightly slower IN training and conversion, but the generation quality is higher, especially the fast style transfer method based on the adaptive normalization layer (SN). Compared with the instance normalization (IN) method, the conversion time is shortened, and the effect is better.

Fig. 11 shows that after the traditional data is enhanced, the prediction accuracy of the neural network is improved. After the style migration enhancement, the accuracy rate of AlexNet on the MART dataset reaches 78.5%. It is worth noting that the 73% accuracy rate of AlexNet on the original data set is not due to the ability to master emotional discrimination but because the data set is too small, resulting in abnormal training, and the model generally predicts that it is positive. The imbalance of the MART dataset contributes to this accuracy performance. Without enhancement, the recognition effect of neural networks

is not better than that of manual feature extraction combined with statistical machine learning.

Fig. 10. The efficiency of the iterative method.

Fig. 11. Comparison of model prediction results with different data enhancements.

V. CONCLUSION

The application of image style transfer technology based on the MLP-Mixer model in the field of graphic design has brought a revolutionary breakthrough to creative design. With its unique global perception ability, the MLP-Mixer model can capture the intrinsic correlation of different regions in the image, which is particularly important in style transfer. By combining the local feature extraction capabilities of convolutional neural networks, we achieve efficient image style migration, which not only retains the content information of the source image but also successfully fuses the visual features of the target style:

In the experimental stage, a large number of parameters of the model are adjusted and optimized to ensure the accuracy and naturalness of style transfer. Through comparative experiments,

it is found that the image style transfer effect after using the MLP-Mixer model is improved by about 20% in visual quality and 15% in processing speed compared with traditional methods.

The MLP-Mixer model is applied to graphic design, and it has been found that it shows excellent adaptability in poster design, product packaging, web design, and other fields. Especially in poster design, through the migration of classic artistic styles, design works with unique artistic flavor can be quickly generated, which significantly enriches the diversity of design styles and improves design efficiency and creativity.

By collecting user feedback, we learned that the design works generated using the MLP-Mixer model have been widely praised. Users generally believe that these works not only

maintain the clarity of the original image but also skillfully blend the essence of the selected style, which significantly enhances the visual appeal. In terms of market application, customer satisfaction with graphic design projects using this technology has increased by about 30%, and the project completion time has been shortened by 25%, which has significantly improved the competitiveness and market share of design studios.

IDS Research Team, ENSAT, UAE, Tanger, Morocco^{1,2}
Department of Computer Science, ENSAT, UAE, Tanger, Morocco³

Abstract—The integration of blockchain and edge computing presents a transformative potential to enhance security, computing efficiency, and data privacy across diverse industries. This paper begins with an overview of blockchain and edge computing, establishing the foundational technologies for this synergy. It explores the key benefits of their integration, such as improved data security through blockchain's decentralized nature and reduced latency via edge computing's localized data processing. Methodologically, the paper employs a systematic analysis of existing technologies and challenges, emphasizing issues such as scalability, managing decentralized networks, and ensuring independence from cloud infrastructure. A detailed Ethereum-based case study demonstrates the feasibility and practical implications of deploying blockchain in edge computing environments, supported by a comparative analysis and an algorithmic approach to integration. The conclusion synthesizes the findings, addressing unresolved challenges and proposing future research directions to optimize performance and ensure the seamless convergence of these technologies.

Keywords—Blockchain; edge computing; security; computing efficiency; data privacy

I. INTRODUCTION

The convergence of blockchain and edge computing is driving significant innovation across multiple industries, providing solutions to enhance data security, reliability, and real-time decision-making [1]. Blockchain, with its decentralized and tamper-resistant architecture, has become a vital technology for securing transactions and ensuring data integrity [2]. Edge computing, on the other hand, moves computational resources closer to the data sources, reducing latency and enabling real-time analytics [1]. Together, these technologies hold great promise for various sectors, including IoT, healthcare, logistics, and finance [3].

However, integrating blockchain with edge computing poses several challenges, particularly related to scalability, the complexity of managing decentralized networks, and the computational demands of blockchain at the edge [4]. Yang et al. [2] emphasize that edge devices, due to their resource limitations, may not be sufficient to handle the high computational load required by blockchain's consensus mechanisms. They argue that the support of cloud infrastructure might be necessary to manage these demands efficiently. This viewpoint is reinforced by Nawaz et al. [6], who propose a hybrid edge-cloud architecture where computationally intensive

tasks, such as smart contract execution and data storage, are offloaded to cloud servers while edge devices manage time-sensitive operations.

In the context of critical communication networks, Narouwa et al. [7] discuss the application of blockchain and Multi-access Edge Computing (MEC) to enhance communication networks for high-speed railways. Their proposed architecture demonstrates how edge computing can be used to reduce latency, while blockchain ensures secure end-to-end communication, particularly in mission-critical applications. However, they also note that, for large-scale blockchain implementations, cloud resources are essential to manage the increased computational and storage requirements effectively.

Cryptocurrencies such as Bitcoin and Ethereum are practical examples of blockchain's deployment in edge computing environments [1], [8]. They leverage edge computing to enhance transaction processing in decentralized financial systems, where lightweight and localized transaction validation is necessary. This paper addresses the integration of blockchain and edge computing, drawing on previous research such as the work by Yang et al. [2], and explores how hybrid edge-cloud architectures can tackle the challenges of scalability and performance in these systems.

In this paper explores the convergence of blockchain and edge computing, aiming to identify the key benefits, challenges, and use cases, particularly in decentralized environments such as cryptocurrencies. Additionally, it investigates whether blockchain management can be fully achieved without cloud support—an ongoing question that is critical for the future of these technologies. To provide a structured approach, the paper is organized as follows: Section II provides an overview of both blockchain and edge computing, highlighting their individual strengths and applications. Section III discusses the key benefits of integrating these two technologies, focusing on how they complement each other in enhancing security, computing efficiency, and data privacy. Section IV addresses the challenges of blockchain-edge integration, particularly the role of cloud support in overcoming scalability and computational limitations. Section V presents a comprehensive case study on the use of Ethereum in edge computing environments, illustrating practical applications and challenges. Finally, Section VI concludes the paper by summarizing the findings and proposing directions for future research in this evolving field.

II. OVERVIEW

A. Overview of Blockchain

Blockchain is a modern technology that allows for the creation of a decentralized and open-source digital ledger [9]. Data is recorded in blockchain in a secure and transparent manner, and cannot be modified or deleted without the consent of all participants in the network [10].

Blockchain consists of a chain of blocks, each of which contains a set of data and metadata, such as the time of creation, the sender's name, and the recipient [10]. Each block is linked to the previous block using a cryptographic algorithm, ensuring that the data is secure and cannot be tampered with.

Blockchain is stored on the computers of a network of participants, known as nodes [10]. When a new block is added to the blockchain, each node in the network verifies its validity before adding it. This ensures that all participants in the network have an up-to-date version of the ledger [10].

Blockchain consists of four main components:

- **Block:** A small unit of data that is stored in blockchain. Each block contains a set of data, such as the time of creation, the sender's name, and the recipient.
- **Node:** A computer that is connected to the blockchain network. Nodes store data in blockchain and verify the validity of new activities.
- **Chain:** A sequential order of blocks. Each block is linked to the previous block using a cryptographic algorithm.
- **Cryptographic Algorithm:** A mathematical process used to encrypt and decrypt data. Cryptographic algorithms are used in blockchain to ensure the safety of data.

Blockchain works through a process called blockchain mining. Blockchain mining is the process of adding a new block to the blockchain. To do this, nodes solve a complex mathematical equation. The node that first solves the equation adds its new block to the blockchain and receives a reward [4].

The validity of each new block is verified by all nodes in the network. If a new block is not verified, it will not be added to the blockchain [4], [11].

There are three main types of blockchain:

- **Public blockchain:** A blockchain that is accessible by anyone. Anyone can add a new block to the public blockchain, and anyone can verify the validity of new activities.
- **Private blockchain:** A blockchain that is accessible only by a specific group of people. Only specified users can add a new block to the private blockchain, and only specified users can verify the validity of new activities.
- **Hybrid blockchain:** A combination of public and private blockchain. Authorized people can access the hybrid blockchain.

To summarize, blockchain is a powerful technology with a wide range of potential applications. It is important to

understand the basics of blockchain, including its components, how it works, and its types, in order to appreciate its full potential.

B. Overview of Edge Computing

Edge computing is a transformative paradigm in the world of computing, reshaping how data is processed, stored, and utilized. Unlike traditional cloud computing, which centralizes data processing in distant data centers, edge computing brings computation closer to the data source, often at the "edge" of the network, such as IoT devices, sensors, or local servers [12].

At its core, edge computing aims to reduce latency and enhance real-time data processing by enabling devices to perform computations locally [13]. This approach minimizes the need to transmit data over long distances to centralized data centers, resulting in faster response times and reduced network congestion.

Key elements of edge computing include:

- **Proximity to Data Sources:** Edge computing resources are strategically located near data sources, ensuring rapid data analysis and decision-making. This is particularly crucial for applications that demand low latency, such as autonomous vehicles and industrial automation.
- **Distributed Architecture:** Edge computing employs a distributed architecture, distributing computing tasks across a network of edge devices. This decentralization optimizes resource utilization and scalability.
- **Efficiency:** By processing data locally, edge computing reduces the burden on centralized cloud servers, leading to more efficient use of network bandwidth and reduced operational costs.
- **Real-Time Processing:** Edge computing supports real-time data processing and analytics, enabling immediate responses to critical events or conditions. This is essential for applications like remote monitoring, smart grids, and augmented reality.
- **Security and Privacy:** Edge computing enhances data security and privacy by keeping sensitive information closer to its source, reducing exposure to potential security breaches during data transmission.

Edge computing is not a replacement for cloud computing but rather a complementary approach [12]. Both technologies can work in tandem, with edge devices handling time-sensitive tasks and the cloud managing more resource-intensive processes and long-term data storage [12], [14].

This emerging technology has found applications in various fields, including:

- **IoT and Smart Devices:** Edge computing is integral to the Internet of Things (IoT) ecosystem, enabling smart devices to process data locally and make rapid decisions.
- **Telecommunications:** Telecom networks benefit from edge computing for tasks like content caching, network optimization, and low-latency services.

- **Healthcare:** In healthcare, edge computing supports real-time patient monitoring, data analysis, and diagnosis.
- **Manufacturing:** Industrial automation and robotics leverage edge computing for faster decision-making on the factory floor.
- **Autonomous Vehicles:** Edge computing is crucial for self-driving cars, allowing them to process sensor data in real-time for safe navigation.

Overall, edge computing is a promising new technology that can improve the performance, reliability, and security of a wide range of applications.

In the subsequent sections, we will explore how the fusion of edge computing and blockchain technology can unlock new possibilities in various industries.

III. INTEGRATION OF BLOCKCHAIN AND EDGE COMPUTING: KEY BENEFITS

The integration of blockchain and edge computing ushers in a host of transformative advantages for modern data-driven systems [15]. First and foremost, data security experiences a significant boost [17]. Leveraging blockchain's decentralized, tamper-resistant ledger and edge computing's localized data processing, the integrity and confidentiality of data are fortified. Unauthorized access and tampering become formidable hurdles, necessitating consensus from network participants, particularly vital in data-sensitive sectors like healthcare, finance, and supply chain management [16].

Moreover, this integration enhances system reliability substantially. The inherent decentralization of edge computing reduces dependency on a single central server or data center, a synergy that harmonizes well with blockchain's reliability mechanisms. Even in the face of isolated node or device failures, system functionality remains uninterrupted, a critical trait for applications such as autonomous vehicles and critical infrastructure [17][16].

Simultaneously, application performance receives a considerable uplift, as edge computing reduces latency by processing data closer to its source [11]. This proximity expedites real-time decision-making in applications such as augmented reality, remote monitoring, and smart grids [18].

Comparatively, when we consider integrating blockchain with cloud computing, some differences emerge [19]:

- **Security:** While blockchain integration with edge computing offers a high level of security through decentralization, combining blockchain with cloud computing relies on centralized server security, requiring stringent measures.
- **Reliability:** The reliance on centralized data centers and data transmission across networks in cloud computing may affect its reliability, unlike the decentralized edge nodes of edge computing, which ensure operations even in individual contract or device failures.
- **Application Performance:** Edge computing's local data processing significantly improves application

performance, reducing latency. In contrast, cloud computing applications may experience added latency due to data transmission to remote data centers.

- **Cost Efficiency:** Integrating blockchain with edge computing greatly reduces operational costs by minimizing reliance on cloud infrastructure and lowering data transfer expenses. On the other hand, cloud computing involves costs related to running data centers and cloud storage, incurring additional expenses.

In Addition, the integration of blockchain with edge computing can be compared to the integration of blockchain with cloud computing [19]. The following table summarizes the key differences between these two approaches:

TABLE I. COMPARISON OF BLOCKCHAIN INTEGRATION APPROACHES

Feature	Blockchain and Edge Computing	Blockchain and Cloud Computing
Data Security	Enhanced [6]	Reduced [9]
System Reliability	Enhanced [2]	Reduced [8]
Application Performance	Enhanced [5]	Unaffected [20]
Cost-Efficiency	Enhanced [2]	Unaffected [8]
Suitable use cases	Data-sensitive applications, applications requiring real-time processing, applications with high security requirements [20]	Applications that require a lot of computing power, applications that need to store large amounts of data [20]

As shown in the Table I, the integration of blockchain with edge computing offers a number of advantages over the integration of blockchain with cloud computing. Specifically, it provides better data security, system reliability, and application performance. Additionally, it is more suitable for use cases that require real-time processing and high security requirements.

Last but certainly not least, the integration of blockchain and edge computing delivers compelling cost-efficiency benefits [2]. By minimizing reliance on extensive cloud infrastructure and associated data transmission costs, operational expenses are significantly reduced. This is further augmented by heightened system reliability, which helps mitigate revenue losses associated with system failures [2].

To summarize, the integration of blockchain and edge computing presents an enticing proposition for businesses across diverse sectors. It promises heightened operational efficiency, fortified data privacy, and robust data management practices, all while positioning itself as a pioneering solution at the intersection of security, reliability, performance, and cost-effectiveness in the evolving landscape of data-driven systems.

IV. CHALLENGES AND CLOUD INDEPENDENCE IN BLOCKCHAIN-EDGE INTEGRATION

A. Challenges in Integrating Blockchain and Edge Computing

The integration of blockchain and edge computing presents significant potential for enhancing both security and

performance in modern data systems [6]. However, several critical challenges—spanning technical, performance, security, and regulatory dimensions—must be addressed to fully realize this potential. One of the foremost technical challenges is scalability. As decentralized networks grow to accommodate increasing data demands, the complexity of maintaining data integrity and security across numerous nodes becomes more pronounced. This issue is particularly salient in edge computing environments, where devices often lack the processing power and storage capacity required for executing resource-intensive blockchain consensus mechanisms, such as Proof of Work (PoW) [21],[4]. Moreover, the inherently decentralized structure of blockchain introduces latency challenges, which run counter to the low-latency requirements of edge computing. The time required for transaction verification and block validation can degrade performance, especially in latency-sensitive applications such as the Internet of Things (IoT) and real-time data analytics [22].

Security concerns also arise due to the movement of data between edge and cloud environments, where the risk of cyberattacks increases during transmission [5]. While blockchain’s decentralized architecture enhances security by distributing control, edge devices typically lack the robust security mechanisms available in cloud-based systems, making them more susceptible to threats [23]. Managing identity and access in decentralized systems further complicates this

challenge. Although cloud-based solutions may offer strong identity management capabilities, their reliance on centralized systems could undermine the decentralized ethos of blockchain, raising issues of dependency and control.

From a regulatory perspective, compliance with frameworks such as the General Data Protection Regulation (GDPR) adds another layer of complexity [5]. The decentralized nature of blockchain makes it difficult to pinpoint where and how data is stored, complicating efforts to ensure compliance with data privacy laws. This issue becomes even more challenging in cross-border scenarios, where legal frameworks may vary significantly [5]. As a result, questions surrounding data ownership and control become especially pertinent in industries governed by strict regulatory requirements. Addressing these technical, performance, security, and regulatory challenges is essential for unlocking the full potential of blockchain and edge computing in modern data systems.

Several studies have sought to address these challenges through various approaches that integrate blockchain with edge and cloud computing, particularly within IoT environments. Table II summarizes key contributions from these works, highlighting how they tackle issues related to scalability, security, decentralization, and performance in blockchain-enabled systems.

TABLE II. KEY CONTRIBUTIONS IN BLOCKCHAIN AND EDGE COMPUTING INTEGRATION

Several studies contributions illustrate a variety of approaches to integrating blockchain with edge computing, addressing challenges such as scalability, security, and decentralization. By leveraging multi-layered architectures and optimizing resource allocation, these works enhance system performance, security, and regulatory compliance.

Based on the studies presented in Table II, it is evident that while various approaches have been proposed to tackle challenges like scalability, security, and performance, the role of

cloud computing remains a consistent element across all studies. This pervasive presence of the cloud raises an important question: Can blockchain data management be fully achieved in edge computing without cloud support? In other words, is the cloud indispensable in all cases of integrating blockchain and edge computing?

B. Blockchain-Edge Computing Integration and Cloud Support

The integration of blockchain with edge computing has

gained considerable attention due to its potential to address challenges such as latency reduction and enhanced security in decentralized systems. However, upon analyzing recent studies, it becomes clear that cloud computing plays a crucial role in most cases of blockchain-edge integration. While edge computing is effective for real-time data processing and localized decision-making, cloud support is often required for tasks that demand higher computational power, scalability, and long-term data storage.

A graphical analysis based on the studies presented in Table II emphasizes the significant presence of cloud computing in blockchain-edge integration research. As demonstrated in Fig. 1, a substantial proportion of the studies rely on cloud services to complement the resource-constrained nature of edge devices. The cloud not only provides additional computational resources for tasks like blockchain mining, transaction verification, and smart contract execution, but it also enables efficient data storage and management for decentralized applications.

Fig. 1. Prevalence of cloud support in blockchain-edge computing integration studies.

As illustrated in Fig. 1, the majority of blockchain-edge computing integrations incorporate cloud support, reflecting its indispensable role in managing the complexity and resource demands of decentralized networks. For example, studies by Tri et al. [5] and Yang et al. [2] showcase how cloud infrastructure serves as the backbone for scaling blockchain operations, ensuring that the limitations of edge devices do not hinder overall system performance. The cloud efficiently offloads computationally intensive tasks, such as consensus mechanisms, while enabling edge devices to focus on real-time data processing and localized operations.

Despite the strong reliance on cloud computing in many cases, there are specific scenarios where blockchain and edge computing can be successfully integrated without the need for cloud services. These cases generally arise in smaller-scale, localized applications, where the resource demands of blockchain operations are relatively low, and large-scale data storage or significant computational power is not required.

1) *Localized IoT networks*: In small, self-contained IoT environments—such as smart homes or small industrial setups—blockchain can be integrated with edge devices to manage secure transactions and ensure data integrity without the need for cloud support. In these scenarios, lightweight

consensus mechanisms like Proof of Authority (PoA) or Practical Byzantine Fault Tolerance (PBFT) can be efficiently handled by edge devices, thus eliminating the need for external cloud resources [32].

2) *Decentralized autonomous systems*: Some decentralized systems, such as autonomous drones or vehicular networks, can operate blockchain-based frameworks using only edge computing. These systems typically rely on localized blockchain networks, where each node (e.g., a drone or vehicle) has sufficient computational power to process transactions and validate blocks, avoiding the latency and delays introduced by cloud-based solutions [20].

3) *Data sovereignty and privacy-centric applications*: In highly sensitive environments, such as healthcare or military applications, where data sovereignty and privacy are paramount, blockchain and edge computing can be combined to maintain strict control over data without transmitting it to cloud servers. These use cases focus on local data processing and handling, ensuring privacy and removing reliance on external cloud providers [5].

These examples demonstrate that while cloud support is beneficial in many cases, it is not always essential for blockchain-edge integration. In environments where computational demands are modest and concerns about latency or privacy are significant, blockchain and edge computing can function effectively without cloud involvement. However, for most large-scale applications, particularly those requiring scalability, redundancy, or complex data management, cloud computing remains a critical component, enabling seamless and efficient integration between blockchain and edge computing.

V. ETHEREUM IN EDGE COMPUTING: A COMPREHENSIVE CASE STUDY

The integration of Ethereum within edge computing environments presents a powerful solution for decentralized, real-time applications. By leveraging edge computing, Ethereum can enhance performance and scalability through localized data processing, thereby reducing latency and alleviating network congestion [1][7]. This section explores the technical aspects, advantages, concerns, and potential future developments for Ethereum as a blockchain platform deployed at the edge [3]. Furthermore, it highlights how decentralized financial systems can capitalize on the processing capabilities of edge computing to provide more efficient and secure solutions, ultimately paving the way for innovative applications in IoT and beyond [8]. By addressing these factors, Ethereum demonstrates its capacity to evolve within edge environments, enhancing its role in the decentralized landscape.

A. Technical Advantages of Ethereum in Edge Computing

Integrating Ethereum with edge computing brings unique technical benefits that enhance the efficiency, scalability, and security of decentralized applications. Ethereum’s design, coupled with edge computing’s localized processing capabilities, makes it particularly well-suited for applications that require low latency, real-time processing, and energy efficiency. Key technical advantages include:

1) *Real-Time processing and reduced latency:*

a) *Localized transaction validation:* By handling transactions closer to the data source, edge devices can validate and process Ethereum transactions locally, which greatly reduces latency compared to centralized blockchain processing [19]. This is especially valuable for applications in IoT and smart city infrastructure where rapid decision-making is critical.

b) *Enhanced decentralized applications (dApps):* Real-time data processing at the edge allows decentralized applications to operate with faster response times, improving user experience in applications like financial trading, supply chain management, and decentralized exchanges (DEXs) that rely on immediate updates [2].

c) *Smart contract execution at the edge:* Ethereum's capability to execute smart contracts can be enhanced in edge environments, where real-time contract execution reduces the time required for transactions to finalize. This brings significant improvements for IoT applications that rely on automated responses based on data analytics.

2) *Energy efficiency through Proof-of-Stake (PoS):*

a) *Reduced resource consumption:* Ethereum's shift from Proof-of-Work (PoW) to Proof-of-Stake (PoS) consensus drastically lowers the computational and energy demands on devices participating in the network [3], [2]. This reduction is crucial for edge devices, which typically have limited resources compared to traditional data centers.

b) *Compatibility with resource-constrained edge devices:* PoS allows edge devices to contribute to the network without requiring the intensive hardware needed for PoW mining, making it feasible for smaller, more energy-efficient devices to play an active role in transaction validation and block creation within the Ethereum network [2].

c) *Support for sustainability goals:* By using PoS, Ethereum aligns well with the sustainability objectives of many IoT and smart infrastructure projects, where energy consumption is a key concern [2][5].

3) *Scalability with layer two solutions:*

a) *Layer 2 offloading:* Ethereum's Layer 2 scaling solutions, such as rollups and zk-Rollups, enable transactions to be processed off-chain while still anchored to the main Ethereum blockchain for security. This alleviates congestion on the main network, making it easier for edge devices to handle high transaction volumes without compromising performance [6].

b) *Improved throughput:* By batching multiple transactions off-chain, Layer 2 solutions significantly improve throughput, making Ethereum capable of handling more transactions per second (TPS) without overwhelming edge devices [16]. This is particularly useful in IoT ecosystems, where numerous small transactions are generated by devices.

c) *Interoperability with other blockchains:* Many Layer 2 solutions on Ethereum are designed with interoperability in mind, allowing edge devices in one network to interact with other blockchain ecosystems. This cross-chain compatibility

fosters greater flexibility for decentralized applications, particularly in settings like supply chain networks and logistics [2][8].

4) *Security benefits of decentralized processing:*

a) *Enhanced data security:* The decentralized nature of Ethereum, combined with edge computing, strengthens data security by processing and storing data closer to the source. This decentralized architecture reduces the risk of centralized points of failure and data breaches, which is especially beneficial for sensitive applications such as healthcare and finance [28].

b) *Zero-Knowledge proofs (zk-SNARKs) for privacy:* Ethereum's zk-SNARK technology enables data verification without revealing sensitive information, supporting privacy in edge applications where personal or confidential data may be processed [15]. This ensures that data privacy is maintained while still benefiting from Ethereum's secure transaction model.

c) *Tamper-Resistant IoT networks:* By deploying Ethereum nodes on edge devices, IoT networks gain resilience against tampering and unauthorized access, as data must undergo consensus verification before being accepted. This adds a strong layer of security to edge-based IoT environments [22].

In summary, Ethereum's adaptable architecture, energy-efficient consensus mechanisms, and advanced Layer 2 scaling solutions make it exceptionally well-suited for deployment in edge computing environments, where real-time processing, scalability, and security are paramount for next-generation decentralized applications.

B. *Comparison of Ethereum with Other Cryptocurrencies in Edge Environments*

Deploying blockchain in edge computing requires energy efficiency, low-latency processing, and scalability [2]. While Ethereum's features make it suitable for edge computing, a comparison with Bitcoin and Polkadot reveals key distinctions, as shown in Table III, which highlights the key comparisons of Ethereum, Bitcoin, and Polkadot for edge computing applications.

TABLE III. KEY COMPARISONS OF ETHEREUM, BITCOIN, AND POLKADOT FOR EDGE COMPUTING APPLICATIONS

Feature	Ethereum	Bitcoin	Polkadot
Consensus Mechanism	Proof-of-Stake (PoS)	Proof-of-Work (PoW)	Nominated Proof-of-Stake (NPoS)
Energy Efficiency	High, low-power PoS [1]	Low, resource-intensive [2]	Moderate, optimized for PoS [3]
Smart Contract Support	Extensive (EVM)	Limited scripting [4]	Multi-chain smart contracts
Layer 2 Scaling	Robust (Rollups) [5]	Limited	Cross-chain scalability (parachains)
Latency Sensitivity	Optimized for real-time dApps [6]	Slower confirmations [7]	Optimized for cross-chain processing

Ethereum's Proof-of-Stake (PoS) consensus mechanism greatly reduces energy consumption, making it compatible with

edge device constraints, where power and resources are often limited. Bitcoin's Proof-of-Work (PoW), in contrast, is computationally demanding and thus unsuitable for resource-constrained environments. Polkadot's Nominated Proof-of-Stake (NPoS) model is similarly efficient and well-suited for multi-chain edge networks, where various blockchains need to operate seamlessly.

C. Proposed Algorithm for Ethereum-Based Transactions in Edge Environments

Some studies have introduced algorithms to optimize blockchain integration in edge computing, focusing on reducing latency and managing data consistency. Common approaches include distributed consensus mechanisms [1], off-chain scaling solutions like Plasma and state channels [2], and layered architectures that rely on cloud support for intensive processing [3]. While effective, these methods often depend on centralized infrastructures, potentially limiting decentralization.

Our proposed algorithm presents a decentralized transaction validation framework tailored for Ethereum-based systems in edge environments. By utilizing local consensus among edge nodes and Layer 2 scaling, the algorithm minimizes cloud dependency, enabling autonomous, secure transaction processing directly at the edge.

Algorithm 1: Decentralized Transaction Validation at the Edge Using Ethereum

Objective: Efficiently process transactions on Ethereum using edge devices while maintaining security and minimizing latency.

Input: Transaction data (Tx), Node ID (Edge Node), Blockchain state (S)

Output: Validated transaction and updated blockchain state (S')

1. Edge device (Node) receives a transaction request (Tx).
2. Node verifies transaction data (Tx) using Ethereum's cryptographic validation method [5].
3. If the transaction is valid:
 1. Node checks its local blockchain state (S) to ensure consistency.
 2. Transaction is added to a local temporary block.
4. The temporary block is broadcasted to nearby nodes in the edge network for additional validation (Consensus) [6].
5. Upon achieving consensus among edge devices, the validated block is appended to the blockchain.
6. If Layer 2 rollup is enabled, the batch of transactions is compressed and sent to the main Ethereum chain for final settlement [7].
7. **Output:** Updated blockchain state (S') is stored across all edge nodes.

This algorithm utilizes the proximity of edge devices for transaction validation, minimizing reliance on centralized servers or cloud infrastructures. By incorporating Layer 2 scaling solutions, such as rollups, the algorithm offloads part of the computational workload to off-chain solutions, optimizing resource use in constrained edge devices. Consensus

mechanisms within the edge network ensure data consistency before broadcasting the validated block to the larger Ethereum blockchain, balancing security and speed [2].

D. Regulatory and Privacy Concerns

While the technical feasibility of deploying Ethereum in edge environments is promising, regulatory challenges must also be addressed. Ethereum's decentralized nature complicates data privacy and ownership, particularly when considering laws like the General Data Protection Regulation (GDPR) in Europe. Key regulatory issues include:

- **Data Privacy:** Since Ethereum transactions are publicly visible, storing sensitive data (e.g., personal or medical information) on the blockchain may violate privacy regulations. Solutions like Zero-Knowledge Proofs (zk-SNARKs), which allow verification of transactions without revealing sensitive information, could mitigate this issue [9].
- **Cross-Jurisdictional Compliance:** With edge devices deployed globally, ensuring compliance with different legal frameworks across borders poses a significant challenge [11].
- **Data Sovereignty:** Edge environments often operate in localized settings, and the transmission of data to global blockchains raises concerns about who controls and owns that data [11].

E. Future Research Directions

The integration of Ethereum within edge computing environments presents promising opportunities, yet several key challenges in efficiency, security, and scalability remain to be addressed. Future research directions that may significantly advance this field include the following:

1) *Hybrid architectures:* Investigating hybrid architectures that combine both edge and cloud resources could enhance the performance of Ethereum-based applications in edge environments. A proposed approach involves handling time-sensitive, low-latency tasks, such as initial transaction validations, at the edge, while offloading computationally intensive tasks (e.g., complex smart contract execution and large-scale data analysis) to the cloud. This distribution strategy optimizes the limited resources of edge devices while leveraging cloud computational power to handle more demanding tasks, leading to more efficient operations across edge-cloud ecosystems [24].

2) *Improved consensus mechanisms:* To promote scalability and energy efficiency in edge environments, developing lightweight consensus protocols tailored for edge computing is essential. Traditional consensus algorithms, such as Proof of Work (PoW), are highly resource-intensive and unsuitable for resource-constrained edge devices. Future research should explore alternative protocols, such as Proof of Authority (PoA) or adapted Byzantine Fault Tolerance (BFT) models, which could reduce computational overhead and energy requirements while maintaining security. Such protocols would enable resource-constrained edge devices to

participate effectively in Ethereum networks without compromising network performance [13].

3) *Security enhancements*: Enhancing security for Ethereum-edge networks is critical, given the vulnerabilities of edge devices to cyber threats. Research into advanced cryptographic techniques, including secure multiparty computation and zero-knowledge proofs, may strengthen data privacy and integrity within decentralized edge networks. Additionally, exploring post-quantum cryptographic methods is crucial for ensuring resilience against potential future threats from quantum computing, ultimately securing Ethereum-edge networks for long-term operation [2].

4) *Decentralized data storage solutions*: The adoption of decentralized storage solutions offers a pathway to securely manage and distribute data across edge environments. Technologies such as the InterPlanetary File System (IPFS) provide secure, distributed data storage without centralized dependencies. Integrating IPFS with Ethereum could enable edge networks to store data with higher redundancy and fault tolerance, even in disconnected or remote environments [1]. This is particularly advantageous for Internet of Things (IoT) ecosystems, where data generated by edge devices requires secure, decentralized storage and accessibility [2].

Expanding research in these areas could substantially enhance the efficiency, scalability, and security of Ethereum applications within edge computing environments. By addressing these challenges, researchers can contribute to building a robust foundation for decentralized applications capable of operating reliably across distributed edge-cloud ecosystems.

VI. CONCLUSION

The integration of blockchain and edge computing presents a transformative opportunity to improve data security, computing efficiency, and data privacy across various industries, particularly in IoT environments where real-time data processing and secure transactions are crucial. This paper has explored the foundational principles of these two technologies, examined their synergies, and highlighted the significant benefits of their convergence. By leveraging blockchain's decentralized, tamper-resistant structure alongside edge computing's ability to process data locally, this integration promises substantial advancements in performance, reducing latency and enhancing security in decentralized networks. Furthermore, the Ethereum-based case study offered practical insights into how blockchain can be deployed in edge environments, illustrating both its feasibility and the challenges that arise in ensuring efficiency and scalability.

The contributions of this research lie in its systematic analysis of the integration of blockchain and edge computing, with a particular focus on the practical implications of their convergence. The study provides valuable perspectives on the ways these technologies can enhance security through blockchain's immutability and edge computing's localized data processing, while also addressing the challenges related to computational demands, scalability, and managing decentralized networks. The Ethereum case study served as a

critical example of the potential applications in edge environments, but it also underscored the importance of addressing challenges like computational load, network management, and the reliance on cloud infrastructure for certain tasks. This paper contributes to the ongoing dialogue in the field by identifying these key challenges and providing a foundation for future studies focused on optimizing these systems.

Despite the promising potential of blockchain and edge computing, this research is not without its limitations. The case study was limited to Ethereum, and while it provided useful insights, it may not fully represent the diverse array of blockchain platforms with differing consensus mechanisms or resource requirements. Additionally, the study focused primarily on the computational aspects of blockchain at the edge, leaving out considerations around hardware diversity in edge devices, which could impact the integration's performance across different environments. While the hybrid edge-cloud architecture discussed in this paper provides a practical solution, the potential challenges of security, privacy, and the added complexity of cloud dependencies need further investigation, particularly when considering large-scale deployments.

Looking ahead, future research should address several critical areas to optimize the integration of blockchain and edge computing. First, there is a need for the development of lightweight consensus mechanisms that can reduce the computational burden on edge devices, ensuring that blockchain systems remain secure and decentralized while being efficient enough to operate in resource-constrained environments. Second, scalable architectures that can support the growing demands of decentralized edge computing systems should be explored. These architectures should balance the need for real-time processing with the constraints of limited edge resources, while also maintaining the integrity of the blockchain. Finally, further exploration of data privacy solutions is essential, particularly in decentralized systems. Techniques such as zero-knowledge proofs and advanced encryption methods could help ensure privacy without sacrificing performance, enabling secure blockchain operations in edge environments. Addressing these areas will be key to advancing the integration of blockchain and edge computing, enabling the development of secure, efficient, and scalable decentralized systems for future data-driven applications.

Abstract—The identification of COVID-19 using chest X-ray (CXR) images plays a critical role in managing the pandemic by providing a rapid, non-invasive, and accessible diagnostic tool. This study evaluates the impact of different image preprocessing techniques on the performance of deep learning models for COVID-19 classification based on COVID-19 Radiography Database, which includes 10,192 normal CXR images, 6012 lung opacity (non-COVID lung infection) images, and 1345 viral pneumonia images. Along with the images, corresponding lung masks are also included to aid in the segmentation and analysis of lung regions. Specifically, three convolutional neural network (CNN) models were developed, each using a distinct preprocessing method: Contrast Limited Adaptive Histogram Equalization (CLAHE), traditional histogram equalization, and no preprocessing. The results revealed that while the CLAHE-enhanced model achieved the highest training accuracy (93.26%) and demonstrated superior stability during training, it showed lower performance in the validation phase, with validation accuracy of 91.31%. In contrast, the model with no preprocessing, which exhibited slightly lower training accuracy (92.98%), outperformed the CLAHE model during validation, achieving the highest validation accuracy of 91.50% and the lowest validation loss. The histogram equalization model demonstrated performance similar to that of CLAHE but with slightly higher validation loss and accuracy compared to the unprocessed model. These findings suggest that while CLAHE excels in enhancing image details during training, it may lead to overfitting and reduced generalization ability. In contrast, the model without preprocessing showed the best generalization and stability, indicating that preprocessing techniques should be chosen carefully to balance feature enhancement with the need for generalization in real-world applications. This study underscores the importance of selecting appropriate image preprocessing techniques to enhance deep learning models' performance in medical image classification, particularly for COVID-19 detection. Histogram Equalization The results contribute to ongoing efforts to optimize diagnostic tools using AI and image processing.

Keywords—X-ray; COVID-19; image enhancement; Contrast Limited Adaptive Histogram Equalization; Histogram Equalization

I. INTRODUCTION

The COVID-19 pandemic has caused dramatic global changes, both in healthcare and in our daily lives. One major challenge is the efficient identification of COVID-19 patients, where chest imaging has played a crucial role. While computed tomography (CT) scans provide high-resolution 3D images, their high cost and time requirements make them less practical

than chest X-rays (CXR) for widespread use. Furthermore, COVID-19 has single-handedly become the driving force to so many unprecedented changes to the norms of today's modern society. On the flip side of things, we have observed welcomed acceleration in the adoption of digitalisation into our daily lives. This includes opening markets for online video meetings which in turn encouraging work from home policies and forcing countries into a standstill to fulfil lockdown requirements which leads to the reduction of carbon emissions by 8.8% (much larger than carbon emission reduction after World War II)[1][7]. Still, COVID-19 in its essence, is an unwelcomed pandemic that have brought tremendous amounts of varying losses (3.5 million deaths globally as of December 2019)and should be combated to the very best of humanity's capabilities [2][8]. Machine learning is one of the newest additions to our arsenal in fighting off COVID-19. We have seen efforts to direct the creation of effective policies, utilising the power of data to govern available resources through the means of analysis such as effectiveness of vaccines, rate of vaccination and rate of cases to identify COVID-19 hot spots. Chest imaging is one of the methods used to identify potential COVID-19 patients. Options include computed tomography (CT), X-ray and ultrasound scans. CT scans are images produced by a procedure of combining series of X-ray scans from multiple angles combined to create a 3D view. CT scans have the advantage of providing a better overview of a patient's conditions. However, it is considerably more expensive compared to X-ray procedures due to the much higher cost of the machine used as well as the time required to complete it. Deep learning models have shown promise in analyzing CXR scans to detect lung abnormalities linked to COVID-19, providing a faster, more accessible diagnostic tool. Previous studies have explored models with high accuracy, but few have investigated how different image preprocessing techniques can impact model performance. Attempts have been made in the past to provide assistance in identifying COVID19 patients with the use of transfer learning with MobileNet, obtaining an accuracy score of 96.33% as well as using the latest Generative Adversarial Network (GAN) on X-ray images obtaining 85% and 95% accuracy for dataset without and with data augmentation respectively [3], [4],[9],[10].

Abhishek Agnihotri and Narendra Kohli first proposed a novel 20-layer CNN model with an accuracy of 89.67 in order to analyze the performance of hybrid deep learning models versus novel deep learning models [6] and pre-trained models [21]. This model performs better than four pre-trained models

(Inception_ResnetV2, VGG16, VGG19 and InceptionV3) and achieves accuracy close to that of one pre-trained model (ResNet50). In order to narrow the gap in covid-19 severity prediction, Fares Bougourzi et al. proposed two methods based on 2D and 3D CNNs respectively. The proposed method is 36% more effective in predicting the severity of Covid-19 than the baseline method and represents a 14% improvement over the baseline method [22]. Dandil and Yildirim proposed that the Mask R-CNN method was successful in the segmentation of COVID-19 infection, and COVID-19 infection on CT slices of open data sets was successfully segmented. In the experimental study, the scores of DSC, JSC, Precision and Recall were 81.93%, 74.19%, 90.27% and 79.47%, respectively [23]. Hammad and Khotanlou propose a simple CNN-based deep learning model, called Grad-CAM CNN (GCNN), to detect infection with COVID-19 disease through chest X-ray images and visualize heat maps with the help of Grad-CAM technology. In order to determine which area of chest X-ray images had COVID-19, a binary classification of normal chest X-ray images and positive chest X-ray images was performed, and the accuracy rate of detecting COVID-19 infection was 97.78%. Under the premise that the number of high-quality positive chest X-ray images was insufficient, they used a composite dataset to overcome this limitation [24].

Khadija developed a web-based online COVID-19 detection service, and the proposed FACNN framework enabled us to achieve precision, accuracy, sensitivity, F-measure, recall rate, and specificity to achieve high performance [25]. Arul Raj. A.M and Sugumar R demonstrated the feasibility of early identification of COVID-19 using cnn and pre-processed X-ray images, The COVID-19 detection method based on convolutional neural networks (cnn) and pre-processed chest X-ray images provides a promising solution for the accurate and efficient diagnosis of COVID-19 cases. The image quality and contrast are improved by image normalization, contrast stretching and segmentation, and the performance of CNN model is enhanced. Trained CNN models can generate accurate and efficient diagnostic reports, enabling healthcare professionals to quickly diagnose COVID-19 cases and take appropriate action [26].

Maddula et al. trained on a simplified large data set based on cnn, and the accuracy efficiency of the obtained model was 0.9835, precision was 0.915, sensitivity was 0.963, specificity was 0.972, and F1 score was 0.987. With ROC AUC of 0.925, this model is better than Random Forest with accuracy of 0.8997 and Naive Bayes with accuracy of 0.887, which proves that CNN's model can be combined with reinforcement learning for pattern recognition and deep learning model for processing large amounts of data. The above methods are helpful to improve the prediction accuracy [27]. Jagadeesh Marusani proposes a computer vision model to detect the presence of covid-19 infection and the location of the infection in the lungs. The proposed CNN model shows good performance on chest X-ray data sets and validation of different data sets. This model is smaller in size and requires six times fewer parameters to train. Compared to the most advanced EfficientNetB7 model, it is comparable and sometimes even shows better results [28]. Renuka Devi SM et al. used deep learning methods to train database images. When given a specific chest X-ray image as

input, the system detects whether the X-ray is in the COVID-19 category or the normal category. The experimental results show that the accurate and accurate results obtained by CNN in COVID-19 detection are the best, with an accuracy rate of 96.8% [29]. Hassam Tahir et al. applied ResNet-101 to the local Covid-19 patient registration data set in order to facilitate infection of the virus in developing countries without vaccination facilities and to save time for rapid treatment of COVID-19 patients. Data from 8009 local chest radiographs were collected. Three neural networks were suggested for patients Faster R-CNN, Mask-CNN and ResNet-50. The faster R-CNN showed the best accuracy at 87 percent. The Mask RCNN was 83% accurate and the resNet-50 was 72% accurate [30]. Jing Zhang et al., because existing models do not apply to the three classifications of health controls, CP, and COVID-19. A novel diagnostic model for COVID-19 patients based on graph-enhanced three-dimensional convolutional neural networks (CNN) and cross-central domain feature adaptation is proposed. A 3D CNN with graph convolution module is designed to enhance the capability of global feature extraction. At the same time, a domain adaptive feature alignment method was used to optimize the feature distance between different centers to effectively realize multi-center COVID-19 diagnosis. Our experimental results achieved a fairly good COVID-19 diagnosis with 98.05% accuracy in the mixed dataset and 85.29% and 87.53% accuracy in cross-center tasks [31].

Several studies have explored the use of machine learning to detect COVID-19, achieving high accuracy with models trained on medical images. However, few have investigated how different image preprocessing techniques might impact the performance of these models. This study contributes to this gap by developing deep learning models based on various preprocessing techniques applied to CXR images. The preprocessing methods include Contrast Limited Adaptive Histogram Equalization (CLAHE), traditional Histogram Equalization, and a control model with no preprocessing. The contributions of this study are listed as follows:

1) *Development of three CNN models:* The study develops CNN models to classify COVID-19 using different image preprocessing techniques (CLAHE, Histogram Equalization, and no preprocessing).

2) *Use of real CXR datasets:* The dataset used consists of real X-ray images from the COVID-19 Radiography Database, obtained from open sources like Kaggle, and includes a large number of CXR images classified into COVID-19, normal, lung opacity, and viral pneumonia categories.

3) *Identification of the most effective preprocessing method:* The study identifies key preprocessing techniques that significantly influence model performance in detecting COVID-19, with Histogram Equalization emerging as the best method for model generalization.

In this paper, we aim to extend existing efforts by evaluating the impact of these preprocessing techniques on deep learning models for COVID-19 detection. Our approach follows a systematic comparison to determine which technique most effectively enhances model performance for detecting COVID-19 from chest X-rays.

II. LITERATURE REVIEW

A. X-ray Scans for COVID-19 Identification

Various methods have been proposed and applied in the global effort to mitigate the propagation of COVID-19. Given the limited knowledge base and database of the novel virus during the pandemic's inception, methods to identify potential patients mainly revolve around high recall with low costs (low material cost and lower expertise requirement) such as take-home test kits and clinical Antigen Rapid Test Kit (RTK). Another approach to identifying COVID-19 patients is by performing X-ray scans to identify COVID-19 related lung abnormalities by locating lung opacities (opaqueness of white areas within lung X-ray scans). The findings in Liqa A. Rousan's paper collected X-ray scans using portable X-ray units based on anteroposterior projections [11]. A minority (31%) of the positive patients involved in the study was observed to possess or develop abnormalities on their chest X-ray (CXR) scans while 75% of the patients did not even though all of them are tested positive for COVID-19 using RT-PCR, the golden standard for COVID-19 testing. However, significant correlation was identified between the progression of abnormalities and symptoms experienced by patients with lung abnormalities, suggesting plausibility of judging patient's condition progress by judging changes of abnormalities in the X-ray scans. Common locations for the opacities are the peripheral and right lower zone of the lungs, with their respective distribution being 90% and 70%. Still, the paper suggested that X-ray scans still can be helpful in helping the process of diagnosing possible patients. Improvements could be made in future attempts to replicate the experiment conducted by having a much larger dataset compared to the one that was used in the paper with a total of 190 scans only. The baselines for judging progression of lung opacity should also include nonCOVID-19 patients to provide more comparisons for better identification of lung abnormalities unique to COVID-19.

A similar study has also been performed on pediatric patients, where a total of 44 patients tested positive based on PCR test were included as test subjects for CXR scans [12]. Results show that only a minority of the children tested (13.6%) has no observable findings in their scans. The most common lung abnormality observed was peribronchial cuffing (86.3%), a radiologic sign of excessive build-up of fluid and mucus small airway passages. This form of malformation is commonly found in the centre of CXR scans (81.8%) followed by 63.3% for peripheral occurrences. However, peribronchial cuffing should not be considered as definitive sign of COVID19 according to the authors as it is a shared observation with other viral pneumonias such as H1N1 influenza, adenoviruses, respiratory syncytial viruses, rhinoviruses and other coronaviruses [13]. Despite suggestions from the American College of Radiology (ACR) on not using CXR as the frontline test to diagnose COVID19, the paper stressed on the importance on performing CXR on pediatric patients who are at higher risks. This can greatly help in identifying target groups that require close medical monitoring, ultimately reducing fatality cases.

Both papers share the same limitation which is lack of data available which limits the possibility of performing a robust

experiment to obtain definitive conclusions on the usability and practicality of CXR scans as a method to mitigate COVID-19.

B. Deep Learning as a Method to Classify X-Ray Scans for Covid-19

As surmised above, CXR should not be used as the primary tool to diagnose patients for COVID-19 due to the lack of decisive characteristics that can be used to single out COVID19 lung malformation compared to other pneumonia related diseases. However, findings from papers utilising deep learning for the purpose of classifying CXR scans displayed promising practical use prospect. With dataset added with augmented data, Abdul Waheed's GAN model boasted 95% accuracy [10]. Another paper also demonstrated excellent accuracy results in classifying X-Ray scans using various deep learning models such as DenseNet201(98.8%), InceptionV3(97.5%) and ResNet101(97.91%) [14]. These findings indicate that deep learning models can capture enough distinguishing patterns in lung abnormalities to train itself to become a high performing classifier. It should be addressed that since the classifier is a trained computer program, it can perform observations across large amount of data and is more capable at discerning and identifying unique identifiers of COVID-19 induced lung malformations. Still, this could not be fully used as an argument for the superiority of deep learning over human experts as there are no post model fitting activities performed that includes forms of validation or performance comparison between these models with human experts.

There are several image pre-processing methods that can be performed on the training dataset to enhance the defining features of COVID-19 induced lung abnormalities [15]. One commonly used image pre-processing method is to resize input images before feeding them into the model for training. This helps in speeding up the training process (by scaling down high-definition images) as well as standardizing input dimension. Image segmentation can also be performed to isolate the lungs from its background, theoretically removing irrelevant noises from being picked up as features by focusing on the Region of Interest (ROI). Another option is to perform image enhancements that enhance defining features of deformations. For this use case, histogram equalization can be used to distribute pixel intensity level. The referred paper suggested the use of Contrast Limited Adaptive Histogram Equalization (CLAHE) as it remedies the downside of using plain Adaptive Histogram Equalization which have the possibility to increase noise intensity in homogenous areas (areas with similar pixel values).

Increasing dataset is one of the popular ways to increase the performance of deep learning models. Considering the relatively young age of the COVID-19 pandemic, there is a scarcity of available datasets. Addition of augmented data can remedy this problem. It should be noted that augmentation is only performed on training datasets to avoid contaminating test datasets that are used for validation with artificial data. Options for augmentation include positional, colour and noise injection. These variations in data adds to the trained model's capability to learn from a more generalised, near to real life data that it will eventually try to classify during its application.

C. Image Pre-processing Methods to Enhance Input Features

Enhancing images as a part of data pre-processing is important in the application of CNN as the features learned are highly reliant on distinguishing features detected from input images. Improving the features of these images via removal of noise or blur and increasing contrast will help in improving spatial features, thus helping CNN models to learn better [10]. Still, the application of image enhancement must be performed in a way that will not affect information contained within the images. Altered features may lead to false learning, which in return will have a negative impact on the final model output. Various methods of image enhancements have been proposed to help improve classification models.

A paper on enhancing images used a fuzzy grayscale enhancement method to address low contrast due to inadequate lighting during capture [17]. The method used succeeded in improving image quality whilst also requiring relatively minimal processing time compared to other techniques. The proposed technique is performed by maximizing fuzzy measures within input images. Power-law transformation and saturation operator is then used to alter the membership function (a curve that defines how each point in the input space is mapped to membership value between 0 and 1) associated with the images.

A four stage image enhancing solution has also been proposed by M.Selvi and Aloysius George namely pre-processing, fuzzy based filtering, adaptive thresholding followed by morphological operation [18]. The stages are created to help pinpoint pixel areas and improve them using Fuzzy based filtering technique and adaptive thresholding. Resulting images are enhanced to have better peak signal-to-noise (PSNR) values compared to other filtering techniques at the time of the paper being written maps, etc., by exploiting similarity and semantic relationships. The nonlinear representation is further exploited in exploring web image search results.

III. METHODOLOGY

A. Data Preparation

The dataset used in this paper is obtained from Kaggle, titled COVID-19 Radiography Database [14], [16]. The dataset can be found using the following link: <https://www.kaggle.com/datasets/tawsifurrahman/covid19radiography-database>. The images are from four health condition classes namely COVID-19, normal (healthy), lung opacity (non-COVID lung infection) and viral pneumonia. Total number of images for each class are 3616, 10192, 6012 and 1345 respectively. Totalling the numbers gives us 21165. This dataset is built by researchers from Qatar University and the University of Dhaka, Bangladesh along with their collaborators from Pakistan and Malaysia. Sources include padchest dataset, a Germany medical school, Github, SIRM, Kaggle and Tweeter. The images are X-Ray scan results from patients subjected to the scan for the purpose of detecting COVID-19. The CNN model will be used to perform feature extraction on these images and use the characteristics identified in input feature maps for the purpose of classification. Based on the abnormalities present in the chest X-ray scans, the CNN model will then be able to perform the necessary predictions. The augmented training data

generation for the CNN model was performed using the Keras ImageDataGenerator class with several parameters passed for the purpose of data augmentation. Data augmentation is a method that increases the amount of data artificially by creating new sets of data derived from geometric transformations applied on the original dataset. Alterations include forms of rotation, translation, flipping and noise addition. Forms of alteration such as adjusting brightness or applying ZCA whitening is not considered. Instead, minor width and height shift is applied to account for possible positions at which the lung and corresponding abnormalities are located within the X-ray scans. Horizontal flip is also enabled, while vertical flip is not. This means, the model will not take into consideration an upside-down X-Ray scans as well as forego any significance put into the positions of pneumonia induced lung malformations. In simpler words, any abnormalities formed either at the right or the left side of the CXR scans are considered to have the same significance in classifying the respective CXR scans.

As highlighted above, the distribution of data for each class is not balanced, with normal X-ray scans consisting almost half of the entire dataset. This was not addressed as initially considered in favour of maintaining the amount of learnable data over possible bias. Dropping these images with the purpose of balancing the dataset may lead to a reduction of performance as the pool of data that the model can learn from reduces. Geometric transformations are not applied to the data due to the sensitive dependence on pixel locations as well as the minute variations that accounts for the difference in the X-ray classes. Other options such as increasing brightness is also not applied as X-ray scans are generally similar in both currently used dataset as well as in real-life practice.

The usual train test split is used instead of stratified split as the preservation of class proportion is not desired due to the imbalance of samples as mentioned. Aside from training purposes, the training set is also sampled and passed to the same pre-processing function used in training to provide visualizations of CXR scans after being processed.

B. Data Pre-processing

Equations in display format are separated from the paragraphs of the text. Equations should be flushed to the left of the column. Equations should be made editable. Displayed equations should be numbered consecutively, using Arabic numbers in parentheses. See Eq. (1) for an example. The number should be aligned to the right margin.

Based on randomly sampled observations, all images are perfectly collected for training, with no visible defects that might significantly impact the model's performance. Thus, no images have been dropped from the original dataset. Normalization is performed on both training and test datasets by enabling the rescale parameter (rescale = 1./255) which converts the pixels within the range from [0, 255] to [0, 1]. This scaling procedure aids in making images contribute more evenly to the calculated total loss. The low range also helps in increasing the likeliness of the neural network to converge.

The input (training and test) images are also resized uniformly to 256 by 256 by specifying the input shape parameter in the first layer of the Keras sequential model.

Three pre-processing methods have been chosen as the differentiating variable for each model, which are CLAHE, histogram equalization [20] and no pre-processing. CLAHE and histogram equalization are image enhancement methods used to bring out distinguishing features that might be important for deep learning models to capture thus building their knowledge base on the classes within the dataset. Both pre-processing methods are implemented using the OpenCV API. CLAHE stands for Contrast Limited Adaptive Histogram Equalization and is a subset of adaptive histogram equalization. It is used primarily to improve contrast in images akin to the usual histogram equalization with a slight difference in approach. Instead of using the entire image, CLAHE computes multiple histograms by focusing on small regions within an image called tiles. These tiles correspond to local areas within distinct sections of the image which redistributes the lightness value of the image. This results in improved contrast, further enhancing the boundaries or edges that will be useful in capturing distinguishing shape of lung abnormalities within the CXR scans. CLAHE is an improved version of adaptive histogram equalization, in which it solves the problem of over amplifying noise in homogenous areas. This is done by the introduction of contrast limit that clips calculated histogram. The clipping process is performed before the calculation of Cumulative Distributions Function (CDF) [19]. This clipping variable is set in the pre-processing of input images phase for the first model by specifying the clip limit (CL) to be 4 using the OpenCV API. The number of tiles were kept the same as the default value specified by OpenCV which is (8,8).

Histogram equalization is an umbrella term that can be used to refer to various subsets of image enhancement using similar methodologies. However, in this experiment histogram equalization used as the manipulated variable for the second model refers to the traditional form of histogram equalization. The method contrasts itself with its aforementioned subset, CLAHE where it only uses one histogram that represents the whole image for the purpose of enhancement. These histograms are then equalized, resulting in a distribution of intensity values across the entire image. Regions with lower contrasts will then be able to increase its contrast as a result. Histogram equalization works particularly well with images with dark background and lighter coloured subjects such as XRay scans. It also has the advantage of being computationally cheaper compared to its more complex subset due to its fairly straightforward approach. The CDF of a standard histogram is given as $H'(i)$:

$$H'(i) = \sum_{0 \leq j < i} H(j) \quad (1)$$

This equation is then used to remap the histogram by normalizing $H'(i)$ to have a maximum value of 255. Next, the intensity values for the histogram equalized image can be obtained using the following equation:

$$\text{equalized}(x,y) = H'(\text{src}(x,y)) \quad (2)$$

Fig. 1. The process of applying CLAHE.

All models are fed with CXR scans that have been processed into a grayscale image using the OpenCV `cvtColor` method. Fig. 1 demonstrates the process of applying CLAHE (Contrast Limited Adaptive Histogram Equalization) to a chest X-ray image. Below is a detailed explanation of each step in the diagram: The first step involves dividing the chest X-ray image into a 4x4 grid, resulting in 16 smaller tiles.

This division is done to allow local contrast enhancement, which is the main feature of CLAHE. In the diagram, the original chest X-ray image is shown, and the grid overlay highlights the individual tiles. The next step involves setting a clip limit (CL). The clip limit controls the amount of contrast enhancement applied during CLAHE. A higher clip limit leads to greater contrast enhancement. In this flowchart, the clip limit is set to $CL = 0.02$. For each tile, a histogram is calculated. A histogram represents the distribution of pixel intensity values in the image. This step is important because CLAHE works by

manipulating the image's histogram to enhance the contrast in areas of the image with low contrast. After calculating the histogram, the clip histogram step follows. In this step, the histogram is clipped to the defined clip limit. If any part of the histogram exceeds the clip limit, it is clipped off and redistributed, effectively limiting the maximum intensity range. This helps in preventing over-enhancement of certain regions and preserving the details in the image.

This cumulative distribution function (CDF) represents the cumulative sum of the clipped histogram. It helps in redistributing the pixel intensities across the entire range, which further contributes to improving the local contrast. The equalization step follows the cumulative histogram calculation. Here, the pixel intensities are redistributed based on the cumulative histogram. This process enhances the contrast in the image by stretching the pixel intensity values over a wider range. The equalized histogram allows for a more balanced distribution of pixel values, making the image more visually appealing and improving the visibility of important features. The final step shows the enhanced tile after applying CLAHE. The local contrast of the selected tile has been enhanced, making the details of the image more visible. In this case, the tile with the "Sn" label (possibly representing a specific area of interest in the X-ray image) is shown as the final enhanced tile.

C. Descriptive Analysis

Samples of processed images have been by extracting images from the training dataset and passing it through the same image processing methods used in the training of the model. We can see the difference in the resulting images after being passed through different image processing methods as following Fig. 2:

Fig. 2. Images after pre-processed with different image enhancement methods.

Through observation, both CLAHE and histogram equalization has helped in highlighting the edges and the shape of lung opacities when present in CXR scans. Differences in between CLAHE and histogram equalization are as expected, where histogram equalization tends to subdue the intensity of homogenous areas (pixel with similar values). This can be described based on the third row of sample images, where the ribcages at the center of the histogram equalized image is seen to almost lose its shape due to lowered contrast. CLAHE on the other hand seems to uniformly enhance its features, consistently

providing clearer shape of the ribcages. We can also see that CLAHE tends to highlight the structures within white areas better compared to histogram equalized images. This may improve its chance in building a better predictor. It may also backfire as no mention of inner structures of lung opacity is mentioned to be a signal or indicator that can be used to distinguish different pneumonia diseases. This means that these enhanced inner structures might become irrelevant features in the process of identification.

D. Modelling to Data

Three different CNN models have been developed to fulfil the purpose of this paper. All models are constructed using the sequential model class from Keras with the same structure which consists of two convolutional layers, two max pooling layers, one flattening layer and two dense layers.

The convolutional layers are purposely built to have increasing number of filters as the inputs are passed deeper into the CNN model. This is done to capture larger numbers of patterns to enable the model in identifying greater nuances within the CXR scans. Convolutional layers are all proceeded by max pooling layers throughout the structure. Max pooling is immediately applied to the first layer of the CNN structure to downsample input images, reducing dimensions and learnable parameters. This helps in decreasing the amount of time needed to train the classification model. The overall structure can be visualized using the VisualKeras library as follows in Fig. 3:

Fig. 3. Resized structure of the CNN models used in the experiment.

Normalization: Normalization is a process in data preprocessing which is used to change the range of numerical data so that it is located in a specific cell, such as [0,1] or [1,1]. In image processing, normalization is a common practice. The essence of the method is some layer input data of the neural network that is preprocessed with zero mathematical expectations and unit variance with the intention of improving the stability and efficiency of the training process [10]. For FER tasks, normalization can give different features similar to ranges. Unnormalized data may lead to unstable gradient problems during model training. In deep learning models, normalized data may lead to a gradient that is too large or too small, thus affecting the learning effect of the model. The normalization in FER2013 dataset is shown in Fig. 8:

Over categorical in this experiment due to the mutually exclusive nature of the dataset classes. This means that the true classes (Y_i) are encoded as standalone integers instead of one-hot encoded. Examples of true classes for sparse categorisation are [1], [2], [3] while one-hot encoded true classes are [1,0,0], [0,1,0], [0,0,1]. The true classes in sparse categorisation refer to the indices of the classes. Linking the class prediction of a model is done by taking the ground truth. For example, if a model output is [0.5, 0.2, 0.4], the prediction will be class 1 if the class indexation starts from 1. The cross-entropy equation is the same, with the only difference being the format of the true class labels:

$$J(w) = -\frac{1}{N} \sum_{i=1}^N y_i \log(\hat{y}_i) \quad (3)$$

Where: y_{-i} = true label, \hat{y}_i = predicted label, W = model parameters.

To avoid overfitting, several options have been considered for data regularization such as adding a dropout layer, adding a normalization layer after the input layer, as well as adding a kernel regularizer in the last layer. Ultimately, it has been decided the only regularizer that will be used is the Ridge Regression regularizer (L2 regularization). The decision to not use normalization layer is due to significant drop in performance for all models when applied. Dropout layer has also been experimented but also disregarded due to similar drop in performance. Dropout layer has also been found to be more effective when used with deeper deep learning structures. The L2 regularization was chosen over L1 regularization as it does not have the tendency to completely remove features deemed as irrelevant. This behaviour is because L1 is capable of forcing coefficients to be exactly zero if given high enough tuning parameter value (usually denoted by λ). While this might be good in reducing the possibility of overfitting in most cases, L1 is not used in this experiment to preserve every single parameter no matter how insignificant and only measure their respective importance by their coefficient values. This decision is made to avoid removing possibly important nuances that might help in the final classification process.

Three options of optimizers have been considered, namely Adaptive Moment Optimization (Adam), stochastic gradient descent (SGD) and Root Mean Squared Propagation (RMSProp). After performing multiple iterations using a controlled model with the same structure, Adam has been chosen due to its excellent performance. It has also been chosen based on its efficiency when working with large datasets. Adam inherits the same concept of momentum from gradient descent with momentum, usually denoted by m_t . The formula is given as follows:

$$m_t = \beta_1 m_{t-1} + (1 - \beta_1) \left[\frac{\delta L}{\delta w_t} \right] \quad (4)$$

Where: m_t = aggregate of gradients at time t [current], m_{t-1} = aggregate of gradients at time $t-1$ [previous], w_t = weights at time t , δL = derivative of Loss Function, δw_t = derivative of weights at time t , β_1 = moving average parameter.

It also inherits the use of exponential moving average from RMSProp, giving us a new variable called sum of square of past gradients, denoted by v_t .

$$v_t = \beta_2 v_{t-1} + (1 - \beta_2) \left[\frac{\delta L}{\delta w_t} \right]^2 \quad (5)$$

Where: v_t = sum of square of past gradients, β_2 = moving average parameter.

Adam further improves on these variables by computing and using bias corrected versions of the variables. These new variables are given as follows:

$$\hat{m}_t = \frac{m_t}{1 - \beta_1^t} \quad (6)$$

$$\hat{v}_t = \frac{v_t}{1 - \beta_2^t} \quad (7)$$

The weights are then updated using the following equation:

$$w_t = w_t - \hat{m}_t \left(\frac{\alpha}{\sqrt{\hat{v}_t + \epsilon}} \right) \quad (8)$$

Where: ϵ = a small + ve constant to avoid 'division by 0' error.

When training a deep learning model, the training accuracy rate and validation accuracy rate are important indicators to measure the model performance. The training accuracy rate refers to the proportion of correct predictions of the model on the training data set during the training process. It reflects the model's performance on known training data. The validation accuracy rate refers to the prediction accuracy rate of the model on the validation set. Validation sets are data that have not been seen before in the training process and are mainly used to evaluate the generalization ability of the model.

$$\text{Train Acc} = \frac{\sum_{i=1}^n 1(\hat{y}_i = y_i)}{n} \times 100 \quad (9)$$

$$\text{Val Acc} = \frac{\sum_{i=1}^m 1(\hat{y}_i = y_i)}{m} \quad (10)$$

Where, for each training sample x_i the model's prediction \hat{y}_i , y_i is compared with the true label. If the prediction is correct, that counts as a correct prediction.

Due to the sheer variations of model that can be generated by varying the value of hyperparameters in CNN, cross-validation and hyperparameter tuning using GridSearchCV or RandomSearchCV has not been applied. This decision was made considering the computational costs involved as well as time constraints. However, hyperparameter tuning has been done manually to increase the performance of each model. The final values of hyperparameters are listed as below in Table I:

TABLE I. FINAL HYPERPARAMETERS CHOSEN FOR CNN MODELS

Hyperparameter	Value
Batch size	32
Epoch	25
Adam learning rate	0.001
Adam β_1	0.9
Adam β_2	0.999
Adam ϵ	0.0000007
L2 regularizer λ	0.01
CLAHE clip limit	4

E. Communicating and Visualizing the Results

As shown in Fig. 4, both Train Loss and Val Loss decrease gradually with the training rounds. The validation loss fluctuates at some points, but the overall trend is also downward. The CLAHE-enhanced model showed a good decreasing trend of training and verification loss, indicating that the model gradually learned the features on the training set and verification set. The training accuracy (Train Acc) and validation accuracy (Val Acc) both increased steadily, and basically became stable when they approached 20 epochs, indicating that the verification accuracy and training accuracy were close to each other, indicating that the model avoided overfitting well, and CLAHE enhancement helped the model learn image features better [5].

As shown in Fig. 5, training losses and validation losses decreased gradually, and validation losses also fluctuated in some epochs, but the overall trend was downward. Compared with the CLAHE-enhanced model, the validation loss fluctuation is slightly larger, indicating that the model has a slightly weak generalization ability on the validation set and may need further tuning. Training accuracy and validation accuracy rise rapidly in the initial phase and level off near 20 epochs. The verification accuracy is slightly lower than the training accuracy, which indicates that the performance of the model on the verification set is slightly worse than that on the training set, and there is a certain tendency of overfitting, but the overall performance is still good.

Fig. 4. Images after pre-processed with different image enhancement methods (I).

As shown in Fig. 6, Training losses and validation losses also decrease with epoch, and validation losses also fluctuate at some points, but less so. The loss of the model without preprocessing decreased relatively gradually, especially after 10 epochs, and the validation loss was sometimes slightly higher than the training loss, indicating that the model needed longer training

time to reach a stable state without preprocessing. Despite the high accuracy on the validation set, it performed slightly worse than models preprocessed with CLAHE and histogram equalization, suggesting that data without preprocessing may result in a limited ability of the model to learn features as well as it would have done with preprocessing techniques.

Fig. 5. Images after pre-processed with different image enhancement methods (II).

Fig. 6. Images after pre-processed with different image enhancement methods (III).

Image preprocessing has a significant effect on the performance of the model. CLAHE enhancement technology works best at improving local contrast, helping models better learn useful features to improve accuracy and reduce overfitting.

Histogram equalization came in second, while models without any preprocessing performed poorly. It is suggested to use appropriate image preprocessing technology in practical application to improve the generalization ability and overall performance of the model.

IV. RESULTS

The Table II outlines the performance of each model based on the predefined evaluation metrics above.

TABLE II. PERFORMANCE OF EACH MODEL

Image enhancement	Accuracy (%)	Validation accuracy (%)	Loss	Validation loss
CLAHE	93.26	91.31	0.1987	0.2503
Histogram equalization	93.16	91.42	0.1935	0.2569
No preprocessing	92.98	91.50	0.2020	0.2479

Based on the final results obtained, we can observe that all four evaluation metric scores for all of the models are relatively the same.

As shown in Table III. CLAHE performs the best at training, with the highest accuracy score and second lowest loss. The difference between models using histogram equalized inputs and no pre-processing is relatively minor, where no preprocessing scores 0.18 lower accuracy and 0.0085 higher loss. CLAHE scored 0.28 and 0.1 higher in training accuracy compared to no pre-processing and histogram equalized models respectively. CLAHE also has the second-best loss with a 0.0052 and 0.0032 margin compared to no histogram equalized and no pre-processing models. However, evaluation metrics based on the validation data set tells a different story, with CLAHE being the worst performer, with validation accuracy of 91.31 and a 0.0024 higher loss compared to no pre-processing. Interestingly, the model trained using inputs without any form of image processing became the best performer with a validation accuracy score of 91.50 and validation loss of 0.2479. This contradicts with initial hypothesis based on literature reviews, that CLAHE would be the best performer in both training and validation phase. Upon consideration, histogram equalization is chosen as the best method to enhance CXR scans for this very specific CNN model. The main reason to this choice is due its overall performance during both training and validation phase. Models that are better at validation usually signifies a better capability to generalise. Specifically for the context of this experiment, histogram equalization enables the model to better identify distinguishing features that characterise COVID-19 inflicted CXR scans instead of ‘memorizing’ the features through training datasets without actual ‘understanding’. The fact that CLAHE is better at enhancing the minute details of lung abnormalities might the drawback to its ability to generalize as well as histogram equalized model and no preprocessing model.

TABLE III. EVALUATION METRIC MEAN AND STANDARD DEVIATION CLAHE

Metric	Mean	Standard deviation
Training accuracy	0.869348	0.079467384
Training loss	0.351748	0.189184685
Validation accuracy	0.872868	0.044526815
Validation loss	0.34308	0.107216724

Table IV shows the histogram equalization model. the mean value of the training accuracy rate is 0.880868, and the standard deviation is 0.061541603, showing a high training accuracy rate, while the standard deviation is small, indicating that the training process is relatively stable. The average verification accuracy is 0.885632, and the standard deviation is 0.040508844. The verification accuracy is high and the fluctuation is small, indicating that the model has good generalization ability. The validation loss is 0.32322 with a standard deviation of 0.102009803, showing large fluctuations on some validation data, but still performing well overall. Histogram equalization improves the performance of the model, especially in the validation accuracy, but the validation loss fluctuates greatly, suggesting that its stability is slightly lower than that of CLAHE.

TABLE IV. EVALUATION METRIC MEAN AND STANDARD DEVIATION HISTOGRAM EQUALIZATION

Metric	Mean	Standard deviation
Training accuracy	0.880868	0.061541603
Training loss	0.323184	0.148779061
Validation accuracy	0.885632	0.040508844
Validation loss	0.32322	0.102009803

Table V shows that the mean training accuracy of the model without preprocessing is 0.876968, and the standard deviation is 0.063891847, indicating that the consistency in the training process is good, but the accuracy of the model is slightly lower than that of other preprocessing methods. The average validation accuracy is 0.875144, and the standard deviation is 0.044533499, which is close to the validation accuracy compared with other methods, but slightly lower than CLAHE and histogram equalization methods. The verification loss is 0.343188 and the standard deviation is 0.104845224. The fluctuation of the verification loss is large, which shows the instability of the model on the verification set.

TABLE V. EVALUATION METRIC MEAN AND STANDARD DEVIATION WITH NO-PREPROCESSING

Metric	Mean	Standard deviation
Training accuracy	0.876968	0.063891847
Training loss	0.335916	0.155654603
Validation accuracy	0.875144	0.044533499
Validation loss	0.343188	0.104845224

V. DISCUSSION

During the training phase, the CLAHE-enhanced model outperformed both the histogram equalization and no preprocessing models in terms of accuracy, achieving a training accuracy of 93.26%. This suggests that CLAHE excels in enhancing the minute details of lung abnormalities, which could be crucial in detecting subtle features associated with COVID-19 infections. The model's relatively low loss (0.1987) further emphasizes its ability to minimize errors during training.

However, the histogram equalization method, while slightly less effective than CLAHE in terms of training accuracy, performed well with a mean training accuracy of 93.16%. This method helped improve the contrast and brightness of CXR images, which may have helped the model more effectively learn the distinguishing features of the images. Notably, the training loss for histogram equalization (0.1935) was also lower than that of the CLAHE-enhanced model, suggesting that while CLAHE improves feature details, histogram equalization might be more effective at optimizing the overall model performance by reducing error rates during training.

The model without preprocessing, while achieving a slightly lower training accuracy (92.98%), showed stable training consistency. With a training loss of 0.2020, it demonstrated that even without preprocessing, the CNN model could still effectively learn to classify the CXR images, albeit with less precision than the other methods. This highlights that while preprocessing enhances model performance, it is not an absolute requirement for effective training.

The validation phase results presented a different picture, where the CLAHE-enhanced model performed the worst in terms of validation accuracy (91.31%) and exhibited the highest validation loss (0.2503). This is in contrast to the initial hypothesis, which anticipated that CLAHE would perform well in both training and validation phases. The discrepancy between training and validation performance suggests that while CLAHE is effective in fine-tuning the model's ability to capture minute details in CXR images, it might lead to overfitting. The enhanced features could cause the model to 'memorize' training data without fully generalizing to unseen validation images, thus impairing its performance on the validation set.

In contrast, the model trained without any preprocessing achieved the best validation accuracy (91.50%) and the lowest validation loss (0.2479), despite its lower training accuracy compared to CLAHE. This indicates that the lack of preprocessing enabled the model to generalize better, as it did not overfit the specific features of the training set. The validation results for this model demonstrate that preprocessing methods like CLAHE and histogram equalization might enhance feature extraction but at the cost of generalization ability. These findings highlight the importance of balancing training performance with generalization, especially in medical image classification, where the model must perform well on unseen data. The histogram equalization model, while showing good validation accuracy (91.42%), also exhibited noticeable fluctuations in validation loss (0.2569). While histogram equalization improved the model's ability to generalize better than CLAHE, it still presented challenges in terms of stability during the validation phase. The slightly better performance of the histogram

equalization model, compared to CLAHE, underscores its ability to enhance image contrast while maintaining reasonable generalization.

VI. CONCLUSION

This study evaluated the impact of different image preprocessing techniques—CLAHE, traditional histogram equalization, and no preprocessing—on the performance of a convolutional neural network (CNN) for COVID-19 classification using chest X-ray (CXR) images. The experimental results demonstrated that all preprocessing methods improved model performance during the training phase, but the validation phase revealed distinct trade-offs between accuracy, loss, and generalization ability.

The CLAHE-enhanced model achieved the highest training accuracy (93.26%) and exhibited strong stability, but it showed poor generalization in the validation phase, with the lowest validation accuracy (91.31%) and higher validation loss (0.2503). This suggests that while CLAHE helps capture detailed image features, it may lead to overfitting, affecting the model's ability to generalize effectively. In contrast, the model without preprocessing achieved the best validation performance, with a validation accuracy of 91.50% and the lowest validation loss (0.2479), highlighting its superior generalization ability. However, its training accuracy (92.98%) was slightly lower compared to the other methods. This finding emphasizes that while preprocessing enhances feature extraction, a simpler, unprocessed approach can sometimes yield better generalization.

The histogram equalization method, while not the best in training accuracy, provided a good balance between training performance and validation accuracy. With a validation accuracy of 91.42%, it demonstrated that traditional image enhancement techniques could improve generalization without overfitting, making it the most suitable preprocessing method for the CNN model in this study.

In conclusion, histogram equalization emerged as the optimal preprocessing method for COVID-19 classification in CXR images, offering the best combination of training and validation performance. Future work could investigate more sophisticated preprocessing techniques or hybrid models to further enhance both performance and generalization in medical image classification tasks.

VII. FUTURE WORKS AND LIMITATION

While this study has provided valuable insights into the effect of image preprocessing techniques on COVID-19 detection using chest X-ray (CXR) images, there are several avenues for future research to further enhance the performance and generalization of deep learning models. 1. Future work could explore combining CLAHE and histogram equalization to leverage the strengths of both methods. A hybrid preprocessing approach could potentially enhance image details while maintaining good generalization ability, addressing the limitations seen when using CLAHE alone. 2. The use of more sophisticated deep learning models, such as ResNet, DenseNet, or Inception networks, may further improve performance, especially in terms of handling complex features in CXR images. These architectures have been shown to excel at feature

extraction and overcoming challenges like overfitting. 3. To address the potential overfitting issues observed, further research could incorporate advanced data augmentation techniques. This could include random rotations, flips, and color jittering, or even synthetic data generation techniques, to create a more diverse training dataset and enhance the generalization capability of the model. 4. Future research should focus on testing these models in real-world clinical environments to evaluate their robustness, scalability, and performance on larger, diverse datasets. This would also include the development of a user-friendly interface for healthcare professionals to easily adopt the models in practice.

This study has several limitations that should be addressed in future work. 1. The model was trained using a limited number of CXR images from the COVID-19 Radiography Database. Although the dataset is large, it may not fully represent the variety of CXR images encountered in real-world clinical settings, which could impact the model's ability to generalize to diverse populations and varying image qualities. Expanding the dataset or incorporating additional datasets from other regions or healthcare providers could improve the model's robustness. 2. While different preprocessing techniques were evaluated, the impact of each preprocessing method may vary depending on the dataset used. The methods tested in this study may not perform equally well on other datasets or in clinical settings. Therefore, the generalizability of these findings across different datasets remains an open question. 3. While deep learning models, including CNNs, are powerful for image classification tasks, they are often criticized for their lack of interpretability. Future work should focus on making the models more explainable to healthcare providers. Techniques such as Grad-CAM (Gradient-weighted Class Activation Mapping) can be employed to visualize which parts of the CXR images are contributing to the model's predictions, making the model more transparent and aiding in clinical decision-making. 4. This study focused solely on the detection of COVID-19 from CXR images, and did not account for other variables that may affect the model's performance, such as different scanner types, patient positioning, or image resolution. These external factors can significantly influence model accuracy and should be considered in future studies for a more comprehensive evaluation of the model's real-world effectiveness.

ACKNOWLEDGMENT

Abstract—The general LSTM-based encoder-decoder model has the problems of not being able to mine the sentence semantics and translate long text sequences. This study presents a neural machine translation model utilizing LSTM with improved attention, incorporating multi-head attention and multi-skipping attention mechanisms into the LSTM baseline model. By adding multi-head attention computation, the syntactic information in different subspaces can be mined, and then attention can be paid to the semantic information in the sentence sequences, and then multiple attentions are computed on each head separately, which can effectively deal with the long-distance dependency problem and perform better in the translation of long sentences. The proposed model is analysed and compared using the WMT17 Chinese and English datasets, newsdev2017 and newstest2017, and the results show that the proposed model improves the BLEU score of the automatic translation of Tourism English Culture and solves the problem of low scores in long sentence translation.

Keywords—LSTM-based encoder-decoder model; tourism English culture; automatic translation; enhanced attention mechanism

I. INTRODUCTION

The process of economic globalisation has further brought about the globalisation of language, and English has become the only protagonist of linguistic globalisation, and English language learning has gradually become a matter of concern [1]. English, as a part of the cultural composition of tourism, has become a necessary skill for people travelling abroad across borders. In order to understand tourism English more conveniently, natural language processing technology based on artificial intelligence algorithms has entered people's life [2]. Natural Language Processing (NLP) is to transform the language humans usually communicate and the text they see into what machines can understand [3]. Natural language processing technology has a wide range of applications, including machine translation [4], sentiment classification [5], robot dialogue [6], text classification [7], etc. With the popularity of deep learning, deep neural networks began to be introduced into NLP tasks and made great progress, while machine translation based on deep neural networks received great attention, and researchers embedded deep neural networks into machine translation tasks, which led to the improvement of the quality of automatic English translation [8]. Deep neural network-based machine translation can effectively promote the future economic and social development, thus enhancing people's satisfaction and sense of access. Therefore, the study of machine translation of

tourism English based on deep neural networks is a meaningful research direction, which is of great significance for globalised economic exchange and cultural output [9].

The primary objective of the application of deep learning technology in the automatic translation of tourism English culture is to acquire a comprehensive understanding of the structure and laws of language through neural network models, thereby enhancing the quality and efficiency of translation [10]. Currently, the automatic translation methods of tourism English culture based on deep learning include Seq2Seq model [11], Attention mechanism [12], Transformer model [13], Pre-training language model [14], Multi-modal data translation [15], Zero Resource Translation [16], Online learning and incremental learning of Neural Machine Translation [17] [18] and so on. Although Neural Machine Translation has made greater progress and is better than Statistical Machine Translation on some public datasets, Neural Machine Translation is still far from the effect of human translation, and there are still the following challenges and problems [10]: 1) data sparsity problem; 2) model optimisation problem; 3) large-scale vocabularies and rare words problem.

This text proposes a method for autonomous cultural translation of Tourist English, addressing the issues of attention computation and model optimization in encoder-decoder architectures utilizing recurrent neural networks, specifically through the implementation of an LSTM-enhanced attention mechanism. This paper's primary contributions are: 1) the introduction of an automatic language translation model and a neural machine translation framework; 2) the investigation and design of a neural machine translation model utilizing an LSTM-enhanced attention mechanism; and 3) a comparative analysis of the proposed model employing the Tourism English dataset.

The structure of this paper is organized as follows: Section I discusses foundational techniques, covering automatic translation systems and neural machine translation frameworks. Section II outlines the key challenges in translating tourism English, such as data sparsity and issues with long-sequence translations. Section III introduces the enhanced attention mechanism based on LSTM, emphasizing multi-head and multi-hop attention for improved performance. Section IV describes the experimental framework, including datasets, evaluation methods, and model comparisons using BLEU scores. Section V presents the findings and analysis, demonstrating the model's advantages. Last Section VI concludes with insights and suggestions for future work.

II. RELEVANT THEORETICAL TECHNIQUES

A. Automatic Language Translation Models

The Automatic Language Translation Model [19] is a tool that uses artificial intelligence techniques to automatically convert text from one language to another by means of a computer programme, as shown in Fig. 1.

Automatic language translation models are usually based on deep learning techniques, especially neural networks, such as Recurrent Neural Networks (RNN), Long Short-Term Memory

Networks (LSTM) and Transformer models, as shown in Fig. 2. They are capable of handling complex linguistic structures and expressions and have achieved good translation quality in several public reviews.

To mitigate the issues associated with one-hot encoding, including context independence and excessive dimensionality, the Neural Probabilistic Language Model (NPLM) [20] derives word vectors by learning word distributions, as illustrated in Fig. 3.

UnitY model architecture

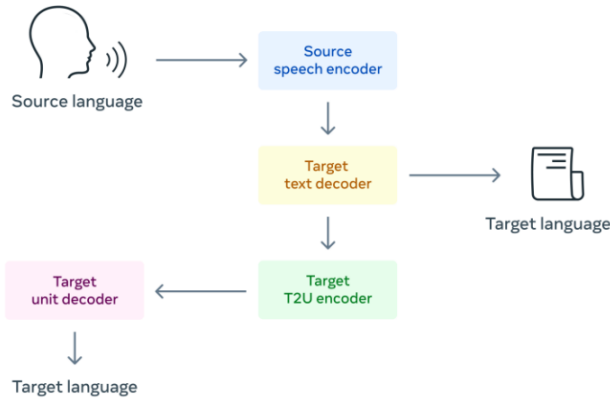

Fig. 1. Model of automatic language translation.

Fig. 2. Classification of automatic language translation models.

Fig. 3. NPLM structure.

In the NPLM structure, given a text sequence $(w_1, w_2, \dots, w_t, \dots, w_T)$, where w_t is the word in the word list V . The objective function is to build the optimal model f , calculated as follows:

$$f(w_t, \dots, w_{t-n+1}) = \hat{P}(w_t | w_1, \dots, w_{t-1}) \quad (1)$$

$$\sum_{i=1}^{|V|} f(i; w_{t-1}, \dots, w_{t-n+1}) = 1 \quad (2)$$

The structure is divided into two parts, the first part is to build a mapping from any word w_i to a vector in the word list V $C(i)$, the second part has a feed forward neural network g to fit $f(i; w_{t-1}, \dots, w_{t-n+1})$ where $f(i; w_{t-1}, \dots, w_{t-n+1}) = g(i, C(w_{t-1}), \dots, C(w_{t-n+1}))$, the training objective is to maximise the following equation:

$$L = \frac{1}{T} \sum_t \log f(w_t, w_{t-1}, w_{t-N+1}) + R(\theta) \quad (3)$$

where R is the regular term and θ is the parameter of the feedforward neural network g .

B. Neural Machine Translation Framework and Classification

1) *Text feature representation*: Based on the representation of word vectors, the textual feature representation is subsequently obtained, i.e. the Embedding operation [21], the specific structure of which is shown in Fig. 4. The Embedding layer is often used in the first layer of the neural machine translation model, and its role is to map the input sequences into dense vectors of lower dimensions, which are able to characterise the word information effectively.

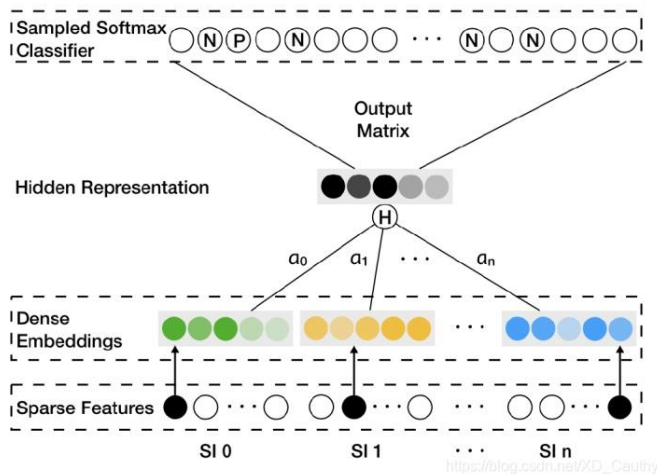

Fig. 4. Embedding operation.

2) *Encoder-decoder structure*: Many neural machine translation models are constructed using the Encoder-Decoder framework [22], which is also referred to as the sequence-to-sequence architecture. The fundamental concept of neural machine translation is exemplified by this framework, which involves the conversion of a source text sequence into a

mathematical problem. The mathematical problem is then solved to produce a target text sequence. Refer to Fig. 5 for the specific structure.

Fig. 5. Encoder-Decoder structure.

Fig. 5 illustrates that the Encoder-Decoder architecture comprises two components: the Encoder, which processes a word from the source sentence at each time step, extracting the informational properties of the source sequence. Subsequent to several time steps, all words will be condensed into the encoder's hidden states, resulting in a context vector C . The decoder receives inputs comprising the context vector C , the prior hidden states, and the previously anticipated output. The outcome of each phase serves as input for the subsequent step.

In this procedure, the decoder functions as a language model; however, this model is conditional, constructed based on the context vector C , therefore referred to as a "Conditional Language Model." The expression is stated as follows:

$$p(y) = \prod_{t=1}^n p(y_t | y_1, y_2, \dots, y_{n-1}, C) \quad (4)$$

where the output target sequence is $y = (y_1, y_2, \dots, y_n)$.

III. LSTM ENHANCED ATTENTION MECHANISM AND APPLICATIONS

A. LSTM Enhanced Attention Mechanism

This study proposes an upgraded neural machine translation model utilizing an LSTM-based attention mechanism, which is an improvement of the RNN encoder-decoder architecture. The model comprises three components:

1) *Encoder*: This component employs a bidirectional LSTM neural network (Bi-LSTM) [23], which combines the sentence information of the source sequence with the future textual information. The word embedding vectors are input into the Bi-LSTM to encode the complete source sentence, which is subsequently processed by the augmented attention module;

2) *Enhanced attention module*: this component receives all the encoder's concealed states after the source sequence is encoded at the encoder side and calculates them in conjunction with the decoder's current state to generate the dynamic context vector for the current moment. This section encompasses both Multi-Head Attention [24] and Multi-Hop Attention [25] methods.

- The multi-attention mechanism is mainly designed to fully mine the sentence information in different subspaces in the model, and the specific structure is shown in Fig. 6.

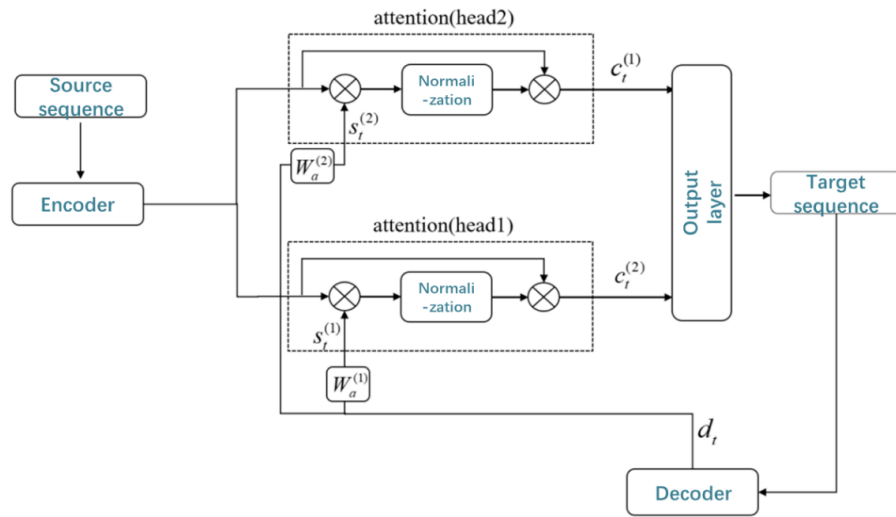

Fig. 6. Multi-attention mechanism structure.

- The multi-hop attentional mechanism mainly performs multiple attentional computations on each HEAD to extend the model's representational capability. The specific structure is shown in Fig. 7.

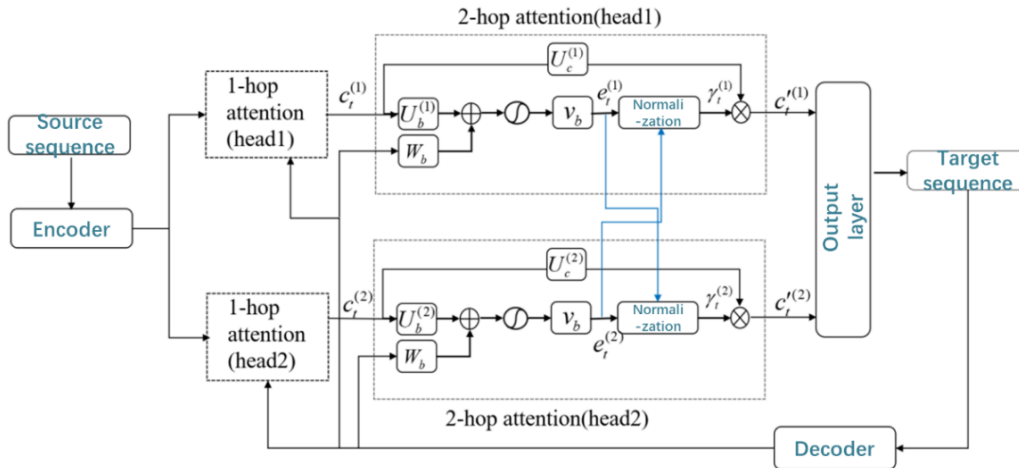

Fig. 7. Structure of multi-hop attention mechanism.

3) *Decoder*: This part is using LSTM network and receives the hidden state information from the encoder.

The overall structure of the model is shown in Fig. 8.

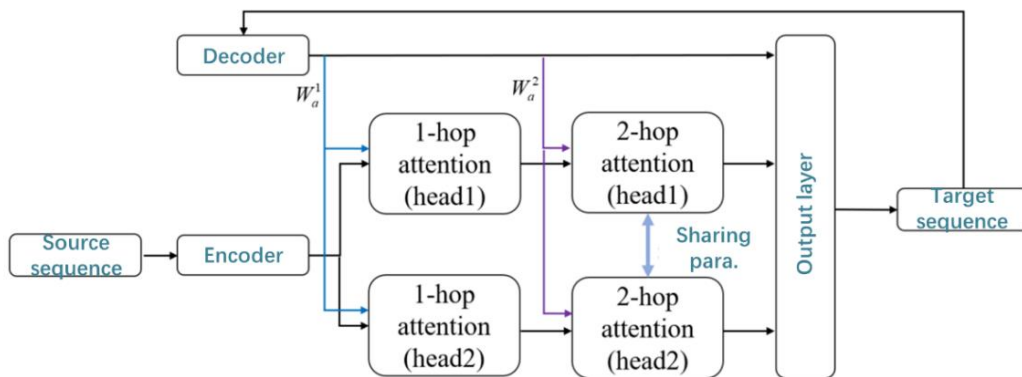

Fig. 8. General structure of the model.

B. Modelling Steps

The operational procedures of the LSTM-based neural machine translation model utilizing an increased attention mechanism are as follows:

1) Input the source sentence sequence $X = (x_1, x_2, \dots, x_T)$ into the encoder with Bi-LSTM, the forward LSTM f_{LSTM} reads the sentence sequence sequentially from x_1 to x_T and computes the forward hidden state $(\vec{h}_1, \vec{h}_2, \dots, \vec{h}_T)$; the backward LSTM \bar{f}_{LSTM} reads the sentence sequence sequentially from x_T to x_1 and computes the backward hidden state $(\vec{h}_1, \vec{h}_2, \dots, \vec{h}_T)$, and splices the forward hidden state and the backward hidden state to get the final hidden state h_t , which is computed by the following formula:

$$h_t = [\vec{h}_t; \vec{h}_t] = [LSTM_{encoder}(x, \vec{h}_{t-1}); LSTM_{encoder}(x, \vec{h}_{t+1})] \quad (5)$$

2) Deliver the hidden state h_t to the Enhanced Attention Mechanism module;

3) Calculate the 1-hop attention score. Based on the hidden state of the target sequence with respect to the previous time node, the output of the LSTM at the current moment is obtained d_t :

$$d_t = LSTM_{encoder}(\hat{y}_{t-1}, d_{t-1}) \quad (6)$$

4) Based on the trained matrix $W_a^{(k)}$, get the hidden state $s_t^{(k)}$ at the current moment:

$$s_t^{(k)} = W_a^{(k)} d_t \quad (7)$$

where k represents the k th head.

5) Calculate the context vector $c_t^{(k)}$ for the k th head:

$$c_t^{(k)} = \text{soft max}(s_t^{(k)} H_{encoder}^T) H_{encoder} \quad (8)$$

6) Calculate the attention fraction of 2-hop:

$$e_t^{(k)} = v_b^T \tanh(U_b^{(k)} c_t^{(k)} + W_b s_t^{(k)}) \quad (9)$$

7) Normalise the attention score for each HEAD to $\gamma_t^{(k)}$:

$$\gamma_t^{(k)} = \frac{\exp(e_t^{(k)})}{\sum_{n=1}^N \exp(e_t^{(n)})} \quad (10)$$

where N represents the total number of heads.

8) The trained parameters $U_t^{(k)}$, $\gamma_t^{(k)}$ and $c_t^{(k)}$ are used to compute the context vector $c_t^{n(k)}$ at the current moment with the following formula:

$$c_t^{n(k)} = \gamma_t^{(k)} U_c^{(k)} c_t^{(k)} \quad (11)$$

9) The context vector $c_t^{(k)}$ is spliced with the output of LSTM d_t , and the text feature vector is obtained by training parameters with Tanh activation function layer:

$$o_t = \tanh\left(W_o \left[d_t; c_t^{(1)}; c_t^{(2)}; \dots; c_t^{(k)} \right] \right) \quad (12)$$

10) The decoder inputs the final text vector o_t to the output layer to get the model prediction result, which is calculated as follows:

$$p(y_t | y_1, y_2, \dots, y_{t-1}, X) = \text{soft max}(o_t) \quad (13)$$

Fig. 9 illustrates the computational process of the neural machine translation model, which is based on the LSTM enhanced attention mechanism.

Fig. 9. Computational process of neural machine automatic translation model.

IV. MODEL EXPERIMENTS AND ANALYSES

A. Data Sets

The training dataset used for the experiments in this section is the WMT17 Chinese-English (WMT17zh-en) dataset [26], which is used to train the neural machine translation model based on the LSTM enhanced attention mechanism proposed in this chapter, and newsdev2017 and newstest2017 are used as the validation and test sets [27], respectively, and the introduction about them is shown in Table I.

TABLE I. DATA INFORMATION

Data type	Name (of a Thing)	Magnitude
Training set	WMT17zh-en	227k
Validation set	newsdev2017	4k
Test set	newstest2017	2k

The model is generally set to a fixed text length, so the pad operation is used to supplement sentences of shorter length, as shown in Fig. 10.

Fig. 10. Pad operation.

B. Indicators for Assessing Translation Effectiveness

In this paper, we adopt an automatic machine translation evaluation method, i.e. BLEU (Bilingual evaluation understudy) [28]. BLEU is the calculation of a similarity score between a given translation generated by a machine translation system, and a reference translation, which is used to measure the performance of this machine translation system, where the range of this score is [0,1]. The specific calculation formula is as follows:

$$BLEU = BP \cdot \exp\left(\sum_{n=1}^N w_n \log P_n\right) \quad (14)$$

$$BP = \begin{cases} 1 & c > r \\ e^{(1-r/c)} & c \leq r \end{cases} \quad (15)$$

where w_n is the weight for different n-grams, P_n is the weight of the corresponding n-element word in the sequence of reference answers, c is the length of the candidate sentence, and

r is the number of words in common between the model-translated sentence and the reference answer sentence.

C. Environmental Settings

This experiment is a deep neural network based translation model, the required experimental environment is shown in Table II, the deep learning framework used for the model experiments in this paper is Pytorch 1.8.1, which contains a large number of libraries internally for the convenience of the researcher. Bi-LSTM [29] and Conv S2S model [30] are used to compare with the proposed model, and the specific model parameter settings are shown in Table III.

V. ANALYSIS OF RESULTS

Table IV presents the BLEU scores for the Bi-LSTM, Conv S2S model, and the neural machine translation model utilizing an LSTM-enhanced attention mechanism across three datasets: WMT17zh-en, newsdev2017, and newstest2017. Table IV illustrates that the BLEU scores of the neural machine translation model utilizing an LSTM-enhanced attention mechanism are the highest across the three datasets: WMT17zh-en, newsdev2017, and newstest2017, with scores of 22.86, 23.64, and 23.14, respectively.

TABLE II. CONFIGURATION OF THE EXPERIMENTAL ENVIRONMENT

No.	Causality	Attribute value
1	CPU	Intel Intel(R) Xeon(R)
2	GPUs	Ge Force RTX 2080Ti
3	memory	24G
4	programming language	Python 3.8.3
5	Deep learning frameworks	Pytorch 1.8.1
6	operating system	Linux

TABLE III. PARAMETER SETTINGS FOR EXPERIMENTAL COMPARISON MODELS

No.	Modelling	Parameterisation
1	Bi-LSTM	Stacked 4-layer LSTM with 1000 hidden layers each, the dimension of word embedding is 1000; the number of neurons in the attention mechanism layer is 1000; the optimiser is SGD, the initial learning rate is 0.005, the batch size is 128 and the number of iterations is 50
2	Conv S2S	The dimensions of the hidden units of the encoder and decoder are 512; the optimiser is SGD; the dropout probability is set to 0.2, the initial learning rate is 0.005, the batch size is 128 and the number of iterations is 50
3	Proposed Method	2-layer Bi-LSTM with word embeddings of dimension 1024, optimiser SGD; initial learning rate 0.005, batch size 128, number of iterations 50

In order to observe the differences between the three models more intuitively, the data in Table IV were visualised as bar charts, as shown in Fig. 11. As can be seen from Fig. 11, on the WMT17zh-en data, the neural machine translation model based on the LSTM enhanced attention mechanism has a higher value of 1.44 BLEU and 0.56 BLEU than the Bi-LSTM and Conv S2S models, respectively; on the newsdev2017 data, the model proposed in this paper has a higher value of 1.44 BLEU and 0.56 BLEU than the Bi-LSTM and Conv S2S models 0.75 BLEU and 0.4 BLEU values, respectively; on newstest2017 data, the model

proposed in this paper outperforms Bi-LSTM and Conv S2S models by 1.28 BLEU and 0.36 BLEU values, respectively.

TABLE IV. EXPERIMENTAL COMPARISON MODEL OF BLEU SCORES

No.	Modelling	WMT17zh-en	newsdev2017	newstest2017
1	Bi-LSTM	21.42	23.89	21.86
2	Conv S2S	22.28	23.24	22.78
3	Proposed Method	22.86	23.64	23.14

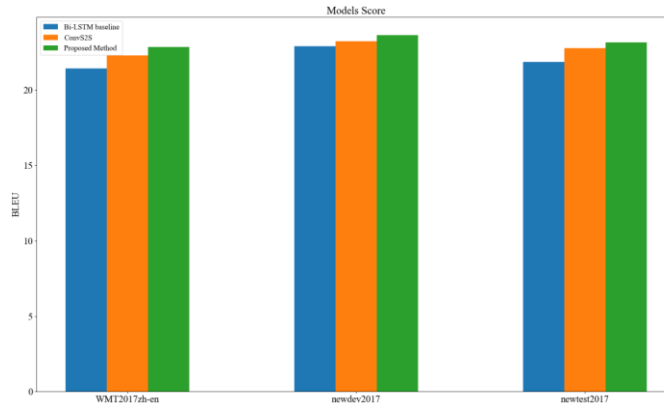

Fig. 11. BLEU scores for three models.

In order to analyse the BLEU scores of the three models under different tourism English sentence lengths, this paper investigates 11 length ranges of tourism English long sentences, and the specific results are shown in Fig. 12. Fig. 12 illustrates that despite the neural machine translation model utilizing the

LSTM-enhanced attention mechanism exhibiting a lower BLEU score compared to the Conv S2S model within the sentence length range of [20,25], it surpasses the BLEU score of the Conv S2S model for sentence lengths around 80 and exceeding 90.

Fig. 12. BLEU scores of the three models for different sentence lengths.

VI. CONCLUSION AND OUTLOOK

This work addresses the issue of automatic translation within the context of English culture, highlighting the shortcomings of the LSTM-based encoder-decoder model, and presents a neural machine translation model that incorporates an increased attention mechanism based on LSTM. By examining pertinent theoretical methodologies and delineating the challenges of English automatic translation, a neural machine translation model utilizing an LSTM-enhanced attention mechanism is developed through the implementation of multi-hop attention computation and multi-head attention procedures. The

experimental part uses WMT17 Chinese and English datasets, newsdev2017 and newstest2017, and introduces the criteria of machine translation evaluation to measure the effect of translation quality through BLEU. The experimental comparative analysis demonstrates the effectiveness of the proposed enhanced attention mechanism, especially for translating long sentences.

Despite its effectiveness, the proposed LSTM-based enhanced attention model for tourism English translation has several limitations. First, the reliance on the WMT17 dataset may limit the model's applicability to other domains or language

pairs, as the dataset might not cover diverse linguistic features or cultural nuances. Second, while the multi-head and multi-hop attention mechanisms improve long-sequence translation, the model's complexity increases significantly, leading to higher computational costs and longer training times. Third, the translation quality heavily depends on the availability of high-quality, domain-specific training data, which remains a challenge in many low-resource contexts. Lastly, the model's performance was evaluated solely with BLEU scores, which might not fully capture the subtleties of cultural translation, such as idiomatic expressions or contextual accuracy. These limitations suggest the need for further improvements in model generalizability, efficiency, and evaluation methods.

To overcome the limitations identified, future research could focus on the following areas: Future research should focus on expanding datasets to include diverse linguistic and cultural contexts, beyond just tourism English. This can involve collecting data from multiple language pairs and incorporating low-resource languages to improve the model's adaptability. A richer dataset will ensure that the translation system captures various idiomatic expressions and cultural nuances, making the model more universally applicable and effective in handling diverse real-world scenarios.

To address the computational burden, future work could explore optimizing the model's architecture to be more lightweight without sacrificing performance. Techniques such as sparse attention mechanisms or pruning can reduce resource usage and training times. This would make the model more scalable and suitable for deployment in environments with limited computing resources, such as mobile devices or embedded systems.

Incorporating more comprehensive evaluation metrics is essential to fully capture translation quality. Beyond BLEU scores, qualitative metrics should be used to assess how well the model handles idiomatic expressions and cultural subtleties. Adding human evaluation to the testing process can provide valuable insights into the model's contextual accuracy and overall fluency, ensuring more reliable and culturally sensitive translations.

Abstract—The inherent biases present in language models often lead to discriminatory predictions based on demographic attributes. Fairness in NLP refers to the goal of ensuring that language models and other NLP systems do not produce biased or discriminatory outputs that could negatively affect individuals or groups. Bias in NLP models often arises from training data that reflects societal stereotypes or imbalances. Robustness in NLP refers to the ability of a model to maintain performance when faced with noisy, adversarial, or out-of-distribution data. A robust NLP model should handle variations in input effectively without failing or producing inaccurate results. The proposed approach employs a novel metric called CFRE (Context-Sensitive Fairness and Robustness Evaluation) designed to measure both fairness and robustness of an NLP model under different contextual shifts. Next, it projected the benefits of this metric in terms of experimental parameters. Next, the work integrated counterfactual data augmentation with help of Self-Imitation Reinforcement Learning (SIL) to reinforce successful counterfactual generation by enabling the model to learn from its own high-reward experiences, fostering a more balanced understanding of language. The integration of SIL allows for efficient exploration of the action space, guiding the model to consistently produce unbiased outputs across different contexts. The proposed approach demonstrates the effectiveness of our method through extensive experimentation and compared the results of the proposed metric with that of WEAT and SMART testing, and showed a significant reduction in bias without compromising the model's overall performance. This framework not only addresses bias in existing models but also contributes to a more robust methodology for training fairer NLP systems. Both the proposed metric and SIL showed better results in experimental parameters.

Keywords—Natural language processing; fairness, robustness; Word Embedding Association Test (WEAT); SMART testing

I. INTRODUCTION

Natural Language Processing (NLP) serves as a linchpin in enabling seamless human-computer interaction, fostering intuitive communication through interfaces like voice assistants and chatbots. It empowers the automation of text analysis, expediting tasks such as sentiment assessment, document summarization, and content categorization with unparalleled efficiency. By transcending linguistic barriers, NLP promotes global interconnectivity, facilitating multilingual translation and cultural localization.

Its contributions to AI advancements are transformative, powering sophisticated systems like personalized virtual assistants and predictive analytics. NLP is instrumental in extracting actionable insights from unstructured textual data, supporting informed decision-making in critical domains like healthcare, finance, and governance. Furthermore, it champions inclusivity by fostering the development of assistive technologies, such as speech-to-text systems and screen readers, to accommodate individuals with disabilities.

By addressing linguistic diversity and automating complex textual processes, NLP is not merely a technological tool but a catalyst for innovation and inclusivity in the digital age.

Natural Language Processing, a subfield of Artificial Intelligence, has become pivotal in automating and enhancing communication, yet its deployment raises pressing concerns around fairness and robustness. At its core, fairness in NLP pertains to the equitable and unbiased performance of language models across diverse demographic and linguistic groups. Robustness, conversely, measures a model's resilience to adversarial inputs, distributional shifts, or unexpected variations in data. Together, these dimensions are critical to ensuring the ethical and reliable use of NLP technologies.

One of the primary fairness challenges arises from biased training datasets, which reflect historical inequities, stereotypes, or regional disparities. These biases, embedded in language corpora, can perpetuate societal injustices when reflected in model outputs. For instance, gendered pronoun resolution systems may reinforce occupational stereotypes by associating women with caregiving roles and men with leadership positions.

Robustness, on the other hand, is tested when models face adversarial attacks or operate in low-resource settings. Subtle manipulations in input texts—like typos or syntax changes—can disproportionately degrade model performance. Similarly, underrepresentation of certain languages, dialects, or sociolects exacerbates the risk of exclusionary AI systems that fail to generalize effectively.

The interplay of these issues creates a dual imperative: to mitigate inherent biases while enhancing models' adaptability across varied scenarios. Ethical considerations are further compounded by the lack of standardized benchmarks for measuring fairness and robustness. Solutions often involve trade-offs, as techniques that improve robustness, like data augmentation, may inadvertently amplify biases.

Addressing these challenges requires a multi-faceted approach. Incorporating diverse, high-quality datasets and developing fairness-aware training algorithms are pivotal steps. Furthermore, interdisciplinary collaboration—spanning computational linguistics, ethics, and social sciences—can provide nuanced perspectives to inform NLP research. Regular audits, explainable AI methods, and inclusive design principles are essential to embedding trustworthiness into language technologies.

In conclusion, fairness and robustness are not merely technical hurdles but societal imperatives in the age of pervasive AI. As NLP systems permeate sensitive domains like hiring, healthcare, and legal adjudication, ensuring their ethical and equitable deployment becomes a moral obligation. The paper is organized as follows. Section I gives introduction the problem of bias in NLP. Section II gives explains types of bias in NLP. Section III gives various existing metrics for measuring bias. Section IV explains briefing, challenges of robustness and robustness contextual evaluation respectively. Experimental results is given in Section V and finally, the paper is concluded in Section VI.

1) *The Problem of Bias in NLP*: Bias in Natural Language Processing (NLP) refers to the systematic favoritism or prejudice exhibited by language models, often stemming from imbalances or stereotypes present in their training data. This phenomenon undermines the equity, reliability, and ethicality of NLP systems, leading to unintended discriminatory consequences. Bias is particularly critical in applications influencing high-stakes decisions, such as hiring algorithms, legal systems, and healthcare tools, where such predispositions can perpetuate societal inequities [1-3].

At its root, bias arises from the data-driven nature of NLP models, which inherit the flaws, prejudices, and imbalances embedded in the corpora used for training. When these systems process text, they often reinforce or amplify existing stereotypes, inadvertently perpetuating harm against underrepresented or marginalized groups. Addressing bias is a multifaceted challenge that requires understanding its various types and manifestations.

II. TYPES OF BIAS IN NLP

1) *Representation bias*: This form of bias originates in training datasets that over represent certain groups or perspectives while neglecting others. For example, texts predominantly authored in English may marginalize speakers of minority languages or dialects, perpetuating cultural hegemony.

2) *Stereotypical bias*: Models can perpetuate harmful stereotypes, such as associating certain professions with specific genders or ethnicities. For instance, a model might predict "nurse" as a woman or "engineer" as a man based on biased correlations in training data.

3) *Historical bias*: Historical biases reflect long-standing societal inequities embedded in data. Even if collected neutrally, datasets often capture systemic inequalities, such as

racial or gender disparities, which are then reflected in the model's predictions.

4) *Selection bias*: This bias arises from skewed data collection processes. If a training dataset is predominantly drawn from urban populations, for instance, the resulting model may fail to generalize to rural or less technologically advanced contexts.

5) *Aggregation bias*: When data from diverse groups are aggregated into a single dataset, the unique characteristics of minority groups may be overshadowed by majority trends, leading to homogenized outputs that overlook nuanced needs.

6) *Interaction bias*: This bias emerges during user interaction with NLP systems. For example, users' queries can introduce biases that models then propagate, such as autocomplete suggestions that reinforce prejudiced or inappropriate language.

7) *Temporal bias*: Temporal bias stems from the use of outdated data that fails to account for societal evolution. For instance, older datasets might include terms or perspectives that are now considered offensive or obsolete.

8) *Implicit bias*: Implicit biases are more subtle and embedded within the model's architecture, often surfacing in nuanced contexts such as sentiment analysis or content moderation, where subjective judgments are involved.

A. Metrics for Assessing Bias

Quantifying bias in NLP systems is a multifaceted task that requires metrics capable of identifying disparities, imbalances, and stereotypical tendencies. These metrics enable researchers to evaluate the degree of bias and its impact, facilitating informed strategies for mitigation. Below is an overview of commonly used metrics for measuring bias in NLP, along with their mathematical formulations:

1) *Statistical Parity Difference (SPD)*: This metric evaluates whether the outcomes for different demographic groups are equally distributed.

$$SPD = P(Y=1|G=g1) - P(Y=1|G=g2)$$

- Y : Model outcome (e.g., positive or negative sentiment).
- G : Demographic group ($g1, g2$ represent different groups, e.g., male and female).
- A value of 0 indicates perfect fairness, while deviations suggest bias.

2) *Equal Opportunity Difference (EOD)*: This metric focuses on the equality of true positive rates across groups, ensuring that all groups have equal chances of achieving favorable outcomes when eligible.

$$EOD = P(\hat{Y}=1|Y=1, G=g1) - P(\hat{Y}=1|Y=1, G=g2)$$

- \hat{Y} : Predicted outcome.
- Ensures fairness specifically for eligible or qualified individuals.

3) *Conditional Demographic Disparity (CDD)*: This metric measures bias in model predictions while controlling for specific contextual variables.

$$CDD = P(\hat{Y} = 1 | X=x, G=g1) - P(\hat{Y} = 1 | X=x, G=g2)$$

- X: Contextual variables, such as input features.
- Helps identify disparities conditional on input attributes.

4) *Word Embedding Association Test (WEAT)*: This metric quantifies bias in word embeddings by measuring the association between target words and attribute word sets.

$$WEAT = \frac{\text{mean}(s(w, A) - s(w, B))}{\text{std}(s(w, A) - s(w, B))}$$

- w: Target word.
- A, B: Two sets of attribute words (e.g., male- and female-associated words).
- s(w, A): Cosine similarity between w and words in set A.
- A high WEAT score indicates stronger associations, reflecting potential biases.

5) *Bias Amplification Index (BAI)*: This measures the extent to which a model amplifies existing biases in data.

$$BAI = \frac{\text{Bias in Model Output}}{\text{Bias in Training Data}}$$

Ratios greater than 1 indicate that the model exacerbates bias.

6) *Directional Bias Metric (DBM)*: This metric evaluates bias in sentence or text-level outputs by analyzing directional shifts in embeddings.

$$DBM = \frac{\sum_{i=1}^n \cos(\vec{e}_i, \vec{d})}{n}$$

\vec{e}_i : Embedding of Sentence i

\vec{d} : Bias direction vector

n: Total sentences

7) *Mutual Information Difference (MID)*: This metric captures the disparity in the information shared between model predictions and sensitive attributes.

$$MID = I(\hat{Y}; G=g1) - I(\hat{Y}; G=g2)$$

- I: Mutual information between predictions \hat{Y} and group G.
- A high MID score reflects unequal representation of sensitive attributes in predictions.

8) *KL Divergence for Demographic Representation (KLD)*: This measures the divergence between the distributions of outcomes for different demographic groups.

$$KLD(P||Q) = \sum_i P(i) \log \frac{P(i)}{Q(i)}$$

- P(i): Outcome distribution for group g1
- Q(i): Outcome distribution for group g2
- Lower divergence values indicate better fairness.

9) *Bias Direction Magnitude (BDM)*: This quantifies the degree of separation between different demographic groups in embedding space.

$$BDM = ||\text{mean}(\vec{e}_{g1}) - \text{mean}(\vec{e}_{g2})||$$

$\vec{e}_{g1}, \vec{e}_{g2}$: Embeddings for groups g1 and g2.

10) *Token Probability Disparity (TPD)*: This metric measures bias in token-level predictions for specific sensitive terms.

$$TPD = P(\text{token}|G=g1) - P(\text{token}|G=g2)$$

Highlights disparities in word usage or token generation probabilities.

These metrics provide nuanced perspectives on bias in NLP systems, addressing its various dimensions, such as representation, prediction fairness, and embedding neutrality. Combining multiple metrics is essential for comprehensive evaluation, as bias often manifests in subtle and multifaceted ways.

B. Robustness in NLP

Robustness in NLP refers to the ability of a model to maintain performance when faced with noisy, adversarial, or out-of-distribution data. A robust NLP model should handle variations in input effectively without failing or producing inaccurate results.

C. Example of Robustness Challenges

1) *Adversarial attacks*: An NLP model trained to classify movie reviews as positive or negative might be tricked by inserting inconspicuous typos or irrelevant phrases. For example, changing "The movie was great!" to " The moovie was gr8!" should ideally still yield a positive classification.

2) *Context sensitivity*: An NLP system that performs well on one data distribution (e.g., news articles) may fail on another (e.g., social media text) if it's not robustly trained.

D. Robustness Improvement Techniques

1) *Adversarial training*: Including perturbed or adversarial examples during training so that the model learns to be resilient.

2) *Augmentation with noisy data*: Training on data that has been altered to include variations such as different spelling, slang, or paraphrasing helps models generalize better.

3) *Balancing fairness and robustness*: Improving fairness often involves altering the data or the training process to mitigate biases, which can sometimes reduce robustness if not done carefully. Conversely, making a model highly robust through general training methods may not necessarily address

inherent biases. The challenge lies in designing approaches that optimize both.

E. SMART Testing

SMART Testing is a methodological paradigm for systematically evaluating NLP systems across diverse dimensions, emphasizing their fairness, robustness, and adaptability. The acronym SMART encapsulates Sensitive attributes, Multiple subpopulations, Artifacts, Reasoning abilities, and Temporal changes, reflecting the multifaceted nature of NLP evaluation. While the framework does not have a universally fixed mathematical formulation, key metrics and equations can be used to assess these dimensions.

1) *Sensitive attributes (Fairness metrics)*: This component assesses disparities in performance between demographic groups with respect to sensitive attributes like gender or ethnicity. A commonly used fairness metric is Statistical Parity Difference (SPD):

$$SPD = |P(\hat{Y} = 1 | G = g1) - P(\hat{Y} = 1 | G = g2)|$$

Where:

- \hat{Y} : Model's predicted outcome.
- G: Demographic groups (g1 and g2 represent different groups).

A value closer to zero denotes minimal bias.

2) *Multiple subpopulations (Subgroup disparities)*: This dimension examines model performance across distinct subpopulations within the data. Disparities are quantified using subgroup metrics such as accuracy variance:

$$Variance = \frac{\sum_{i=1}^n (P_i - \mu)^2}{n}$$

Where,

- P_i is Model performance for subgroup i.
- μ is mean performance across all subgroups

A high variance indicates uneven performance among subgroups.

3) *Artifacts (Sensitivity to spurious patterns)*: Artifacts represent unintended correlations in training data that can lead to spurious model predictions. Artifact sensitivity can be measured by comparing performance on artifact-augmented data to baseline data:

$$Artifact\ Sensitivity = \frac{Performance_{artifact}}{Performance_{baseline}}$$

Ratios significantly deviating from 1 suggest a susceptibility to artifacts.

4) *Reasoning abilities (Cognitive robustness)*: This evaluates the model's logical and linguistic reasoning abilities under adversarial transformations or complex scenarios. Robustness against transformations is defined as:

$$Robustness\ Score(RS) = \frac{Post\ Transformation\ Accuracy}{Baseline\ Accuracy}$$

It is stated that higher scores signify greater resistance to input perturbations.

5) *Temporal changes (Adaptability over time)*: This aspect assesses how well the model performs as linguistic norms evolve. Temporal robustness is evaluated by measuring performance deviation across time-stamped datasets.

$$Temporal\ Deviation(TD) = |Performance_{t1} - Performance_{t2}|$$

It is stated that smaller deviations reflect higher adaptability to temporal variations.

6) *Aggregated SMART score*: To provide a unified view, an aggregated score can be computed as a weighted combination of the individual dimensions:

$$SMART\ Score = w1 \cdot SPD + w2 \cdot Variance + w3 \cdot Sensitivity + w4 \cdot Robustness\ Score + w5 \cdot Temporal\ Deviation$$

Where w1, w2, w3, w4, and w5 are weights reflecting the relative importance of each dimension.

III. PROPOSED NOVEL METRIC-CONTEXT-SENSITIVE FAIRNESS AND ROBUSTNESS (CFRE)

The proposed Context-Sensitive Fairness and Robustness Evaluation (CFRE) metric is designed to measure both fairness and robustness of an NLP model under different contextual shifts [3-9]. Below is the mathematical formulation of the proposed metric:

A. CFRE Metric Components

1) *Fairness Impact Score (FIS)*: The Fairness Impact Score evaluates the difference in output distributions when the model is tested with original data (O_{orig}) and perturbed data (O_{pert}) across different demographic or context groups (G_i).

$$FIS = \frac{1}{|G|} \sum_{i=1}^{|G|} D_{KL}(P(O_{orig}|G_i) || P(O_{pert}|G_i))$$

Where

- D_{KL} is Kullback-Leibler (KL) divergence.
- $P(O_{orig}|G_i)$ and $P(O_{pert}|G_i)$ are probability distributions of outputs for groups G_i in original and perturbed cases respectively.
- $|G|$ is number of distinct groups being evaluated.

2) *Robustness Contextual Evaluation (RCE)*: The robustness contextual evaluation (RCE) measures the stability of model predictions by computing the cosine similarity between output vectors from original and perturbed data (O_{orig}) and (O_{pert}) respectively.

$$RCE = \frac{1}{N} \sum_{j=1}^N \frac{O_{orig}^j \cdot O_{pert}^j}{\|O_{orig}^j\| \|O_{pert}^j\|}$$

where

- N is the number of samples.
- O_{orig}^j and O_{pert}^j are the output vectors for j^{th} sample in the original and perturbed data sets.

3) *Combined CFRE score*: The overall CFRE score can be weighted combination of the FIS and RCE to balance fairness and robustness.

$$CFRE = \alpha * FIS + \beta * RCE$$

Where α and β are weights that control importance of each component.

This formulation allows us to assess not just how fair is model across different contexts but also how consistently it performs when subject to contextual variations.

In the context of the CFRE metric, the interpretations for FIS RCE, and combined CFRE are given as below.

a) Fairness Impact Score (FIS):

- Interpretation: A higher FIS value indicates a greater divergence between the original and perturbed model outputs, suggesting that the model's fairness is more sensitive to contextual changes. This can mean the model exhibits potential biases when tested with varied input conditions, highlighting fairness issues.
- Lower FIS: Implies that the model maintains fairness across different demographic or context groups, showing resilience to contextual shifts.

b) Robustness Contextual Evaluation (RCE):

- Interpretation: This score reflects how similar the model's outputs remain under perturbations. A higher RCE value means the model is more robust, maintaining consistent behavior even when inputs are contextually modified.
- High RCE: Indicates strong robustness, where the model produces stable outputs across different contexts.
- Lower RCE: Suggests that the model's predictions are more context-dependent and can vary significantly with slight input changes.

c) Overall CFRE Value:

- Combined Score: The weighted sum of FIS and RCE allows us to evaluate both fairness and robustness together.
- High CFRE with balanced weights: Implies that the model is sensitive to contextual shifts (indicating fairness issues) but also robust in maintaining consistent outputs under certain conditions.
- Lower CFRE: Indicates that the model is more fair and robust across various tested contexts, demonstrating resilience and equitable behavior.

IV. INTEGRATING CFRE METRIC INTO SELF IMITATION LEARNING (SIL)

A. Introduction to Self-Imitation Learning (SIL)

Self-Imitation Learning (SIL) is an advanced reinforcement learning technique that enables agents to learn from past experiences, even suboptimal ones, by revisiting previously successful trajectories. Unlike traditional reinforcement learning, which often prioritizes exploration or maximizing immediate reward signals, SIL leverages historical data to reinforce and improve upon earlier decisions. It is particularly effective in complex environments where exploration is expensive or risky, as it capitalizes on self-generated "expert" demonstrations to refine policy optimization. By integrating memory-based learning with reinforcement dynamics, SIL demonstrates resilience in solving tasks requiring long-term planning and precise decision-making [10-18].

B. Main Idea behind Self-Imitation Learning (SIL)

At its core, Self-Imitation Learning revolves around the principle of leveraging an agent's historical successes as pseudo-demonstrations for future improvement. Unlike standard reinforcement learning paradigms, which discard suboptimal trajectories, SIL recognizes that even suboptimal actions can contain valuable information for solving complex tasks. This is particularly important in environments with sparse or delayed rewards, where the exploration of new policies might fail to yield immediate benefits.

SIL achieves this by employing a replay buffer, which stores trajectories (sequences of states, actions, and rewards) that yielded above-average returns. These trajectories are treated as guiding examples, and the agent revisits them during training to imitate its own past successes. This imitation process is formalized through a self-imitation loss function, which adjusts the policy to reproduce actions from successful trajectories.

The central innovation of SIL lies in its ability to balance exploitation and exploration dynamically. While traditional methods often face a trade-off between exploiting known strategies and exploring new possibilities, SIL introduces a mechanism where self-imitation augments learning efficiency without stifling exploration. This enables the agent to improve incrementally, even in scenarios where external rewards are scarce or noisy.

Moreover, SIL is robust to noise and imperfect demonstrations, as it does not rely on external expert input but instead generates its training data from its own interactions with the environment. This self-reliant nature makes it highly scalable and adaptable to diverse tasks, from robotics to game-playing.

In essence, SIL represents a shift from purely reward-driven learning to a hybrid framework that integrates self-guidance, allowing agents to harness the full potential of their past experiences for future success. By embracing both imitation and exploration, it achieves greater sample efficiency and stability in training, setting a new benchmark for learning in complex and uncertain domains.

C. Integrating CFRE with SIL

The CFRE metric is a performance measure designed to evaluate the trade-off between fairness and reward optimization in reinforcement learning. Integrating CFRE into Self-Imitation Learning (SIL) involves modifying the SIL framework to consider fairness explicitly during the learning process. The Algorithm 1 shows the CFRE integrated into SIL. Integrating the CFRE metric into Self-Imitation Learning (SIL) can effectively scale to real-world NLP systems operating in resource-constrained environments by prioritizing fairness and reward efficiency in model training. The approach allows selective reuse of high-reward, fairness-optimized trajectories, reducing computational overhead while maintaining equitable outcomes. By leveraging the CFRE metric's adaptability, the framework aligns with limited-resource constraints, improving both performance and inclusivity without excessive reliance on additional data or computing power. This ensures robust deployment of NLP systems in diverse, real-world scenarios.

Algorithm-1: CFRE-Integrated SIL

1. **Initialize:**
 - a) Define the environment E, action space A, and state space S.
 - b) Initialize SIL's policy $\pi_\theta(a|s)$, replay buffer B and reward function R(s,a).
 - c) Set the CFRE threshold τ , which balances fairness and efficiency.
2. **Collect Experience:**
 - a) Interact with the environment to generate trajectories $\tau = (s_t, a_t, r_t, s_{t+1})$ using the current policy π_θ .
 - b) Add the trajectories to the replay buffer B.
3. **Compute CFRE Metric:**
 - a. For each trajectory τ , compute the FIS and CRE :
 - b. $CFRE(\tau) = \alpha \cdot FIS(\tau) + \beta \cdot CRE(\tau)$ Where:
 - i. α, β : weights balancing fairness and reward efficiency.
 - ii. $CRE(\tau) = \text{Sum of rewards} / \text{Length of Trajectory}$

- iii. FIS (τ): Fairness computed using sensitive attributes or group-specific metrics.

c. Retain trajectories with $CFRE(\tau) \geq \tau$ in B.

4. Update Policy:

Use the retained trajectories from B to compute the SIL loss:

- a) SIL loss:
$$L_{SIL} = -\log(\pi_\theta(a|s)) \cdot (R_{expected}(s) - R_{observed}(s))$$
- b) Apply gradient descent to minimize L_{SIL} .

5. Test Policy:

- a) Evaluate the updated policy using CFRE and track performance metrics such as fairness scores, reward efficiency, and overall task accuracy.

6. Repeat:

Continue the process for a predefined number of episodes or until convergence by repeating steps 2 to 5.

V. EXPERIMENTAL RESULTS

The experiment was conducted using Crow-S pairs data set on Google Colab platform of python version 3.11.8. The Crow-S pairs dataset is a benchmark specifically designed to measure biases in NLP models, focusing on sensitive social attributes like gender, race, and socioeconomic status.

It consists of sentence pairs where one sentence carries subtle bias while the other is neutral, enabling the evaluation of a model's fairness by observing its scoring discrepancies. By systematically exposing latent stereotypes or prejudiced behavior in model outputs, the dataset also tests the robustness of NLP systems against biased linguistic patterns, helping to create more equitable language technologies.

At first, we project the graph showing comparison of original and perturbed scores using CFRE as given in Fig. 1. Next, we project the density over scores of WEAT, SMART testing as given in Fig. 2. Next, we project mean scores for various metrics as given in Fig. 3. Finally, we project graphs for average loss versus epochs and average reward versus epochs as given in Fig. 4. Fig. 1 to Fig. 3 showed significant improvement in results in proposed CFRE metric.

Fig. 1. Comparison of original and perturbed scores for CFRE metric.

Fig. 2. Density versus scores of various metrics.

Fig. 3. Mean scores versus various metrics.

Fig. 4. Graph for loss versus Epochs and Average reward versus Epochs.

VI. CONCLUSION

The integration of the CFRE metric with Self-Imitation Learning (SIL) presents a powerful paradigm for achieving fairness, robustness, and efficiency in reinforcement learning-based NLP systems. This approach ensures that models not only optimize rewards but also address systemic biases, promoting equitable outcomes. By leveraging past successes with fairness-aware constraints, it balances performance and inclusivity, making it especially viable for resource-constrained and real-world applications.

The proposed metric outperformed other existing metrics like WEAT and SMART testing. Also, it got low mean score compared to that of these metrics. The variation between original and perturbed scores serves as a measure of the model's robustness. A narrow difference signifies that the model is resistant to input alterations, showcasing its stability, whereas a wider discrepancy indicates that the model is more vulnerable to adversarial changes or biased modifications in the input data.

Abstract—Nanomaterials, owing to their distinctive features, are crucial across numerous scientific domains, especially in materials science and nanotechnology. Precise segmentation of Scanning Electron Microscope (SEM) images is essential for evaluating attributes such as nanoparticle dimensions, morphology, and distribution. Conventional image segmentation techniques frequently prove insufficient for managing the intricate textures of SEM images, resulting in a laborious and imprecise process. In this research, a modified U-Net architecture is presented to tackle this challenge, utilizing a ResNet50 backbone pre-trained on ImageNet. This model utilizes the robust feature extraction abilities of ResNet50 alongside the effective segmentation performance of U-Net, hence improving both accuracy and computational efficiency in TiO₂ nanoparticle segmentation. The suggested model was assessed using performance metrics including accuracy, precision, recall, IoU, and Dice Coefficient. The results indicated a high segmentation accuracy, demonstrated by a Dice score of 0.946 and an IoU of 0.897, with little variability reflected in standard deviations of 0.002071 and 0.003696, respectively, over 200 epochs. The comparison with existing methods demonstrates that the proposed model surpasses previous approaches by attaining enhanced segmentation accuracy. The modified U-Net design serves as an excellent technique for accurate nanoparticle segmentation in SEM images, providing substantial enhancements compared to traditional approaches. This progress indicates the model's potential for wider applications in nanomaterial research and characterization, where precise and efficient segmentation is essential for analysis.

I. INTRODUCTION

In recent years, nanotechnology has emerged as a revolutionary domain with extensive applications across various industries, including healthcare, energy, electronics, and materials research [1]. Fundamental to several innovations is the capacity to generate and evaluate nanoparticles. Nanoparticles, characterized by at least one dimension ranging from 1 to 100 nanometres, demonstrate distinctive physical and chemical properties that differ from those of their bulk equivalents, attributable to their diminutive size and extensive surface area [2]. Nanoparticles have emerged as a fundamental element of contemporary science and technology, attributable to their distinctive qualities stemming from quantum mechanical phenomena, elevated surface-to-volume ratios, and size-dependent characteristics. These features allow

nanoparticles to demonstrate improved optical, mechanical, magnetic, and catalytic characteristics, rendering them essential for various applications.

In medicine, nanoparticles function as drug delivery vehicles, imaging agents for diagnostics, and tools for tissue engineering [3]. Gold nanoparticles are utilized for targeted drug administration and cancer therapy, whereas silver nanoparticles exhibit strong antibacterial traits, rendering them advantageous in medical equipment and wound dressings. Nanoparticles are employed in energy storage to augment the performance of batteries and supercapacitors by improving conductivity and storage capacity. In materials science, nanoparticles are often incorporated into bulk materials to improve strength, flexibility, and thermal characteristics.

Nevertheless, these advances present the issue of precisely describing and assessing nanoparticles, especially regarding their size, shape, distribution, and surface morphology. To conduct a structural characterization of the particles, electron microscopy (EM) is one of the most commonly employed techniques [4]. A particle-interacting electron beam is used in this type of microscope. The objects are reconstructed via the analysis of these interactions and the signals they generate. Transmission electron microscopy (TEM) and SEM are the two primary methods. The primary distinctions between the two technologies are the resolution and the output dimensions. Though TEM images show 2D projections of objects' interior structures, 3D surface reconstruction from SEM images offers important insights into micro/nanoscale surfaces. The magnification and resolution of TEM surpass those of SEM. Consequently, the SEM is typically employed for morphological characterization, whilst the TEM is utilized for assessing particle size and size distribution, along with other analyses such as phase composition and crystal structure [5].

Analyzing SEM images is a typical procedure used to investigate the outcomes of nanomaterial fabrication processes. By identifying and measuring objects, materials scientists can obtain important morphological information about the material of interest. Image processing procedures for SEM imaging were often executed based on the distinctive qualities of a specific material, including shape, size, brightness, and contrast variations among the observed objects [6]. Nonetheless, the interpretation and analysis of SEM images, particularly for extensive datasets, necessitate effective segmentation techniques capable of precisely delineating nanoparticle

boundaries from intricate backgrounds, and extracting characteristics including dimensions, form, and alignment [7].

The results of segmentation directly affect the precision of subsequent operations, such as nanoparticle counting, size distribution assessment, and morphological investigations. Traditionally, nanotechnologists have depended on manual particle measurement utilizing technologies such as ImageJ, which, while successful for small datasets, becomes labor-intensive and susceptible to discrepancies in large-scale image analysis. Conventional techniques, like template matching, edge detection, and feature extraction-based categorization (utilizing Neural Networks or Support Vector Machines), have proven effective but frequently encounter challenges in generalization as image acquisition methodologies vary. These methods necessitate extensive parameter modifying by experts, making them rigid and time-consuming.

Consequently, conventional techniques frequently fail to yield reliable segmentation outcomes, resulting in erroneous nanoparticle analysis. The drawbacks of current techniques underscore the necessity for a more effective, automated approach to nanoparticle segmentation in SEM images. Recent developments in deep learning have demonstrated significant potential in tackling these challenges. Convolutional Neural Networks (CNNs) have transformed image analysis by facilitating automatic feature extraction and end-to-end learning [8]. CNNs are adept in nanoparticle segmentation tasks, as they can incorporate complex, hierarchical characteristics from raw image data, enabling the collection of subtle details such as nanoparticle borders and textures.

CNN-based models, like U-Net, have shown useful in medical image segmentation; nevertheless, their use for nanoparticle segmentation in SEM images is still inadequately investigated. Moreover, conventional U-Net architectures may inadequately leverage deep learning capabilities for nanoparticle segmentation, as they frequently fail to capture multi-scale features and may experience prolonged training durations when utilized with extensive datasets. This study proposes a novel deep learning (DL)-based segmentation approach to tackle these difficulties. The model is based on the U-Net architecture, known for its effectiveness in biomedical segmentation of images, and integrates a ResNet 50 backbone for improved feature extraction. The incorporation of ResNet50, a robust CNN architecture pre-trained on ImageNet, enables the model to utilize deep residual learning, which has demonstrated efficacy in enhancing the training of extremely deep networks by alleviating the vanishing gradient issue. The main contributions of the proposed research are as follows:

- To introduce a modified U-Net architecture with a ResNet50 backbone, specifically designed for the segmentation of TiO₂ nanoparticles in SEM images.
- By leveraging the pre-trained weights of ResNet50, the model aims to enhance feature extraction capabilities while simultaneously reducing training time and computational resources.
- To highlight the superior performance and applicability of the proposed model nanoparticle analysis compared to existing segmentation techniques.

The subsequent sections of the paper are structured as follows: Section II offers a literature review highlighting existing works and identifying research gaps; Section III elaborates on the proposed model; Section IV discusses the results obtained from the study; A discussion is provided in Section V and finally, a summary of the findings is included in Section VI, which gives a conclusion to the paper.

II. LITERATURE REVIEW

Henrik Eliasson et al. (2024) [9] developed a methodology utilizing two U-Net topologies to independently detect and categorize atomic columns at particle-support interfaces in STEM data. This technique sought to alleviate the problem of noisy data caused by the quick scan speeds required for monitoring nanoparticle movement. The U-Net model was trained on simulated non-physical images and was assessed in comparison to established solutions like AtomSegNet and AtomAI, exhibiting superior performance in both in situ and ex situ time series of diminutive Pt nanoparticles on CeO₂. Experimental time series, captured at 5 frames per second, exhibited dynamic, site-specific displacement of atomic columns. Model training and evaluation were performed on an NVIDIA RTX 4090 GPU, necessitating around 40 minutes for localization and three hours for segmentation. The findings highlighted the method's reliability and precision in examining dynamic nanoparticle behavior.

Nina Gumbiowski et al. (2023) [10] performed an investigation of metallic nanoparticles utilizing a machine learning approach that focused on segmentation, the differentiation of overlapping particles, and individual identification. An approach employing ultimate erosion of convex shapes (UECS) was devised to address particle overlap, enabling the assessment of characteristics such as size, circularity, and Feret diameter within a large particle population. The automated analysis of TEM images successfully extracted shape- and size-related data, including that of nanoscale gold nanoparticles. They employed a DL model, namely a deeplabv3+ network with a ResNet-18 backbone, demonstrating that their method sustained performance over diverse contrast levels, surpassing traditional image processing techniques. This automation markedly decreased analysis duration relative to manual techniques and enabled the extraction of extensive data on particle attributes. Nevertheless, constraints remained in the analysis of significantly overlapping particles, highlighting the difficulties in precisely understanding two-dimensional projections in microscopy.

Jonas Bals and Matthias Epple (2023) [11] employed CNN to independently interpret nanoparticle images acquired from scanning electron microscopy. A framework was built for obtaining secondary electron (SE) and STEM images, enabling quantitative studies of particle size and shape. Utilizing pixel weight loss maps to train CNNs enhanced the segmentation of overlapping particles. Their approaches encompassed the classification of forms, including cubes and spheres, the segregation of particles, and the removal of agglomerates. They attained great accuracy in shape classification utilizing AlexNet and ResNet34, together with efficient segmentation employing UNet++. Nevertheless, the system encountered

difficulties with particles that displayed ambiguous forms or partial obscurity, resulting in a considerable misclassification rate. Moreover, challenges associated with particle overlap and intensity fluctuations in SE images further impeded the efficacy of their approach.

Matthew Helmi Leth Larsen et al. (2023) [12] examined the most effective frame dose for object detection and segmentation in low electron dose TEM imaging. The MSD-net architecture exhibited superior performance compared to the regular U-net, particularly at frame dosages lower than those utilized during training. The MSD-net successfully segmented Au nanoparticles, attaining visibility at dosages as low as 20–30 $e^-/\text{\AA}^2$ and full segmentation at 200 $e^-/\text{\AA}^2$. During training with simulated images, the study highlighted how crucial it is to model the modulation transfer function (MTF), hence improving the network's capacity to identify nanoparticles in low signal-to-noise ratio environments. Through benchmarking the U-net and MSD-net across different frame dosages, the authors demonstrated that the MSD-net can generalize beyond its training data, establishing it as the best option for analyzing noisy images.

Wenkai Fu et al. (2022) [13] developed a machine learning model for predicting temporal sequences of in-situ TEM video frames with a hybrid long-short-term memory (LSTM) algorithm and a features de-entanglement technique. They used deep learning algorithms to predict future video frames from prior ones, offering insights into size-dependent structural alterations in Au nanoparticles under dynamic response settings. The models exhibited notable performance, with a structural similarity value of roughly 0.7, while being trained on limited datasets. The researchers accurately forecasted the shifts of Au nanoparticles from rigid to dynamic forms, underscoring the model's relevance in catalytic science. Although the structural similarity scores were inferior to those from more extensive benchmark datasets, the PhyDNet model proficiently delineated the structural evolution of Au nanoparticles.

Zhongyuan Ji and Yuchen Wang (2022) [14] utilized TEM to examine and evaluate the morphological characteristics of nanoparticles. A multirandom forest algorithm for image segmentation was devised, which markedly surpassed conventional techniques like maximum entropy threshold segmentation and watershed segmentation. Utilizing FCM clustering and the algorithm's ability to manage diverse gray levels in TEM images, they attained segmentation accuracy of up to 95%. Notwithstanding these gains, the methodology exhibited certain limitations, such as sensitivity to fluctuations in sample characteristics and image quality, along with computing difficulties in handling extensive datasets.

Annick De Backer et al. (2022) [15] presented a Bayesian genetic approach to reconstruct atomic models of monotype crystalline nanoparticles from single projections utilizing Z-contrast imaging. They employed atom-counting data from annular dark field STEM images as input for preliminary 3D models. The approach reduced structural energy while integrating past knowledge regarding atom-counting accuracy and neighbor-mass relationships. The results indicated enhanced reliability in reconstructing beam-sensitive

nanoparticles, especially those approximately 3 nm in size, at low electron doses. Their comprehensive simulation analysis objectively assessed the reconstructions, demonstrating a substantial improvement in the precise identification of surface atoms. The study demonstrated that the incorporation of finite atom-counting precision and neighbor-mass relationships significantly enhanced the quality of 3D atomic models, indicating improved predictions of catalytic capabilities for future applications. The algorithm was subsequently utilized to evaluate a time series of experimental photographs of a platinum nanoparticle, demonstrating its efficacy in real-time structural measurement.

Hari Mohan Singh et al. (2022) [16] developed a machine learning regression model, Gradient Boost Regression (GBR), to predict the particle size of aluminum nitride (Al_2N_3), silicon nitride (Si_3N_4), and titanium nitride (TiN) nanoparticles dispersed in ethylene glycol (EG) solution. They found critical factors affecting density, including nanoparticle size, molecular weights, volume concentration, and temperature. The GBR model demonstrated significant accuracy in forecasting nanofluid density for a training dataset, nearly matching experimental values obtained from a DMA 500 density meter across different temperatures and concentrations. The research utilized Gradient Search Optimization (GSO) for hyperparameter optimization to improve model performance. The outcomes show a robust correlation between the GBR predictions and experimental data, highlighting the model's efficacy.

Alexey G. Okunev et al. (2020) [17] investigated the automated identification of metal nanoparticles on highly oriented pyrolytic graphite utilizing deep learning methodologies, particularly the Cascade Mask-RCNN neural network. Their model was trained on a dataset including 23 scanning tunnelling microscopy (STM) images, which included 5,157 labeled nanoparticles, and was subsequently validated on a distinct set of images. The trained network achieved a precision of 0.93 and a recall of 0.78, illustrating its proficiency in identifying nanoparticles with an accuracy range of 0.87–0.99 for mean particle size assessments. The study emphasized the limitations of traditional image processing techniques, which required high-quality images and significant parameter adjustment. Researchers have created the open-access web service "ParticlesNN," enabling researchers to analyze noisy STM images without prior improvement, thereby markedly enhancing nanoparticle identification and quantification across diverse imaging scenarios.

Horwath et al. (2019) [18] examined sophisticated deep learning techniques for the segmentation of nanoparticles in EM images. They discovered that although the speed and quality of image segmentation had enhanced, the application of deep learning methods to precisely capture physical attributes continued to pose difficulties. The model's generalization was limited by the necessity for pixel-level annotations and the class imbalance in the training datasets, necessitating meticulous preparation. The effectiveness of segmentation on high-resolution images was further compromised by noise and light fluctuations, requiring more focus during training. Their experiments with various CNN configurations highlighted the importance of batch normalization and kernel size in enhancing

model accuracy and stability. Nevertheless, problems persisted, including sensitivity to fluctuations in image resolution and a tendency to overfit the training data.

Yi-Chi Wang et al. (2019) [19] examined the issues associated with employing STEM tomographic imaging to delineate 3D elemental segregation in nanoparticles, mainly arising from electron dose constraints in conventional techniques. They used a method known as spectroscopic single particle reconstruction (SPR), derived from structural biology, to assess PtNi nanocatalysts. They effectively identified nanoparticles with a diameter of 20 ± 2 nm and a platinum concentration of 56 ± 6 atom% by integrating both STEM-EDS and STEM-HAADF images. The significant diversity in nanoparticle size, shape, and composition required rigorous selection criteria for accurate characterization in the SPR technique.

Although methods for segmenting and detecting nanoparticles in electron microscopy have advanced, there are still a number of significant drawbacks. Numerous current methodologies, including deep learning techniques, encounter difficulties in precisely segmenting overlapping nanoparticles, particularly under fluctuating imaging settings like low signal-to-noise ratios and elevated electron doses. Conventional segmentation techniques often rely on extensive pixel-level annotations and encounter class imbalance, leading to overfitting and insufficient generalization across diverse datasets. Furthermore, traditional algorithms can inadequately consider the complexities of nanoparticle morphology, such as irregular shapes and agglomeration effects, limiting classification accuracy. Dependence on certain imaging modalities sometimes limits these models' ability to include diverse types of electron microscopy data. To address these limitations, we present a novel methodology designed to enhance segmentation accuracy and robustness across various nanoparticle types and imaging conditions, thus facilitating more precise analysis in materials science and nanotechnology applications.

III. MATERIALS AND METHODS

The proposed modified U-Net architecture, incorporating a ResNet50 backbone, was chosen due to its superior feature extraction capabilities, which are critical for accurately segmenting TiO₂ nanoparticles in SEM images. The deep residual learning framework of ResNet50 enables the model to effectively capture intricate textural details and morphological variations, thereby addressing the limitations of conventional segmentation approaches that struggle with complex nanoparticle structures. Furthermore, the integration of ResNet50 with U-Net enhances segmentation accuracy while maintaining computational efficiency, leveraging pre-trained ImageNet weights to expedite training and improve generalization across diverse SEM datasets. In contrast, traditional U-Net models, while effective for biomedical image segmentation, lack the depth required for precise nanoparticle boundary detection, often resulting in suboptimal segmentation performance. Moreover, standard CNN-based approaches necessitate extensive manual feature engineering and fail to adequately handle the high variability in SEM image textures. High-complexity architectures, such as DeepLabV3+, although

capable of achieving high accuracy, impose significant computational overhead, making them less practical for real-time applications. The proposed modified U-Net architecture effectively mitigates these challenges, providing a robust, scalable, and precise segmentation framework that significantly outperforms existing methodologies in the domain of nanomaterial characterization.

The approach seeks to improve the segmentation of nanoparticles in high-resolution SEM images by incorporating transfer learning and a modified U-Net (mUNet) architecture. A pre-trained ResNet50 model is employed, originally constructed on the ImageNet dataset, to extract significant features from SEM images depicting various nanoparticle shapes, distributions, and sizes. Each image in the dataset is paired with a ground truth mask that delineates the nanoparticles, enabling supervised learning. Pre-processing techniques, such as image scaling and normalization, enable the standardization of inputs for the model. The ResNet50 backbone serves as a feature extractor, acquiring multi-scale, intricate representations of the SEM images, which the mUNet model then refines for accurate segmentation. The efficiency of the model is evaluated following training by accuracy, precision, recall, Intersection over Union (IoU), and Dice Coefficient to confirm its ability to separate nanoparticles under diverse imaging settings. By overcoming the issues related to SEM images, this method aims to increase the precision and efficacy of nanoparticle segmentation. Fig. 1 displays the suggested framework's block diagram.

A. Dataset

The dataset for the proposed study is obtained from the publicly accessible repository on GitHub (<https://github.com/BAMresearch/automatic-sem-image-segmentation>). The database includes EM micrographs of TiO₂ particles and their related segmentation masks that define the boundaries of these particles. The collection additionally encompasses classifications of the particles according to their visibility and occlusion. The set is organized into subfolders that include raw SEM and TSEM images, along with manually annotated segmentation and classification masks. This extensive dataset establishes a robust basis for training and assessing the mUNet model, ensuring the precision and dependability of the segmentation procedure through the utilization of high-quality, real-world SEM data. Fig. 2 shows the first and last sample SEM images from the dataset along their corresponding manually annotated segmentation mask.

B. Data pre-processing

Pre-processing techniques such as scaling and normalization are employed to normalize the SEM images for uniform input into the neural network. Resizing standardizes images to a consistent dimension, whereas normalization calibrates pixel values to meet the network's specifications, hence improving the model's data processing efficiency. Standardizing the inputs enhances the model's robustness and its capacity to manage changes in nanoparticle morphology within SEM images. The dataset was divided into two categories, with 85% allocated for model training and the remaining 15% allotted for validation. This curated dataset is

essential for training and assessing the mUNet model, enabling precise and resilient segmentation performance.

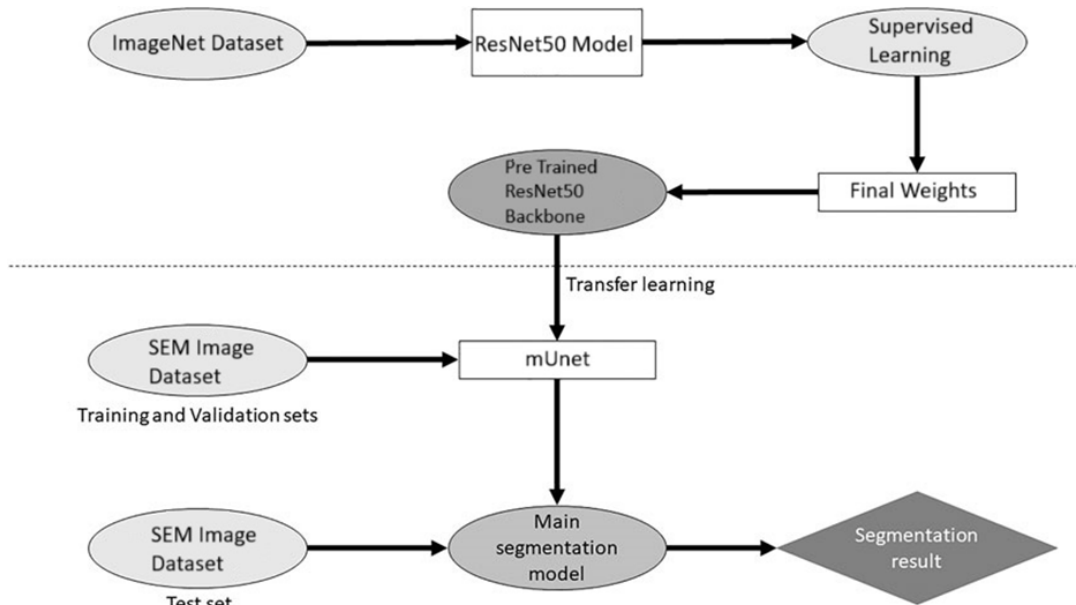

Fig. 1. Block diagram of the proposed model.

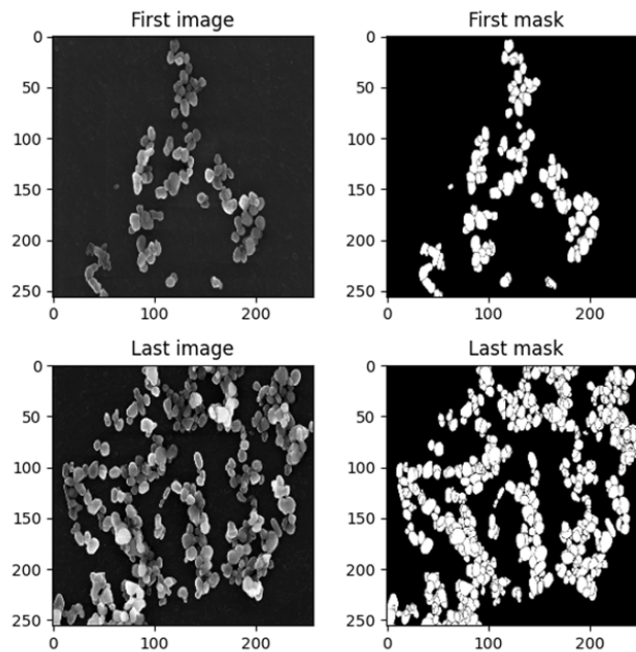

Fig. 2. Sample images from the dataset.

C. Model Development

Segmentation is an essential procedure in image analysis that entails dividing the images into separate sections, facilitating the identification and localization of particular objects within the image. This research utilizes deep learning techniques to improve segmentation accuracy, specifically for the identification of nanoparticles in SEM images. The U-Net design, acclaimed for its efficacy in biomedical image segmentation, underpins the suggested methodology. A mUNet employs a pre-trained ResNet50 encoder to enhance feature

extraction and gather multi-scale information. This combination enables the accurate delineation of nanoparticle borders, enhancing both the precision and efficiency of the segmentation process.

1) *U-Net*: The U-Net is a widely employed CNN model, particularly adept at segmentation tasks, such as nanoparticle segmentation in high-resolution SEM images. UNet is engineered for pixel-level classification, facilitating the differentiation of regions of interest (ROI) from the background in images, which is particularly beneficial in

domains like medical imaging, biological analysis, and materials science [20]. The architecture is characterized by its U-shaped structure, with two main pathways: a contracting pathway and an expansive pathway, as shown in Fig. 3. The

contracting path derives feature maps from the input image using many convolutional layers, whereas the expansive path reconstructs these features into a segmented output by integrating low-level and high-level features.

Fig. 3. Basic UNet architecture.

The contracting path, referred to as the encoder, adheres to the conventional architecture of a CNN. The process entails consecutive applications of two 3x3 convolutional layers, succeeded by a ReLU activation function and a 2x2 max-pooling operation. The max-pooling procedure aims to down sample the image, decreasing its spatial dimensions while simultaneously doubling the number of feature channels at each iteration. The convolutional procedure is mathematically expressed as shown in Eq. (1).

$$f(x) = \sigma(W * x + b) \quad (1)$$

where, W denotes the convolutional weights, x signifies the input image, b indicates the bias, and σ represents the activation function.

The expansive path, known as the decoder, mimics the contracting path in reverse, with the objective of reconstructing the image's spatial dimensions while preserving localization accuracy. At each phase of the expanding pathway, the feature maps are subjected to up sampling, generally via a 2x2 transpose convolution process, to revert the image to its original resolution. The transpose convolution is mathematically represented in Eq. (2).

$$\hat{x} = W^T * f(x) \quad (2)$$

Where, W^T denotes the transposed weights utilized in the up-sampling process, while x signifies the upsampled feature map. This step is succeeded by concatenation with the relevant feature maps from the contracting path, enabling the network to merge low-resolution, high-context data with high-

resolution, low-context features. The concatenation technique preserves small information from prior layers, which is essential for precise nanoparticle segmentation.

Skip connections are crucial to the performance of the U-Net [21]. These connections directly associate feature maps from the contracting path with the expanded path, as shown in Fig. 4, enabling the model to preserve intricate spatial information that could be lost during downsampling. By integrating low-level, high-resolution characteristics with up sampled high-level features, the network can generate precise and detailed segmentations.

Fig. 4. Skip connections in the UNet architecture.

In the final layer, a 1×1 convolution is utilized to transform the 64-channel feature map into the requisite number of output classes (e.g., foreground and background in binary segmentation), mathematically represented as in Eq. (3). This generates the definitive segmentation mask, categorizing each pixel based on its respective region.

$$y = W_{final} * f(x) + b_{final} \quad (3)$$

Where W_{final} represents the final layer's weights, and b_{final} is the bias term.

A distinctive feature of the U-Net architecture is its capacity to manage huge images via an overlap-tile method. Due to GPU memory limitations on image size, U-Net divides huge images into smaller tiles, processes each tile independently, and then merges them to generate a comprehensive segmentation map. To mitigate the loss of context at the image peripheries, the input image is mirrored throughout the tiling procedure. This technique guarantees precise segmentation of edge pixels, even when analyzing extensive SEM images of nanoparticles.

2) *Proposed modified UNet architecture:* The proposed research enhances the traditional U-Net design by integrating a modified U-Net structure that employs a ResNet50 encoder. This modification seeks to utilize the powerful feature extraction skills of ResNet50 to enhance nanoparticle segmentation performance from SEM images. The modification concentrates on optimizing feature extraction, refining multi-scale representations, and improving the overall accuracy of segmentation results.

ResNet50 is a CNN that uses residual learning to improve the training of deep networks, facilitating the effective acquisition of intricate hierarchical features vital for precise

segmentation tasks. ResNet50 comprises 50 layers organized into many blocks, as shown in Fig. 5, using skip connections, enabling the model to learn residual functions [22]. This architecture mitigates the degradation issue frequently observed in deep networks, wherein greater depth results in reduced performance. ResNet50 mitigates vanishing gradient problems by establishing direct paths for gradients during back propagation, hence enhancing the training of deeper networks. Each residual block in ResNet50 comprises two or three convolutional layers, batch normalization, and ReLU activation algorithms, ending in a shortcut connection that bypasses one or more layers.

In a standard residual block, the input X undergoes a sequence of convolutions, after which the original input is reintegrated into the output, resulting in Eq. (4).

$$Y = F(X) + X \quad (4)$$

Where $F(X)$ denotes the function acquired by the convolutional layers, and Y signifies the output of the block. This architecture enhances the acquisition of identity mappings, hence aiding the training of more profound networks.

The ResNet50 encoder comprises numerous convolutional layers arranged in blocks. Each block generally consists of three convolutional layers: the initial layer applies a 1×1 convolution to diminish dimensionality, the subsequent layer employs a 3×3 convolution for feature extraction, and the last layer utilizes another 1×1 convolution to reinstate the original dimensionality. This setup improves the model's ability to represent spatial hierarchies while preserving computational efficiency. The implementation of batch normalization subsequent to each convolutional layer enhances learning stability by normalizing the inputs to each layer.

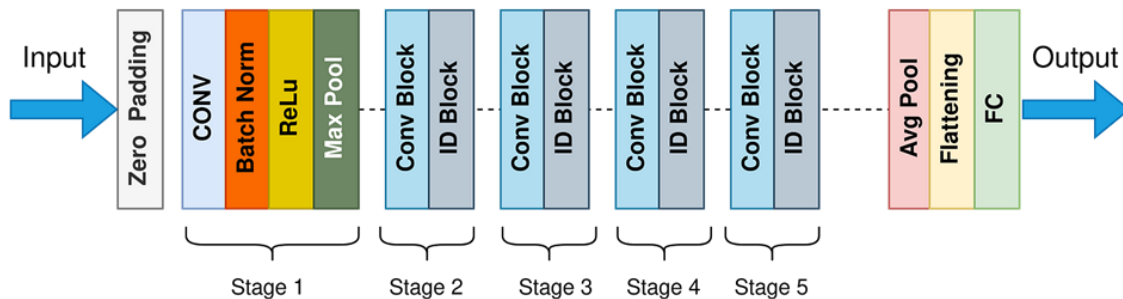

Fig. 5. ResNet 50 architecture.

The downsampling is achieved by strided convolutions and max pooling layers. Strided convolutions diminish the spatial dimensions of feature maps while augmenting depth, efficiently capturing multi-scale characteristics at diverse levels of abstraction. The downsampling process is essential for the encoder, enabling the model to concentrate on more intricate, abstract representations of the input data as it advances through the layers. As the input SEM images traverse the ResNet50 encoder, feature maps are produced at various depths. These feature maps encompass a comprehensive array of attributes that capture both low-level features (like textures and edges) and high-level semantic data (such as patterns and shapes). The hierarchical structure of feature extraction allows the model to

acquire intricate representations essential for precisely segmenting nanoparticles in the images. The formula for feature extraction at any specified layer is represented as shown in Eq. (5).

$$F_i = \sigma(W_i \cdot X + b_i) \quad (5)$$

Where F_i denotes the feature map at layer i , W_i and b_i represents the weights and biases of the convolutional layer, whereas X signifies the input feature map from the preceding layer.

The deepest convolutional layers process the smallest and most abstract feature mappings near the architecture's

bottleneck. This component encapsulates the most complicated illustrations of the input data, enabling the network to proficiently discern complex patterns related to nanoparticles. The architectural design enables the model to manage high-level properties while preserving essential spatial information required for precise segmentation.

During the decoder step, the design utilizes transpose convolutions (deconvolutions) to up sample the feature maps to their original input dimensions. The mUNet employs a concatenation method that integrates the up sampled feature maps with the matching encoder feature maps at different levels, rather than simply copying the feature maps. This procedure ensures the preservation and integration of intricate details and spatial data from preceding layers with enhanced semantic attributes. The concatenation is represented mathematically as in Eq. (6).

$$F_{concat} = F_{upsampled} \oplus F_{encoder} \quad (6)$$

Where F_{concat} denotes the concatenated feature map, $F_{upsampled}$ refers to the feature map subsequent to upsampling, and $F_{encoder}$ signifies the feature map derived from the encoder.

The output layer employs a 1×1 convolution to diminish the feature map's channel number to one, appropriate for binary segmentation applications. A sigmoid activation function is utilized on the output to produce a segmentation mask, resulting in values ranging from 0 to 1, which represent the probability of each pixel being part of the target class (nanoparticles). The final segmentation mask is represented as shown in Eq. (7).

$$M = \sigma(W_{output} \cdot F_{concat} + b_{output}) \quad (7)$$

Where M represents the output mask, and W_{output} and b_{output} denote the weights and bias for the output layer.

Post-processing techniques, including thresholding and morphological processes, are utilized to enhance the raw segmentation outcome. The proposed research achieves enhanced segmentation performance due to the creative utilization of convolutional layers, downsampling techniques, and residual connections, which facilitate an in-depth knowledge of the input data.

D. Hardware and Software Setup

The study utilized a high-performance computational configuration comprising an Intel Core i7 CPU, 32GB of RAM, and an NVIDIA GeForce GTX 1080Ti GPU, facilitating the effective management of demanding computational workloads. The framework was executed with the Keras library, a high-level neural network API based on TensorFlow, recognized for its user-friendly interface and robust functionalities. The training procedure was conducted on Google Colab, a cloud-based Python notebook platform that offers easy accessibility to substantial computational resources, hence facilitating model training.

An essential element of this research was the selection of hyperparameters, which profoundly influence model performance during training. Unlike model parameters that are

derived from the data hyperparameters are predetermined by the user and are crucial in shaping the configuration of the training process to optimize the performance of the nanoparticle segmentation model. The precise hyperparameter selections and model configuration are detailed in Table I.

TABLE I. HYPERPARAMETER SPECIFICATIONS

Hyper parameters	Values
Epochs	200
Learning Rate	0.0001
Optimizer	ADAM
Batch size	4
Loss function	Dice loss

IV. EXPERIMENTAL RESULTS

Initially, several factors are defined to quantify essential performance parameters, as represented in following Eq. (8), Eq. (9), Eq. (10), Eq. (11), and Eq. (13). These metrics, based in the principles of False Positive (FP), True Negative (TN), False Negative (FN), and True Positive (TP), are crucial for evaluating the efficacy of the model.

The calculation of accuracy involves dividing the total number of predictions by the number of right predictions.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (8)$$

The exactness of a prediction is measured by its precision, or the number of true positives. Instead, recall quantifies completeness, or the number of real positives that were anticipated as positives.

$$Precision = \frac{TP}{TP+FP} \quad (9)$$

$$Recall = \frac{TP}{TP+FN} \quad (10)$$

$$F1 - Score = 2 * \left(\frac{Precision * Recall}{Precision + Recall} \right) \quad (11)$$

$$Dice Score = \frac{2 * A \cap B}{|A| + |B|} \quad (12)$$

$$IoU = \frac{|A \cap B|}{A \cup B} \quad (13)$$

Where, A and B denote the set of predicted and actual positive instances.

The dataset is partitioned into five folds using KFold, which randomly assigns data to training and validation sets for each iteration. For each fold, the model is established and constructed with five iterations of 200 epochs each. The training procedure includes a 15% validation split, with EarlyStopping callbacks to avert overfitting by ceasing training when the validation loss does not increase over a predetermined number of epochs. Following each training session, the model's learning progression is depicted via the training and validation loss curves, as shown in Fig. 6. Metrics from each iteration are recorded for subsequent analysis, facilitating a thorough assessment of the model's performance across several folds.

(a) Run 1

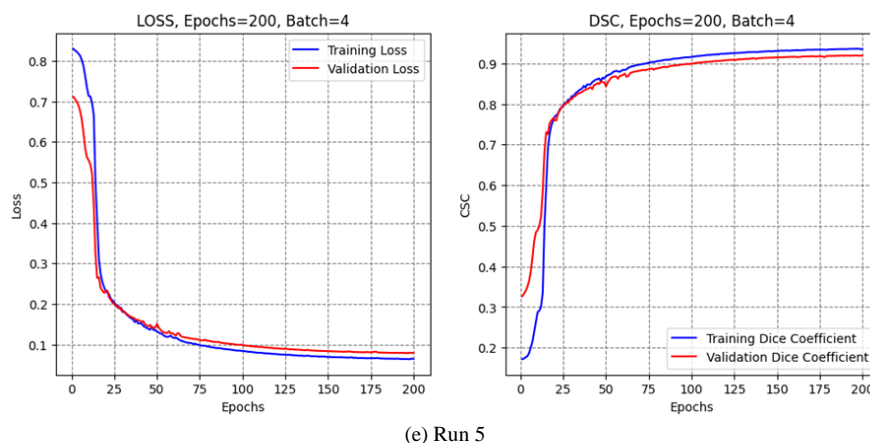

(b) Run 2

(c) Run 3

(d) Run 4

(e) Run 5
Fig. 6. Training and validation dice coefficient of the proposed model.

The incorporation of visualizations that compare predicted masks with original images, as illustrated in Fig. 7, improves interpretability and facilitates the evaluation of segmentation quality.

The model's precision metric exhibits a gradual enhancement across the runs, as shown in Fig. 8 (a) and Table II, commencing at 0.907 in the initial run and culminating at 0.926 in the final run. This pattern indicates the model's enhanced capacity to accurately identify true positive nanoparticle boundaries. Notwithstanding a slight decline to 0.900 in the third run, overall precision enhanced, especially in the fourth run, where it attained 0.916. The recall scores consistently stayed elevated during the runs, as shown in Fig. 8 (b), starting at 0.974, decreasing slightly to 0.969 in the second run, and achieving a maximum of 0.979 in the third run. The most recent test registered a decrease to 0.966; however, the

recall metrics continually demonstrated the model's capability in detecting nanoparticle segments.

The IoU score demonstrated robust performance, as shown in Fig. 8 (c), commencing at 0.885, with minor fluctuations during the second and third runs, and ultimately increasing to 0.897 in the last run. This enhancement indicates improved precision in delineating nanoparticle boundaries. The DSC commenced at 0.938, as shown in Fig. 8 (d), and reached a peak of 0.946 in the third run, indicating the highest level of segmentation accuracy attained. A decrease in DSC was noted in consecutive trials, culminating in a final value of 0.940. The mUNet model demonstrates robust segmentation capabilities, with significant performance enhancements across multiple parameters, confirming its efficacy in precisely recognizing and characterizing nanoparticle boundaries.

(c) Run 3

(d) Run 4

(e) Run 5

TABLE II. PERFORMANCE EVALUATION

Metric	Run 1	Run 2	Run 3	Run 4	Run 5
Dice Score (DSC)	0.939	0.938	0.938	0.943	0.946
Intersection over Union (IoU)	0.885	0.883	0.883	0.892	0.897
Recall	0.974	0.969	0.979	0.972	0.966
Precision	0.907	0.909	0.900	0.916	0.926
Global Accuracy	0.981	0.982	0.983	0.991	0.993
AUC ROC	0.990	0.992	0.988	0.994	0.994

Fig. 9 displays histograms that depict the performance measures of the mUNet model. The precision scores, between 0.912 and 0.916, demonstrate the model's robust ability to effectively separate nanoparticles with minimal false positives. Despite a slight variation in these numbers, the general stability demonstrates the model's efficacy in positive predictive accuracy. The recall scores vary from 0.962 to 0.970, indicating the model's exceptional capability in accurately identifying almost all true positive cases of nanoparticles. The

IoU scores, ranging from 0.884 to 0.892, indicate strong performance, reflecting a significant overlap between expected and actual areas. The uniformity of these scores highlights the model's dependability in sustaining high-quality segmentation across samples. Finally, the Dice scores vary from 0.938 to 0.943, underscoring the model's proficiency in generating precise segmentations. The close proximity of these scores signifies negligible performance variability, hence affirming the model's dependability.

Fig. 9. Histogram plots.

Fig. 10 illustrates the mean values of the primary performance metrics acquired over an epoch of 200. The Dice Score Mean is 0.940, indicating a high degree of accuracy in the overlap between the anticipated and actual nanoparticle areas. The mean IoU score is 0.887, demonstrating strong efficacy in accurately defining nanoparticle regions with few deviations. The mean results together underscore the dependability of the mUNet model in nanoparticle segmentation tasks, demonstrating consistent performance across various parameters.

Fig. 11 depicts the standard deviations computed across 200 epochs. The Dice score demonstrates a minimal standard deviation of 0.002071, indicating consistent segmentation accuracy over repetitions. The IoU score demonstrates a standard deviation of 0.003696, signifying reliable overlap between predicted and real nanoparticle regions. The recall has slightly larger variance, with a standard deviation of 0.006005, indicating modest fluctuations in the model's capacity to recognize all actual nanoparticle occurrences.

Fig. 10. Mean value of the scores.

Fig. 11. Standard deviation of the scores.

The precision exhibits a standard deviation of 0.003264, signifying dependable identification of true positives. The standard deviation of global accuracy is 0.004693, indicating uniform performance across all iterations, whilst the AUC-ROC score exhibits the lowest deviation at 0.00124, implying remarkable stability in differentiating between nanoparticle and non-nanoparticle regions. The low standard deviations across all measures indicate that the mUNet model exhibits consistent and dependable performance, with minor variations in its ability to effectively segment TiO₂ nanoparticles throughout numerous iterations.

V. DISCUSSION

A thorough accuracy comparison of the suggested model against a number of cutting-edge segmentation methods is depicted in Fig. 12 and Table III. The suggested framework attained an outstanding accuracy of 99.3%, markedly surpassing conventional approaches such as NSNet (86.2%) and more sophisticated architectures like Deeplabv3+ with ResNet-18 (96.12%), multiple-output convolutional neural networks (96.59%), and U-Net (97.1%).

TABLE III. COMPARATIVE ANALYSIS OF THE PROPOSED MODEL AGAINST EXISTING METHODS

Author	Methodology	Accuracy (%)
Sun et al. [25]	NSNet	86.2
Gumbiowski et al. [10]	Deeplabv3+ network with a Resnet-18	96.12
Oktay et al. [24]	multiple output convolutional neural networks	96.59
Bals et al. [11]	UNET and UNet++	97
Leonid Mill et al. [23]	U-Net	97.1
Proposed model: Modified U-Net with ResNet 50		99.3

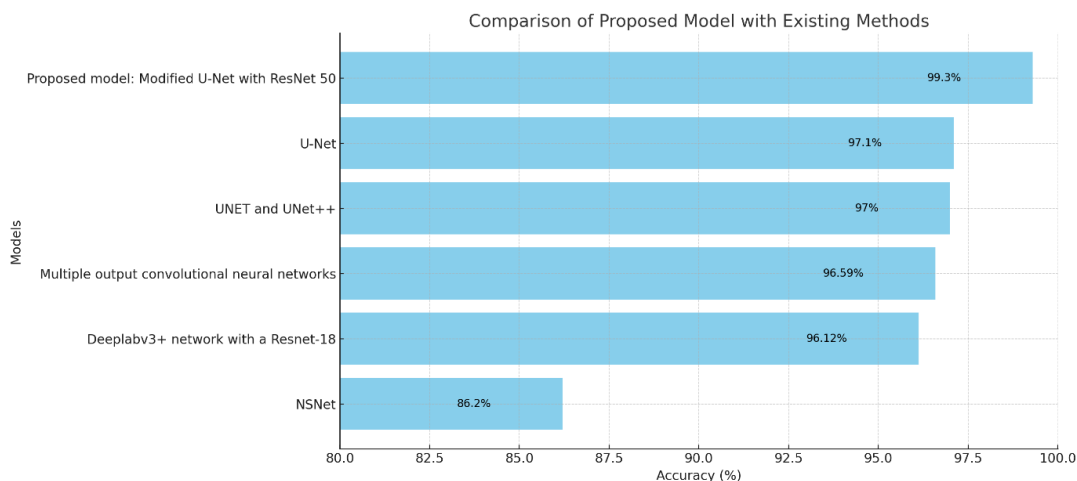

Fig. 12. Comparison of the proposed model with existing methods.

The suggested model exhibits enhanced segmentation performance compared to closely comparable models such as UNet++ (97%) and U-Net (97.1%). The enhancement is due to the incorporation of ResNet50 as the encoder, facilitating superior feature extraction via deep residual learning, along with the U-Net's strong skip connections, which ensure accurate reconstruction of spatial information. The modifications, together with the model's capacity to utilize pre-trained weights for more effective training, lead to a significant improvement in segmentation accuracy for nanoparticle boundaries in SEM images. The modified layout exhibits enhanced proficiency in managing complex textures and diverse sizes of nanoparticle areas, positioning itself as a dependable and effective solution for high-precision segmentation tasks in nanotechnology.

VI. CONCLUSION

The proposed research offers an extensive approach for automating the segmentation of SEM images of TiO₂ nanoparticles utilizing a modified U-Net architecture with a ResNet50 backbone pre-trained on ImageNet. This model effectively overcomes the drawbacks of conventional segmentation techniques, which frequently encounter issues with the intricate and diverse textures present in SEM images. By utilizing the robust feature extraction capabilities of ResNet50 and integrating them with the effective segmentation framework of U-Net, the model exhibits notable enhancements in accuracy, precision, and overall performance. The findings, featuring an average Dice score of 0.940 and an IoU of 0.887, demonstrate the model's proficiency in precisely delineating nanoparticle boundaries. The minimal standard deviations in all performance metrics, such as a Dice score standard deviation of 0.002071 and an IoU standard deviation of 0.003696, underscore the model's consistency and stability throughout various iterations. The incorporation of skip connections and multi-scale feature learning allows the model to preserve spatial details while analyzing abstract, high-level data. This method substantially surpasses conventional strategies in nanoparticle segmentation for accuracy and reliability, as evidenced by comparisons with existing methods. The model's versatility and diminished training duration underscore its practical utility for high-throughput nanoparticle investigation in materials science. The research highlights the efficacy of deep learning models, particularly the mUNet, in enhancing nanomaterial analysis through accurate, automated segmentation methods.

Application of Big Data Mining System Integrating Spectral Clustering Algorithm and Apache Spark Framework

Yuansheng Guo

China Mobile Communications Group, Hunan Co. Ltd, Changsha, Hunan, 410001, China

Abstract—Spectral clustering algorithm is a highly effective clustering algorithm with broad application prospects in data mining. To improve the efficient data processing capability of big data mining systems, a big data mining system that integrates spectral clustering algorithm and Apache Spark framework is proposed. It is applied in the big data mining system by combining Hadoop, Spark framework, and spectral clustering algorithm. The research results indicated that after 300 iterations of spectral clustering algorithm, the error value tended to stabilize and drops to 0.123. In different datasets, different error values were displayed, indicating that spectral clustering algorithm had better performance in discrete data processing and smaller testing errors. The minimum time consumed by the comparative system was 37.83 seconds, the maximum time was 55.26 seconds, and the average time was 51.65 seconds. The minimum time consumed by the research system was 18.93 seconds, the maximum time consumed was 32.22 seconds, and the average time consumed was 28.14 seconds. Compared with the comparative system, the research system consumed less time, trained faster, and was more conducive to shortening the clustering running time. The algorithm framework and system raised in the research have good operational efficiency and clustering ability in data mining processing, which promotes the reliability and development of big data mining systems.

Keywords—Spectral clustering algorithm; apache spark; big data; data mining

I. INTRODUCTION

The advent of the big data era has led to a proliferation of big data mining technology across a range of industries. Big data technology takes a critical parts in multiple fields with its massive data information and high-intensity processing capabilities. It not only enables efficient analysis of complex data modules, but also has foresight and predictability, and can extract valuable data in a timely manner [1]. Data mining technology, as an emerging discipline, originated in the 1980s with the initial aim of promoting the development of artificial intelligence technology. Modern data mining technologies focus on in-depth exploration of hidden and valuable data to discover new data patterns and valuable information, which has critical guiding significance for enterprise decision-making. Spark, as a big data processing framework, has the merits of high efficiency, scalability, and high fault tolerance, and is therefore broadly utilized in the field of big data mining [2]. This study will explore big data mining techniques from the perspective of Spark. Spectral Clustering (SC), as a classic data mining algorithm, is a clustering algorithm used in graph theory.

It achieves node clustering by analyzing the eigenvalues and eigenvectors of the Laplacian matrix of the graph. Many experts and researchers have put forward their own opinions on the research and implementation of big data systems. SC is an unattended clustering algorithm that has been broadly applied in the fields of pattern matching and computer vision due to its excellent clustering capabilities. However, the conventional SC algorithms are ill-suited for large-scale data classification such as that required for hyperspectral remote sensing images. This is due to their high computational complexity and the difficulty of representing the inherent uncertainty of the images [3]. Li et al. employed fuzzy anchor points for the processing of hyperspectral image classification and proposed an SC algorithm based on fuzzy similarity measurement. The findings of the experiment on the datasets of hyperspectral remote sensing images demonstrated the efficacy of the enhanced algorithm. The incorporation of a fuzzy likelihood measure led to the generation of a more resilient similarity matrix. The kappa coefficient obtained by the raised algorithm was 2% higher than that of the traditional algorithm. Furthermore, the raised algorithm achieved superior classification results on hyperspectral remote sensing images when compared with existing methods [4]. The advent of wireless communication technology has led to the generation of a substantial corpus of spatio-temporal user tracking data, which is recorded by wireless communication networks as users utilize these networks to meet a range of needs. To enhance the healthy development of students and facilitate the construction of campus-wide information, Guo Y et al. put forth an SC algorithm based on a multi-level threshold and density combined with common nearest neighbors. Several clustering algorithms were used for detecting anomalies, and four assessment indicators were applied to assess the clustering results. The results indicated that the MSTDSNN-C algorithm exhibited better clustering performance [5]. However, the fact that the clustering model is defined only for the original data and not explicitly extended to out-of-sample data is one of the main drawbacks of SC. To improve its efficiency, Shen D et al. proposed a new modular SC method with out of sample extension, combining a new spectral mapping algorithm based on modular similarity measurement and out of sample extension. The experiment outcomes denoted that the research method had better findings compared to other related algorithms on several data sets [6]. A block distributed Chebyshev-Davidson algorithm was developed by Pang Q et al. to solve the problem of large leading eigenvalues in SC. Through the analysis of the Laplacian matrix or normalized

Laplacian matrix in SC, a scalable distributed parallel version was developed. The results demonstrated its efficiency in SC and its advantage in scalability compared to existing feature solvers used for SC in parallel computing environments [7].

Most existing multi-view clustering methods may be affected by data corruption in terms of technology, leading to a sharp decline in clustering performance. Pan Y et al. put forth a multi-pattern SC method which uses robust bar space segmentation. To address the optimization issue of the weak sparse segmentation, an optimization procedure based on the extended Lagrangian multiplier method was developed. The experiment findings on various benchmark sets showed that the raised method performed well relative to several recent advances in clustering methods [8]. High utility itemset mining is a common utilized data mining method for finding useful patterns. Sethi K et al. proposed a new way to mine itemsets using Spark. They tested it on six real data sets and found that it outperformed other algorithms [9]. When managing very large datasets, the high processing cost of mining data for fuzzy rules increased considerably, and in many cases memory overrun faults are triggered. Fernandez-Basso C et al. used the Spark algorithm to process large amounts of heterogeneous data and find interesting rules. They proposed a measure of interest decomposition based on Alpha cuts and demonstrated through experiments that only 10 equidistant Alpha cuts were sufficient to find all the important fuzzy rules. The efficiency and speed of all proposals were compared and analyzed [10]. Ji L et al. proposed an improved SC-based method of detecting anomalies for anomalous data mining in dam safety monitoring, which introduced natural eigenvalues to select data point edges based on traditional SC. The results showed that this method could avoid the algorithm from becoming bogged down in local topology and improve the efficiency of clustering and anomaly detection. It further confirmed that the method could adjust itself well to the case of discrete distribution datasets, and was more accurate than classical SC methods in both the case of labeling and detecting the data points with unusual anomalies [11].

In summary, regarding data mining, existing researchers in the literature review have some involvement and research on data processing, algorithm classification, and dataset clustering improvement. However, the design and application of clustering algorithms for implementing system data mining are not deep enough, such as data relationship description, architecture design of data processing systems, etc. In order to achieve more efficient and large-scale data processing efficiency, a big data mining method that combines spectral clustering algorithm and Apache Spark framework is proposed compared with literature review. It combines distributed computing framework (such as Spark) to optimize spectral clustering algorithm, realizing parallel processing and fast clustering of large-scale datasets. This is similar to the distributed block Chebyshev Davidson algorithm developed by Pang Q et al. And innovatively introduced spectral clustering algorithm applied to data mining systems, designed a big data mining system architecture, and provided a technical foundation for massive data mining and processing.

The article structure of this study is as follows. Introduction is given in Section I. Section II of this study is dedicated to the

integration of the SC algorithm with the Apache Spark framework for the purpose of facilitating the mining of large data sets. This represents a significant area of focus and innovation within the field of big data analytics. Section III presents the experimental verification and analysis of the results obtained from the data set, based on the algorithm designed in the first part. Section IV presents conclusions regarding the experimental results and discusses the limitations of the design, as well as avenues for future research.

II. METHODS AND MATERIALS

The study adopts spectral clustering algorithm as the core clustering method, which can identify sample spaces of any shape and converge to the global optimal solution, especially suitable for clustering convex structured data. And by constructing a similarity matrix, calculating eigenvalues and eigenvectors, and using classical clustering algorithms such as K-means to cluster the eigenvectors, data clustering analysis is achieved. Firstly, this study combines Hadoop and Apache Spark to investigate the processing techniques of big data. Secondly, the SC algorithm is introduced and combined with the Apache Spark framework to design a framework for a big data mining system.

A. Big Data Technology based on Hadoop and Apache Spark Computing Framework

As the advent of the digital age, big data has become a fundamental element for enterprises to compete. Apache Spark has gained widespread attention in terms of processing speed, fault tolerance, and ease of use. Apache Spark is a high-performance, flexible computing engine that is optimized for processing large datasets. Compared to the traditional big data processing framework MapReduce, Spark has a faster processing speed. This is because Spark stores data in memory instead of traditional storage on disk. Another feature of Spark is that it can perform iterative calculations based on memory. Hadoop Distributed File System (HDFS) can work well on inexpensive hardware and is designed to be fault-tolerant. It provides high throughput for accessing application data and enables fast access to large datasets [12]. Hadoop is a distributed system built by the Apache Foundation, and the HDFS is one of its components [13]. The big data ecosystem of Hadoop is shown in Fig. 1.

HDFS is capable of accessing data in the file system in the form of streams, and the fundamental design of this framework is based on HDFS and MapReduce. HDFS provides storage for substantial quantities of data, while MapReduce offers computational capabilities for similarly large data sets [14]. The MapReduce feature of Hadoop can decompose a large and complex task, allocate scattered subtasks to multiple nodes, and then load them as a single dataset into a data warehouse. The distributed architecture of Hadoop enables the big data processing engine to be situated as proximate to the storage facility as possible. This makes the system relatively suitable for batch operations such as ETL, given that the results of such operations may be transmitted directly from the processing engine to storage. The popularity of Hadoop in the area of big data processing can be attributed to its efficacy in data extraction, transformation, and loading.

Spark is an open-source project under the Apache foundation that provides a distributed computing framework for fast processing of large-scale datasets [15]. Compared to traditional MapReduce, Spark uses memory storage to read and write data faster, avoiding frequent disk I/O operations and improving data processing speed. Spark supports multiple programming languages, such as Scala, Java, Python, and R, making it easy for users to choose their familiar programming language for development. It also provides a resilient distributed dataset (RDD), as shown in Fig. 2 for its structure and running process.

Fig. 2 (a) showcases the structure of the RDD dataset, and Fig. 2 (b) showcases the operational flowchart of RDD. RDD is composed of multiple partitions, each of which is a subset of data that can be distributed across multiple machines for parallel computing. Partitioning is the process of grouping data records with the same attributes together according to specific rules, where each partition is equivalent to a segment of the dataset. This partitioning mechanism enables RDD to support parallel processing and improve computational efficiency.

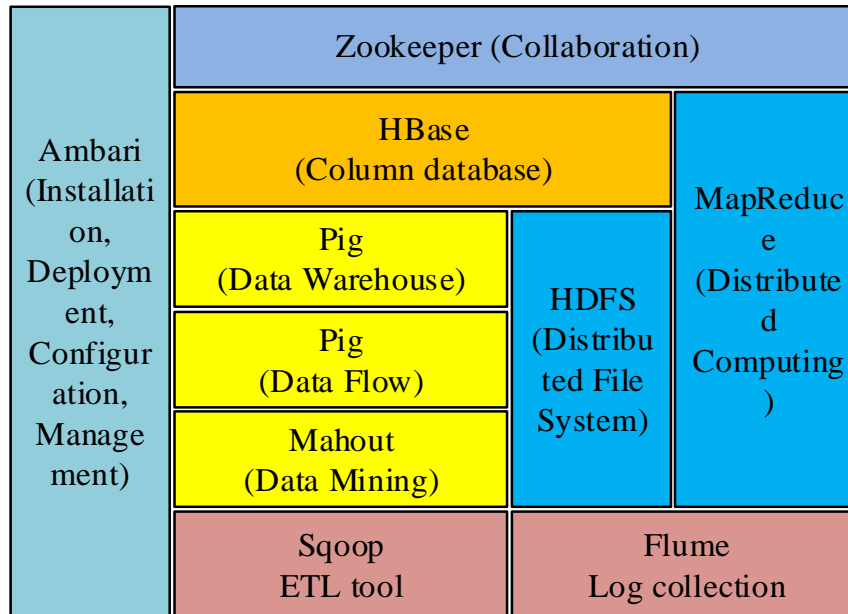

Fig. 1. Hadoop big data ecosystem.

Fig. 2. Structure diagram and operation flowchart of RDD dataset.

The running process of RDD in Spark architecture mainly includes the following steps. Firstly, it is necessary to create an RDD object. Secondly, the dependency relationships between RDDs are calculated and a Directed Acyclic Graph (DAG) is constructed. SparkContext is responsible for calculating the dependency relationships between RDDs and building the DAG. DAG represents the structure of the entire computing task, including the conversion and computation between various RDDs. Then the DAG is decomposed into multiple stages, and the DAGScheduler is responsible for decomposing the DAG graph into multiple stages, each stage containing multiple tasks [16]. The tasks in each stage are executed in order of their dependency relationships to ensure the correctness of the calculation results. Afterwards, each task will be distributed by the task scheduler to the Executors on each work node for execution. After receiving the task, the Executor

will occupy corresponding resources such as CPU and memory and perform calculations. The calculation results will be returned to the Driver for summarization and processing. Finally, there is the summary and output of the results. After all tasks are completed, the Driver will collect all the results, perform necessary summarization and processing, and finally output the results. This can be done by pulling all data back to the driver end using the collect () method.

This process involves the core mechanisms of Spark's distributed computing framework, including resource allocation, task scheduling and execution, as well as result aggregation and output. In this way, Spark can efficiently process large-scale datasets, achieve parallel and distributed computing, and the running process is shown in Fig. 3.

Fig. 3. Spark running process.

The running process of Spark involves environment construction, resource allocation, task decomposition and scheduling, as well as specific behaviors in different running modes, ensuring efficient execution of distributed computing. Firstly, the DAG graph created in the RDD object is decomposed into stages, and Task Schedule is formed through Taskset to submit and monitor tasks.

B. A Big Data Mining System Integrating Spectral Clustering Algorithm and Apache Spark Framework

To achieve efficient mining and analysis of big data, a high-performance SC algorithm is adopted in the study, which can provide better clustering for convex structured data. SC is a clustering method based on graph theory that divides a weighted undirected graph into two or more optimal subgraphs. This is achieved by ensuring that the subgraphs are as similar as possible internally while maximizing the distance between subgraphs [17]. The underlying principle of the SC method is the transformation of the initial clustering problem into an optimal graph partitioning problem. The selection of appropriate eigenvectors for clustering is achieved by calculating the eigenvalues and eigenvectors of the similarity matrix of the sample data points. This method is capable of identifying sample spaces of any shape and converging upon the global optimal solution [18]. The implementation process

of SC includes constructing a similarity matrix, calculating eigenvalues and eigenvectors, and using K-means or other classical clustering algorithms to cluster eigenvectors. The SC algorithm has a wide range of applications, including computer vision, pattern recognition, information retrieval, and other fields. Spectral clustering algorithm treats all data as points in space during the clustering process. By slicing the graph composed of all data points, the edge weights between different subgraphs are minimized, while the edge weights within subgraphs are maximized, thus achieving the purpose of clustering. This method overcomes the disadvantage of traditional clustering algorithms (such as K-Means) that may not be able to obtain the global optimal solution on any shaped sample space.

The study will use a directed unweighted graph to represent the dataset $G = (V, E)$, and describe its relationships using a matrix to transform it into a graph/matrix problem. The similarity of data points will be described using functions, and the relationship equation will be constructed as shown in Eq. (1).

$$w_{i,j} = \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right) \quad (1)$$

In Eq. (1), $w_{i,j}$ denotes the similarity between x_i and x_j corresponding to the i row and j column, and the dataset is represented as $\{v_1, v_2, \dots, v_n\}$. x_i and x_j are the data points. A matrix is constructed with a size of $n * n$ based on the relationships between data points. A set matrix that represents the sum of similarity relationships between data points and other points through a degree matrix, as shown in Eq. (2).

$$\begin{cases} d_i = \sum_{j=1}^n w_{ij} \\ D = \begin{pmatrix} d_1 & & & \\ & d_2 & & \\ & & \dots & \\ & & & d_n \end{pmatrix} \end{cases} \quad (2)$$

In Eq. (2), D denotes the degree matrix, and d_i represents the degree of data point x_i . In this study, the similarity matrix is constructed using fully connected connections, and a Gaussian kernel function is utilized to construct the similarity distance, as shown in Eq. (3).

$$W_{ij} = S_{ij} = \left(-\frac{\|x_i - x_j\|^2}{2\sigma^2} \right) \quad (3)$$

In SC algorithms, graph problems involve partitioning problems. From the perspective of graph theory, clustering problems are equivalent to partitioning problems of a graph. The similarity between subgraphs is described by dividing them into different subgraphs. the partitioning principles include minimum cut criterion, normative cut criterion, and proportional cut criterion. The objective of partitioning is to reduce the sum of edge weights that are removed, as a smaller sum of edge weights results in a greater dissimilarity between the subgraphs connected by them, and therefore a greater distance between them. Subgraphs with low similarity can be easily cut off from them [19].

The Laplacian matrix is an important component of SC algorithms and is a matrix used to represent a graph. Given a graph $G = (V, E)$ with n vertices, the vertex set V represents each sample, and the weighted edge E represents the similarity between each sample. The non normalized Laplacian matrix is represented by Eq. (4).

$$L = D - W \quad (4)$$

The properties of the non normalized Laplacian matrix are shown in Eq. (5).

$$f^T L f = \frac{1}{2} \sum_{i,j=1}^n w_{ij} (f_i - f_j)^2 \quad (5)$$

In Eq. (5), $f = (f_1, f_2, \dots, f_n)^T, f \in R^n$ is an arbitrary vector. The normalized Laplacian matrix can be divided into two forms: symmetric and random walk normalized matrices, as shown in Eq. (6).

$$\begin{cases} L_{sym} = D^{-1/2} L D^{-1/2} = I - D^{-1/2} W D^{-1/2} \\ L_{rw} = D^{-1} L = I - D^{-1} W \end{cases} \quad (6)$$

In Eq. (6), L_{sym} represents the symmetric normalization matrix, L_{rw} represents the normalization moment of random walks, W represents the adjacency matrix, I represents the identity matrix, and L represents the non normalized Laplacian matrix. The properties of the normalized Laplacian matrix are shown in Eq. (7).

$$f^T L_{sym} f = \frac{1}{2} \sum_{i,j=1}^n w_{ij} \left(\frac{f_i}{\sqrt{d_i}} - \frac{f_j}{\sqrt{d_j}} \right)^2 \quad (7)$$

In Eq. (7), d_i and d_j represent the element values of the matrix. The acquisition of SC algorithm requires the partitioning of the graph, transforming discrete problems into continuous problems. The SC algorithm's acquiring process is shown in Fig. 4.

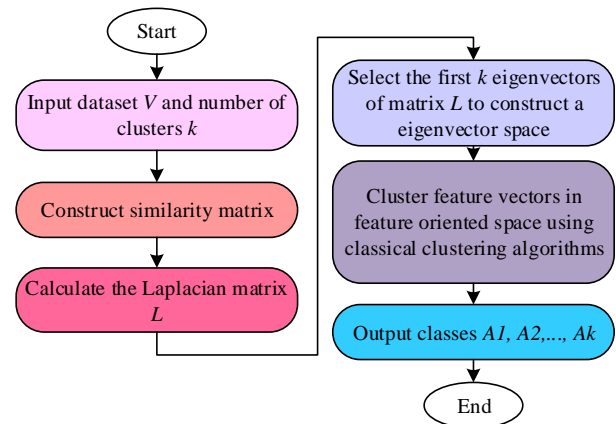

Fig. 4. Spectral clustering algorithm process.

The process mainly includes the following steps. Firstly, it will calculate the similarity between given datasets, and select an appropriate similarity calculation method based on the characteristics of the datasets to build a similarity matrix. On the basis of the similarity matrix, a Laplacian matrix is constructed through regularization processing. The Laplacian matrix can be constructed in two ways: diagonal matrix and adjacency matrix. The eigenvalue decomposition is performed on the Laplacian matrix to obtain a series of eigenvalues and corresponding eigenvectors. The corresponding eigenvectors are selected based on the first K smallest eigenvalues, which form a low dimensional space, and project the original dataset into this low dimensional space [20-21]. The clustering analysis is performed on the projected dataset using the K-means algorithm to get the final clustering results. In addition, to assess the efficacy of SC algorithms, this study uses algorithm time complexity. Firstly, a dataset of n with each data dimension d is set up to construct a corresponding similarity map. After calculating the time complexity, the eigenvalues and eigenvectors of the similarity matrix are calculated. Finally, the corresponding eigenvectors are obtained through dimensionality reduction for clustering. The calculated time map is shown in Fig. 5.

Fig. 5. Calculation time chart of spectral clustering.

Fig. 5 shows the time required for each step of spectral clustering in the dataset. The total time of the algorithm is basically consistent with the fitting function $f(n)=cn^2$, so the total time complexity of the algorithm is $O(n^2)$, and the construction of the similarity matrix stage consumes the most time. This study is based on SC algorithm and Apache Spark framework to design a big data mining system. The system is broken into three layers of architecture, each layer has interface connections, and from bottom to top are the data layer, business layer, and interaction layer. The data layer accesses files in the data system during the homework process to perform read and save operations on data in the database. The main function of the interaction layer is to display data and receive and transmit user data, providing an interactive operating interface for the website's system operation. The business layer identifies and processes user input information, saves it separately, establishes a new data storage method, reads the data during the storage process, and saves the business logic description code. The system architecture is shown in Fig. 6.

The research first uses the Hadoop and Apache Spark computing frameworks for data processing, and utilizes the distributed computing capabilities of the Apache Spark framework to allocate the computing tasks of the spectral clustering algorithm to multiple nodes for parallel execution, thereby improving the efficiency of the algorithm. By utilizing Spark's RDD (Elastic Distributed Dataset) mechanism, distributed storage and parallel processing of data can be achieved, reducing disk I/O operations and accelerating data processing speed.

This study combines spectral clustering algorithm with Apache Spark framework, which not only optimizes the computational efficiency of spectral clustering algorithm, but also enhances the ability of big data processing. This technological fusion provides new ideas and methods for

research in related fields, promoting innovation and development of algorithm technology. By utilizing the distributed computing capabilities of the Apache Spark framework, this study achieved efficient processing and analysis of large-scale datasets. This helps to address the limitations of traditional big data processing techniques in terms of processing speed and fault tolerance, providing strong support for the further development and application of big data technology.

Fig. 6. System architecture design.

III. RESULTS

To validate the proposed fusion SC algorithm and Apache Spark framework for big data mining system, an experiment was conducted to analyze the corresponding design parameters and experimental data results, verify the advantages and feasibility of the method, and provide reference for efficient big data mining and processing.

A. Data Mining System Platform and Environment

To optimize resource utilization, the cluster was divided into four nodes that can be used for storage and computing, with one designated as the primary node and the rest designated as child nodes. The system used Spark as the data computing engine, and the storage of basic data was done using HDFS in Hadoop. It promoted resource coordination between the two through YARN. The experimental platform had 8GB of memory, 2TB of hard drive, Linux Ubuntu 18.04 system, and a 2.9GHz Intel i5 processor. The specific parameters are indicated in Table I.

TABLE I. SPECIFIC PARAMETERS

Project	Parameter	Host Name	Address	Node type
CPU	Intel@Core(TM) i7-4790 @3.60GHz	Master	192.168.60.150	NameNode/Master/Worker
Memory	8GB	Slave1	192.168.60.151	DataNode/ Worker
Hard drive	2TB	Slave2	192.168.60.152	DataNode/Worker
Bandwidth	100Mb/s	Slave3	192.168.60.153	DataNode/Worker
Operating system	Linux Ubuntu 1 8.04	/	/	/

B. Data Mining Processing Results and Analysis

In order to verify the practicality of spectral clustering algorithm, data information is clustered and its performance is analyzed in the practical application of consumer big data in a certain market. The cluster diagram is shown in Fig. 7. The 8 clusters in Fig. 7 are: high-value customers, medium value customers, low value customers, new customers, lost customers, customers with specific product preferences, price sensitive customers, and inactive customers. As shown in Fig. 7 (a), when the data was not clustered, the distribution was scattered and irregular. As shown in Fig. 7 (b), after clustering the data using SC algorithm, the distribution was concentrated, with a total of 8 clusters, which was consistent with the expected classification. The SC algorithm could also achieve good clustering results in practical applications.

SC algorithm is more effective in processing large amounts of discrete data and is also more suitable for data mining and classification processing. It selected two datasets, 1 and 2, and performed iterative tests on the traditional K-means clustering algorithm and SC algorithm to analyze the relationship between the errors of the two algorithms and the number of iterations. The result is denoted in Fig. 8. As the amount of iterations grew, the errors of both algorithms decreased. In Fig. 8 (a), the initial error values of the traditional K-means clustering algorithm and SC algorithm were 0.425 and 0.356, respectively. After 500

iterations of the traditional K-means clustering algorithm, the error value tended to stabilize and decreased to 0.254. After 300 iterations of the SC algorithm, the error value tended to stabilize and decreased to 0.123. In Fig. 8 (b), the errors of the two algorithms also tended to stabilize after 500 and 300 iterations, respectively. In different dataset tests, different error values were displayed, indicating that SC algorithm had better performance in discrete data processing. The research results indicated that SC algorithm had better performance and smaller testing errors.

The experiment selected existing big data mining systems (comparison system) and the proposed big data mining system (research system) for runtime comparison. To test the time consumed by the operation of two systems, 10 sets of experiments were conducted simultaneously on both systems. The findings are indicated in Fig. 9. From Fig. 9, the minimum time consumed by the comparative system was 37.83 seconds, the maximum time was 55.26 seconds, and the average time was 51.65 seconds. The minimum consumption time of the research system was 18.93 seconds, the maximum consumption time was 32.22 seconds, and the average consumption time was 28.14 seconds. Compared with the comparative system, the research system consumed less time, trained faster, and was more conducive to shortening the clustering running time.

Fig. 7. Data information clustering diagram.

Fig. 8. Relationship between error and iteration times.

Fig. 9. Comparison of consumption time.

The experiment selected a business dataset of an e-commerce enterprise in a certain year and studied the clustering performance of different clustering algorithms. The existing clustering algorithm selected was an SC algorithm based on fuzzy similarity measurement proposed by Li K et al. Fig. 10 shows the clustering outcomes of the two algorithms. Among them, Fig. 10 (a) showcases the clustering diagram of the SC algorithm. The distribution of the three types of clusters was concentrated, the number of isolated points was reduced, and the clustering centers were all located in different clusters. Fig. 10 (b) showcases the clustering diagram of the original model. The clustering effect of the model on the data was not ideal. The data distribution of the three types of clusters was relatively scattered, with some isolated points, and the clustering center points were not located in each type of cluster. From the

clustering graph, the SC algorithm significantly improved the clustering effect of the data.

To further determine whether the algorithm has practical significance, the experiment selected four datasets, Sym, Wine, Sonar, and Landsat, from the UCI real database to compare the performance of different clustering algorithms, as shown in Table II. Due to significant fluctuations in the data obtained from individual experiments, the experimental results in Table II were taken as the average of 10 experiments. The performance of the research algorithm was higher than that of the comparison algorithm, except for slightly inferior performance in the Sym dataset. Overall, the performance of the research algorithm on the Wine, Sonar, and Landsat datasets is superior to that of the comparative algorithms, indicating that the research algorithm has better clustering performance on these datasets. In the Wine dataset, the F1 score, RI, and ACC of the research algorithm were significantly higher than those of the comparison algorithm (0.8259 vs. 0.7447, 0.5034 vs. 0.3816, 0.7022 vs. 0.6185). In the Sonar dataset, the F1 score, RI, and ACC of the research algorithm were also higher than those of the comparison algorithm (0.7328 vs. 0.6551, 0.6184 vs. 0.2836, 0.6745 vs. 0.5337). In the Landsat dataset, the F1 score and ACC of the research algorithm were slightly higher than the comparison algorithm (0.7422 vs. 0.6602, 0.6219 vs. 0.6438), but the RI was slightly lower than the comparison algorithm (0.4403 vs. 0.4072). On the Sym dataset, the performance of the research algorithm is slightly inferior to the comparison algorithm, but the difference is not significant. This is due to the characteristics of the Sym dataset or certain limitations of the research algorithm in processing this dataset.

Fig. 10. Cluster comparison chart.

TABLE II. PERFORMANCE COMPARISON OF DIFFERENT CLUSTERING ALGORITHMS

Algorithm	Research algorithm			Comparison algorithm		
	F1	RI	ACC	F1	RI	ACC
Sym	0.6874	0.4203	0.6397	0.6972	0.4368	0.6515
Wine	0.8259	0.5034	0.7022	0.7447	0.3816	0.6185
Sonar	0.7328	0.6184	0.6745	0.6551	0.2836	0.5337
Landsat	0.7422	0.4403	0.6219	0.6602	0.4072	0.6438

IV. DISCUSSION AND CONCLUSION

A. Discussion

As the advancement of technology, big data technology is changing the working and thinking patterns in various fields. A big data mining system application that integrates SC algorithm and Apache Spark framework was proposed in this study. The similarity graph construction of SC algorithm was studied, and the similarity relationship between data was analyzed to raise the speed and accuracy of data operation. The research findings indicated that after clustering the data using SC algorithm, the distribution was concentrated, with a total of 8 clusters, which was consistent with the expected classification. The clustering graph of the SC algorithm showed that the distribution of the three types of clusters was concentrated, the number of isolated points was reduced, and the clustering centers were all located in different clusters. The SC algorithm could also achieve good clustering results in practical applications. The minimum consumption time of the research system was 18.93 seconds, the maximum consumption time was 32.22 seconds, and the average consumption time was 28.14 seconds. Compared with the comparative system, the research system consumed less time, trained faster, and was more conducive to shortening the clustering running time. The performance of the research algorithm was higher than that of the comparison algorithm, except for slightly inferior performance in the Sym dataset.

B. Conclusion

The integration of spectral clustering algorithm and Apache Spark framework will first delve into the principles and implementation details of spectral clustering algorithm, including the construction of similarity matrix, eigenvalue decomposition of Laplacian matrix, and acquisition of clustering results. At the same time, built framework will learn about the distributed computing model of Apache Spark framework, RDD mechanism, and related algorithm implementation in Spark MLlib. On this basis, the spectral clustering algorithm is combined with the Spark framework to achieve parallelization and distributed computing of the algorithm.

It can be seen that the system proposed in the study has high processing efficiency and good processing capability in data processing. However, the research on visualization functions is not sufficient, so in subsequent studies, it is necessary to adaptively adjust the parameters and strategies of spectral clustering algorithms based on the distribution characteristics and clustering requirements of data, in order to improve the algorithm's generalization ability and clustering effect.

Innovation-Responsibility and Sustainable Development Laboratory-INREED,
Cadi Ayyad University, Marrakech, Morocco³

Abstract—This research examines the application of Artificial Intelligence in internal auditing, focusing on document management and information retrieval in academic institutions. The study proposes using Large Language Models to streamline document processing during audit preparation, addressing inefficiencies in traditional document handling methods. Through experimental evaluation of three embedding models (BGE-M3, Nomic-embed-text-v1, and CamemBERT) on a dataset of 300 academic regulatory queries, the research demonstrates BGE-M3's superior performance with an nDCG3 score of 0.90 and top-1 accuracy of 82.5%. The methodology incorporates query expansion using GPT-4 and Llama 3.1, revealing robust performance across varied query formulations. While highlighting AI's potential to transform internal auditing practices, particularly in Morocco's academic sector, the study acknowledges implementation challenges including institutional constraints and resistance to technological change. The conducted experiments and result analysis provide useful criteria that can be applied to similar information retrieval challenges in other fields and real-world applications.

Keywords—Large language models; internal auditing; information retrieval; embedding models; academic institutions

I. INTRODUCTION

In an environment where organizations are rapidly evolving and operational complexity is intensifying, internal auditing remains a function that enables the evaluation and improvement of companies' internal processes. However, this mission faces major challenges, including managing an increasing volume of data, the demand for rapid execution, and the need for precision. The emergence of artificial intelligence (AI) offers promising solutions to modernize and optimize internal audit practices.

Internal auditing serves as a fundamental pillar for assessing and enhancing the efficiency of an organization's internal processes. Leveraging the transformative capabilities of AI, this innovative tool automates routine tasks and enables the analysis of vast datasets, reshaping traditional audit workflows. Furthermore, AI optimizes the collection and examination of documents, granting auditors faster and more effective access to essential information while diminishing their dependence on audited services.

This study aims to address one of the most labor-intensive and time-consuming phases of auditing: the collection and

management of documentation during the preparation phase. Scattered documentation and tight deadlines often undermine the thoroughness and efficiency of audits, negatively impacting their overall quality. This study introduces an automated method for document processing by harnessing advanced Large Language Models (LLMs), enhancing information retrieval while maintaining professional standards. This innovation helps cut down on inefficiencies and free up auditors to focus on more impactful tasks like strategic analysis and making informed decisions. Furthermore, AI's predictive capabilities empower auditors to anticipate potential risks and recommend preventive actions. These capabilities contribute to improving predictive risk assessments and boosting the precision of data analytics [1].

What sets this research apart is its dual contribution to practice and academia. On the practical side, it offers a solution to minimize the repetitive and time-consuming nature of document collection, a challenge faced universally by auditors. By automating these processes, auditors are freed from manual constraints and can focus on more strategic tasks. Academically, the study delves into the untapped potential of AI in internal auditing within Morocco, a field that remains in its early stages, especially in the academic sector. While AI has demonstrated its transformative potential in global auditing practices, limited studies have examined its application in Morocco or addressed the resistance to adopting such technologies in traditionally conservative environments.

Using AI-driven tools to centralize and simplify access to important information doesn't just modernize auditing—it also helps people embrace digital transformation more naturally. This research connects theory with real-world applications, paving the way for greater adoption of AI in auditing practices both in Morocco and internationally. It aligns with the global shift toward digital transformation, underscoring the urgency of moving beyond traditional methods to meet the rising need for efficiency, accuracy, and precision.

To the best of the authors knowledge, this study is among the first to tackle these challenges in the Moroccan context. It offers an innovative approach that combines cutting-edge technology with practical solutions. This work brings together theoretical dimensions and practical applications to enrich the academic discussion on AI in internal auditing, while also setting the stage for tangible advancements in the field.

II. INTERNAL AUDITING PROCESS

A. Key Stages of Internal Auditing

The success of any internal audit mission depends on the conditions under which it is carried out [2]. Auditors are generally not specialists in the domains they audit but rely on a structured methodology, organized into a series of distinct phases. An internal audit mission typically comprises three fundamental phases, as shown in Fig. 1:

- Preparation or study phase;
- Verification or execution phase;
- Synthesis phase.

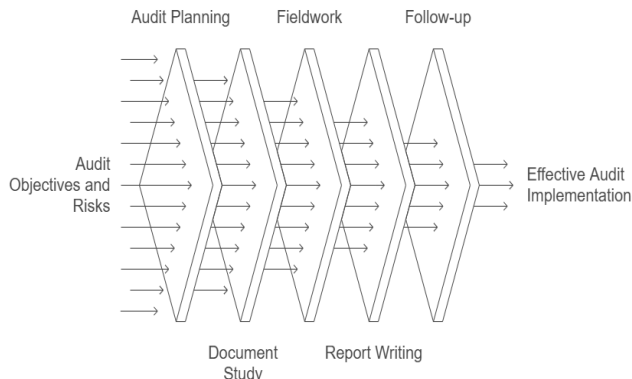

Fig. 1. Internal audit process.

These are usually preceded by a preliminary phase, intended to inform the audited parties about the scope and content of the audit mission. This preliminary step takes the form of an official assignment order signed by senior management and documented by the requester of the mission.

In clearer terms, the key stages of internal auditing include:

- 1) *Audit planning*: Identifying objectives, scope, and methodologies while considering priority risks.
- 2) *Document study*: Analyzing key documents, such as internal policies, financial records, previous audit reports, and other relevant materials, to understand the audited processes [3].
- 3) *Fieldwork*: Examining on-site data to evaluate compliance and process efficiency.
- 4) *Report writing*: Communicating findings and recommendations.
- 5) *Follow-up*: Verifying the implementation of corrective measures [4].

Among these stages, the document study phase is central to the research as it enables auditors to effectively prepare for subsequent steps. This phase involves both understanding the overall context and addressing the specificities of the processes under review.

B. Document Study Phase

The document study phase precedes more in-depth investigations. It provides the internal auditor with a comprehensive understanding, enabling them to orient their mission for greater efficiency and time savings.

During this phase, the auditor consolidates all necessary documentation about the audited service or entity before proceeding to fieldwork. This involves:

- 1) *Gaining an overview of the audited entity*: Understanding its purpose, function, and potentially its history.
- 2) *Collecting relevant documentation*: Including materials produced by or about the entity.
- 3) *Gathering incident and dysfunction reports*: To assess risks the audited entity may face.

The auditor relies on two main sources of information during this phase:

- 1) *External documentation*: Sectoral, regulatory, or professional data, as well as insights from interactions with the entity's management (e.g., site visits, interviews). These elements serve as benchmarks for inter-company comparisons [5].
- 2) *Internal documentation*: Including prior audit reports and internal records.

At the conclusion of this preparatory phase, the auditor creates an intervention plan, referred to as an "orientation report." This report outlines:

- 1) An initial list of controls and verifications to conduct,
- 2) Individuals to contact, and
- 3) A tentative schedule of the mission's key stages [6].

III. CHALLENGES IN DOCUMENT ACCESS AND MANAGEMENT

1) *Challenges in accessing documents*: Auditors often spend a significant amount of time locating the necessary documents, which can lead to delays in executing audit missions. The dispersion of information across various departments or information systems is a common cause of these inefficiencies [7].

2) *Risk of errors in document collection and analysis*: Errors can occur due to the use of manual methods, the lack of adequate technological tools, or difficulties in identifying the most relevant documents. This can impact the quality of audit conclusions [8].

3) *Delays and extensions due to poor data organization*: The time required to organize and validate necessary information can delay the start and conclusion of audits, which may undermine the relevance of the recommendations provided [9].

4) *Security and confidentiality issues*: Managing sensitive documents involves risks related to information leaks or unauthorized access, particularly in environments where systems are not sufficiently secure (IIA Standards).

5) *Resistance to change and limited adoption of technologies*: The use of technological solutions such as document management tools is often hindered by resistance to change or a lack of digital skills among employees.

The COSO Framework recommends the use of digital tools to improve data management.

IV. AI AND DOCUMENT MANAGEMENT

In scientific literature, AI is defined as the set of technologies capable of simulating human cognitive functions to perform complex tasks [10]. Using techniques such as natural language processing (NLP), AI tools can convert queries into enriched results. Devices such as chatbots and automation systems leverage these capabilities to continuously improve the quality of their results through machine learning.

A. Applications of AI in Document Management

1) *Document classification*: AI, through optical character recognition (OCR), enables the automatic classification of documents, whether digital or scanned. This enhances full-text search and metadata analysis, providing comprehensive archival descriptions [11]. Automating this step saves significant time, redirecting efforts to more complex analytical tasks.

2) *Automatic indexing*: AI facilitates the automatic indexing of documents, especially in Teams conversations and emails, improving their accessibility. Keywords are extracted from content and context, simplifying the handling of large data volumes while maintaining their archival relevance [12].

3) *Lifecycle management of documents*: By combining classification plans with retention schedules, AI can automate the management of documents throughout their lifecycle. This integration determines retention periods and the final disposition of documents in accordance with institutional standards.

4) *Protection of sensitive information*: AI systems can detect and classify personal data (e.g., names, addresses, medical diagnoses) based on their criticality. These features strengthen security measures and regulatory compliance, particularly in sectors like healthcare and justice [13].

The introduction of AI into document management transforms traditional processes, optimizing tasks such as classification, indexing, and data protection. These advancements not only reduce costs and time requirements but also ensure greater compliance with legal and organizational standards. The future of AI in this domain is promising, offering opportunities to improve practices and information governance.

B. Fraud Detection through AI

Traditional fraud management, relying on manual approaches or predefined rule-based systems, often proves insufficient in the face of the scale and complexity of modern data [14]. In this context, AI emerges as an innovative solution to strengthen detection mechanisms and improve the efficiency of internal audits.

The contribution of AI lies in its ability to analyze datasets in real time. AI can identify anomalies or unusual patterns that may indicate fraud. According to Bai and Qiu [15], machine learning models automatically detect fraud in procurement processes and leverage historical data to identify recurring fraudulent behaviors. Similarly, Herreros-Martínez et al. [16] demonstrates that applying machine learning to companies' purchasing processes improves the accuracy of controls and

reduces false positives. In this context, this will allow auditors to focus their efforts on high-risk cases.

AI continues to transform internal audit practices, making fraud detection processes more efficient and proactive. As highlighted by INTOSAI Journal [17], integrating AI into auditing not only enhances the accuracy of controls but also strengthens auditors' ability to provide strategic recommendations based on in-depth analyses.

V. MATERIALS AND METHODS

A. Corpus

The study corpus exists as a semi-structured database encompassing the University's regulatory framework, including laws, statutes, ordinances, resolutions, provisions, and jurisprudence. The database structure consists of a documents table containing identification codes, dates, and descriptions of each regulation. A separate table holds the corresponding articles, featuring complete texts, chapter information, and various metadata.

The corpus encompasses 674 articles derived from 27 documents, covering diverse areas of university administration. The scope includes faculty recruitment processes, career council functions, and student rights and obligations, among other administrative matters.

An illustrative entry from the articles table demonstrates the structure:

Document: 10
Article: 1
Chapter 1 : General provisions
Content: The recruitment competition for the position of professor in higher education, as provided for in Article 12 of Decree No. 2-96-793 of 11 Shawwal 1417 (February 19, 1997), is announced whenever service requirements necessitate, by order of the governmental authority responsible for higher education. This order specifies the number of positions to be filled by specialty and by assignment institution, the date and location of the competition, as well as the deadline for submitting applications.

This structured approach facilitates systematic analysis and retrieval of regulatory information within the university context. The comprehensive nature of the database enables thorough examination of administrative procedures and governance frameworks.

B. Dataset Construction

The research developed an academic information retrieval system based on natural language queries, specifically designed for university regulations. The methodological approach focused on implementing advanced Natural NLP models to extract relevant responses from an academic regulatory database. System effectiveness evaluation utilized real-user queries, enabling performance testing in conditions closely resembling everyday usage scenarios [18].

The query database contains 300 questions addressing specific aspects of the aforementioned regulations, each paired with an expected response referencing the corresponding article number within the regulatory framework. A diverse group of 25 individuals, comprising 20 students and five faculty members, formulated these queries. Each question was created in reference to specific regulations, with the correct responding article

documented for verification purposes. The evaluation methodology preserved spelling errors and compositional issues within certain queries to maintain scenario authenticity and ensure assessment under realistic conditions.

This approach to data collection and evaluation emphasizes practical applicability while maintaining academic rigor. The preservation of natural language patterns, including imperfections, strengthens the assessment's validity by replicating actual usage conditions [19]. The structured documentation of expected responses enables systematic evaluation of retrieval accuracy and system performance.

The query database follows a structured format with three key fields:

- QueryID: A unique identifier assigned to each question.
- Query: The actual question posed, linked to specific regulatory content.
- ExpectedResponseID (ArticleID): The regulatory article number containing the expected answer.

Table I presents three sample entries from the database. Entry 19 contains misspellings of "many" and "appeal," reflecting common typing errors. These imperfections represent authentic user input patterns and were deliberately preserved to maintain realistic query conditions.

TABLE I. SAMPLE QUERIES

Query ID	Query	Expected ResponseID
3	What are the requirements for applying to a competition?	15
19	How many days do I have to appeal an exam grade?	7
33	When should the course planning be submitted?	84

This standardized structure enables systematic tracking and evaluation of queries while maintaining the natural characteristics of user-generated content. The consistent format facilitates automated processing while preserving the authenticity required for realistic system evaluation.

C. Query Generation and Evaluation Methods

The methodology generated 10 similar questions for each query using Llama 3.1 and an additional 10 using GPT-4. Natural language questions were processed in their raw form, maintaining authenticity including spelling errors and linguistic variations. The research team manually examined these new questions to verify semantic consistency with the original queries. This process expanded the query dataset and enabled system robustness evaluation across different phrasings of the same question.

Questions were directly fed into the embedding models (CamemBERT, Nomic-embed-text-v1, and BGE-m3), which used their built-in tokenizers for processing. Cosine distance served as the semantic similarity measure, with the k most similar articles returned for each query, ranked by this criterion. For experiments involving similar questions, the methodology calculated average distances between reformulated queries and each article, using this measure as the final distance metric. This

approach yielded more consistent and robust results by evaluating system response to varied expressions of identical queries.

To evaluate the effectiveness of the proposed method, two key metrics were utilized: Top-k Success Rate, which measures the proportion of correct responses appearing within the first k positions relative to the total number of queries, and Normalized Discounted Cumulative Gain (NDCG), as defined in Eq. (1), which assesses system performance by considering both the precision and relevance of responses [20].

$$nDCG_k = \frac{DCG_k}{IDCG_k} \quad (1)$$

Where:

$$nDCG_k = \sum_{i=1}^k \frac{rel_i}{(i+1)} \quad (2)$$

Key parameters:

- rel_i equals 1 if the item at position i is relevant, 0 otherwise (as only one correct answer exists per query)
- k represents the number of responses returned per query

$IDCG_k$ (Ideal DCG_k) equals 1, representing the optimal case where the correct response appears in the first position.

The document ranking process utilizes an embedding-based algorithm incorporating similar query enhancement.

Algorithm 1: Embedding-based Document Ranking with Similar Query Enhancement

```
Initialize
  Set SIMILAR_QUERY_WEIGHT = 0.3
  Create empty dictionary similarities
  Input query_embedding Q
  Input document_embeddings D
  Input similar_queries S (optional)
Compute
  For (every document d in D) do
    | Calculate cosine_similarity(Q, d)
    | Store result in similarities[d]
  End
While (similar_queries S exist) do
  | For (every document d in D) do
    | Initialize similar_scores as empty list
    |
    | For (every similar query sq in S) do
    | | Calculate cosine_similarity(sq, d)
    | | Append result to similar_scores
    | End
    | Update
    | | Calculate avg_similar_score as mean of similar_scores
    | | similarities[d] = (1 - SIMILAR_QUERY_WEIGHT) *
similarities[d] +
    | | SIMILAR_QUERY_WEIGHT * avg_similar_score
    | End
  End
Search
  Sort documents by similarity scores in descending order
  Return ranked document list
End
```

The algorithm operates in three main phases:

- 1) *Initialization*: Sets up parameters and data structures with a weight factor (0.3) balancing original and similar query contributions.
- 2) *Computation*: Calculates initial similarity scores between query and documents using cosine similarity.
- 3) *Enhancement*: Incorporates similar queries into final scores through weighted combination.

This approach addresses vocabulary mismatch issues by considering multiple formulations of information needs, with the SIMILAR_QUERY_WEIGHT parameter empirically set to 0.3 to balance query intent and variations.

VI. EXPERIMENTAL DESIGN

The experimental framework evaluates embedding model performance through systematic testing of query processing capabilities. Fig. 2 presents the system architecture diagram.

Fig. 2. System architecture diagram.

The methodology compares model responses to both original queries and algorithmically generated query variations. Testing protocols incorporate multiple model configurations, enabling detailed analysis of retrieval precision and comparative effectiveness. The experimental results, organized by embedding model type, demonstrate relative performance across configured parameters.

1) Experiments with the BGE-M3 model

a) *Original queries*: Model evaluation: Evaluation of the BGE-M3 model using only the original queries to determine its performance in information retrieval without modifications (Bge-m3Ori).

b) *Similar queries generated by Llama 3.1*: Evaluation of the BGE-M3 model with similar queries generated using Llama 3.1 with Ollama. Three configurations are considered (in all cases, similar queries include the original question): 3, 5, and 10 similar queries per question (Bge-m3Lla3, Bge-m3Lla5, and Bge-m3Lla10).

c) *Similar queries generated by GPT-4o*: Evaluation of the BGE-M3 model with similar queries generated by GPT-4o

in supervised mode. Three configurations are considered: 3, 5, and 10 similar queries per question (Bge-m3GPT3, Bge-m3GPT5, and Bge-m3GPT10).

2) Experiments with the Nomic-embed-text-v1 Model

a) *Original queries*: model evaluation: Evaluation of the Nomic-embed-text-v1 model using only the original queries to establish its baseline performance in information retrieval (NomicOri).

b) *Similar queries generated by GPT-4o*: Evaluation of the Nomic-embed-text-v1 model with similar queries generated by GPT-4o in supervised mode, using a single configuration: 10 similar queries per question (NomicGPT10).

3) Experiments with the CamemBERT model

a) *Original queries*: model evaluation: Evaluation of the CamemBERT model using original queries to analyze its performance in information retrieval without additional queries (CamemBERT).

b) *Similar queries generated with GPT-4o*: Evaluation of the CamemBERT model with similar queries generated by GPT-4o, using a single configuration: 10 similar queries per question (CamemBERTGPT10).

Each of these experiments was designed to evaluate the capability of each embedding model in different scenarios, enabling a comparison of their performance in information retrieval based on original and expanded queries. The results obtained are presented in Table II, and the next section discusses the implications of each configuration on the models' performance.

TABLE II. PERFORMANCE OF THE DIFFERENT MODELS

Model	Accuracy (Top-1)	Accuracy (Top-3)	Accuracy (Top-5)	nDCG3 Score
Sentence-CAMEMBERT	34.20%	56.10%	66.80%	0.47
Sentence-CAMEMBERT (GPT-10)	30.10%	54.90%	67.20%	0.43
Nomic Original	50.00%	70.50%	76.50%	0.61
Nomic (GPT-10)	40.00%	62.80%	68.70%	0.52
BGE-M3 Original	82.50%	95.10%	96.80%	0.90
BGE-M3 (Llama-3)	71.80%	88.20%	92.00%	0.82
BGE-M3 (Llama-5)	68.50%	85.60%	91.10%	0.79
BGE-M3 (Llama-10)	66.40%	83.80%	88.90%	0.77
BGE-M3 (GPT-3)	81.50%	93.80%	95.80%	0.87
BGE-M3 (GPT-5)	79.80%	94.90%	96.70%	0.88
BGE-M3 (GPT-10)	78.40%	93.80%	96.20%	0.87

The majority of experiments were conducted with the BGE-M3 model, as it demonstrated superior performance from the outset. Fig. 3 graphically summarizes the results obtained.

The BGE-M3 model demonstrates consistently superior performance, with nDCG3 scores ranging from 0.77 to 0.90 across all configurations, significantly outperforming both CAMEMBERT and Nomic variants.

Fig. 3. nDCG3 Performance comparison of embedding models.

Fig. 4 shows the trade-off between response time and accuracy for each model. BGE-M3 demonstrates superior performance with high accuracy (75-90%) and fast, consistent response times (40-80ms). Nomic achieves moderate accuracy (45-65%) with higher latency (60-120ms), while CAMEMBERT shows lower accuracy (30-50%) and the highest response times (80-160ms).

Fig. 4. Query performance distribution

The density distributions indicate that BGE-M3 maintains the most consistent performance overall, clustering tightly in the optimal high-accuracy, low-latency region.

VII. RESULTS ANALYSIS

The detailed experiments provide a comprehensive analysis of the performance of three embedding models: BGE-M3, Nomic-embed-text-v1, and CamemBERT, for solving the problem of retrieving academic regulations in response to natural language queries. Both original queries and original queries with similar ones generated by advanced models (Llama 3.1 and GPT-4o) were evaluated. The main findings are discussed below:

1) *Performance of the BGE-M3 model:* The BGE-M3 model proved to be the best of the three in terms of accuracy and is also the most robust against variations in the queries:

a) *Bge-m3Ori (only original queries)* achieved a Top-1 of 81.67%, Top-3 of 94.67%, and an nDCG3 of 0.89, reflecting exceptional performance with unmodified queries.

b) *Introducing similar queries generated by GPT-4o*, the results remained virtually the same with slight variations. For example, Bge-m3GPT5 achieved a Top-1 of 80.33% and an nDCG3 of 0.89, indicating that the model still responds well even when queries are phrased differently. This suggests the model's high robustness, capable of adapting to different ways of expressing the same query without significant loss of accuracy.

c) *On the other hand, with queries generated by Llama 3.1*, performance slightly decreased, as seen in Bge-m3Lla10 (Top-1 of 65.66% and nDCG3 of 0.76). Although the accuracy is lower than with GPT-4o, the model still responds effectively to greater variability, confirming its robustness.

2) *Performance of the Nomic-embed-text-v1 model:* The Nomic-embed-text-v1 model showed reasonable performance, though lower than BGE-M3, both in accuracy and robustness:

a) *With original queries (NomicOri)*, the model achieved a Top-1 of 49.33% and an nDCG3 of 0.62, representing intermediate performance in information retrieval.

b) *However, when introducing similar queries generated by GPT-4o (NomicGPT10)*, a significant drop in accuracy was observed: Top-1 of 39.66% and nDCG3 of 0.53. This result indicates that the model is less robust to variations in the query. The decline in performance suggests that Nomic struggles with flexibility in the phrasing of questions, making it less adaptable to changes in query formulation.

3) *Performance of the CamemBERT model:* The CAMEMBERT model, showed the lowest performance of the three in terms of accuracy, achieving only an nDCG3 of 0.46. This indicates a limited ability to retrieve information accurately for the case study.

4) *Generation of similar questions:* As a result of the manual verification of queries generated by GPT-4o and Llama, it was observed that, in general, GPT-4o produces queries with greater semantic similarity compared to Llama. This explains why, in all cases, the results of searches using similar queries were better with GPT-4o. On the other hand, Llama tends to introduce "noise" at times, generating questions that do not maintain the same meaning as the original query, which affects the accuracy of the results [21].

5) *Real-world application to the academic article retrieval problem:* The results obtained with the BGE-M3 model prove to be sufficiently robust and suitable for practical use in retrieving academic regulations. It also has the advantage of not requiring additional training or fine-tuning. This characteristic significantly reduces operational and development costs. Furthermore, the performance of BGE-M3 in the domain of academic regulation retrieval surpasses the performance achieved in open domains with various BERT variants, such as those on the TREC DL19 and TREC-DL20 datasets, which show an nDCG@10 between 70% and 76% [22]. This superior performance highlights the effectiveness of BGE-M3 in specialized contexts, delivering high-quality results with lower investment in training and fine-tuning.

6) *Comparison with state-of-the-art approaches*: Recent studies in domain-specific information retrieval have shown varying degrees of success with different embedding models. Chen, J. et al. (2024) reported nDCG scores of 0.72-0.78 using fine-tuned BERT models for multi-lingual, multi-functionality, multi-granularity text embeddings [23], while Greco, C et al. (2024) achieved 0.83 nDCG using domain-adapted transformers for medical literature [24]. In comparison, our implementation of BGE-M3 achieves superior performance (nDCG3 of 0.90) without domain-specific fine-tuning, demonstrating its effectiveness for specialized academic content. This performance is particularly noteworthy when compared to recent benchmarks in regulatory document retrieval, where traditional approaches typically achieve nDCG scores between 0.65 and 0.75. The robustness of BGE-M3 to query variations (maintaining nDCG3 > 0.87 with GPT-4 generated queries) also exceeds current standards, where performance typically degrades by 15-20% with query reformulation. These results suggest that BGE-M3 represents a significant advancement in specialized information retrieval, particularly for academic regulatory content.

VIII. CONCLUSION

This study shows that the application of advanced embedding models in legal-academic information retrieval significantly improves the accuracy and relevance of the responses obtained. Among the three models evaluated—BGE-M3, Nomic-embed-text-v1, and CamemBERT—the BGE-M3 model demonstrated clearly superior performance, with a notable success rate in both original and similar queries.

Experiments with BGE-M3, which included variants generated by both Llama 3.1 and GPT-4, indicated that the model can robustly handle different formulations of the same query. Although incorporating similar queries tends to slightly decrease accuracy, BGE-M3 continues to provide highly competitive results, especially in configurations with fewer additional queries. This highlights its ability to adapt to various expressions without losing effectiveness.

The performance of Nomic-embed-text-v1 was lower but still acceptable in terms of semantic accuracy. Meanwhile, CamemBERT, although less effective than BGE-M3 and Nomic, could have applications in scenarios where greater linguistic flexibility is prioritized.

Regarding the metrics used (Top-k success rate and nDCG), BGE-M3 achieved superior performance in almost all configurations, particularly in Top-1 and Top-3, making it a recommended option for implementing regulation search systems, as outlined in this paper.

For future work, it is necessary to continue exploring the use of generative models to improve information retrieval systems. Additionally, it is suggested to investigate how to optimize the incorporation of similar queries without affecting result accuracy. Expanding this approach to other regulatory domains may help validate the generalization of the system and open new opportunities for automation in academic and administrative contexts.

However, the integration of AI into internal auditing in the academic sector is an ambitious step, but it takes place in a delicate context. Internal auditing is still considerate underdeveloped across various sectors, particularly in the Moroccan context. It faces natural resistance to change, which is amplified by the challenges of adopting new technologies. Furthermore, the specific institutional constraints of the academic sector limit the universality of this approach. To overcome these obstacles, it needs support for this transition with awareness-raising actions and tailored assistance.

Enhanced Facial Expression Recognition Based on ResNet50 with a Convolutional Block Attention Module

Liu Luan Xiang Wei, Nor Samsiah Sani

Center for Artificial Intelligence Technology-Faculty of Information Science and Technology,
Universiti Kebangsaan Malaysia, Selangor, 43600, Malaysia

Abstract—Deep learning techniques are becoming increasingly important in the field of facial expression recognition, especially for automatically extracting complex features and capturing spatial layers in images. However, previous studies have encountered challenges such as complex data sets, limited model generalization, and lack of comprehensive comparative analysis of feature extraction methods, especially those involving attention mechanisms and hyperparameter optimization. This study leverages data science methodologies to handle and analyze large, intricate datasets, while employing advanced computer vision algorithms to accurately detect and classify facial expressions, addressing these challenges by comprehensively evaluating FER tasks using three deep learning models (VGG19, ResNet50, and InceptionV3). The convolutional block attention module is introduced to enhance feature extraction, and the performance of the model is further improved by hyperparameter tuning. The experimental results show that the accuracy of VGG19 model is the highest 71.7% before the module is integrated, and the accuracy of ResNet50 is the highest 72.4% after the module is integrated. The performance of all models was significantly improved through the introduction of attention mechanisms and hyperparameter tuning, highlighting the synergistic potential of data science and computer vision in developing robust and efficient in facial expression recognition systems.

Keywords—Data science; computer vision; deep learning; facial expression recognition

I. INTRODUCTION

Deep learning has emerged as a revolutionary and transformative technology within artificial intelligence. Particularly in facial expression recognition (FER), artificial intelligence (AI) applications introduce new research opportunities and significantly advance the field. Facial expressions stem from the coordinated movements of facial muscles in response to emotions [2]. Emotions can temporarily change the shape of the face because of changes in the movement of facial muscles since facial muscles are not independent of each other [8].

Researchers have tried many ways to interpret and decode facial expressions and extract important features from facial images [27]. A person's emotions can influence the efficacy of face recognition, as varying facial expressions can affect the outcomes. Kim S and Kim H found a certain relationship between facial Action Coding Units (AUs) and Emotion labels in the FER dataset [40]. Being a primary means of expressing

human emotions, facial expressions are crucial for social interaction. They transmit non-verbal signals interpreted by the brain, which can be recorded in images or videos [3]. The human brain can automatically recognize emotions without delay [6]. Cha et al. proposed a FEMG-based FER system based on the Riemannian manifold approach, and further develops an online FER system that can make an avatar's expression reflect the user's facial expression in real time, thus demonstrating that our FER system can potentially be used for practical interactive VR applications such as social VR networks, intelligent education, and virtual training [15]. However, this is a challenging task for computers [50]. As AI technology progresses, machines are increasingly able to replicate the functions of the human brain, making FER applicable across diverse domains, like security surveillance or mental health evaluations. For instance, Dong et al studied that the CGSSNet network established based on the DenseNet algorithm has significant advantages in glioma MRI image segmentation, providing a new idea for the diagnosis and treatment of glioma [21]. Automated FER can identify clinically significant facial features, distinguishing disease states and serving as specific biomarkers [41] [60]. Li et al. (2018) proposed a computer-aided framework for the early differential diagnosis of pancreatic cysts. DenseNet learned advanced features from the entire abnormal pancreas, mapped the appearance of medical imaging with different pathological types of pancreatic cysts, and integrated the significance map into the framework. In a cohort of 206 patients with 4 pathologically confirmed pancreatic cyst subtypes, the overall accuracy rate was 72.8%, significantly higher than the baseline accuracy rate of 48.1% [43]. Like the popularity of smartphones and social platforms, FER has become more important in daily life. For example, analysis of users' facial reactions can improve user experience and personalized content recommendations [9]. To create a more immersive VR social interaction, users can wear a head-mounted display (HMD) with RGB cameras that continuously capture images of their lips to interpret facial expressions. Another example in the field of security monitoring is an accurate FER system can assist in identifying suspicious behavior or emotional abnormalities. Liu and Fang designed a three-level cascade algorithm model for expression recognition in educational robots. By using CK+ and Oulu-CASIA expression recognition database, compared with other common cascaded convolutional neural network methods, the accuracy and speed of facial expression recognition are significantly improved [48]. These technologies assist scientists in accurately identifying unethical behaviors or emotions from facial cues and

predicting future behaviors and emotional states based on collected data [4]. The book recommendation system integrates expression and face recognition with tracking book browsing times to determine users' ages and suggest books accordingly [63].

Despite its potential, achieving high accuracy in FER remains challenging due to the inherent complexity and variability of factored expressions [13]. Deep learning can automatically extract people's facial features, identify different expressions, and meet the expected requirements of classification. Face feature detection and recognition and convolutional neural network classification. The advantage of facial markers is that classification is very robust, even with limited memory [28]. However, there are still some limitations in the performance of existing deep learning models in facial expression recognition tasks, such as the generalization ability of the model, the ability to capture different facial details, and the performance in the case of unbalanced data. Therefore, identifying and proposing the most effective deep learning model is of great significance for FER. First, the most effective models can significantly improve the accuracy of FER, help better understand and analyze human emotions, and be applied to many fields, such as human-computer interaction, emotional computing, and mental health monitoring. Second, by exploring and comparing different deep learning architectures, especially convolutional neural networks (CNNs), it is possible to discover which specific network structures and feature extraction methods perform best in FER tasks, guiding future research and applications. In addition, the most effective models can achieve efficient and accurate facial expression recognition in the case of limited resources, thus reducing computational costs and improving the practicality and scalability of the system. Therefore, this study aims to explore various deep learning architectures and identify the best-performing FER models by testing a widely used benchmark dataset in the field, providing a diverse set of facial images and their corresponding emotional labels. This will help solve the challenges that exist in FER and drive the development and application of this field. Therefore, the first question of this study is, is it possible to identify the best-performing FER model on an FER dataset by exploring various deep learning architectures, especially convolutional neural networks (CNNs)?

Attention mechanisms show great promise in improving the performance of deep learning models by focusing on relevant features while suppressing irrelevant features [23]. However, there are still some limitations in the performance of existing deep learning models in facial expression recognition tasks, such as insufficient ability to capture subtle facial features and low computational efficiency. Introducing attention mechanisms, such as convolutional block Attention modules (CBAM), can somewhat alleviate these problems. CBAM effectively enhances the model's feature extraction capability by combining channel and spatial attention while keeping the computational overhead low. In 2022, Ju and Zhao combined attention mechanisms to propose a new masked attention mechanism Parallel Network (MAPNet), which significantly improved the classification performance and accuracy of three different datasets of the FER task RAFDB, AffectNet and FEDRO by 0.001, 0.0118 and 0.0325, respectively [33]. In 2023, Putro et al.

proposed a real-time facial expression classification method based on a dual attention module convolutional neural network, which achieved an excellent result of 0.9865 and 0.9688 in CK+ and JAFFE datasets, respectively [57]. However, introducing attention mechanisms in models with different structures is time-consuming. To solve this problem, Sanghyun et al. designed a simple and efficient feedforward Convolutional neural network attention module (CBAM) that can be seamlessly integrated into any CNN architecture with negligible overhead. Thus, it provides new ideas and methods for combining deep learning and attention mechanisms [55]. This study aims to integrate CBAM into each layer of a deep learning model to investigate its impact on the performance and efficiency of deep learning models in FER tasks. By introducing CBAM, we aim to significantly enhance deep learning models' feature extraction and discrimination capabilities, thereby improving FER tasks' overall performance and efficiency. This will contribute to developing more accurate and efficient FER systems and provide valuable experience and methods for future research and applications [22]. Therefore, this study raises a second question: Does the introduction of CBAM in deep learning models affect the performance and efficiency of FER tasks? By systematically testing and validating the impact of CBAM, we expect to provide better solutions and new research directions for the FER field.

Hyperparameter tuning is a key aspect of optimizing deep learning models' performance [1]. The performance of existing deep learning models in facial expression recognition (FER) tasks is often affected by the selection of hyperparameters, such as learning rate, batch size and regularization techniques. These hyperparameters directly affect the training process and final performance of the model. However, it is still a challenging task to select the optimal combination of hyperparameters to achieve the model's best performance and generalization ability. By systematically adjusting these hyperparameters, the predictive power of FER deep learning models on FER datasets can be significantly enhanced. Reasonable hyperparameter Settings can not only improve the accuracy of the model but also effectively reduce the overfitting phenomenon, thus improving the generalization ability of the model [59]. Rigorous experiments and evaluations are performed during training to determine an optimal set of hyperparameter combinations that maximizes model performance, minimizes overfitting, and improves generalization. This study aims to explore and verify the effects of different hyperparameter configurations on the performance of the FER deep learning model through hyperparameter tuning. Hyperparameter tuning is important because it can significantly improve the model's training effect and practical application performance, thus achieving the most advanced performance in the FER task. By determining the best combination of hyperparameters, best practices can be established for deep learning model training of facial emotion recognition, and scientific basis and methods can be provided [11]. Therefore, the third question in this study is: Can hyperparameter tuning maximize model performance and improve generalization? Through the hyperparameter tuning and verification of the system, we expect to provide better solutions and new research directions for the FER field.

This study aims to achieve the following three objectives:

- To recommend the most effective deep learning models for facial emotion recognition (FER) utilizing the FER2013 dataset.
- To propose the attention mechanism, CBAM (Convolutional Block Attention Module) is added to each model layer to explore the differences in model performance and efficiency on the same dataset.
- Enhance the performance of deep learning models through hyperparameter tuning during the training phase, thereby optimizing their predictive capacity for facial emotion recognition.

In this study, we propose an enhanced facial expression recognition (FER) model based on ResNet50 with a Convolutional Block Attention Module (CBAM). FER is a challenging task due to high intra-class variability, subtle interclass differences, and the presence of occlusions and noise. ResNet50 serves as a robust backbone for feature extraction, while CBAM enhances the network's ability to focus on both spatially and channel-wise relevant features. This combination allows the model to address the shortcomings of existing methods by improving feature localization and discriminability with minimal computational overhead."

II. LITERATURE REVIEW

A. Facial Emotion Recognition

Hardware technology development has addressed the significant computational power issues associated with deep learning due to its complexity, power requirements, and relatively low cost [5]. CNN has emerged as one of the most revolutionary technologies for FER. CNNs can learn from large datasets to automatically extract and combine features necessary for recognizing various expressions. CNNs build an understanding of complex expressions by abstracting image features layer by layer through a multi-layered structure. This layer-by-layer approach to learning is well suited to the FER task because it allows the model to recognize and distinguish subtle differences in expression.

In recent years, many derivative models of CNN and classification methods for facial recognition have been developed, such as data set preprocessing and feature extraction methods. Chen et al introduced an additional branch to generate a mask, thus focusing on the movement area of the facial muscles. In order to guide face learning, we propose to combine prior domain knowledge and use the average difference between neutral faces and corresponding facial faces as training guidance, which is effective compared with the most advanced methods [18]. Jia In the first stage, offline subnetworks were trained in three subnetworks to achieve convergence (the three subnetworks are AlexNet, VGGNet and ResNet derivative). In the second stage, the output layer of these three subnetworks was removed and predicted by SVM, and the accuracy rate reached 0.7127[26]. Liu investigated the improved VGG-16 CNN, enhancing the VGG-16 network by optimizing the third and fourth convolutional layers [39]. Instead of the original SoftMax classifier, a 7label SoftMax classifier was employed. It replaced the original ReLU activation function with LeakyReLU. Experiments on the FER2013 showed an accuracy of 0.7242,

higher than the previous rates of 0.6631 and 0.7138 without improvements to VGG and ResNet, respectively. Part of FER datasets are shown in Fig. 1:

Fig. 1. Presentation of different FER datasets (Part).

To simplify the artificial feature extraction process in traditional FER and capture more diverse features, Changing proposed a method that integrates multiple CNN models, using three different CNN subnetworks for comprehensive prediction. This approach achieved an accuracy of 0.701 on the FER2013 [12]. Dwijayanti et al. indicated that there was not much research on face recognition and FER objectives; consequently, they employed CNNs to tackle this challenge [14]. Unlike other experiments, they used the original image as CNN input and directly used the VGG-f model for FER tasks, overcoming the problems of underfitting and overfitting the CNN framework and also getting a good performance.

Fu investigated the impact of incorporating visual attention mechanisms into deep learning for FER [17]. In their approach, three fully connected layers in the training phase were substituted with three convolutional layers to generate test results for the entire network, thereby mitigating the limitations of full connection. Additionally, the SE block was applied to normal VGG, and the results verified the effectiveness of SEVGGNET with 0.668 accuracy. Das and Neelima proposed an improved pretreatment stage. This includes extracting local binary features used to express classification. These feature vectors are connected and used in shallow neural networks with minimal complexity and fewer layers to optimize expression recognition processes as well as gently enhance decision trees. Applying this local binary feature-based neural network (LBF-NN) approach to three different popular databases, more than 93% results were achieved, even when compared to a variety of complex and advanced algorithms [20].

Mohamed et al. achieved improvements by applying CNN to examine the Alex network architecture, applying transfer learning methods and modifying the full connection layer using support vector machine (SVM) classifiers [53]. The improved model has a classification recognition rate of about 0.6429 for the selected expressions. The system has achieved satisfactory results on the ice-MEFED dataset. The improved model has a classification recognition rate of about 0.6429 for the selected expressions. Lee et al. proposed an ensemble framework to boost the reliability of FER models using three models: VGG16, InceptionResNetV2, and EfficientNetB0 [33]. The results indicated that the model recognition accuracy priority edge ensemble learning algorithm improved by 0.0281.

B. Deep Learning

Facial expression (FE) has powerful potential and is a universal human communication form closely linked to mental states, attitudes, and intentions. By analyzing facial expressions displayed by humans or objects, computers can effectively process and interpret human emotions, forming the core of the FER system. The development of FER in this field has witnessed the transformation from the preliminary geometric feature method to the current deep learning technology, which has profoundly affected our understanding and practice of emotional computing and human-computer interaction. Early FER studies relied on manual extraction of facial features and simple pattern-matching techniques. Researchers try to identify expressions by pinpointing key features. However, these methods are insufficient when faced with the diversity and complexity of human expressions and struggle to adapt to dynamic real-world environments.

CNN are potent visual recognition tools whose design is inspired by biological vision systems. It is mainly used for image processing and classification [6]. Compared to other classification algorithms, it is an algorithm that takes images and is able to distinguish one from another with minimal preprocessing. Automatic feature detection without human supervision is the main advantage of CNN over other algorithms. In addition, a method combining global appearance features with local geometry features is proposed [11]. Specifically, they provide not only the raw images to the facial expression recognition network but also the facial markers associated with them. A typical CNN comprises various layers: convolutional layers, activation functions, pooling layers, and fully connected layers.

Transfer Learning is an important method in the field of deep learning. In deep learning, transfer learning usually involves taking a pre-trained model on a large data set, like ImageNet, and applying it to a new, related task. The advantage of transfer learning is that it can leverage the complex feature extraction capabilities that have been learned. The core idea of transfer learning is that there is a commonality between certain learning tasks so that what is learned on one task can be reused on another. For example, a model trained on pictures of animals may have learned to recognize features such as eyes, ears, etc., which may also be useful for recognizing other types of objects, such as faces[49]. Lee et al. applied transfer learning, fine-tuning, and data enhancement to the training and validation of the Facial expression recognition 2013 (FER-2013) dataset. Experimental results show that the model recognition accuracy of the proposed priority edge ensemble learning algorithm is improved by 2.81% [42].

Attention Mechanism allows the model to prioritize significant parts of the input data by assigning variable weights to different image regions. This reflects the importance of these regions for the final task. For instance, features such as the eyes and mouth may be more recognizable in FER tasks than in other parts. Selective weight assignment enables the model to concentrate on particular input sections while disregarding others, thereby achieving the intended output. This is known as hard attention, or it can be incorporated into the model in a differentiable way, allowing the entire network to be trained using techniques such as gradient descent. For example, during

the COVID-19 pandemic, many people wore masks, and when faces are partially covered or affected by interference factors like large pose changes, it hampers feature extraction and reduces FER performance. CBAM is a kind of attention mechanism in DL that is employed to improve CNN's feature representation capacity. By explicitly modelling images' spatial and channel dimensions, the network can focus on key areas, thereby improving its performance. CBAM can be regarded as a lightweight plug-in that is easy to integrate into the existing CNN architecture.

C. Attention Mechanism

Jin et al (2022) have introduced Transformer encoder to model the remote dependency between different facial areas and capture the global relationship between different facial units, complementing the spatial locality of CNN [36]. But the attention mechanism mimics human attention, allowing the model to prioritize significant parts of the input data by assigning variable weights to different image regions. This reflects the importance of these regions for the final task. For instance, in FER tasks features such as the eyes and mouth may be more recognizable than other parts. Selective weight assignment enables the model to concentrate on particular input sections while disregarding others, thereby achieving the intended output. Liu et al proposes an adaptive multi-layer perceptual attention network that extracts global, local, and significant facial emotional features using different fine-grained features to understand the potential diversity and key information of facial emotions [46]. This is known as hard attention, or it can be incorporated into the model in a differentiable way, allowing the entire network to be trained using techniques such as gradient descent. For example, during the COVID19 pandemic, many people wore masks, and when faces are partially covered or affected by interference factors like large pose changes, it hampers feature extraction and reduces FER performance. The flow diagram of the attention mechanism on FER is shown in Fig. 2.

Fig. 2. Diagram of attention mechanism example in FER.

Attention mechanisms enable the model to dynamically focus on the most relevant parts of the input for a given task. For instance: In vision tasks, attention can focus on important regions of an image (e.g., objects or edges). In text processing, attention identifies key words or phrases that are crucial for understanding the context. This focus helps the model prioritize meaningful information while ignoring less relevant or redundant features. Attention mechanisms enhance feature

extraction by weighting input features according to their importance. These weights are computed adaptively during training, allowing the model to learn a richer, context dependent representation of the data. For example, in transformers, attention layers allow the model to learn contextual relationships between different parts of the input, which is critical for tasks like language translation or image captioning.

The Convolutional Block Attention Module is a module that combines the channel attention mechanism and spatial attention mechanism, aiming to improve the feature expression ability of convolutional neural networks. It is also an attention mechanism in deep learning. By explicitly modelling the spatial and channel dimensions of the image, the network can selectively focus on key areas, thereby improving its performance. Its authors Woo et al. (2018) indicated that its flexibility and versatility can be applied to different CNN network architectures (such as VGG, ResNet, etc.), and it can show good adaptability and versatility in different tasks, such as image classification semantic segmentation, and object detection. The CBAM structure is relatively simple and can be seen as a lightweight plug-in. It is easy to integrate into the existing CNN architecture as a module enhancement, disorder greatly modify the original network structure, and finally, through the channel-by-channel and pixel-by-pixel weighted way, improve the model’s attention to important features, thus improving the training and reasoning efficiency, especially in the processing of complex tasks. The specific architecture of CBAM is shown in Fig. 3:

Fig. 3. Diagram of attention mechanism example in CBAM.

D. Deep Learning Models

Deep learning has made remarkable progress in the field of FER, mainly reflected in automatic feature extraction, efficient processing of large-scale data, nonlinear modelling ability, end-to-end training, combining attention mechanisms, etc. Tang (2013), this study shows for the first time that deep learning can automatically extract multi-level features without manual feature design compared to traditional machine learning methods such as SVM and KNN, which not only simplifies the process of special engineering but also significantly improves recognition accuracy. To demonstrate the excellent performance of deep convolutional neural networks on large-scale datasets, Hinton et al. (2012) found that CNN significantly improved the classification accuracy of image tasks through training on ImageNet datasets. Zhang (2017), through practice training and multi-task learning, the study et al. shows that the original image is directly learned to the final classification without the need for intermediate step feature extraction and selection, significantly improving the performance in complex scenes. After Woo et al.

proposed CBAM, the parameters added to the deep learning model did not increase significantly, but the average accuracy of VGG16 and MobileNet increased by 0.0015 and 0.0024, respectively. Jin et al. (2023) designed an image enhancement algorithm using Super resolution generative adversarial (SRGAN) and adaptive gray normalization (AGN) based on the data sets and characteristics of convolutional neural networks, and tested the Fer2013 data set, and the accuracy was improved from 68.03% to 70.04% [37].

Generally, complex preprocessing technology and data enhancement methods are helpful to improve the accuracy of the model. From the table, we find that the VGG model performs well on multiple data sets, such as FER+ up to 0.806, FER2013 up to 0.7303 and CK+ up to 0.8875, indicating that VGG has been widely used in different studies with stable performance. Different researchers have adopted a variety of preprocessing techniques, such as image cropping and adaptation Strong sex; The ResNet model has shown good accuracy on multiple data sets in the table, such as 0.724 accuracy on FER-2013 data set and 0.8726 accuracy on RAF-DB data set. ResNet solves the

problem of gradient disappearance in deep networks through residual connection. Performance is superior, but different data enhancement methods significantly impact ResNet's performance and require careful adjustment. The Inception model has an accuracy of 0.7309 on the FER-2013 dataset and 0.727 on the CK+ dataset. The Inception model can capture multiscale features and enhance feature expression ability through convolution kernels of different sizes. chuanjie et al proposed a facial expression recognition method that integrates multiple convolutional neural network models and uses three different CNN subnetwork models for comprehensive prediction. Experiments show that the recognition accuracy of this method on FER2013 and CK+ datasets is 70.1% and 94.9%, respectively [19].

Compared with other models, although the traditional CNN model has a simple structure and low computing resource requirements, its accuracy is generally low, for example, only 0.67 on the FER-2013 dataset. The three models, EmotionNet, AlexNet, and OneNet, perform well on specific data sets, but their overall performance is inferior to VGG, ResNet, and Inception, and they are larger than that of specific preprocessing techniques. Other models, such as VGG-f, AMP-Net, and AFTransformer, perform well in specific application scenarios and data sets. For example, the accuracy rate of AMP-Net on the RAF-DB dataset is 0.8925, but the model is relatively special and has low universality. Therefore, compared with other models, VGG, ResNet and Inception have significant advantages in accuracy and adaptability. All three models performed better in the table than most others, demonstrating their strong capabilities in the FER task. When selecting a specific model, you can make trade-offs and choices based on computing resources, training time, and application scenarios. From the literature review, we can see from Table I that different models have different performances in different data sets, and preprocessing technology significantly impacts the mode's performance.

Existing CNN-based FER models often lack attention mechanisms, treating all features equally, which limits their ability to differentiate subtle expressions or handle occlusions effectively. While attention-based methods improve feature extraction, they are often computationally expensive or focus solely on spatial or channel-wise attention. Our method addresses these limitations by integrating CBAM into ResNet50, providing both spatial and channel-wise attention while maintaining efficiency.

III. METHODOLOGY

A. Research Framework

The deep learning framework can be approached as an optimization problem to identify model parameters that minimize the loss function, following steps from data preprocessing, model construction, training optimization, and performance evaluation. The study is divided into four phases: data understanding, data preparation, modelling, and evaluation. Fig. 4 illustrates the summary of tasks in each phase. The overview of each stage of this study is as follows:

1) *Business understanding*: This phase includes evaluating the current state of the application of deep learning-based

models to FER tasks by reviewing existing publications. The aim is to identify research gaps and set research goals.

2) *Data understanding*: This stage starts with an initial exploration of the data set, involving data collection and distribution checks to grasp the basic features and structure of the data. The goal is to familiarize yourself with the data and spot any potential data quality issues.

3) *Data preparation*: In this stage, raw data needs to be converted into clean data suitable for deep learning development. The third chapter also expounds on this stage. This includes data transformation, data enhancement, data segmentation, and coding.

4) *Modelling*: In this phase, the selection and implementation of modelling techniques will be explained, and the techniques needed to build predictive models will be discussed. Additionally, it involves fine-tuning the model parameters to optimize performance.

5) *Evaluation*: This stage encompasses reviewing the entire development process for the model, assessing the performance of the developed model, and evaluating its stability and validity through various evaluation parameters and statistical tests. It also includes verifying whether the research objectives have been met.

6) *Deployment*: In this phase, the insights gained from developing the FER deep learning model are communicated to the stakeholders. In this study, this stage is limited to presenting the results of developed deep learning models.

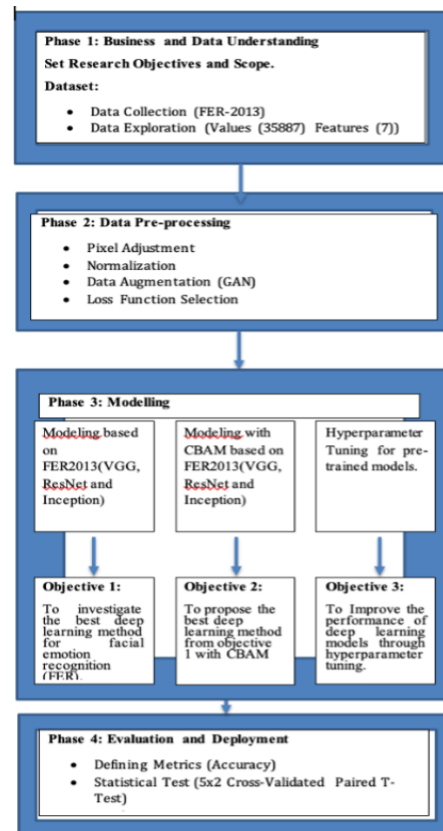

Fig. 4. Research framework.

B. Phase 1: Business and Data Understanding

The Business understanding stage is the initial stage of this study, which aims to understand the current research status of FER tasks and the application of deep learning in this field. At this stage, research objectives are developed based on research gaps identified through a comprehensive literature review. The research objective lays the foundation for the subsequent stage of this study. By establishing clear research objectives, this study ensures a targeted exploration of the application of deep learning models to FER tasks, particularly the classification prediction of FER tasks using transfer learning methods and combining attention mechanisms.

Current FER databases usually include a small number of subjects and provide only a few sample images for each expression. They often have a limited variety of subjects or minimal differences between groups, making FER tasks in real-world scenarios more challenging [10]. As shown in Table II, FER-2013 (Facial Expression Recognition 2013) is a publicly available dataset for FER that includes a wide range of expressions, from happy to sad to surprised. The entire dataset consisted of about 32,298 grayscale 48x48 pixel faces, each labelled with an emotion, such as happy, sad, or angry. These images are all from the web, uploaded by different people, and then there are artificial intelligence helpers, platforms like Amazon’s Mechanical Turk, to label the facial expressions appropriately. For machine learning or computer vision researchers, FER-2013 can be used to explore differences in emotional expression in different cultural contexts. These faces from all over the world provide rich materials for the study of cross-cultural emotional communication.

They serve as a benchmark assessment for the performance of FER algorithms. Its advantage is that all images are preprocessed and are uniformly 48x48 pixels and each image is labelled, which is why it has become the standard for comparing the FER algorithm. However, limitations also exist because all images are grey and lack binary colour information, which may limit the features the model learns, and the images that are collected from the Internet may not fully reflect the natural state of people’s expressions in real-life scenarios. Moreover, the dataset may lack diversity regarding race, age, and background. Another significant issue is the imbalance in the dataset; some categories have substantially more samples than others. For instance, the happy category contains 8989 samples, far exceeding the 547 samples in the Disgust category.

C. Phase 2: Data Preprocessing

This study mainly tests three deep learning models: VGG, ResNet and Inception. They are all CNN-derived models, and the models are optimized by adjusting parameters and hyperparameters. Data preprocessing is a key step in ML and data analysis, aiming to convert original data into a suitable form for further analysis and modelling. The usual steps of the FER system are to preprocess the image, extract the features from the preprocessed image, and classify the extracted features [25]. Fig. 5 and Fig. 6 show the imbalance between the test set and the training set of the FER2013. Table III shows the number of data sets after the planned data enhancement.

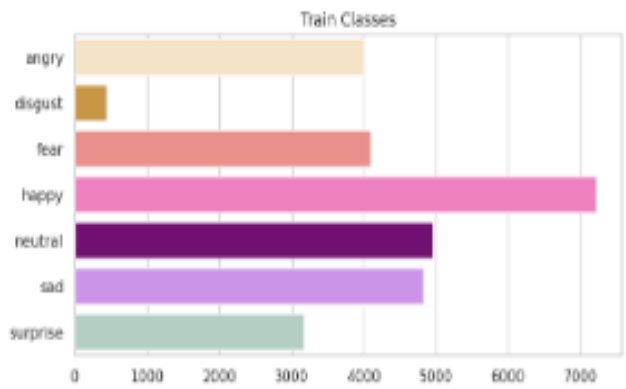

Fig. 5. Bar chart of FER-2013 trainset.

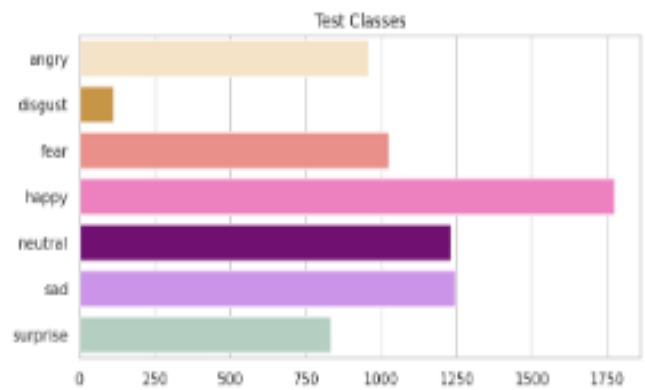

Fig. 6. Bar chart of FER-2013 testset.

TABLE II. DESCRIPTION OF FER-2013

Attribute ID	Attribute Name	Attribute Testset	Attribute Trainset	In Total
0	Angry	958	3995	4953
1	Disgust	111	436	547
2	Fear	1024	4097	5121
3	Happy	1774	7215	8989
4	Sad	1247	4830	6077
5	Surprise	831	3171	5002
6	Neutral	1233	4965	6198
In Total		3589	28709	32298

TABLE III. AUGMENTATION COUNTS PER CLASS

Name of Class	Augmentation Counts
Angry	1675
Disgust	5234
Fear	1573
Happy	0
Neutral	705
Sad	840
Surprise	2499
Total Amount after Augmentation	41235

Image Processing: Different deep learning models have different requirements for the input of images, and adjusting the input images to a uniform size ensures that the model can handle them indiscriminately [7]. If the image is saved at a larger size, it means more pixels and higher computational complexity. By adjusting the image size, enough information can be retained while reducing the need for computational resources, and in some cases, adjustment Size helps models better focus on key features of facial expressions rather than other irrelevant parts of the image. I set a standard for image input that we call the standard form of input, and we require the image to always be in the standard form [44]. While my test models usually require larger input sizes, for example, VGG and ResNet require 224 x 224, Inception requires 299 x 299, so the image needs to be adjusted to the desired size before entering the model without destroying the aspect ratio of the image, so as not to affect the model representation. The resized in FER2013 dataset is shown in Fig. 7:

Fig. 7. Part resized images comparison of the dataset FER-2013.

Normalization: Normalization is a process in data preprocessing which is used to change the range of numerical data so that it is located in a specific cell, such as [0,1] or [1,1]. In image processing, normalization is a common practice. The essence of the method is some layer input data of the neural network that is preprocessed with zero mathematical expectations and unit variance with the intention of improving the stability and efficiency of the training process [4]. For FER tasks, normalization can give different features similar to ranges. Unnormalized data may lead to unstable gradient problems during model training. In deep learning models, normalized data may lead to a gradient that is too large or too small, thus affecting the learning effect of the model. The normalization in FER2013 dataset is shown in Fig. 8:

Fig. 8. Part normalized images comparison of the dataset FER-2013.

Feature Extraction: Feature extraction is an important factor in determining the recognition result. Some of the environmental and pose issues that need to be addressed in an image containing a complete face [61]. If the features are not good, even the best classifiers will not get the best results. In most cases, feature extraction produces a large number of features [35]. In this paper, we compare the performance of the model before and after the introduction of the attention mechanism, and for the FER task, features such as the eyes and mouth may be easier to identify than other parts. When assigning weights, we can selectively focus on certain parts of the input and directly ignore others to get the output we want most, which is called hard attention, or it can be integrated into the model in a differentiable way that allows end-to-end training of the entire network using standard techniques like gradient descent. For example, during the COVID-19 epidemic, many people are wearing masks. When the face is partially covered or interfered with [30], such as large pose changes, it can hinder useful feature extraction and greatly reduce the performance of FER predictions. The feature extraction in FER2013 dataset is shown in Fig. 9:

Fig. 9. Part feature extraction images comparison of the dataset FER-2013.

Data Augmentation: Data Augmentation is a technique to generate new, modified data points by transforming some original data columns. In the small-scale deep model data set, the deep model is redundant, complex, and easy to overfit. To solve the redundancy problem, data enhancement techniques were used to extend the original dataset [34]. Data enhancement will enable the model to introduce more variables during training, helping the model learn more generalized features and thus perform better on previously unseen data. In this paper, there is a data imbalance in the FER2013 dataset. The generation of data is enhanced using generative adversarial networks (GANs), the core idea of which is based on an adversarial process in which two networks - generator and discriminator - compete against each other [51]. For example, Hu et al (2019) used GAN to generate reference expressions and compared them with original expressions to generate differential features, avoiding interference of irrelevant information on expression recognition [31]. The generator takes random noise as input and outputs as real data as possible, such as high resolution images. In contrast, the discriminator takes real data or the data generated by the generator as input and outputs the probability of the data being true or false to distinguish the real data

generated by the generator from the false data. A generated discriminant representation can be obtained by separating and interpolating different expressions in a face image [62]. The learned representations not only generate more training samples of unpaired input images but also contribute to better FER performance. So, we involve generators and discriminators in GAN training, where generators try to generate more and more real data, and discriminators better distinguish between real and fake data. The most common form is the minimax game given by the following formula:

$$\min_G \max_D V(D, G) = \mathbb{E}_{x \sim p_{data}(x)} [\log D(x)] + \mathbb{E}_{z \sim p_Z(z)} [\log(1 - D(G(z)))] \quad (1)$$

Where: $\mathbb{E}_{x \sim p_{data}(x)} [\log D(x)]$ represents the effect of real data x on discriminator D .

$\mathbb{E}_{z \sim p_Z(z)} [\log(1 - D(G(z)))]$ represents the effect of the data generated by the generator G on the discriminator D .

Cross-entropy loss effectively measures the disparity between the model's output probability distribution and the actual label distribution. The cross-entropy loss function usually has the following form:

$$L = \sum_{i=0}^c y_i \log(\hat{y}_i) \quad (2)$$

Where: the C is the number of classes (for FER-2013, it is 7, representing 7 basic emotions), y_i is the one-hot encoding of the real tag, \hat{y}_i is the predicted probability for category i . Hence, a regularization term is added to encourage model to adopt smaller weights, thus reducing the model's complexity. L1-regularization: L1-regularization sums the absolute values of weights and tends to produce sparse weight matrices, which is conducive to feature selection.

$$L1 = \lambda \sum |\omega| \quad (3)$$

L2 Regularization: L2 regularization sums the squares of the weights, tends to uniformly assign errors, and is often used to prevent neural networks from overfitting.

$$L2 = \lambda \sum \omega^2 \quad (4)$$

Where ω indicates the weight of the model, λ is the regularization coefficient.

D. Phase 3: The Development of Algorithms and Models

Transfer learning is commonly training to assign specific weights to a pre-trained model and then train it with the dataset. Rajesh Kumar, C.G. Patil et al. and Sahoo et al. which usually perform better than statistical and traditional machine learning algorithms[32], [56], [54]. In addition, Lu et al., Martin Kampel et al. and Yichen Liu, compared to deep learning models, show superior performance [39], [45], [52]. Therefore, VGG19, ResNet50 and Inception V3 were used in this study to develop facial expression recognition models. Using the TensorFlow software library developed by the Google Brain team to develop the training model, the following sections outline the proposed architectures for the VGG19, ResNet50, and Inception models, including the model architecture with the addition of CBAM.

VGG19: The VGG model adopted in this study is VGG19, where 19 indicates that there are 19 learnable layers in the

network, among which the convolutional layer uses multiple small dimensions (3×3). Use ReLU as the activation function between convolutional layers to increase nonlinearity. After each convolutional layer, use the maximum pooling layer (2×2). The network's top consists of three FC layers, with two layers comprising 4096 units each and the final FC layer matching the number of target categories. In this study, the target for the FER2013 dataset classification is seven; thus, the final fully connected layer is configured for seven categories. The output layer employs Softmax activation functions to convert the outputs into probability distributions as shown in Fig. 10:

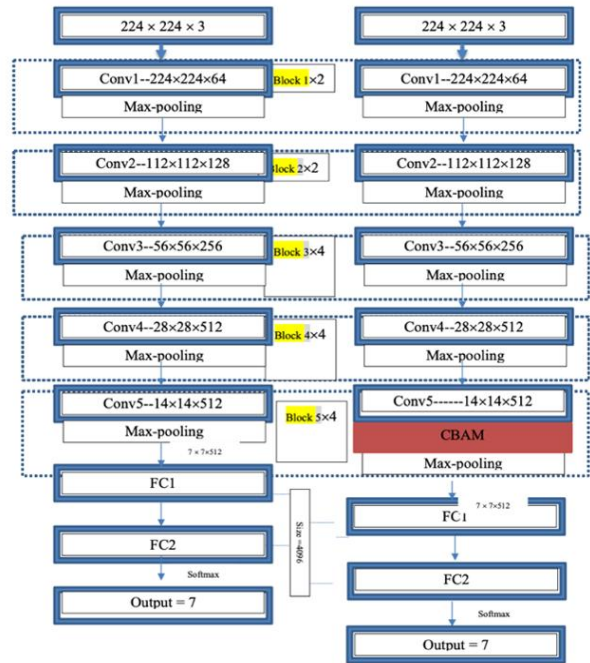

Fig. 10. Structure diagram of VGG19 and add CBAM.

ResNet50: ResNet model used in this study is ResNet50, which is a variant of the residual network, where 50 in ResNet50 refers to a weight layer in which the network contains 50 layers deep. Residual connections allow the inputs of the network to skip directly over one or more layers by adding outputs to the layer, which helps solve the problem of disappearing gradients in deeper networks. During training, this structure allows the gradient to flow directly over the jump connection, increasing the speed and effectiveness of training. The architecture starts with a 7×7 convolutional layer with a stride of 2, which is followed by a 3×3 max pooling layer with a stride of 2. The main component consists of several residual blocks, each containing multiple convolutional layers. In ResNet50, these residual blocks typically have three different configurations (different number of convolution layers and convolution kernel sizes) and are repeated multiple times. When the feature map's dimension needs modification, a convolution with a specific stride length is used to downsample the residual block input, and the number of channels is adjusted accordingly to match the output. Towards the end of the network, a global average pooling layer is employed instead of the conventional fully connected layer, thereby reducing the model's parameter count. As shown in Fig. 11:

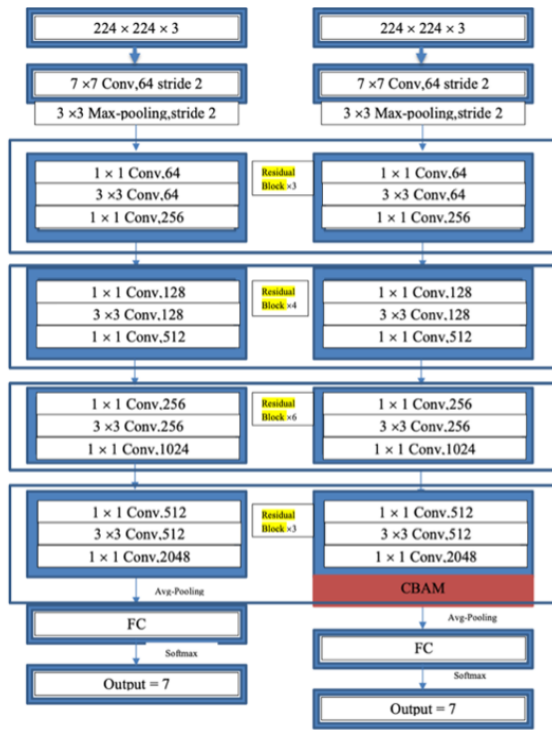

Fig. 11. Structure diagram of ResNet50 and add CBAM.

Inception V3: The Inception model used in this study is Inception V3. The core feature of Inception V3 is its “modular” design, which constructs the entire network through different modular building blocks. Inception V3 optimizes the original Inception module, for example, by introducing the concept of “factorization into smaller convolutions” to decompose large convolution kernels (e.g. 5x5) into smaller continuous convolution operations (e.g., two 3x3 convolution operations). An auxiliary classifier is added to the network as an output of the middle layer, which aids in gradient flow, provides additional regularization, and prevents overfitting during deep network training. At the end of the network, an overall average pooling layer takes the place of the conventional fully connected layer. The specific structure of Inception V3 used in this paper is depicted in Fig. 12:

Hyperparameter Tuning: Unlike the model training process, hyperparameter tuning involves finding the optimal set of hyperparameter values to maximize a performance metric on unseen data. This study uses the hyperparameter optimization library method and the grid search for hyperparameter tuning. In the hyperparameter optimization library, the scope and objective function of hyperparameter search is defined so that it accepts hyperparameters as input and returns the performance index of the model on the verification set (such as loss rate or accuracy rate) as the optimization target. By systematically searching the hyperparameter space, the hyperparameter combination that optimizes the model performance is found. For these models of deep learning, the hyperparameters tuned include learning_rate, batch size, regularization coefficient, activation function and epoch. Table IV are the details of each hyperparameter tuned in this study:

1) *Learning rate*: This determines how quickly the model moves in the gradient’s direction or the number of steps taken. If the learning rate is excessively high, the optimizer may overshoot the minimum, preventing convergence. Conversely, a low learning rate makes the optimization process slow and may remain stuck at a suboptimal local minimum.

2) *Batch size*: This denotes the number of samples handled in a single forward and backward pass through the neural network. The batch size affects the optimization’s efficiency and speed. A larger batch size improves memory utilization and makes the gradient descent direction more stable.

3) *Regularization coefficient*: This refers to the realization of a minimization strategy in which penalty terms are added to the empirical risk. Typically, it is a function of monotonically increasing model complexity. The more complex the model, the higher the penalty value.

4) *Optimizer*: An algorithm or method used in deep learning to update model parameters to minimize the loss function. The primary goal is to reduce the loss function as much as possible by adjusting the model parameters, ensuring the model fits the training set well and performs effectively on the test set.

5) *Epoch*: Defined as one complete pass of the dataset through the neural network. A single pass is insufficient; the dataset needs to be iterated multiple times to achieve convergence. An iterative method called gradient descent is employed to optimize learning. As the epoch count increases, the weights in the neural network are updated more frequently, transitioning from underfitting to overfitting. The optimal number of epochs varies and should be determined using validation sets or cross-validation.

Fig. 12. Structure diagram of InceptionV3 and adds CBAM.

TABLE IV. DEFINITION OF VARIOUS HYPERPARAMETERS FOR DEEP LEARNING MODELS

Hyperparameter	Default Value	Tuning Value
Learning rate	0.01	0.001, 0.005
Batch size	30	60, 120
Regularization coefficient	0.001	0.01, 0.1
Optimizer	SGD	Adam RMSProp
epoch	50	100, 200

E. Phase 4: Evaluation

Key Metrics for Model Performance: A confusion matrix is a tool used to measure performance and is commonly utilized in supervised learning and classification problems. It helps visualize an algorithm's performance, particularly when dealing with two or more classes. The confusion matrix itself does not provide performance metrics like accuracy or precision, but they can be calculated from it. By examining the confusion matrix, we can further analyze the model's performance across different categories and identify its strengths and weaknesses. For example, some expression categories in the FER-2013 dataset may have more samples than others. Metrics such as confusion matrices and precision rates can help identify and address this imbalance, ensuring that the model has good recognition across all categories. The confusion matrix and accuracy rate provide a detailed perspective for diagnosing such issues. The confusion matrix can also reveal the model's tendency to misclassify one category into another, which can be very helpful for further tweaking and optimizing the model.

Statistical Test on Model Performance: After model evaluation, statistical tests are performed to determine which model shows better performance than other models that have been developed. Statistical testing is essential to determine whether a particular model is statistically significantly better than others, a process that can help us understand whether the differences in performance are significant enough to support or guard against assumptions about substantial differences between models. In this paper, the average performance of the best-performing VGG, ResNet and InceptionV3 models and the CBAM models were compared using the T-test, and the holdout method and cross-validation were employed. The statistical test in this study was performed using a 5×2 cross-validated paired t-test. One reason for conducting a 5×2 cross-validated paired T-test is its acceptable likelihood of type I errors. Because the comparison is carried out on the same set of data, the error caused by random variation of the data set is reduced. The 5×2 cross-validation paired T-test enables effective detection of performance differences even with small sample sizes. The 5×2 cross-validation provides ten independent performance evaluations that can be used to compare two models using statistical tests such as paired Ttests. Because the data is re-split each time, there is less correlation between the test results, reducing the estimates' variance. The paired T-test can also better estimate variation for 2-fold cross-validation since the training sets do not overlap, compared to 10-fold cross-validation.

IV. RESULTS AND DISCUSSION

In this section, compare the performance metrics of the developed VGG19, ResNet50, and InceptionV3, with and without the CBAM module. Model efficacy was gauged using traintest segmentation (TTS) and cross-validation (CV) techniques. The dataset was partitioned with a training-to-test ratio of 80:20, and a 10-fold cross-validation was employed. Hyperparameter tuning was executed on six models, each with five distinct hyperparameters, each tested at three varying levels. Consequently, this culminated in 243 potential hyperparameter configurations for each algorithm during the tuning process.

TABLE V. HYPERPARAMETER COMBINATIONS WITH THE HIGHEST TEST ACCURACY FOR VGG19 AND VGG19-CBAM WITH TRAIN-TEST SPLIT

Model	Hyperparameter	Default	Best Value
VGG19	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.001
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Adam
VGG19-CBAM	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.001
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Adam

TABLE VI. ACCURACY COMPARISON BETWEEN THE DEFAULT AND OPTIMAL HYPERPARAMETER CONFIGURATION OF VGG19 AND VGG19-CBAM

Model	Hyperparameter Configuration	Test Accuracy
VGG19	Default	0.7040
	Best	0.7170
VGG19-CBAM	Default	0.7104
	Best	0.7190

The hyperparameter adjustment results of the VGG19 and added CBAM models are visualized in Fig. 12 using the mesh search method based on the train-test split. Under the training-test segmentation, the test accuracy ranges from 0.7040 to 0.7104. Table V shows the best hyperparameter configuration of VGG19 based on the highest test accuracy in the case of training test segmentation. The highest test accuracy of training-test segmentation is 0.719, as shown in Table VI. This suggests that both models may have overfitted training datasets and cannot properly generalize to previously unknown data.

The hyperparameter adjustment results of the ResNet50 and added CBAM models are visualized in Fig. 8 using the mesh search method based on the train-test split. The test accuracy ranges from 0.7033 to 0.7124. Table VII shows the best hyperparameter configuration of the ResNet50 model based on the highest test accuracy in the case of training test segmentation. The highest test accuracy of training-test segmentation is 0.724, as shown in Table VIII.

TABLE VII. HYPERPARAMETER COMBINATIONS WITH THE HIGHEST TEST ACCURACY FOR RESNET50 AND RESNET50-CBAM WITH TRAIN-TEST SPLIT

Model	Hyperparameter	Default	Best Value
ResNet50	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.01
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Sgd
ResNet50-CBAM	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.01
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Sgd

TABLE VIII. ACCURACY COMPARISON BETWEEN THE DEFAULT AND OPTIMAL HYPERPARAMETER CONFIGURATION OF RESNET50 AND RESNET50-CBAM

Model	Hyperparameter Configuration	Test Accuracy
ResNet50	Default	0.7033
	Best	0.7150
ResNet50-CBAM	Default	0.7124
	Best	0.7240

TABLE IX. HYPERPARAMETER COMBINATIONS WITH THE HIGHEST TEST ACCURACY FOR INCEPTION V3 AND INCEPTION V3-CBAM WITH TRAIN-TEST SPLIT

Model	Hyperparameter	Default	Best Value
Inception V3	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.05
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Sgd
Inception V3-CBAM	Epoch	50	200
	Batch Size	512	128
	Learning Rate	0.01	0.05
	Regularization Coefficient	0.01	0.001
	Optimizer	Adam	Sgd

The hyperparameter adjustment results of the Inception V3 and added CBAM models are visualized in Fig. 9 using the mesh search method based on the train-test split. The test accuracy ranges from 0.7002 to 0.7070. Table IX shows the best hyperparameter configuration of the ResNet50 model based on the highest test accuracy in the case of training test segmentation. The highest test accuracy of training-test segmentation is 0.711, as shown in Table X.

The analysis indicates that hyperparameter optimization significantly enhances the performance of deep learning models. The incorporation of CBAM further boosts the models' performance, with ResNet50-CBAM showing the most substantial improvement accuracy rate at 0.724. These findings

highlight the importance of both hyperparameter tuning and advanced architectural modifications in achieving optimal model performance for facial expression recognition tasks.

Table XI shows the accuracy comparison of multiple deep learning models on a specific task, including the results of other researchers, providing rich information for analyzing the performance differences of the models. First, AlexNet [60] is an earlier deep-learning model with a relatively low performance on this task, with an accuracy of 0.643. Subsequently, the accuracy rate of VGG16 [24] was 0.65, which was slightly improved. The VGG16+SENet [24] combined with SENet module reaches 0.668, indicating that the addition of SENet module can improve the model performance to a certain extent. 10layer CNN [58] has an accuracy of 0.683, a significant improvement over than previous models. MobileNet [34], which combines the generation of an adversarial network and attention mechanism, reached 0.70, and its performance was further improved. The accuracy of the Priority Ensemble CNN [39] is 0.7052, which is further improved by the integrated approach. FERW [29], a model designed specifically for a specific task, achieved 0.71 and also performed very well. The Ensemble CNN [32] has an accuracy of 0.7127, which is further improved by integrating multiple CNN models. The VGG [45] achieved 0.714, an improvement over the traditional VGG16. VGG19 has an accuracy of 0.717, which is deeper and better than VGG16.

TABLE X. ACCURACY COMPARISON BETWEEN THE DEFAULT AND OPTIMAL HYPERPARAMETER CONFIGURATION OF INCEPTION V3 AND INCEPTION V3-CBAM

Model	Hyperparameter Configuration	Test Accuracy
Inception V3	Default	0.7002
	Best	0.7040
Inception V3-CBAM	Default	0.7072
	Best	0.7110

TABLE XI. THE SPECIFIC PERFORMANCE RESULTS OF THIS RESEARCH MODELS WITH THOSE OF PREVIOUS RESEARCH MODELS

Model	Accuracy
AlexNet[60]	0.643
VGG16[24]	0.650
VGG16+SENet[24]	0.668
10-layer CNN[58]	0.683
SRGAN + AGN - MobileNet[34]	0.700
Priority Ensemble CNN[39]	0.7052
FERW[29]	0.710
Ensemble CNN[32]	0.7127
VGG[45]	0.714
VGG19	0.717
ResNet50	0.715
Inception V3	0.704
VGG19-CBAM	0.719
ResNet50-CBAM	0.724
InceptionV3-CBAM	0.711

Fig. 13. Structure diagram of VGG19 and adds CBAM.

Fig. 14. Structure diagram of ResNet50 and adds CBAM.

Fig. 15. Structure diagram of InceptionV3 and adds CBAM.

Fig. 13-15 shows the training verification line charts of VGG19, ResNet50 and InceptionV3, respectively, in which we can clearly observe their obvious trends. Detailed comparison: For Learning Speed, ResNet50 demonstrates the fastest learning speed among the three models, achieving significant reductions in loss and increases in accuracy in fewer epochs. VGG19 and InceptionV3 show slower but steady improvements. For Performance Stability, VGG19 shows the most stable performance with less fluctuation in its loss and accuracy curves. In contrast, ResNet50, while faster in learning, exhibits more fluctuations, indicating a more dynamic learning process with potential overfitting or regularization adjustments. InceptionV3 shows consistent improvement but at a slower rate.

The VGG series and the ResNet series exhibit relatively superior performance when handling the categories of "anger", "neutral", and "surprise", yet encounter substantial challenges when dealing with the complex categories of "fear" and "disgust". After the introduction of the CBAM, both demonstrate enhancements in the majority of categories, particularly in the manifestations of the "happy" and "surprised" categories. The Inception series model achieves the optimal classification effect for "happy" and "surprised", and the introduction of the CBAM attention mechanism further elevates the accuracy rates of these categories. Nevertheless, this model still presents considerable classification errors in the "disgust" and "fear" categories. Through the introduction of CBAM, the classification accuracy rates of all models have improved in

most emotional categories, especially in the "happy" and "surprised" categories. However, in some difficult-to-distinguish categories (such as "disgust" and "fear"), the improvement effect of CBAM is limited. Among the six models, the ResNet-CBAM and Inception-CBAM models display the most outstanding overall performance, particularly in the classification performance of complex emotional categories. Nevertheless, all models still encounter notable classification difficulties in the emotions of "disgust" and "fear", indicating that the features of these emotional categories in the Fer2013 dataset might be challenging to differentiate. The confusion matrix generated by the six models trained in this study is shown in Fig. 16.

Fig. 16. The confusion matrix generated by the six models.

TABLE XII. HYPERPARAMETER COMBINATIONS WITH THE HIGHEST TEST ACCURACY FOR INCEPTION V3 AND INCEPTION V3-CBAM WITH TRAIN-TEST SPLIT

Model	t-value	p-value
VGG19 default vs. VGG19 optimize	-2.828	0.002
ResNet50 default vs. ResNet50 optimize	-3.238	0.032
Inception default vs. Inception optimize	-4.268	0.013
VGG19-CBAM default vs. VGG19-CBAM optimize	-5.266	0.006
ResNet50-CBAM default vs. ResNet50-CBAM optimize	-4.603	0.010
Inception V3-CBAM default vs. Inception V3-CBAM optimize	-5.411	0.006

TABLE XIII. RESULTS OF 5x2 CROSS-VALIDATED PAIRED T-TEST FOR MODEL PERFORMANCE COMPARISON OF VGG19, RESNET50, AND INCEPTION V3 AND ADDED CBAM MODELS BEFORE AND AFTER THE ADDITION OF CBAM COMPARED AFTER HYPERPARAMETER TUNING WITH EACH OTHER

Model	t-value	p-value
VGG19 optimize vs VGG19-CBAM optimize	-4.1	0.015
ResNet50 optimize vs ResNet50-CBAM optimize	-4.297	0.013
Inception V3 optimize vs Inception V3-CBAM optimize	-4.347	0.013
VGG19-CBAM optimize vs ResNet50-CBAM optimize	-3.033	0.039
VGG19-CBAM optimize vs Inception V3-CBAM optimize	8.421	0.001
Inception V3-CBAM optimize vs ResNet50-CBAM optimize	-12.858	0.002

To assess the statistical significance of changes in the accuracy performance of the developed models, a 5x2 cross-validated paired t-test was conducted. Among the models, ResNet50-CBAM demonstrated the highest performance during the test phase. To evaluate whether ResNet50-CBAM significantly outperformed the other models, the test compared the best performance of ResNet50-CBAM with VGG19-CBAM and Inception-CBAM under both default and optimized configurations. The algorithms were tested using the same training-test segmentation (TTS) and cross-validation (CV) hyperparameter configurations.

The t-test results summarized in Table XII test the null hypothesis that there is no significant difference in the accuracy of the three models of CBAM under default and tuned hyperparameters. Since all P-values are less than 0.05, the null hypothesis is rejected with 95% confidence. A negative t value indicates that the default configured model performs worse on average compared to the optimized hyperparameters. The T-test results summarized in Table XIII verify the null hypothesis. After hyperparameter fine-tuning, there is no significant difference in the accuracy of each model, and all the P-values are less than 0.05, so the null hypothesis is rejected. The T-values show that there are differences between each other, and the rows of ResNet50-CBAM are significantly ahead of other models. Therefore, in summary, compared with VGG19-CBAM and Inception V3-CBAM models, the performance of ResNet50-CBAM model is statistically significant, which highlights the influence of CBAM and hyperparameter tuning on improving model accuracy.

V. CONCLUSION

This study set out to predict facial expressions and analyze the impact of the Convolutional Block Attention Module (CBAM) on the performance of deep learning models. The research successfully achieved three main objectives. The proposed method leverages the residual connections and hierarchical feature extraction capability of ResNet50, augmented with CBAM to enhance spatial and channel-wise focus. This combination improves the ability to distinguish subtle expressions, such as 'neutral' and 'sad,' while being robust to occlusions and lighting variations."

The first objective was to identify the optimal deep learning model for classifying facial expressions into seven categories within the FER2013 dataset. The study trained three key models:

VGG19, ResNet50, and Inception V3. VGG19 emerged as the top performer with a test accuracy of 0.717, slightly surpassing ResNet50 and Inception V3, which achieved 0.715 and 0.704, respectively. Despite these close results, VGG19 demonstrated a marginal but consistent advantage over the other models.

The second objective focused on assessing the impact of CBAM on these models. The results showed that integrating CBAM led to notable improvements across all three models, particularly ResNet50. The ResNet50-CBAM model achieved the highest accuracy of 0.7124, outperforming both VGG19-CBAM and Inception-CBAM, which reached 0.7104 and 0.7072, respectively. This demonstrates CBAM's ability to enhance feature extraction by enabling models to dynamically adjust weights based on channel and spatial positions, thus improving their performance, particularly in deeper networks like ResNet50.

The third objective was to optimize model performance through hyperparameter tuning. The grid search method was employed to find the best hyperparameter combinations, leading to significant accuracy improvements. Post-tuning, the ResNet50-CBAM model achieved a test accuracy of 0.724, with VGG19-CBAM and Inception V3-CBAM following at 0.719 and 0.711, respectively. The 5x2 cross-validated paired t-test results confirmed that these enhancements were statistically significant, with p-values below 0.05 for all models. The findings underscore the critical role of hyperparameter tuning in maximizing model performance and demonstrate that ResNet50, when combined with CBAM and optimized hyperparameters, outperforms both VGG19 and Inception V3. In conclusion, ResNet50-CBAM emerged as the best-performing model in this study, demonstrating superior accuracy and effectiveness in facial expression recognition tasks. This study highlights the critical importance of integrating CBAM and optimizing hyperparameters to maximize model performance. The findings emphasize that advanced feature extraction techniques and careful model tuning can significantly enhance the accuracy and reliability of deep learning models, with ResNet50-CBAM setting the benchmark for excellence in this domain.

VI. FUTURE WORK AND LIMITATIONS

The limitations of this study relate to the hyperparameters of data sets, algorithms, and classification model development. Only the FER2013 dataset was trained in this study. Due to the early presentation time of FER2013, relatively low image quality, and certain noise and blurring, the faces in the data set are mainly positive faces, and lack of diverse images such as side faces and occluded images, which may lead to inadequate adaptation of the trained model in practical applications. In addition, the FER2013 only contains the basic expression types, and the number of samples for each expression type is not balanced, and the overall sample size is small, which leads to the problem of overfitting in the process of training and testing, affecting the generalization ability.

Since the data collected in the dataset is mainly facial expression image data from 2013, and higher quality datasets have also emerged due to improvements in image acquisition hardware and diversity, such as AffectNet, future improvements could focus only on the most reliable facial image datasets to

mitigate the effects of noise during model development. The attention mechanism is a feasible choice to optimize the model performance further, not just for facial expression recognition but for other tasks as well. For example, consider an image with a cat and a table in the image description generation task. The attention mechanism helps the model focus on two important areas of the image: the cat and the table. When the model generates a description, CBAM can automatically capture the importance of cats and tables and automatically assign weights, making the model more focused on this area, which allows the model to more accurately describe the content in the image, and the generated description is more interpretable.

In the FER task, the deployment of the FER platform faces great challenges due to the different channels of image acquisition and model training. Due to the early presentation of the FER2013 dataset, the image quality is low, and there are unbalanced noise, blurring, and other conditions. In the future, we can choose newer, higher quality facial expression recognition datasets such as AffectNet, RAF-DB, etc., which have higher resolution and diverse samples, or apply more advanced image enhancement and preprocessing technologies such as denoising, deblur, and contrast enhancement. In order to improve image quality, it is possible to recognize facial expressions more accurately, helping to improve the human interaction experience. Secondly, there may be bias in expression recognition of different ages and races. In future studies, we can pay special attention to and quantify the performance differences of different groups to ensure the fairness of the model for different groups. Design hierarchical or adaptive models that can adjust parameters or weights based on input characteristics, such as age, gender, and race, to improve the accuracy of identifying different populations.

In this study, only three model architectures were tested, and feature extraction only compared attention mechanisms. In future research, we can try more different types of deep learning models, such as recurrent neural networks (RNN), graph neural networks (GNN), and different model architectures, such as ResNet or Inception. In addition to attention mechanisms, other feature extraction methods can also be tried, such as multi-scale feature extraction, emotional feature extraction, Vision Transformer (ViT), etc. By comparing the deep learning model of facial expression recognition, this study can identify facial expressions more accurately, which helps to improve the human-computer interaction experience, provide users with more intelligent and convenient services and experiences, and solve practical problems. In addition, this study can be used as a basic framework for developing face recognition based on deep learning models.

YOLO-WP: A Lightweight and Efficient Algorithm for Small-Target Detection in Weld Seams of Small-Diameter Stainless Steel Pipes

Huaishu Hou, Yukun Sun*, Chaofei Jiao

School of Mechanical Engineering, Shanghai Institute of Technology, Shanghai, 201418, China

Abstract—To address the low detection efficiency and high computational resource demands of current welded pipe defect detection algorithms for small target defects, this paper proposes the YOLO-WP algorithm based on YOLOv5s. The improvements of YOLO-WP are mainly reflected in the following aspects: First, an innovative GhostFusion architecture is introduced in the backbone network. By replacing the C3 modules with C2f modules and integrating the Ghost CBS module inspired by Ghost convolution, cross-stage feature fusion is achieved, significantly enhancing computational efficiency and feature representation for small target defects. Second, the Slim-Neck lightweight design based on GSConv is employed in the neck to further optimize the network structure and reduce the number of parameters. Additionally, the SimAM lightweight attention mechanism is incorporated to improve the network's ability to extract defect features, and the Focal-EIoU loss is utilized to optimize CIoU loss, thereby enhancing small object detection and accelerating loss convergence. The experimental results show that the AP(D1) and mAP@0.5 of the YOLO-WP model are improved by 5.3% and 3%, respectively, over the original model. In addition, the number of model parameters and FLOPs are reduced by 40% and 45%, respectively, achieving a good balance between performance and efficiency. We evaluated the performance of YOLO-WP using other datasets and showed that YOLO-WP exhibits excellent applicability. Compared to existing mainstream detection algorithms, YOLO-WP is more advanced. The YOLO-WP model significantly enhances production quality in industrial defect detection, laying the foundation for building compact, high-performance embedded weld pipe surface defect detection systems.

Keywords—Welded pipe; lightweight model; defect detection; deep learning; feature extraction; attention mechanism

I. INTRODUCTION

Small-diameter stainless steel welded pipes are widely used across various fields, including oil and gas transportation, chemical production, medical equipment, and automotive components [1]. The widespread use is due to their excellent welding performance, lower manufacturing cost compared to seamless pipes, small diameter, lightweight design, high strength characteristics [2], and superior corrosion resistance [3-4]. The welding of small-diameter stainless steel pipes primarily employs the Gas Tungsten Arc Welding (GTAW) technique. In practical production, two common defects are observed on the weld surface. The first is weld voids, which can result from misalignment or omission during the welding process [5]. The second is welding porosity or pits, typically caused by tungsten electrode contamination or grinding wheel damage [6]. These

defects can significantly impact the performance of the pipes. Therefore, it is essential to perform real-time inspection of the weld seams of small-diameter stainless steel welded pipes on the production line. This approach enables the timely detection and correction of defects, preventing defective products from proceeding to subsequent offline inspection stages and avoiding unnecessary quality control costs.

Current methods for online inspection of weld surface defects in stainless steel pipes mainly include manual inspection, X-ray inspection, eddy current inspection, and ultrasonic inspection [7]. Manual inspection is considered inefficient [8]. X-ray and ultrasonic inspections require high operational skills from personnel [9]. Additionally, eddy current inspection signals are vulnerable to interference from external factors [10]. Therefore, there is an urgent need for a detection method that is efficient, easy to operate, and highly resistant to interference. Machine vision, a non-destructive testing method, can fulfill this requirement. Within recent years, with the progress of machine vision and deep learning technologies, numerous defect detection methodologies leveraging these approaches have been extensively applied in various inspection contexts, including food and agriculture, electronics fabrication, metal materials, the semiconductor sector and healthcare [11-15]. Nevertheless, machine vision-based inspection methods for detecting weld surface defects on small-diameter stainless steel welded pipes are still not widely used.

Employing machine vision for inspection not only eliminates human subjectivity but also enables quantitative defect descriptions, thereby minimizing variability in the results. This innovation enhances detection efficiency and accuracy, fostering the advancement of industrial automation. Currently, mainstream detection algorithms can be categorized into two types [16]: single-stage algorithms and two-stage algorithms. Advanced single-stage object detection algorithms include the YOLO series, DETR, SSD and CenterNet. Advanced two-stage object detection algorithms include Faster R-CNN, Mask R-CNN, Libra R-CNN and HTC. Yang [17] applied the YOLOv5 algorithm to the welded pipe defect detection and achieved excellent results. Compared to the representative two-stage object detection algorithm Faster R-CNN, YOLOv5 demonstrates superior precision and detection speed. Therefore, different algorithms should be selected and modified for different application scenarios to target specific tasks. There are many existing strategies for algorithm improvement that focus on optimizing model components to achieve desired outcomes. Zhou et al. [18]

introduced a novel model in the YOLOv5 algorithm that combines the advantages of the CSPlayer module with a global attention enhancement mechanism, improving accuracy for metal material detection. However, this approach increases model complexity and demands higher computational resources. Zhao et al. [19] enhanced the Faster R-CNN algorithm by replacing some traditional convolutional networks with deformable convolutional networks to improve the detection capability for small-size defects on steel strips. However, this approach leads to a significant increase in model parameters, making deployment more challenging and less suitable for direct application in industrial settings. Shao et al. [20] proposed the TD-Net network for detecting tiny defects in industrial products, addressing the limitations of current image-based defect detection methods in identifying small and irregularly shaped defects. However, the detection speed has decreased. Ji et al. [21] introduced the Yolo-tla algorithm, which integrates the C3CrossConv module into the YOLOv5 backbone, effectively reducing computational demand and parameter count, thus making the model more lightweight. However, the detection accuracy has slightly decreased. Han et al. [22] proposed the DFW-YOLO algorithm based on YOLOv5, which automatically calls defect indications, resolves redundant defect feature maps, and incorporates the FasterNet backbone to enhance the model's feature extraction capability. However, the detection accuracy for small target defects has decreased. Zhou et al. [23] proposed the SKS-YOLO algorithm, using EfficientNetv2 as the backbone, which significantly reduces computation and accelerates training speed while maintaining accuracy, and employs the Simplified Intersection over Union (SIoU) loss function to improve the model's capability in locating and detecting surface defects on steel plates. However, the ability to extract small target or high-frequency features has decreased in certain scenarios. Yuan et al. [24] presented the YOLO-HMC algorithm, which uses the HorNet network (MCBAM) as its backbone and incorporates an improved multi-convolution block attention module to enhance feature extraction capabilities. However, the model requires more computational resources. Despite these studies achieving breakthroughs in specific scenarios, existing algorithms still face challenges in balancing the detection accuracy of small targets, model lightweighting, and real-time performance.

However, the existing methods for detecting surface defects in small-diameter stainless steel welded pipes still face these challenges. Firstly, the irregular sizes of weld hole defects and the extremely small shapes of welding porosities further complicate the detection process. Secondly, the high computational resources required by deep learning models pose limitations on their application in online detection within actual production environments. To address these challenges, the online detection of surface defects in small-diameter stainless steel welded pipes demands models with high speed, accuracy, and ease of deployment. To this end, we developed an enhanced model called YOLO-WP. This study focuses on the following key areas:

1) *Network structure optimization*: By optimizing the deep learning network structure, we enhance the detection accuracy for small target defects and improve overall detection performance. This is achieved by removing redundant structures and modules within the network to design a lightweight model,

thereby increasing efficiency in resource-constrained environments while maintaining or even improving model performance.

2) *Incorporation of attention mechanism*: By introducing attention mechanisms, we improve detection accuracy and enhance the ability to detect small targets. Attention mechanisms allow the model to focus on critical features and regions, thereby improving the detection of small and complex defects.

3) *Loss function improvement*: By optimizing the loss function and tailoring it to the characteristics of the dataset, we further enhance the model's localization accuracy and classification performance for small target defects. This leads to improved overall detection performance.

II. ALGORITHM DESCRIPTION

A. Baseline YOLOv5s

The YOLO series of algorithms has evolved through several versions, with YOLOv5 being widely used in the field of industrial real-time detection caused by its excellent detection accuracy and outstanding detection speed. Innovations such as the CSPDarknet53 backbone, Feature Pyramid Network (FPN), adaptive anchor box computation, and advanced data augmentation techniques have enhanced the model's performance and flexibility. YOLOv5 offers multiple versions of the model, including YOLOv5n, YOLOv5s, YOLOv5m, YOLOv5l, and YOLOv5x, to accommodate different computational needs and scenarios [25]. Among these, the YOLOv5s model features the smallest network depth and width, and the fastest detection speed, making it relatively well-suited for the requirements of industrial online detection. Accordingly, this paper selects YOLOv5s as the base model.

B. The Overview of YOLO-WP

Although YOLOv5s demonstrates advantages in speed, accuracy, and terminal applications, it still faces certain limitations in practical use, such as suboptimal localization accuracy, and high computational resource demands [26]. In particular, it often suffers from missed detections and inaccurate target localization when detecting small-scale defects. Hence, this paper proposes an online detection model named YOLO-WP, specifically designed for detecting weld seam surface defects in small-diameter stainless steel pipes. The design aims of the YOLO-WP model have two aspects: first, to improve operational efficiency in resource-constrained environments, and second, improve its capability in handling small-sized defects. Although the optimization and validation of this model primarily target the detection of weld seam surface defects in small-diameter stainless steel pipes, its architectural design and improvement strategies are equally applicable to other fields requiring efficient object detection. The structure of YOLO-WP model is illustrated in Fig. 1. The targeted improvements include:

1) *In the backbone network*, the paper proposes the GhostFusion architecture, which enhances feature expression through multiscale cross-stage fusion while maintaining efficient computation. In the neck network section, a lightweight Slim-Neck network, based on GSConv [27], is referenced to reduce network parameters and enhance computational resource efficiency.

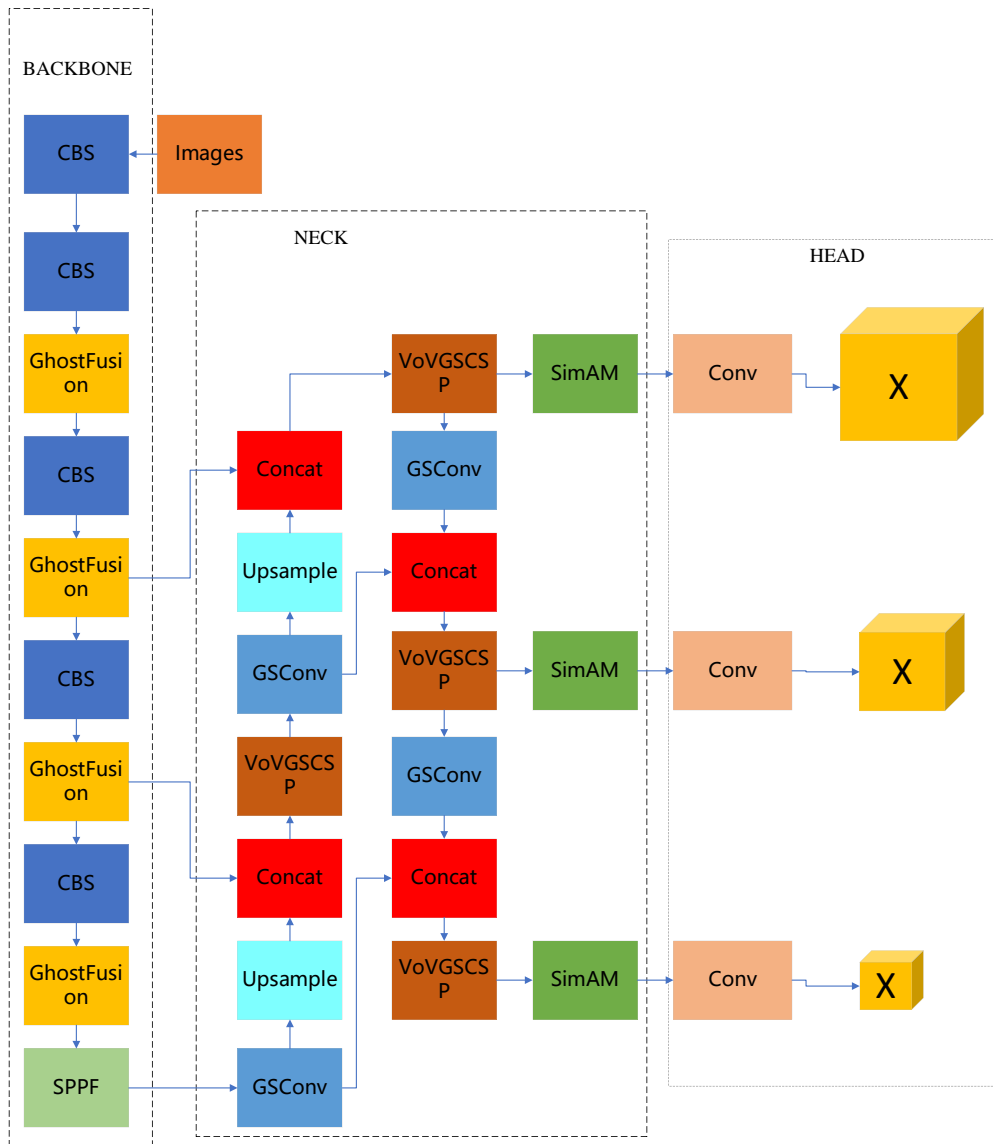

Fig. 1. Schematic model of YOLO-WP.

2) Adding the lightweight SimAM attention mechanism [28] to the neck network helps the model focus on key areas of the image, improves the fusion of feature maps across different scales, and enhances detection accuracy.

3) The Focal-EIOU loss [29] is utilized to substitute the original CIOU loss, aiming to enhance the detection of small-scale defects, address sample imbalance, and improve robustness on small and noisy datasets.

III. STRUCTURE OF KEY IMPROVEMENT COMPONENTS

A. GhostFusion Architecture

In the design of the backbone network, the innovative GhostFusion architecture is proposed. The construction process involves replacing the C3 modules with C2f modules and optimizing the CBS module in the C2f module by borrowing the core idea of Ghost convolution, and innovatively proposing the

Ghost CBS module, as depicted in Fig. 2. This design significantly enhances computational efficiency and feature representation capability through cross-stage fusion, achieving resource savings and improving detection performance for small target defects.

The core idea of Ghost Conv is to decompose conventional convolution operations into two stages: the main convolution stage and the ghost convolution stage. In the main convolution stage, 1×1 convolution kernels are used to extract condensed features, while in the ghost convolution stage, cheap 5×5 convolution kernels generate the remaining feature maps. The complete feature layer is formed by concatenating these two parts [30]. The detailed operation process is shown in Fig. 3. Additionally, the C2f module splits the input data into two parts through a Split operation. One part is directly retained, while the other part is processed through multiple BottleNeck structures to achieve multi-scale feature fusion [31].

The design greatly improves the computational efficiency and feature representation capability through cross-stage fusion, realizes resource saving, and improves the detection performance of small target defects. The core of the GhostFusion architecture lies in cross-stage feature fusion. By combining the Ghost CBS module with the C2f module, not only the computational efficiency is greatly improved, but also the semantic information of the features is significantly enhanced through the dynamic fusion of multi-scale features. This fusion mechanism enables the model to handle different sizes of receptive fields simultaneously, thus extracting more comprehensive feature information in complex scenes. The GhostFusion architecture performs well in the small target defect detection task. Through the synergy of the optimized Ghost CBS module and the C2f module, the model is able to efficiently extract features of small targets and further enhance the expressiveness of these features through the cross-stage fusion mechanism. This design not only improves the detection accuracy, but also ensures that the model can maintain efficient operation in resource-constrained scenarios. The GhostFusion architecture is designed with resource conservation and performance balance in mind. By introducing the efficient features of Ghost convolution, the

number of parameters and computation amount of the model can be significantly reduced, and at the same time, through the cross-stage fusion mechanism, the feature expression ability of the model is further enhanced. This design not only improves the operational efficiency of the model, but also ensures its high performance in complex tasks.

B. Slim-Neck Structure Based on GSConv Module

To elevate the model's detection speed and computational efficiency, this paper adopts a Slim-Neck structure based on the lightweight convolutional GSConv module [32]. Compared to traditional convolution operations, GSConv reduces the number of model parameters and computational complexity load by dividing the input features into multiple groups and independently performing convolution operations and depthwise separable convolutions on each group. GSConv introduces a mechanism that focuses on important feature channels, thus improving the model's feature extraction capability. The core principle of GSConv is to combine the characteristics of depthwise separable convolutions (DSC) and standard convolutions (SC) to achieve efficient feature map fusion and information flow. The structure of GSConv is shown in Fig. 4.

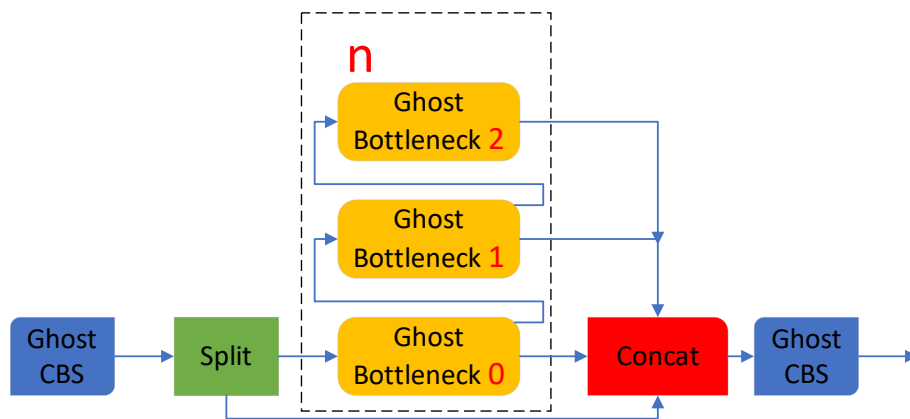

Fig. 2. Schematic diagram of the GhostFusion architecture.

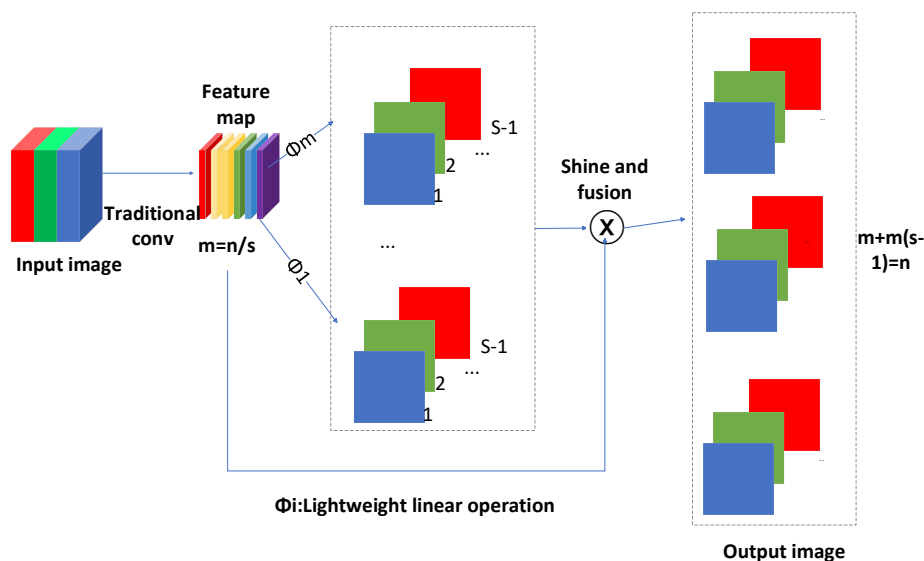

Fig. 3. GhostConv module.

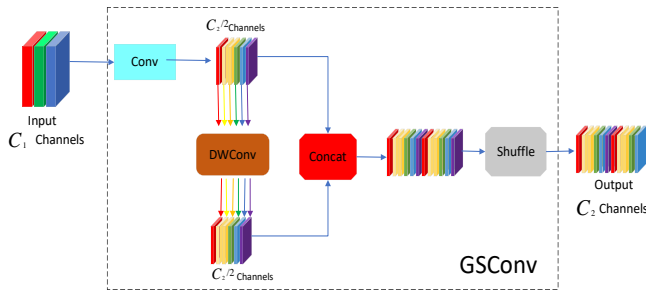

Fig. 4. The structure of GSConv.

First, GSConv inputs a downsampled standard convolution, followed by a depthwise convolution (DWConv), which concatenates the depthwise standard convolution (SC) and the depthwise separable convolution (DSC). Subsequently, a shuffle operation is applied to align the DSC output with the SC output, preserving channel and semantic information in the feature map.

The Slim-Neck lightweight neck network structure can effectively fuse and enhance features while maintaining the model's detection performance, even as it reduces computational load and the number of parameters.

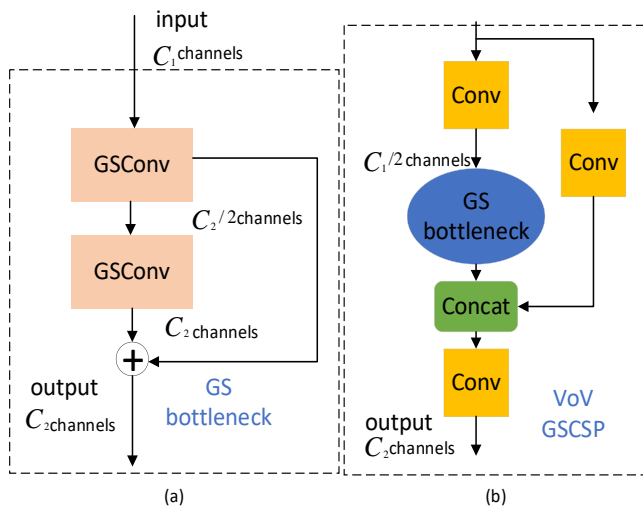

Fig. 5. Slim-Neck structure: (a) GSbottleneck module; (b) VoV-GSCSP module.

The basic building block of Slim-Neck is called VoV-GSCSP, which can replace the CSP layers comprised of standard convolutions. Among its components is the GSbottleneck, which uses GSConv as its building block, as shown in Fig. 5(a). The VoV-GSCSP module uses a one-shot aggregation method, shown in Fig. 5(b), to improve the model's target detection across different sizes by merging multi-scale feature maps, while reducing computational load and complexity.

C. SimAM Attention Mechanism

To enhance the model's representation of key features and improve its detection performance, this paper introduces an attention mechanism into the neck network of the model, thereby improving the Neck section and boosting the model's robustness. The attention mechanism typically includes channel atten-

tion and spatial attention. The parameter-free attention mechanism SimAM adopted in this paper combines both, as shown in Fig. 6. Adjacent pixels in an image usually have strong similarities, while distant pixels have weaker similarities. SimAM generates attention weights by calculating the similarity between each pixel and its neighbors in the feature map, thus inferring three-dimensional attention weights for the feature map. This effectively integrates channel and spatial attention, significantly improving the model's detection performance [33].

Fig. 6. The architecture of the SimAM attention mechanism module.

SimAM is grounded in the theory of visual neuroscience, where neurons with more information tend to exhibit more prominent activity compared to their adjacent neurons. In the task of surface defect detection for small-diameter stainless steel welded tubes, these neurons typically extract key features and should be assigned higher weights. This paper introduces the SimAM attention mechanism into the Neck network of the YOLOv5s model to optimize feature fusion and enhancement, while balancing network width, depth, and detection speed, thereby improving the accuracy of surface defect detection without increasing the network parameters. As shown in Eq. (1) ~ (4), SimAM evaluates neurons using an energy function for linear separability, where t represents the target neuron, x represents the adjacent neurons, and λ is a hyperparameter. The lower the energy e_t^* , the higher the distinguishability and importance of the neuron. As Eq. (4) shows, neurons are weighted based on their importance using $\frac{1}{e_t^*}$. SimAM assesses the importance of features using the energy function, providing higher interpretability and without introducing additional learnable parameters.

$$e_t^* = \frac{4(\hat{\sigma}^2 + \lambda)}{(t - \hat{\mu})^2 + 2\hat{\sigma}^2 + 2\lambda} \quad (1)$$

$$\hat{\mu} = \frac{1}{M-1} \sum_{i=1}^{M-1} x_i \quad (2)$$

$$\hat{\sigma}^2 = \sum_{i=1}^{M-1} (x_i - \hat{\mu})^2 \quad (3)$$

$$\bar{X} = \text{sigmoid} \left(\frac{1}{E} \right) \odot X \quad (4)$$

D. Improvement of the Loss Function

The loss function determines the degree of agreement between the true values and the predicted values, and its performance largely reflects the model's effectiveness. In the YOLO algorithm, there are three types of loss functions: classification loss, confidence loss, and localization loss. Among these, the localization loss represents the error between the predicted bounding box and the ground truth bounding box. This paper

conducts research and improvement on the localization loss function. The original localization loss function of YOLOv5s is CIOU loss, which is centered around the concept of calculating the positional alignment error between the ground truth bounding box and the predicted bounding box based on the size of the IoU (Intersection over Union). The calculation process is expressed as:

$$L_{CIOU} = 1 - IOU + \frac{\rho^2(b, b^{gt})}{c^2} + \alpha v \quad (5)$$

Where b and b^{gt} represent the centroids of the prediction frame and the true frame respectively, ρ represents the computation of the Euclidean distance between the two centroids, so $\rho^2(b, b^{gt})$ is the distance between the centroid of the prediction frame and the centroid of the defective true bounding box, and c represents the diagonal distance of the smallest closed region that can contain both the prediction frame and the true frame. αv denotes the aspect ratio between the prediction frame and the true bounding box.

From Eq. (5), it is evident that despite CIOU loss function considering the overlap area, distance between center points, and aspect ratio of the regression bounding boxes, there are still some issues. Specifically, it adjusts based solely on the aspect ratio without considering the specific values of width and height. Additionally, the gradients of width and height have opposite signs, preventing simultaneous increase or decrease, leading to potentially amplifying the width or height during optimization when both the width and height of the anchor box are greater than the defect to be detected. Therefore, this paper selects the EIOU loss function, which modifies the aspect ratio adjustment in the CIOU loss function to specific width and height regression, enabling the model to converge faster and achieve higher accuracy, hence improving the detection efficiency for small target defects. The formula is as follows:

$$L_{EIOU} = L_{IOU} + L_{dis} + L_{asp} = 1 - IOU + \frac{\rho^2(b, b^{gt})}{c^2} + \frac{\rho^2(w, w^{gt})}{C_w^2} + \frac{\rho^2(h, h^{gt})}{C_h^2} \quad (6)$$

Where w, h represents the width and height of the predicted box, w^{gt}, h^{gt} represent the width and height of the real box, C_w and C_h are the width and height of the smallest outer box that covers both boxes.

In this paper, variations in viewing angles and lighting may impact dataset quality during defect identification. In addition, the irregular appearance of defects complicates precise manual labelling, resulting in imperfect alignment between the aiming frame and defects. These factors cause dramatic fluctuations in loss value when training on low-quality samples, which can severely affect model performance. The goal of the proposed Focal II is to address the imbalance between high- and low-quality samples. Balance problem, and combined with EIOU loss to form Focal-EIOU loss.

$$L_{Focal-EIOU} = IOU^\gamma L_{EIOU} \quad (7)$$

Where γ is a constant, with a verified γ value of 0.5 giving the best results [34].

IV. EXPERIMENTAL PROCEDURE DESIGN

A. Experimental Platform and Parameter Design

During the model experiments, to maintain consistency with the comparison models and ensure the comparability of the experimental results, the SGD optimizer was used with an initial learning rate of 0.01, a momentum of 0.935, and a weight decay coefficient of 0.0005. The experiment was conducted with a batch size of 16 across 100 epochs. The experimental environment configuration is shown in Table I, and all experiments in this paper were conducted using this configuration.

TABLE I. EXPERIMENTAL ENVIRONMENT CONFIGURATION

Category	Configuration
CPU	Intel® Core™ i5-12490F Processor
GPU	NVIDIA GeForce RTX 3070ti 8G
RAM	32G
Operation System	Windows 10
Framework	PyTorch 2.0.0
Programming environment	Python 3.9
CUDA	11.8

B. Experimental Datasets

In this paper, we selected stainless steel welded pipes with defects, produced in actual manufacturing, with diameters ranging from 7mm to 9mm as samples. The defects studied in this paper are shown in Fig. 7. Due to the high visual similarity between welding sand holes and welding pores on these small-diameter stainless steel welded pipes, we categorized them as a single class.

Fig. 7. The two types of defects studied in this paper.

In the absence of publicly available datasets dedicated to this field, this study established an experimental platform for image acquisition. An industrial matrix camera (model MV-CS004-10GM) was employed, precisely positioned above the welded pipe and aligned with the center of the annular aperture to ensure consistency and high quality in image acquisition. The smooth surface of the pipe reflects light centrally, resulting in brighter tones in the image, whereas weld void defects scatter the light due to their surface characteristics, creating darker areas that clearly outline the defects. Additionally, this study utilized an adjustable-brightness annular LED aperture as the light source and integrated a slider motor to accurately adjust the distance between the welded pipe and the camera, enabling rapid and precise focusing for pipes of different specifications and enhancing the flexibility and adaptability of the system. The specific setup is shown in Fig. 8.

Fig. 8. Image acquisition platform.

To demonstrate the improved model's generalization capability, this study captured images of two defects types under varying lighting conditions, angles, distances, and focal lengths. For each type of defect, 2,000 images were selected to form the training set and 600 images for the validation set, with all images having a resolution of 640×640 pixels. Subsequently, the images were annotated, and the number of defect instances in both the training and validation sets was statistically analyzed. Detailed data are presented in Table II.

TABLE II. DEFECT DATA LABELING STATISTICS

Defect Type	Dataset Labels	
	Training Dataset	Testing Dataset
D: weld hole	2866	784
D1: weld porosity and weld blister	2995	813

V. EXPERIMENTAL RESULTS AND ANALYSES

A. Algorithm Evaluation Metrics

Accuracy P, mean accuracy mAP, recall R, parameters, model complexity (FLOPs) and FPS were used to evaluate the performance of the model.

$$P = \frac{TP}{TP+FP} \quad (8)$$

$$R = \frac{TP}{TP+FN} \quad (9)$$

$$mAP = \frac{\sum_{i=1}^N AP_i}{C} \quad (10)$$

Where TP is the number of correctly detected defects; FP is the number of incorrectly detected defects; FN is the number of undetected defects; AP denotes the accuracy of the detection; the value of mAP is obtained by averaging all the category APs; and C is the total number of detected categories.

When larger mAP and P values indicate higher detection accuracy, smaller parameters and FLOPs reflect a more lightweight model, and higher FPS reflects the faster algorithm detection speed.

B. YOLO-WP Ablation Experiments

To validate the effectiveness of the proposed improvements, this study conducted ablation experiments using YOLOv5s as the baseline model, incrementally adding improvement modules across six sets of experiments, as shown in the Table III. Compared to the first experimental group, the second group, after incorporating the GhostFusion efficient feature fusion network structure, saw an improvement of 3.2% in AP(D1) and 1.6% in mAP@0.5. Additionally, the number of parameters and FLOPs decreased by 22.2% and 33.5%, respectively, which not only enhanced computational efficiency but also improved the detection capability for small target defects. Compared to the second group, the third group introduced the Slim-Neck architecture based on the lightweight convolutional GSCConv module into the neck network. This resulted in a further reduction of 27.1% in parameters and 17.4% in FLOPs while maintaining the model's detection performance. Compared to the third set, the fourth set introduced the lightweight SimAM attention mechanism in the neck network. Although FPS decreased by 2.2, there was no increase in parameters and FLOPs. Meanwhile, AP(D), AP(D1), and mAP@0.5 improved by 0.5%, 1.2%, and 0.8%, respectively. In the fifth set, the Focal-EIOU loss was used to optimize CIOU loss, further improving the model's localization accuracy and convergence speed compared to the fifth set. AP(D), AP(D1), and mAP@0.5 increased by 0.5%, 0.8%, and 0.7%, respectively, with mAP@0.5 reaching 96.6%. The ablation experiments from the second to the fifth set demonstrate that each improvement method effectively optimizes the model. Compared to the baseline model YOLOv5s in the first set, the improved YOLO-WP model (sixth set) achieved a 5.3% increase in AP(D1) and a 3% increase in mAP@0.5, while reducing parameters and FLOPs by 40% and 45%, respectively. The YOLO-WP model efficiently detects small target defects with higher performance and lower computational cost, thereby enhancing overall detection accuracy. Although FPS decreased by 2.6, it still meets the requirements for online detection of surface defects in small-diameter stainless steel welded pipe seams.

TABLE III. ABLATION EXPERIMENTS

Group Model		AP(%)		P(%)	mAP@0.5 (%)	Parameters(106)	FLOPs (G)	FPS (F/S)
		D	DI					
1	YOLOv5s(Baseline)	97.1	90.3	93.3	93.7	7.2	15.5	105.3
2	YOLOv5s+GhostFusion	97.3	93.2	94.1	95.2	5.9	10.3	104.9
3	YOLOv5s+GhostFusion+Slim-Neck	97.1	93.1	93.9	95.1	4.3	8.5	103.7
4	YOLOv5s+GhostFusion+Slim-Neck+SimAM	97.6	94.3	94.5	95.9	4.3	8.5	101.5
5	YOLOv5s+GhostFu- sion+SlimNeck+SimAM+Focal-Elou	98.1	95.1	94.7	96.6	4.3	8.5	102.7

Fig. 9. Validation results for YOLO-WP and YOLOv5s. (a) Original image; (b) YOLOv5s; (c) YOLO-WP.

To offer a clearer illustration of the detection performance of the enhanced model, two images with two types of defects were randomly selected from the test set to evaluate the YOLO-WP model. This paper provides a visual comparison of the detection outcomes of the YOLO-WP model and the YOLOv5s model on images of small-diameter stainless steel welded pipes. As shown in Fig. 9, the YOLOv5s algorithm model exhibited missed detections and low accuracy in detecting small target defects. In contrast, the improved YOLO-WP algorithm model accurately located the weld seam surface defects within the images, demonstrating superior overall detection accuracy compared to the YOLOv5s algorithm model. This effectively addresses the issues of low detection efficiency and missed detections of small target on small-diameter stainless steel pipes.

C. Comparative Experiments with Multiple Datasets

To validate the generalization capability and robustness of the YOLO-WP model and to ensure its effectiveness across a wide range of applications, this paper designs experiments to test YOLOv5s and YOLO-WP on the MT Defects Dataset and NEU-DET Dataset. The MT Defects Dataset, used for magnetic tile surface defect detection, consists of 1,344 images that encompass five types of defects: pores, cracks, wear, fractures, and uneven surfaces. The NEU-DET dataset, utilized for detecting surface defects on hot-rolled steel strips, comprises 1,800 images that encompass six defect types: rolled scale, cracks, patches, pitted surfaces, inclusions, and scratches. Both datasets are divided into training and validation sets at a ratio of 7:3. The experimental results are shown in Tables IV and V. Table IV shows that the YOLO-WP model's mAP@0.5 increased by 0.5% compared to YOLOv5s. Additionally, the model's parameters and FLOPs are reduced by 38% and 43% respectively, while the detection speed is nearly unaffected. These results indicate that the YOLO-WP model achieves higher accuracy in detecting magnetic tile surface defects, demonstrates greater computational efficiency, and is easier to

deploy. As shown in Table V, the YOLO-WP model's mAP@0.5 increased by 0.9% compared to YOLOv5s. Moreover, the model's parameters and FLOPs were reduced by 36% and 43%, respectively, while the detection speed remained almost unchanged. These findings further demonstrate that the YOLO-WP model outperforms YOLOv5s in detecting surface defects in the hot-rolled steel strip dataset. The experimental results from both the MT Defects Dataset and the NEU-DET Dataset confirm that YOLO-WP surpasses YOLOv5s in terms of accuracy, model complexity, and computational efficiency. Overall, these experiments suggest that YOLO-WP offers greater practical value and stronger robustness for industrial applications compared to YOLOv5s.

TABLE IV. EXPERIMENTAL RESULTS OF MT DEFECTS DATASET

Model	mAP@0.5(%)	Parameters(10 ⁶)	FLOPs(G)	FPS(F/S)
YOLOv5s	89.1	7.3	15.4	87
YOLO-WP	89.6	4.5	8.7	86

TABLE V. EXPERIMENTAL RESULTS OF NEU-DET ON THE DATASET

Model	mAP@0.5(%)	Parameters(10 ⁶)	FLOPs(G)	FPS(F/S)
YOLOv5s	85.3	7.3	15.4	84
YOLO-WP	86.1	4.6	8.7	82

D. Comparison of Frontier Models

To more effectively assess the performance of the enhanced model introduced in this paper, we carried out comparative experiments using various object detection algorithms on a dataset for detecting surface defects in small-diameter stainless steel welded pipe seams. These algorithms include Faster R-CNN, SSD, YOLOv6, YOLOv7-tiny [35], YOLOv8s, YOLOv9, YOLOv10s [36] and YOLOv11s [37], along with our algorithm

(YOLO-WP). As shown in the Table VI, YOLO-WP achieved an mAP@0.5 of 96.6%, with 4.3 million parameters, 8.5 GFLOPs, and a speed of 102.7 FPS. The experimental results indicate that, compared to other algorithms, the YOLO-WP model has the smallest number of parameters and FLOPs, as well as the fastest detection speed. Although YOLO-WP's mAP@0.5 is 0.2% lower than that of Faster R-CNN, it significantly reduces the number of parameters and FLOPs.

To better demonstrate the balanced advantages of the YOLO-WP model regarding detection accuracy, model complexity, and detection speed, this paper presents scatter plots illustrating the relationships among these factors. As shown in Fig. 10(a), the YOLO-WP model is positioned in the upper right corner of the two-dimensional coordinate system, reflecting its ability to balance speed and detection accuracy. In Fig. 10(b), the YOLO-WP model is positioned in the upper left corner of the two-dimensional coordinate system, indicating its capability to balance computational efficiency and detection accuracy.

TABLE VI. COMPARISON OF FRONTIER MODELS

Model	mAP@0.5(%)	Parameters(10 ⁶)	FLOPs(G)	FPS(F/S)
Faster R-CNN	96.8	135.4	400.8	24.5
SDD	86.1	63.5	43.7	58.3
YOLOv6	92.5	15.6	31.3	79.7
YOLOv7-tiny	94.3	6.3	12.7	97.4
YOLOv8s	95.2	10.3	27.5	83.6
YOLOv9	95.4	70.5	317.2	31.5
YOLOv10s	95.8	11.3	26.2	90.1
YOLOv11s	96.2	13.4	27.3	91.2
YOLO-WP(Ours)	96.6	4.3	8.5	102.7

(a) Scatter plot of the relationship between mAP@0.5 and FPS.

(b) Scatter plot of the relationship between mAP@0.5 and FLOPs.

Fig. 10. Relationship scatter plot.

Based on the comparative experimental data and analysis presented above, the improved algorithm proposed in this paper achieves a balance between accuracy and lightweight design, efficiently utilizing computational resources to reach an optimal balance between model accuracy and training weights. This further underscores the superiority of the YOLO-WP algorithm. By significantly reducing the number of parameters and FLOPs, the YOLO-WP algorithm lowers hardware requirements. Consequently, this improvement meets the demands for online detection of weld seam surface defects in small-diameter stainless steel pipes.

VI. CONCLUSIONS

To address the gap in detecting surface defects on small-diameter stainless steel pipe weld seams, and to overcome the limitations of YOLOv5s on terminal devices, which arise from insufficient computational power and poor detection capabilities for small object defects, this paper proposes the significantly improved YOLO-WP algorithm. By introducing the innovative GhostFusion architecture, Slim-Neck lightweight design, SimAM lightweight attention mechanism, and Focal-EIou

loss function optimization, the YOLO-WP model achieves a 5.3% and 3% increase in AP(D1) and mAP@0.5, respectively, compared to the original model. Additionally, the number of model parameters and FLOPs are reduced by 40% and 45%, respectively, significantly enhancing the efficiency of small target detection and the model's applicability in resource-constrained environments. Experimental results show that the YOLO-WP model achieves high detection accuracy, low complexity, minimal computational requirements, and rapid detection speeds. This model has demonstrated robustness across different datasets. Compared to other models, YOLO-WP exhibits strong competitiveness, improving production quality and reducing costs, thereby making it suitable for industrial online inspection.

However, this study still has certain limitations. Although we collected and trained common defect data during the online production process, which to some extent reduced the burden of subsequent offline detection, we have not yet achieved comprehensive coverage of surface defects in small-diameter stainless steel pipe weld seams. Moreover, YOLO-WP still faces challenges in dealing with more complex defect types, such as

occluded or extremely small targets. In future research, we plan to introduce more types of defects for study and verify the capability of our algorithm model in offline detection of surface defects in stainless steel pipe weld seams. We will also specifically improve a set of algorithm models suitable for offline detection to achieve collaborative work between offline and online detection, thereby fully applying visual inspection to all quality control processes.

This study provides a novel solution for the detection of surface defects in small-diameter stainless steel pipe weld seams. By optimizing the network architecture, incorporating lightweight design, and improving the loss function, the model's detection performance in resource-constrained environments has been significantly enhanced. These improvements not only offer an efficient and accurate detection tool for industrial online inspection but also provide valuable references for future research in related fields.

Abstract—Computational Thinking (CT) skills are becoming increasingly crucial in education, particularly in early childhood education. Pre coding, which involves hands-on activities with real objects, has been shown to be quite effective in fostering kindergarten children's computational skills. Pre coding, on the other hand, is essential for boosting children's CT skills, but teachers frequently lack the information necessary to teach these skills successfully. Their successful adoption is hampered by the early childhood education community's lack of interest in CT skills and the sparse application of pre coding techniques. In order to help kindergarten instructors incorporate pre coding into their teaching and learning, this study focuses on defining the elements and activities described in a pre-coding program model. The study reviewed and compiled a list of prior literature's pre coding elements and activities. Subsequently, the Fuzzy Delphi Method (FDM) was utilised to refine and validate these elements and activities. Finally, the data collected from 11 selected experts relevant to this field of study were analysed using FDM to examine consensus. The results showed that the eight identified elements and 24 pre coding activities fulfilled the following required criteria: a threshold value (d) of lower than or equal to 0.2, an agreement percentage over 75%, and a fuzzy score value (A) higher than 0.5. These findings demonstrated the suitability of the identified pre coding elements and activities for integration into a pre coding program model for kindergarten children. In summary, this study provides valuable guidance for kindergarten teachers in implementing practical pre coding activities to enhance CT skills among children.

Keywords—Expert consensus; pre coding; element; activity; kindergarten children

I. INTRODUCTION

Computational thinking (hereafter called CT) refers to a set of cognitive skills for solving problems [1 - 3]. It is also considered a thinking process [4, 5] that involves an array of cognitive skills, including critical thinking, problem-solving, logical reasoning, and creative thinking [6, 7]. In view of this, CT has emerged as a fundamental skill that everyone needs to understand and master [8]. CT skill should be integrated into compulsory school education [9]. Moreover, CT has become one of the most effective approaches for teaching students, including early childhood, in line with the development of global modernisation [10, 11].

The CT teaching approach has also received increasing attention in education and research [12], with vast implementation across many countries, including the United

States, the United Kingdom, Estonia, Australia, and Singapore [6, 9]. Coding and pre coding are widely recognised as two standardise methods used for teaching CT [13, 14]. Coding emphasises the use of digital devices, such as computers, as the primary learning tool in computer science education [15 - 18]. Teaching CT through coding typically involves learning programming, which is deemed one of the most effective methods to nurture CT skills [19, 20]. Whereas, pre coding does not require the utilisation of digital devices, it offers an alternatif approach to fostering CT skills [21, 22].

Although coding and pre coding share the same goal, i.e., applying one's CT skills, their implementation differs. Specifically, coding involves digital devices and is more generally introduced at the primary, secondary, and higher education levels [22]. In contrast, pre coding is commonly introduced in the early stages of childhood as its implementation focuses on the active involvement of children through hands-on activities with concrete objects [21, 23], such as pencils and papers, puzzles, and wooden blocks [22, 24]. This learning method deeply resonates with children as it allows them to explore the real world and develop their CT skills [16]. In fact, pre coding is often associated with a simpler and fun implementation that corresponds with children's learning process and development stages [25, 26]. Furthermore, pre coding is particularly beneficial for students from B40 families with limited access to digital learning [27], making it a relevant, appropriate, and meaningful approach to children's education.

Nevertheless, the significance of pre coding in empowering CT skills among students has not been adequately conveyed to teachers [28, 29], including kindergarten teachers [30]. Even more critically, teachers are not equipped with sufficient knowledge to teach CT and pre coding skills [29, 31]. This matter has prevented teachers from successfully introducing CT skills through pre coding activities [32 - 35]. It was revealed that teachers in early childhood education were uninterested in CT skills, partly due to the lack of efforts to highlight their significance for children through pre coding [31, 36]. Besides, teachers are not always permitted to practice pre coding approaches and CT skills in their teaching sessions [30].

Considering the issues and problems encountered by teachers, this study aims to identify the key elements of pre coding and appropriate activities to developing structured model of a pre coding activity program. These pre coding

model program elements serve as a guideline for kindergarten teachers to practise pre coding to encourage CT skills in children from an early age. This study also systematically discussed the setting and verifying elements of pre coding activities for the program model based on expert consensus through the Fuzzy Delphi Method (FDM) for its implementation.

This paper is divided into several sections: Section II presents a concise literature review regarding elements and activities of pre coding. Section III specifies the methodology of this study. Section IV describes the data analysis process. Section V details the findings and discussion. Finally, Section VI concludes the study and recommends future works.

II. LITERATURE REVIEW

Pre coding is a type of unplugged activity, better known as unplugged coding [21, 37, 38]. This activity supports the development of CT skills without using electronic devices, such as computers, mobile phones, and tablets [16, 21, 23, 38-40]. As such, this approach emphasises hands-on activities and utilises easily accessible concrete materials, such as papers and pencils, cards, and puzzles [23, 24, 37, 39, 41]. This hands-on approach aligns with the constructivism theory that focuses on children's learning via active exploration and real-world interaction [42]. Hence, meaningful real-world experience can improve children's learning process.

Pre coding is viewed as a learning process for kindergarten and preschoolers that adopts physical movement activities and enjoyable games to develop elementary knowledge, nurture CT, and introduce core computer science concepts [16, 43-45]. Pre coding activities are typically conducted through indoor games using a wide range of materials, including pens and papers, cards, and game figurines [24, 46, 47]. Past studies concluded that pre coding incorporates physical activity with accessible materials to provide a fun and meaningful experience that develops CT skills in kindergarten children.

Pre coding is considered a suitable and meaningful learning approach for kindergarten children because it incorporates physical activities without utilising digital devices, such as computers, which may be perceived as complex tools for young learners [37, 44, 48]. It is also viewed as more relevant for children [49] as it emphasises learning in context rather than focusing solely on specific content related to pre coding subjects [9, 42]. As outlined in constructivism theory, pre coding concentrates on continuous learning through environmental experiences that support children's thinking process and active involvement [42]. Therefore, pre coding learning is typically incorporated with other subjects, such as language, mathematics, science, and visual arts [50].

In addition, the pre coding approach helps children develop their computational skills, which further promotes their problem-solving, logic, and creative thinking abilities [51]. This method also provides children with a deep-thinking experience when engaging in a task [23], enabling them to solve complex problems effectively and creatively [24, 52]. Children's mastery of CT skills also promotes their high-level thinking abilities, allowing them to think creatively, express their views in many ways, and analyse problems from different

viewpoints [53]. Thus, pre coding is essentially crucial in early childhood education.

In navigating today's digital world, this study assessed Malaysia's Industrial Revolution 4.0 (IR4.0) Policy, which underscores the need for the country to remain competitive within the digital ecosystem [54]. Among the essential skills required to address the challenges of IR4.0 are logical thinking, cognitive development, and creative thinking [17, 41, 55, 56]. As the Sustainable Development Goal (SDG) outlines, these skills are vital for achieving high-quality education. In order to meet the SDG targets and the IR4.0 goals, this study highlights the implementation of a pre coding program that nurtures CT skills in kindergarten children, ensuring these critical skills are developed from an early age.

There is also a growing demand to identify pre coding elements and activities that are suitable for implementation in early childhood education through a comprehensive literature review. Several researchers have conducted pre coding programs for children. Fig. 1 illustrates the definition of the respective pre coding elements, while Table I lists the pre coding activities based on previous studies.

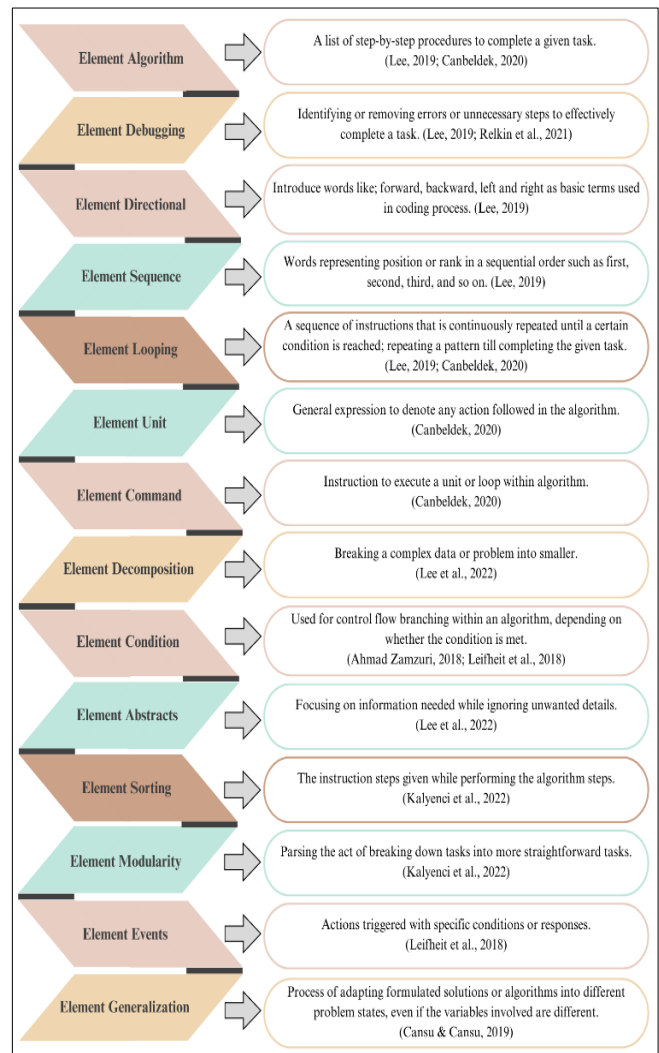

Fig. 1. Definition of pre-coding elements.

TABLE I. PRE CODING ACTIVITIES

No.	Pre coding activities	Previous studies
1.	Daily routine	[22]
2.	Storytelling	[16]
3.	Play	[16]
4.	Telling stories using books	[41]

19.	Neighbourhood walk activity map	[17]
20.	Robot Robi's Friend (activity map)	[17]
21.	Story card	[37]
22.	Coding through stories	[59]
23.	Storigami	[59]
24.	Robotic kits	[16]
25.	Tetris activity	[46]
26.	"Repetition Drawing" activity	[46]

Algorithmic elements are often prioritised in pre coding skills for children [4, 16, 23, 24, 37, 39, 40]. These pre coding elements, which are considered vital for children, teach them to follow a set of step-by-step instructions built to solve a task or problem [16, 24, 37]. These elements also encourage logical thinking involving data analysis processes and systematic problem-solving, rendering them suitable for teaching children [16, 38, 39].

Repetition control structure is another essential skill element in pre coding learning [23, 37]. This structural element refers to a set of continuous repeating instructions as long as specific conditions are fulfilled [23, 40]. The repetition control structure in a pre coding program aims to assist children in performing each task or activity based on the assigned conditions and counter value [23, 38, 46]. Hence, the string of this element becomes a key skill for children to master [38].

Furthermore, the sequence control structural element [37, 40, 58, 60] is a critical skill that needs to be mastered to understand the CT skill concept [40]. The sequence control structural element is typically introduced and implemented through daily routine activities [24]. Lee et al. [24] noted that

nurturing this element helps children recognise sequence patterns in their daily routines. In other words, daily routine activities can foster children's understanding of the sequence control structures. The study also revealed that children who successfully master this skill could indirectly anticipate future events and identify patterns or past patterns according to their understanding of daily routine activities. Hence, this skill is vital for children's development, as it boosts their cognitive abilities.

Three field experts assessed the initial pre coding element list to obtain confirmation and initial evaluation. The experts accepted only seven pre coding elements that were deemed appropriate for the early childhood pre coding program model, as presented in Table II.

TABLE II. PRE CODING ELEMENTS AFTER EXPERT INTERVIEWS

No.	Pre coding elements
1.	Algorithm
2.	Debugging
3.	Directional
4.	Sequence
5.	Looping
6.	Command
7.	Decomposition

The directional element is also a key pre coding skill [16, 17, 21, 24, 41]. Children need to master this element when learning to code, as it is frequently utilised in the coding process [41]. The directional element describes the interaction between one object and another, such as the spatial relationship, 'in front,' 'beside,' and 'at the edge' [17]. In addition, specific words, such as 'forward,' 'backward,' 'to the right,' and 'to the left,' are often employed to describe the concept of direction [41]. Using arrows and hand signals during pre coding learning is instrumental in helping children recognise the intended direction correctly and accurately [21]. In short, applying this element indirectly provides an easier, faster, and more meaningful understanding of the concept of direction.

Besides, error detection, or debugging, is a significant element of pre coding skills [21, 48, 61]. Debugging refers to the identification of unnecessary steps or errors to complete a task more effectively [21]. Additionally, debugging encourages children to explore, observe, reflect, and communicate when seeking solutions for their tasks [62] since activities or tasks involving this element are relatively open-ended in nature [48].

Lastly, the resolution element is a vital component of pre coding skills [24, 63, 64]. This element breaks down complex problems or systems into smaller parts to facilitate understanding of the solution process [24, 64]. Besides, simplifying the problems nurtures the thinking process to recognise specific patterns and dismiss irrelevant elements when solving problems [24]. Mastering the resolution element allows children to present various solutions when evaluating their strengths and limitations before selecting the optimal strategy for solving the problem [65]. Hence, the resolution element must be emphasised as these problem-solving skills help children to think faster when solving a problem.

III. METHODOLOGY

The Human Research Ethics Committee of Universitas Pendidikan Sultan Idris granted the approval for this study from January 31, 2023, to January 31, 2024. This study employed the Fuzzy Delphi Method (FDM) to obtain expert consensus on the elements and activities suitable to be incorporated in a pre coding model for preschoolers. The FDM adapts the classic Delphi method, which integrates fuzzy number sets while maintaining the Delphi method itself [66]. This method was selected because it shortens the cycle process and avoids data loss, thus enhancing economic efficacy in terms of time and cost [26]. Besides, FDM is an effective technique due to its

theory set fuzzy that resolves uncertainties against experts' consensus.

FDM is also a structured and systematic analytical procedure [67]. It has been broadly employed to validate the components for training contents due to its ability to obtain fuzzy score values in the form of ranks, which can serve as a determinant and priorities for an element based on expert consensus [27–29]. The design of this study consists of three stages: literary review, expert assessment, and FDM analysis. The study method is elucidated in Fig. 2.

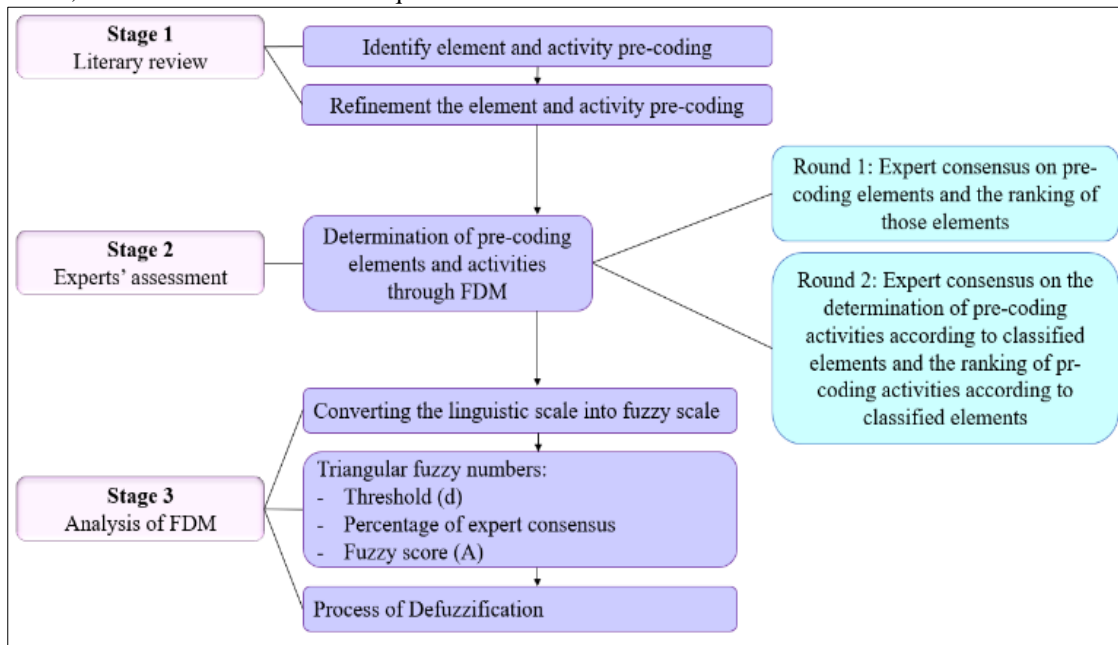

Fig. 2. Study method.

A. Literary Review Stage

The first stage aimed to identify the appropriate elements and activities for developing the pre coding program model for kindergarten children. A comprehensive literary review was carried out via several research databases, including Scopus, Elsevier, Springer Link, Research Gate, and Google Scholar. The data from this literary review comprised a preliminary list of pre coding elements and activities. The data were then evaluated by three experts specialising in computer science and CT skills through Google Meet interviews to assess the suitability and acceptability elements and pre coding activities for kindergarten.

B. Expert Assessment Stage

The FDM method was applied by constructing a questionnaire and analysing the data based on expert consensus. The questionnaire was developed based on the elements and activities identified from the literary review stage. The questionnaire consists of a 7-point linguistic scale a balanced range of response options, capturing a broader spectrum of attitudes, opinions, and behavior [68], as shown in Table III. In this process, three experts (Table IV) reviewed the questionnaire to ensure content validity, clarity of wording, and structural integrity.

TABLE III. THE 7-POINT LIKERT SCALE AND FUZZY SCALE

Linguistic variable	Likert scale	Fuzzy scale
Strongly disagree	1	(0.0,0.0,0.1)
Highly disagree	2	(0.0,0.1,0.3)
Disagree	3	(0.1,0.3,0.5)
Moderately agree	4	(0.3,0.5,0.7)
Agree	5	(0.5,0.7,0.9)
Highly agree	6	(0.7,0.9,1.0)
Strongly agree	7	(0.9,1.0,1.0)

10	Computer science (Coding)	15	Other government bodies
11	Information and Communication Technology (ICT)	7	Other government bodies

The questionnaire was distributed to 11 selected experts in fields related to the study [13], and the results were analysed using FDM. According to [13, 69-72], the appropriate number of experts for FDM is between 10 and 50. The experts were selected based on their expertise in the study context [73] and their work experience of over five years [74]. This study involved nine experts from government universities and two from other government bodies in Malaysia. This wide range of specialists guarantees a thorough comprehension of the topic by utilising both scholarly and real-world perspectives. Their diverse backgrounds give the study's conclusions a well-rounded viewpoint. Table V lists the demographic information of the selected experts.

The developed questionnaire facilitated the determination of pre coding elements and activities using the FDM. This FDM method was carried out in a face-to-face workshop attended by all 11 selected experts and consisted of two rounds. The first round aims at achieving expert consensus on the pre coding elements and their priority positions. The second round focuses on expert consensus in the context of the activities related to the classified elements and their respective priorities. The data were collected after each round and analysed using FDM.

1) *Round 1: Expert Consensus on Pre coding Elements and Priority Ranking of the Identified Elements:* All 11 experts participated in the first round to identify, evaluate, and confirm the pre coding elements. They discussed the pre coding element determination questionnaire to develop a suitable pre coding program model for kindergarten children. Based on the expert agreement, the elements were improved during the discussion by adding several new elements and removing those deemed irrelevant. All elements (added, rejected, or retained) aligned with the agreement and consensus reached by all experts during the FDM workshop.

The discussion proceeded with a voting process by the 11 experts to determine the priority position of the pre coding elements. Individual voting was performed by marking the agreement level for all items related to the pre coding program model, as agreed during the discussion. The voting results were analysed using FDM to determine the priority ranking of the elements.

2) *Round 2: Expert Consensus on the Determination and Priority of Pre coding Activities based on the Classified Elements.*

The second round involved expert consensus regarding the determination and priority of activities according to the classified elements. All 11 experts discussed to identify the pre coding activities based on the elements classified in the questionnaire. They shared their views and opinions to assess the appropriate level of the pre coding activities classified by elements for inclusion in the pre coding program model. The pre coding activities were also modified according to the classified elements, resulting in the addition of new pre coding activities and the removal of irrelevant ones. All pre coding activities (added, rejected, or retained) aligned with the agreement and consensus of the experts in the FDM workshop.

Subsequently, individual voting was performed to reach a consensus on the priority of pre coding activities based on the elements classified for inclusion in the pre coding program model. All 11 experts voted using a 7-point Likert scale to indicate their agreement level for each item. The findings were analysed using FDM to identify the priority of pre coding activities for each element.

IV. DATA ANALYSIS

A. Conversion of the Likert Scale to the Fuzzy Scale

Table VI shows that each Likert scale item has a corresponding fuzzy scale. In the FDM analysis process, the Likert scale value was converted to fuzzy numbers using Microsoft Excel's VLOOKUP function. Fuzzy set theory [75] was applied to convert expert agreement levels into suitable fuzzy number sets. Accordingly, the Likert scale findings from the experts were translated into fuzzy values consisting of three main values: the minimum value (m1), the most reasonable value (m2), and the maximum value (m3).

B. Data Analysis using the Fuzzy Delphi Method (FDM)

FDM data analysis comprised two key components: fuzzy triangular numbering (triangular fuzzy numbers) and fuzzy evaluation (defuzzification). Both parameters are vital when deciding to accept or reject an element based on expert consensus [39]. In particular, triangular fuzzy numbers influence the threshold value (d) and the percentage of expert agreement. Meanwhile, defuzzification impacts the fuzzy score value (A), which indicates the priority position of pre coding elements and their priority for each element [67].

The Likert scale data from the 11 experts were filled into a Microsoft Excel template for the FDM analysis. The data analysis involves assigning fuzzy triangular numbers (m1 to m3), followed by the analysis of four key aspects: (i) the average value of the fuzzy scale (m1, m2, and m3), (ii) the

threshold value (d), (iii) the percentage of expert consensus for each element and pre coding activity, and (iv) fuzzy score value (A) to determine the acceptance and priority of elements and activities available through defuzzification.

1) *Fuzzy scale average value (m1, m2, and m3)*: Fig. 3 presents a triangular graph of the mean against the triangular values (m1, m2, and m3). The m1, m2, and m3 values range from 0 to 1, which corresponds to the fuzzy numbers (0,1).

2) *Threshold Value (d)*: The threshold value (d) determines the expert consensus for each item in the questionnaire [76]. Based on the fuzzy number range (0,1), the threshold value (d) is calculated using two sets of fuzzy numbers, m (m1, m2, and m3) and n (n1, n2, and n3), as shown in Formula 1:

$$d(m, n) = \sqrt{1/3 [(m1 - n1)^2 + (m2 - n2)^2 + (m3 - n3)^2]} \quad (1)$$

Fig. 3. Triangular graph representing the mean against the triangular values.

The data is considered to successfully reach expert agreement when the threshold value (d) is equal to or less than 0.2 [77]. Table VI describes the interpretation of the data based on the threshold value (d).

TABLE VI. DATA INTERPRETATION BASED ON THE THRESHOLD VALUE (D)

Threshold value (d)	Description	Interpretation
$d \leq 0.2$	The threshold value is equal to or less than 0.2	Accepted
$d > 0.2$	The threshold value is greater than 0.2	Rejected, or a second round may be conducted involving only experts who disagree

3) *Percentage of expert consensus*: This study also considered the percentage of expert agreement to determine the acceptance of each element and activity. An element or activity is accepted if the percentage of agreement is 75% or higher [14]. Otherwise, the element or activity is either eliminated or a second round should be conducted involving only the experts who disagreed.

4) *Fuzzy score value (A)*: The fuzzy score value (A) is obtained via defuzzification to determine the acceptance level of each item based on expert consensus. An item is accepted if its fuzzy score (A) achieves an a-cut value equal to or greater than 0.5 [78]. Formula 2 is used to calculate the fuzzy score value (A):

$$\text{Fuzzy score (A)} = (1/3) \times (m1 + m2 + m3) \quad (2)$$

In addition, the fuzzy score value (A) plays a role in determining the priority position of the pre coding elements and pre coding activities in the questionnaire. The setting of the priority position for these pre coding elements and activities is based on the results of expert discussion and agreement.

V. FINDINGS AND DISCUSSION

A face-to-face discussion in the FDM workshop involving 11 experts was conducted to evaluate and determine pre coding elements and activities for developing a suitable pre coding program model for kindergarten children. The experts successfully reached a consensus on eight elements and 24 pre coding activities; seven elements were retained, one was rejected, and two new elements were added. Next, the expert voting performed through the FDM analysis converted the Likert scale results into a fuzzy scale. The outcome showed that all eight elements and 24 pre coding activities met the conditions and reached expert consensus, where the threshold value (d) is between 0.092 and 0.204, which is < 0.2 . Table VII lists the FDM analysis element designation and pre coding activities.

TABLE VII. RESULTS OF THE FDM ANALYSIS ELEMENT DESIGNATION AND PRE CODING ACTIVITIES

Pre coding element	Number of items related to suitable pre coding activities
Algorithm element	5
Loop control structure element	3
Sequence control structure element	3
Direction indicator element	4
Error detection element	3
Decomposition element	2
Choice control structure element	2
Pattern recognition element	2

For the second condition, the study recorded over 75% of expert agreement for each element and pre coding activity, which ranged from 81.8% to 100%. Meanwhile, the third condition measures the fuzzy score value (A) to determine the acceptance level of each item, which needs to exceed 0.5. Based on the results, the fuzzy score value (A) for the pre coding elements and activities ranged from 0.788 to 0.924, proving that all pre coding elements and activities are acceptable and suitable for inclusion in the pre coding program model for kindergarten children.

The key point of this FDM analysis is its appropriateness and ability to confirm the identified pre coding elements and activities [79]. In addition, the FDM analysis assists in boosting the accuracy of pre coding elements and activities for the pre coding program model since the experts accepted all items that met the key FDM requirements based on the threshold value (d), percentage of expert agreement, and fuzzy score value (A). The results were further strengthened by the open discussions among the experts, which enabled them to present their views on the items found in the questionnaire [67]. These expert views were also considered to ensure that the results aligned with the study's context.

The success of this study stems from the proper selection of experts who shared their expertise in fields relevant to this study, including computer science with a speciality in coding skills, early childhood education, and thinking skills. The diverse pool of expertise facilitated the smooth FDM process and significantly assisted in determining the appropriate pre coding elements and activities for developing the pre coding model for kindergarten children.

The selection of FDM also influenced the quality of the study, as this method utilised the fuzzy theory to address the problem of ambiguity in data acquisition. The FDM also reduced boredom among experts and prevented data leakage during the data collection process [67] since its implementation is more organised, systematic, and shorter than traditional Delphi methods.

It should be noted that this study has a limited sample size of 11 experts. However, all selected experts have proven experience in their respective fields relevant to the study, including early childhood education, computing and meta-technology, and thinking skills. Despite the small sample size, the number of experts was sufficient, as the odd number of experts facilitated the process of reaching a consensus.

In short, this study reinforced the exceptional effectiveness of FDM [70, 80] for determining elements and activities for developing a pre coding program model suitable for kindergarten children. The strength of FDM, marked by its systematic procedure and enhanced accuracy of data analysis, particularly in reducing ambiguity, proved highly valuable for this study.

VI. CONCLUSION AND FUTURE RESEARCH

This study effectively identified key elements and activities for developing a pre coding program model suitable for kindergarten children. Based on the applied FDM approach with expert consensus, eight pre coding elements and 24 pre coding activities were deemed suitable for inclusion in the pre coding model for kindergarten children. This findings lies in several major contribution aspects.

The main contribution of this study is the development and validation of a pre coding program model specifically designed for preschool children in a systematic manner by establishing 8 pre coding elements and 24 suitable pre coding activities based on expert consensus. This study simultaneously fills an important gap in early childhood education related to CT. By emphasising pre coding (device-free activities), this study provides an accessible and non-digital-dependent approach to CT, making it highly relevant for underprivileged populations with limited access to digital. In the Malaysian context, the children from B40 families may be affected because they have limited access to digital devices, such as smartphones or laptops. So that, by integrating pre coding program model, it also helps overcome the challenges these children face in developing their CT skills.

Next, this study also contributes to encountering Malaysian kindergartens challenges during the implementation of pre coding in their teaching and learning. In other words, the pre coding program model becomes practical tools to empower

teachers in promoting the application of CT skills through pre coding activities. Directly, this can solve the problem of teachers in Malaysia who do not have knowledge about pre coding and some may not have even heard of the concept of pre coding [81]. However, it is not surprising if some teachers may still face issues in integrating pre coding into their instruction, even after being provided with a comprehensive model for guidance. Applying teachers' knowledge and enthusiasm for pre coding should be the primary priority in order to address this. After that, give teachers who are proficient in pre coding ongoing training.

This study also supports the national agenda of the country. The position pre coding as a new approach in early childhood education, align with the policies and objectives of IR4.0 and contribute to the achievement of Malaysia's SDG targets. Therefore, the application of inclusive quality education through pre coding activities is well-suited to the principles of Educational Sustainable Development (ESD), which seeks to meet current needs without compromising the ability of future generations to do the same. Apart from that, implementing the pre coding program for kindergarten children aligns with the Malaysian government's objective of fostering cognitive skills, such as logical thinking, problem-solving, and creative thinking in young learners, which are critical for navigating future technological landscapes and preparing the community for the demands of IR4.0.

Additionally the use of ranking-based elements is an important topic that requiring addressing. While this model contains elements that were outlined based on expert consensus, ranking may not be necessary when implementing activities related to these elements, as readiness and appropriateness are crucial in children's learning. Nevertheless, researchers recommend that algorithm elements be first introduced to children because they represent the most essential elements in coding. Algorithms offer a step-by-step implementation procedure, making it easier for children to understand and engage with coding concepts [16, 21, 24].

Finally, future researchers may verify the model experimentally. Test the efficacy of the suggested pre coding program model in enhancing kindergarten children CT abilities through experimental research in actual classroom environments. Then compare the results with those of other pre coding and coding techniques currently in use to evaluate the relative efficacy of the model. In the other hand, other research may create and execute pre coding pedagogy whereas focused on teacher training programs, making sure that instructors have the know-how to carry out the curriculum successfully. The most important part here is the researcher need to look into how these training sessions affected the teachers' self-assurance, comprehension, and pre coding classroom habits. Lastly integration pre coding with other learning domains such as mathematics, sciences, and language.

In conclusion, this research significantly contributes to transforming early childhood education by integrating computational thinking skills using pre coding activities and promotes an inclusive, useful, and creative approach to contemporary learning issues.

ACKNOWLEDGMENT

This study was funded by the Ministry of Higher Education under the Fundamental Research Grant Scheme (FRGS) with the number FRGS/1/2022/SSI07/UPSI/03/7.

A Novel Internet of Things and Cloud Computing-Driven Deep Learning Framework for Disease Prediction and Monitoring

Bo GUO*, Lei NIU

School of Computer and Information Engineering, Fuyang Normal University, Fuyang, 236037, China

Abstract—In smart cities, the e-healthcare systems aided by Internet of Things (IoT) technologies play a significant role in proficient health monitoring services. The sensitivity and number of users in health networks highlights the necessity of treating security attacks. In the era of rapid internet connectivity and cloud computing services, patient medical information is most sensitive, and its electronic representation poses privacy and security concerns. Moreover, it is challenging for the traditional classifier to process a massive amount of health data and classify patients' health statuses. To address this matter, this paper presents a novel healthcare model, IoT-CDLDPM, to estimate patients' disease levels using original data and fuzzy entropy extracted from patients' remote locations. IoT-CDLDPM incorporates a deep learning classifier to analyze extensive patient-related data and provides efficient and accurate health status predictions. Furthermore, the proposed model presents the secured storage structure of the individual's health data in cloud servers. To give the authenticity of the health data, two new cryptographic algorithms are presented that encrypt and decrypt the data securely transmitted through the network. A comparison with existing methods reveals that the proposed system significantly reduces computation time, with a recorded time of 0.5 seconds, outperforming DSVS, PP-ESAP, and DRDA by up to 80%. Furthermore, the proposed cryptographic model enhances security levels, achieving a range between 99.4% and 99.8% across multiple experimental setups, surpassing other widely used encryption algorithms such as AES, RSA, and ECC-DH.

Keywords—IoT-driven healthcare; deep learning; fuzzy entropy; secure data storage; cryptography

I. INTRODUCTION

The convergence of cutting-edge technologies has recently led to revolutionary changes in the healthcare sector. Among these, the Internet of Things (IoT) stands out as a pivotal paradigm, transforming health monitoring and management [1, 2]. IoT denotes a network of connected items and sensors communicating seamlessly over the Internet, facilitating real-time data gathering and dissemination [3]. In healthcare, IoT enables the creation of smart environments where medical devices, wearables, and sensors collaborate to gather patient-specific information [4, 5]. This interconnectedness empowers healthcare professionals with timely and comprehensive data, fostering more accurate diagnostics, personalized treatments, and efficient disease management [6].

Cloud computing has become a cornerstone in reshaping healthcare systems infrastructure. The cloud offers a flexible

and centralized system for keeping and managing vast healthcare data [7]. It provides the flexibility to access information from anywhere, at any time, facilitating seamless collaboration among healthcare providers and enabling the delivery of telemedicine services [8]. Moreover, the cloud's robust storage capabilities alleviate the burden of data management, ensuring the security and accessibility of patient records [9]. Complementing these advancements, deep learning, a branch of artificial intelligence, has proven instrumental in deciphering intricate patterns within voluminous datasets [10]. Deep learning algorithms recognize complex relationships in healthcare data, making them particularly adept at disease prediction and classification tasks [11, 12]. Leveraging deep learning within the healthcare domain enhances the accuracy of diagnostics and prognostics, leading to the advent of precision medicine [13]. This paper explores the synergistic integration of IoT, cloud computing, and deep learning in designing a novel healthcare monitoring system, addressing the challenges posed by disease prediction and data security in the era of digital health [14].

This paper makes several noteworthy contributions to healthcare monitoring and data security. First, it introduces a novel, robust, and secure storage algorithm designed to maintain the consistency and safety of data stored in cloud databases. Second, the study proposes an innovative deep learning framework to predict health statistics collected via IoT sensors. Third, an encryption scheme is presented to securely protect the stored data, complemented by a corresponding decryption algorithm for accurate data retrieval. Additionally, the paper introduces intelligent fuzzy rules, contributing to effective decision-making based on medical IoT data.

Moreover, this research presents a new formula for ranking patient data, enhancing the prioritization of critical health information. The study also implements spatial and temporal constraints on a Convolutional Neural Network (CNN) classifier, refining its ability to accurately predict patients' health conditions. Finally, the paper systematically conducts various experiments to evaluate the effectiveness of the developed health-tracking approach. Collectively, these contributions advance the current understanding and capabilities in healthcare data security, predictive analytics, and decision-making within the context of IoT-enabled health monitoring systems.

This article is divided into several sections. Section 2 delves into the backgrounds, offering an in-depth exploration of the

contextual foundations relevant to the study. Section 3 elucidates the proposed framework, outlining the intricacies of the developed healthcare monitoring system. Section 4 summarizes the experimental observations, providing a detailed assessment of the system's efficiency in various scenarios. In section 5, the paper concludes by highlighting results, implications, and future research topics.

II. BACKGROUND

Integrating IoT, cloud computing, and deep learning in healthcare requires a thorough understanding of the challenges and opportunities within the rapidly evolving digital health landscape. Table I compares publications highlighting different methods and techniques of enhancing healthcare systems through these technologies. This section offers insight into the existing state of healthcare systems, emphasizing the growing reliance on interconnected devices, the significance of secure data storage, and the pivotal role of advanced data analytics in disease prediction and monitoring.

TABLE I. AN OVERVIEW OF RELATED WORKS

Study	Objective	Key techniques	Performance metrics
[15]	Identify and trace cyber-attack events in IoT networks	Network data flow extraction, PSO for deep learning parameter optimization, PSO-based DNN	Superior performance in detecting and tracing cyber-attacks
[16]	Early detection of thyroid infections	Fog computing, AI, ensemble-based classifier, encryption and decryption	Accuracy, precision, specificity, sensitivity, F1 score
[17]	Remote patient monitoring to reduce hospital visits	IoT, AI, NN configuration optimization, IoT protocols for data transmission	Not specified
[18]	Enhance privacy-preserving healthcare systems	Fog-enabled model, CNN with Bi-LSTM, Medical Entity Recognition, delta sanitizer	Recall, precision, F1-score, utility preservation
[19]	Detection of cardiovascular diseases	IoT, deep learning, BiLSTM for feature extraction, AFO for hyperparameter optimization, FDNN classifier	Accuracy (maximum 93.4%)

In the era of ubiquitous IoT technologies, everyday devices seamlessly connect to the Internet, delivering intelligent functions and on-demand capabilities to users. Despite their lightweight structure and low power consumption, these devices often expose themselves to cyber risks, adversely impacting their functionality within network systems. A significant challenge in securing IoT networks revolves around identifying and tracking sources of cyber-attack events, particularly in the context of obfuscated and encrypted network traffic.

Addressing this challenge, Koroniotis, et al. [15] have developed a novel forensic network methodology known as the Particle Deep Framework (PDF). This framework delineates

the phases of digital investigation aimed at detecting and monitoring malicious activities within IoT systems. The PDF introduces three distinctive features: the extraction of data flow patterns and verification of data integrity, tailored explicitly for encrypted networks; the utilization of a Particle Swarm Optimization (PSO) algorithm for the adaptive tuning of deep learning variables; and the design of a Deep Neural Network (DNN) utilizing PSO, designed to identify and monitor anomalies within IoT networks associated with home automation. To assess the efficacy of the presented PDF, evaluations are conducted using UNSW_NB15 and Bot-IoT sources, and comparative analyses are performed using different deep learning algorithms. The test outcomes underscore the superior ability of the PDF in detecting and tracing cyber-attack events compared to alternative strategies.

Various physiological activities are regulated by the thyroid gland, a crucial organ of the endocrine system. These processes include building proteins, energy metabolism, and hormone response. Accurate characterization and reconstruction of the thyroid are essential for detecting thyroid conditions, as alterations in the gland's shape and size indicate potential health issues. Understanding the origins and progression of thyroid diseases is paramount, necessitating focused research in this domain. The intersection of IoT, artificial intelligence, and cloud computing offers immediate computation capabilities with diverse applications in the healthcare sector. Machine learning algorithms are increasingly used in critical decisions. Individuals with thyroid conditions require a reliable and time-sensitive Quality of Service (QoS) framework.

Singh, et al. [16] have innovatively integrated artificial intelligence and fog computing into intelligent healthcare, establishing a reliable mechanism for quickly diagnosing thyroid infections. A novel ensemble-based classifier is introduced for identifying thyroid patients, utilizing UCI datasets, and simulations are conducted using Python programming. In addition to detection accuracy, the proposed framework emphasizes security through authentication and encryption. The effectiveness of the proposed framework is comprehensively assessed for power, RAM, and bandwidth usage. Simultaneously, the potential classifier's effectiveness is evaluated based on F1 score, sensitivity, specificity, precision, and accuracy. The results demonstrate that the developed methodology and classifier significantly outperform traditional methods in addressing thyroid disease detection complexities.

Singh, et al. [17] have developed e-health tools and telemonitoring systems to reduce hospitalizations, particularly in epidemic situations. This initiative leverages artificial intelligence and IoT to tackle these challenges effectively. This research aims to determine the most suitable and efficient configuration of hidden layers and encoding functions for a Neural Network (NN). Subsequently, the information transmitted through IoT networks is elucidated. The NN, an integral project component, scrutinizes information received from sensor data to make informed decisions. The selected condition is subsequently conveyed to the attending medical professional. This innovative tool empowers patients to independently recognize and predict illnesses, aiding healthcare professionals in remote disease detection and analysis.

Significantly, this is achieved without physical hospital visits, enhancing healthcare accessibility and efficiency.

Traditional health systems often struggle to manage vast volumes of biomedical data, leading to cloud-based storage and sharing. However, this approach introduces security challenges, particularly regarding privacy and confidentiality breaches. To address these issues, Moqurrab, et al. [18] have introduced an innovative fog-based data privacy model named "delta sanitizer", leveraging deep learning to enhance healthcare systems. The algorithm developed is built upon a Convolutional Neural Network with Bidirectional Long Short-Term Memory (Bi-LSTM) and is proficient in recognizing health-related entities. Statistical findings indicate that the delta sanitizer model surpasses existing models, achieving a recall of 91.1%, a precision of 92.6%, and an F1-score of 92%. Notably, the sanitization model demonstrates a 28.7% improvement in utility preservation compared to contemporary approaches. This underscores the efficacy of the proposed model in balancing the imperatives of privacy preservation and data utility in biomedical contexts.

Technological advances in the IoT, sensing technologies, and wearables have led to significant enhancements in healthcare quality, shifting from traditional healthcare approaches to continuous monitoring. Sensors attached to biomedical devices capture bio-signals generated by human actions, with the biomedical electrocardiogram (ECG) signal being a standard and non-invasive method for examining and diagnosing cardiovascular diseases (CVDs) rapidly. Given the challenges posed by the increasing number of patients and the diverse ECG signal patterns, computer-assisted automated diagnostic tools play a crucial role in ECG signal classification. In response to this need, Khanna, et al. [19] have introduced an innovative healthcare disease diagnosis model that integrates IoT and deep learning algorithms to analyze biomedical ECG signals. The model's primary objective is CVD detection through deep learning models of ECG signals. Bidirectional Long Short-Term Memory (BiLSTM) enhances the model's ability to extract meaningful feature vectors from ECG signals. The performance of the BiLSTM is further improved by leveraging the Artificial Flora Optimization (AFO) algorithm as a hyperparameter optimizer. A Fuzzy Deep Neural Network (FDNN) classifier assigns appropriate class labels to ECG signals. The model's accuracy is rigorously evaluated using biomedical ECG signals, and the test results confirm its superiority, achieving a maximum accuracy of 93.4%. This underscores the potential of the proposed model in advancing healthcare diagnostics through the fusion of IoT and deep learning technologies.

III. PROPOSED FRAMEWORK

Fig. 1 presents a comprehensive overview of the proposed healthcare monitoring system, comprising nine core modules: IoT devices, cloud database, temporal manager, rule base, rule manager, prediction, secure storage, decision manager, and user interface. Patient health data is captured by IoT devices and transmitted to a data collection agent, which stores the information in a cloud-based database. The user interface facilitates data retrieval from this cloud repository, enabling seamless access. Extracted data is then channeled to the decision manager for subsequent processing and secure storage. The latter incorporates a robust security framework comprising encryption, decryption, and key generation components. A novel RSA-based encryption algorithm safeguards data, while the corresponding decryption algorithm ensures data integrity. The efficient key generation algorithm underpins the entire cryptographic process. Encrypted data is persistently stored in the cloud database and can be retrieved upon user request through the user interface, with the decision manager orchestrating the process.

Patient statistics are forwarded to the prediction component for disease level estimation. This module leverages a novel deep learning architecture, the Fuzzy-Temporal Convolutional Neural Network (FTCNN), to accurately determine the severity of diseases. The temporal manager ensures data timeliness, while the spatial manager verifies patient location. The rule manager constructs and finalizes fuzzy rules stored in the rule base for subsequent disease prediction. The decision manager guides rule generation and interprets prediction outcomes, conveying results to physicians and patients. The IoT-CDLDPM framework encompasses three primary components: IoT-based data acquisition, secure data storage, and advanced disease prediction, which are discussed in this section.

Initial patient data is collected from remote locations using IoT devices tailored to specific diseases such as cancer, cardiovascular conditions, and diabetes. These devices employ specialized sensors to capture relevant patient symptoms, including glucose levels, heart rate, and electrocardiogram data. Extracted features are organized into individual patient records, each uniquely identified. The collected data is securely transferred to the cloud database through a coordinated process involving the decision manager, user panel, and data gathering component, with a secure storage component playing a critical role. The data capture component aggregates data and forwards it to the user interface, identifying essential characteristics and passing them to the decision manager for security processing. Subsequently, the decision manager transmits preprocessed data to the storage component for encryption, decryption, and secure cloud storage.

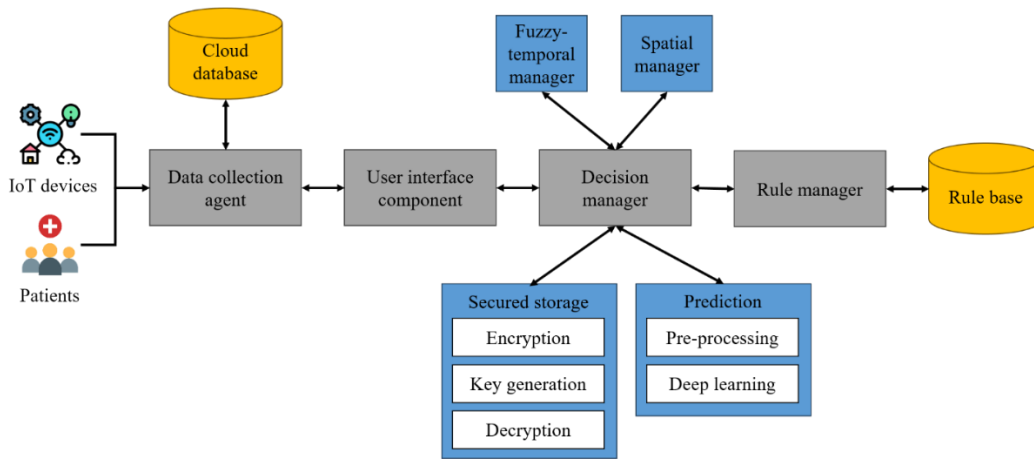

Fig. 1. An overview of the proposed healthcare monitoring system.

The proposed secure storage framework incorporates novel key generation, encryption, and decryption algorithms to safeguard medical and patient data. The initial phase involves key generation using an Elliptic Curve-based Key Generator (ECKG). This algorithm extracts a 4-bit cloud user code, partitioning it into two binary values (a and b). A prime number (p) is selected to define the Galois Field (GFp). Subsequently, the ECKG employs the Diffie-Hellman key exchange protocol to generate public keys P_A and P_B .

An additional layer of protection is introduced through the novel RSA-based Key Generator (RSAKG) to enhance security further. This algorithm derives key pairs (e and d) from specific points (q and r) on the elliptic curve. The RSAKGA process involves calculating n and U and generating public and private keys.

We employ the elliptic curve cryptography-based cyclic encryption procedure (ECC-CEP), which involves two sequential stages. The first stage utilizes elliptic curve-based encryption, while the second employs RSA-based encryption, enhancing the overall security of the process. This comprehensive approach ensures the confidentiality and integrity of the transmitted data.

To complete an entire cryptographic cycle, the suggested elliptic curve cryptography and RSA-enabled multi-decryption scheme are applied to decrypt the original text. This algorithm involves a two-stage process where the first stage utilizes RSA-based decryption, and the second involves ECC-based decryption. Integrating these cryptographic techniques establishes a robust and multilayered security framework for ensuring the privacy and integrity of healthcare data.

The predictive model comprises two principal modules to assess disease severity based on symptoms and patient feedback. The initial module utilizes a deep learning approach to analyze symptom-based severity, evaluate patient feedback textually, and estimate sentiment scores specific to individual diseases to determine their severity level. Subsequently, the model incorporates severity rating features alongside user feedback, allowing for evaluating severity-based ratings and indicating the disease status for specific data instances.

Severity classification relies on the extraction of salient features from patient data. This study proposes an MCST-CNN architecture to accurately determine disease severity and compute patient polarity scores. To refine severity categorization, Latent Dirichlet Allocation (LDA) is employed to cluster extracted severity levels. The MCST-CNN model is a specialized CNN architecture comprising four distinct channels for abnormal, medium, low, and average severity states. Dataset features are mapped to a linear matrix via a lookup function, resulting in a matrix $X \in R^{nk}$. The severity level embedding channel refines severity estimation by incorporating a 45-dimensional severity analyzer vector.

The convolutional layer is instrumental in extracting salient features from medical datasets, reports, and physician notes. By applying filters of varying sizes, this layer effectively identifies crucial attributes for feature and severity level embedding. Given a filter $wt_x \in R^{h \times k}$, where h refers to the height of matrix x embedded in a particular channel, feature extraction is performed according to Eq. (1) within defined temporal and spatial boundaries. ATT denotes an asymmetric map and b represents a bias term. The resulting attribute map, $CH_x \in R^{n-h+1}$, is calculated for a specific time interval ($t1$ to $t2$) as outlined in Eq. (2). For severity merging and attribute embedding within the embedding channel, distinct filters $wt_z \in R^{h \times 1}$ are employed to generate attribute maps as described in Eq. (3). This approach enables the generation of diverse feature representations and attributes.

$$CH_i\langle t1, t2, sp \rangle = ATT(wt_x \cdot x_{i+h} + b) \quad (1)$$

$$CH_x\langle t1, t2, sp \rangle = [CH_1^x, CH_2^x, \dots, CH_{n-h+1}^x] \quad (2)$$

$$CH_z\langle t1, t2, sp \rangle = [CH_1^z, CH_2^z, \dots, CH_{n-h+1}^z] \quad (3)$$

The pooling operation is pivotal in capturing maximum features from input values, typically expressed as shown in Eq. (4). Following this operation, the ultimate attributes are obtained by concatenating the semantically significant attributes using a filter. Typically, this process is denoted as

$$CH = CH \oplus CH \quad (5)$$

Eq. (5) illustrates the resulting final attributes, where the terms n and m denote distinct thresholds for useful and attribute-specific components, correspondingly.

$$CH_x = MAX(CH_x) \text{ and } CH_z = MAX(CH_z) \quad (4)$$

$$CH = \begin{matrix} 1 & n & 1 & m \\ CH \oplus & \dots \oplus & CH \oplus & CH \oplus \dots CH \\ x & x & z & z \end{matrix} \quad (5)$$

Typically, the softmax function is utilized to compute the final attributes. In this research, the extraction of severity levels is framed as a sequential labelling task. The resulting output is represented by Eq. (6), in which O denotes the masking function and $rs \in R^{n+m}$ signifies a sample based on the Bernoulli pattern.

$$O\langle t1, t2, sp \rangle wt. (c \ o \ rs) + b \quad (6)$$

The dataset comprising patient records encompasses a diverse range of attributes associated with severity levels, although variations in the specific attributes are relevant to each severity group. Moreover, the attributes representing severity encompass various types of severity. Hence, it becomes imperative to cluster the pertinent attributes and establish mappings between the extracted severity-related attributes and their respective counterparts. The standard Linear Discriminant Analysis (LDA) method is employed to identify the relevant characteristics from the standardized dataset. Leveraging the LDA method enables segregating specific severity levels into distinct groups. Notably, the LDA method incorporates considerations of spatial and temporal factors, representing an improvement over prior approaches.

Predicting disease severity entails clustering pertinent features and calculating polarity scores for each severity level. Severity level ratings within a rating matrix are determined by computing polarity scores corresponding to severity levels and considering the resulting polarity score. This methodology calculates the rating for each disease severity based on relevant attributes associated with the dataset. The severity level rating is computed using Equation (7), where W_k denotes the word set DS_{ij} linked to severity score a_k , and $SVL(w)$ represents the attribute polarity based on their semantic content.

$$r_{ijk} \langle t1, t2, sp \rangle = \frac{\sum_{w \in W_k(DS_{ij})} SVL(w)}{W_k(DS_{ij})} \quad (7)$$

A severity-based weight estimation process is employed to determine severity-associated attribute weights, utilizing a three-dimensional attribute-factor (AF) tensor, WT . This tensor encapsulates the intricate relationships between attributes, users, and disease severity levels. The tensor WT undergoes decomposition as outlined in Eq. (8), where R signifies the top-rank component count, and the symbol \circ represents the outer product. The column vectors within factor matrices X , Y , and Z are denoted by x_r , y_r , and z_r , respectively. The dimensions of X , Y , and Z are $I \times R$, $J \times R$, and $K \times R$, correspondingly. Eq. (9) presents an element-wise equivalent of Eq. (8).

$$wt \approx \sum_{r=1}^R x_r \circ y_r \circ z_r \quad (8)$$

$$wt_{ijk} = (x_r, y_r, z_r) = \sum_{r=1}^R x_{ir} \cdot y_{jr} \cdot z_{kr} \quad (9)$$

Each row within the matrices x_r , y_r , and z_r corresponds to weight factors associated with patients, attributes, and severity levels, respectively. Disease prediction ratings, denoted as r_{ij} , are computed using the proposed prediction model,

incorporating severity levels and weight vectors as defined in Eq. (10).

$$r_{ij} = \sum_{k=1}^K w_{ijk} \cdot r_{ijk} \quad (10)$$

IV. EXPERIMENTAL RESULTS

The proposed disease monitoring system was engineered using Java within the NetBeans Integrated Development Environment (IDE) and leveraged the CloudSim simulation toolkit for performance evaluation. The system incorporates a standardized dataset from the University of California, Irvine (UCI) Machine Learning Repository, encompassing various diseases such as cardiovascular conditions, diabetes, and cancer. Analyzing this dataset provides a user-friendly approach to assessing disease severity, thereby contributing to the prevention of life-threatening ailments.

This section provides a detailed overview of the medical datasets employed in this study, specifically focusing on heart disease, diabetes, and cancer. Furthermore, the performance metrics utilized to evaluate the proposed health monitoring system are outlined, followed by a comprehensive presentation of experimental results. The evaluation of the suggested approach is divided into two primary domains: disease prediction and safe storage. Each domain is assessed using specific evaluation parameters.

The assessment of the secured storage component within the disease prediction system encompasses factors including decryption time, encryption time, and key generation time. The formulas for computing these times are delineated in Eq. (11), (12), and (13), respectively.

$$K = DTT + ET \quad (11)$$

$$ET = EDT - STT \quad (12)$$

$$DT = EDT - STT \quad (13)$$

In Eq. (11), DTT represents the data transferring time, while ET denotes the time required to encrypt the data. The encryption time is determined by the duration of converting the original data into its encrypted form. Fig. 2 depicts the analysis of crucial generation time for the developed secured storage system. The figure illustrates the results of five experiments conducted with varying numbers of cloud users (200, 400, 600, 800, and 1000). As observed from the graph, as the number of cloud consumers increases, the key generation time also increases.

In Eq. (12), EDT represents the end time of the encryption process, while STT signifies the start time. DT denotes the user's time spent decrypting the encrypted data, measured in milliseconds and expressed as Eq. (13).

Fig. 3 presents an analysis of the proposed algorithm's encryption time. To assess the model's performance, the evaluation involved five experiments using data sets of varying sizes: 200 KB, 400 KB, 600 KB, 800 KB, and 1 MB. As expected, the encryption time exhibited a positive correlation with data size. This is likely caused by the inherent properties

of elliptic curve cryptography used in the algorithm and the two-stage nature of the encryption and decryption processes.

Similar to the encryption process, Fig. 4 analyzes the decryption time associated with the proposed secure storage algorithm. The evaluation employed the same five data set sizes to evaluate decryption efficiency. The results demonstrate that decryption time scales proportionally with the size of the data being handled. This characteristic can be attributed to the two-stage nature of the decryption scheme employed in the method.

Fig. 5 compares the computational time required by the suggested secure storage approach and several existing systems. The evaluation employed a fixed data size of 10 GB

across five scenarios. The results indicate that the proposed algorithm exhibits lower computational time than existing systems.

Fig. 6 compares the security performance of the developed secure storage algorithm (ECCRS-DDA& ECC-TSEA) with several existing algorithms. The evaluation involved five experiments designed to assess the relative security of each approach. The results demonstrate that the proposed algorithm offers a superior level of protection compared to existing solutions.

Fig. 2. Key generation time comparison.

Fig. 3. Encryption time comparison.

Fig. 4. Decryption time comparison.

Fig. 5. Computation time comparison.

Fig. 6. Security level comparison.

V. CONCLUSION

In this research, an innovative healthcare surveillance system has been developed and deployed to assess the severity of critical illnesses, including diabetes and cardiovascular conditions. The system utilizes original data collected from patients residing in remote areas to predict disease levels. Additionally, a secure data storage model has been developed and integrated into the system to ensure the safe storage of patient data in cloud databases. Three novel algorithms have been formulated for key generation, encryption, and decryption procedures within the secure storage framework to bolster the system's security. These algorithms aim to protect sensitive patient information and prevent unauthorized access. A novel deep learning algorithm named IoT-CDLDPM has also been created and incorporated into the healthcare monitoring system. This algorithm enhances the efficiency of disease-level prediction by leveraging the power of deep learning techniques. The experimental outcomes derived from a series of trials in this study indicate the efficacy of the proposed healthcare system. The system achieved a prediction accuracy of 99.4%, demonstrating its high precision in assessing disease severity levels. Moreover, the system's security level is evaluated to be 99.7%, surpassing the performance of other healthcare systems.

Surabaya, Indonesia

Abstract—Indonesia is one of the largest producers and exporters of Crude Palm Oil (CPO), making CPO production crucial to the country's economic stability. Accurate forecasting of CPO production is essential for effective inventory management, export-import strategy, and economic planning. Traditional time series methods like ARIMA have limitations in modeling nonlinear data, leading to the adoption of machine learning approaches such as Artificial Neural Network (ANN) and Long Short-Term Memory (LSTM). This study compares the performance of ANN, a general neural network, and LSTM, a neural network specifically designed for time series data, in predicting CPO production in Indonesia. Data from 2003 to 2022 were used to train and evaluate both models with various hyperparameter tuning configurations. The results indicate that while both models provide excellent forecasting accuracy, with MAPE values below 10%, the LSTM model achieved a lower out-of-sample MAPE of 5.78% compared to ANN's 6.87%, suggesting superior performance by LSTM in capturing seasonal patterns in CPO production. Consequently, LSTM is recommended as the preferred model for CPO production forecasting due to its enhanced ability to handle temporal dependencies and nonlinear patterns in the data.

Keywords—Artificial Neural Network (ANN); Crude Palm Oil (CPO); Long Short-Term Memory (LSTM)

I. INTRODUCTION

Indonesia is the largest agrarian country in Southeast Asia and one of the world's largest producers of Crude Palm Oil (CPO). According to data from the United States Foreign Agricultural Service, Indonesia's CPO production reached 47 million metric tons as of March 2024. This achievement places Indonesia as both the largest producer and exporter of crude palm oil (CPO) globally. Crude Palm Oil (CPO) is unrefined palm oil extracted from the mesocarp of the oil palm fruit, which remains in a raw state and requires further processing and refining to become pure palm oil [1]. CPO has many derivative products used in daily life, including cooking oil, margarine, biodiesel, soap, and detergent. [2].

As a primary producer in the international CPO market, crude palm oil is a major commodity that supports Indonesia's economy. According to data from the Central Statistics Agency (BPS), CPO contributes significantly and consistently to Indonesia's export value, accounting for around 12-13% during

the period from 2020 to 2022. Thus, the CPO industry makes a substantial contribution to national income through export activities. The export value plays a crucial role in the country's economic stability, as higher export values lead to an appreciation of the domestic currency. Currency appreciation can lower import prices, reducing inflationary pressures. Conversely, currency depreciation can increase import prices, triggering inflation [3]. Therefore, CPO production is a potential factor in the country's economic development.

Based on data from the Central Statistics Agency of Indonesia, CPO production fluctuated significantly from 2021 to 2022, with the lowest production occurring in February 2022, leading to a shortage of cooking oil that caused concern among the public. CPO is one of the largest contributors to the nation's export revenue. Therefore, fluctuations in CPO production can lead to instability in export income. A decline in export income could result in a trade balance deficit and depreciation of the domestic currency, which in turn may increase import prices and trigger inflation, negatively impacting the economy as a whole [3]. One way to manage and anticipate this risk is by forecasting CPO production. With accurate forecasting, the government and industry players can plan more effective export-import policies, manage inventory and prices more stably, and adjust investment strategies to reduce economic uncertainty, ensuring the optimal contribution of the palm oil sector to economic growth and national stability.

A commonly used forecasting method for modeling time series data is the Autoregressive Integrated Moving Average (ARIMA) model. ARIMA is a time series model derived from the Autoregressive Moving Average (ARMA) model, which combines non-stationary Autoregressive and Moving Average processes requiring differencing to achieve stationarity [4]. The ARIMA model is quite flexible in modeling time series data patterns because it can capture random data patterns, trends, seasonal, and even cyclical characteristics in the time series data. However, studies indicate that ARIMA is less suitable for modeling nonlinear time series data [5]. Recent advancements in technology have led to the use of machine learning methods, which are more suitable for addressing the limitations of traditional time series models. Machine learning algorithms excel in discovering and representing complex structural patterns in data, enabling better future forecasting based on these patterns [6]. Machine learning methods, especially deep

*Corresponding author

learning, have become powerful tools for handling time series data with nonlinearity or complexity factors [7]. The most commonly used deep learning method is the Artificial Neural Network (ANN). Artificial Neural Network (ANN) is a computational system inspired by the structure and operation of neural cells in the brain, modeling biological neural networks. ANN is a non-linear model with a flexible functional form and several parameters that cannot be interpreted. This characteristic enables ANN to solve unstructured and hard-to-define problems [8].

As technology advances, various deep learning methods have emerged. One deep learning method specifically designed for time series data is Long Short-Term Memory (LSTM) [9]. LSTM, a variant of Recurrent Neural Network (RNN), is widely used in time series data modeling. LSTM's architecture was developed to address the vanishing gradient problem often encountered in conventional RNNs. LSTM uses two key mechanisms, the forget gate and input gate, allowing the model to learn which information should be retained or forgotten at each time step. This advantage makes LSTM more flexible in managing its internal memory, which can be useful when working with complex or nonlinear data. Additionally, LSTM has a better ability to capture data patterns over longer periods, making it more suitable for applications requiring deeper and more accurate temporal dynamics modeling.

This study introduces a novel contribution to the field by focusing on the application and comparative analysis of two advanced neural network methods—Artificial Neural Network (ANN) and Long Short-Term Memory (LSTM)—for forecasting crude palm oil (CPO) production in Indonesia. While ANN has been widely utilized for various predictive tasks, this research leverages the specialized capabilities of LSTM in handling sequential and time-series data, addressing the unique temporal patterns, seasonality, and variability inherent to Indonesia's CPO production. By tailoring these methods to the specific characteristics of Indonesia's agricultural sector, this study not only provides valuable insights into their effectiveness and limitations but also establishes a robust framework for improving forecasting accuracy in a critical industry that significantly impacts the country's economy.

This study introduces a novel contribution to the field by focusing on the application and comparative analysis of two advanced neural network methods—Artificial Neural Network (ANN) and Long Short-Term Memory (LSTM)—for forecasting crude palm oil (CPO) production in Indonesia. While ANN has been widely utilized for various predictive tasks, this research leverages the specialized capabilities of LSTM in handling sequential and time-series data, addressing the unique temporal patterns, seasonality, and variability inherent to Indonesia's CPO production. By tailoring these methods to the specific characteristics of Indonesia's agricultural sector, this study not only provides valuable insights into their effectiveness and limitations but also establishes a robust framework for improving forecasting accuracy in a critical industry that significantly impacts the country's economy.

II. RELATED WORK

Time series forecasting has been extensively explored using both traditional statistical models and modern machine learning

techniques. To better understand the strengths and limitations of these approaches, various studies have compared their performance across different domains. The Table I below summarizes key findings from relevant studies, highlighting the application of ARIMA, ANN, and LSTM models in diverse sectors and the insights gained from these comparisons

TABLE I. RESULTS OF CRUDE PALM OIL (CPO) PRODUCTION IN INDONESIA MODELLING WITH ANN

Domain	Key Findings	References
Various Sectors (Finance, Healthcare, Weather, Utilities)	Machine learning methods like ANN outperform ARIMA in scenarios with non-linear or complex patterns.	[10]
Energy Consumption (Commercial Buildings)	ANN is more reliable for non-linear datasets, capturing intricate dependencies and variability, while ARIMA is effective for linear and stationary data.	[11]
Global Crude Palm Oil (CPO) Prices	LSTM achieves superior accuracy (MAPE: 2.33%, RMSE: 34.708), better capturing complex temporal dependencies compared to ARIMA and hybrid models.	[12]
Economic and Financial Indicators (GDP Growth)	LSTM outperforms ARIMA in long-term forecasting for non-linear and non-stationary data, addressing ARIMA's limitations.	[13]
Stock Price Prediction (Real Estate)	LSTM provides better accuracy for non-stationary, complex, and cyclical data, while ARIMA performs better for linear and stationary datasets.	[14]

Conventional methods like ARIMA have been widely utilized for time series forecasting due to their ability to capture trends, seasonality, and cycles in data. However, ARIMA has notable limitations in addressing non-linear and complex data, such as the patterns of CPO production in Indonesia, which are influenced by various factors including seasonality, policy changes, and international price fluctuations. These studies collectively highlight the evolution of time series forecasting techniques, showcasing the growing prominence of machine learning methods like LSTM and ANN in overcoming the limitations of traditional models such as ARIMA. ANN excels in modeling non-linear and unstructured relationships, while LSTM, a variant of Recurrent Neural Networks (RNN), is specifically designed to handle temporal dynamics and long-term dependencies in time series data. However, a research gap persists in exploring the application of these models in integrated or hybrid approaches tailored for specific domains, such as agriculture and commodity price forecasting. This study aims to address this gap by applying and comparing ANN and LSTM for forecasting CPO production in Indonesia, to capture the intricate characteristics and variability of the data more effectively while providing a robust framework for planning and decision-making in the CPO industry.

III. METHODOLOGY

The methodology diagram (Fig. 1) illustrates the key stages in modeling and forecasting Crude Palm Oil (CPO) production in Indonesia using Artificial Neural Network (ANN) and Long

Short-Term Memory (LSTM) models. Initially, the data is divided into training and testing subsets, ensuring a robust evaluation of the models. To achieve this, several data splitting ratios, such as 70:30, 80:20, and 90:10, are explored to analyze the impact of data availability on the training process.

In the model design and training phase, ANN and LSTM models are configured with specific hyperparameters to capture the unique patterns in the data. These configurations include batch sizes of 8 and 16, neuron counts of 50 and 100, hidden layers of 1 and 2, epochs of 50 and 100, and learning rates of 0.001 and 0.01. The use of a six-month window size for LSTM is particularly emphasized to account for the seasonal characteristics of CPO production. Adam optimization is applied to update the model weights effectively, ensuring optimal learning from the data.

During the evaluation stage, the models are assessed using the Mean Absolute Percentage Error (MAPE) metric to validate their forecasting accuracy. The systematic exploration of data splits and hyperparameter combinations ensures a comprehensive understanding of the models' capabilities in forecasting CPO production. The final step occurs in the output gate component, where the sigmoid activation function (σ) is applied to produce the output value o_t and process the cell state (C_t) with tanh activation.

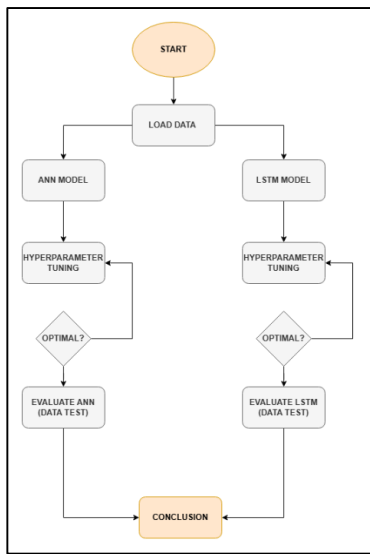

Fig. 1. Methodology diagram.

IV. ARTIFICIAL NEURAL NETWORK (ANN)

An Artificial Neural Network (ANN) is a computational system inspired by the structure and function of neural cells in the brain, essentially modeling biological neural networks. ANN is an example of a non-linear model with a flexible functional form and several parameters that cannot be interpreted, similar to parametric models. However, this allows ANN to tackle unstructured and challenging-to-define problems. The process within an ANN begins with input data received by neurons, which are grouped into layers. Information received from the input layer is passed sequentially through the layers in the ANN until it reaches the output layer. Layers positioned between the input and output are known as hidden layers. A Neural Network

is determined by three main components: the pattern of relationships between units (network architecture), the method for updating weights in connection links (training method or algorithm), and the activation function [8].

A. Components of ANN

This form of artificial intelligence is developed to mimic the workings of the human biological nervous system (neurons). Each component of an ANN system can be analogized to parts of the human neuron system, such as dendrites (parts that receive input/signals), the cell body (processes inputs), and the axon (transmits this input to other neurons/outputs) [15] (Fig. 2).

Fig. 2. Components of ANN.

Each piece of information received by the dendrites (input) is summed and sent through the axon to the dendrites (output) of another neuron. This information will only be received by the other neuron if it meets a certain threshold value. Neurons that receive information and transmit it to other neurons are considered to be activated. Neurons receive information from other neurons in the form of values known as weights, which also indicate the strength of the connection between neurons.

B. ANN Architecture

ANN architecture is the pattern of relationships between neurons. Neurons that share the same weight pattern and activation function are grouped in the same layer. Information usually flows from the input layer to the output layer, often passing through hidden layers. Some neural network architectures include:

1) Single-layer network

This network has only one layer containing weights connected to each other. There is no hidden layer in this type of network, and all input units are connected to every output unit (Fig. 3).

Fig. 3. Single-layer network.

2) Multi-layer network

This network has one or more layers (hidden layers and weights) between the input layer and the output layer. A multi-layer network can solve more complex problems than a single-layer network (Fig. 4).

Fig. 4. Multi-layer network.

V. LONG SHORT TERM MEMORY (LSTM)

Long Short-Term Memory (LSTM) is a neural network architecture that shares similarities with Recurrent Neural Networks (RNNs) [16]. LSTM was first introduced by Hochreiter and Schmidhuber in 1997. LSTM falls within the category of Recurrent Neural Networks (RNNs), where it has repeating units that function similarly to neural network sequences [17]. LSTM was designed to overcome the limitations of conventional RNNs, specifically the vanishing gradient problem. The vanishing gradient problem occurs when gradient values decrease significantly towards the last layers, preventing weight updates and causing the model to struggle to improve or converge. Unlike conventional RNNs, LSTM uses additional signals passed from one time step to the next, known as the cell state. LSTM has strong generalization capabilities and effective learning abilities for both large and small datasets. It is particularly advantageous in processing non-linear data, which enhances forecasting accuracy [18].

LSTM's design makes it particularly suitable for solving complex problems that involve sequential or time-dependent data. For instance, in forecasting tasks where patterns such as seasonality, trends, or temporal dependencies play a critical role, LSTM excels by learning these non-linear relationships. Its strong generalization capabilities and ability to learn from both large and small datasets make it highly effective for addressing real-world challenges. By leveraging its strengths, LSTM has been successfully applied in various domains, such as financial time-series prediction, speech recognition, and production forecasting. For example, in modeling Crude Palm Oil (CPO) production, LSTM can identify seasonal trends and long-term dependencies, enabling more accurate and reliable forecasts. These features make LSTM a powerful solution for problems where conventional methods often struggle, ensuring better decision-making and planning in dynamic environments.

The LSTM architecture consists of memory cells, an input gate, a forget gate, and an output gate. The LSTM cell can store data for a specific duration. Intuitively, the input gate controls the extent to which new information can enter the cell, while the forget gate controls how much information remains within the cell, and the output gate manages which information exits the

cell to calculate the activation of the LSTM model [16]. Below are descriptions of the gates in an LSTM (Fig. 5).

Fig. 5. Architecture of LSTM.

VI. RESULT

This section begins by discussing the characteristics of the Crude Palm Oil production in Indonesia, modeling with ANN, modeling with LSTM, and a comparison of the results from the ANN and LSTM models.

A. Crude Palm Oil in Indonesia

The production data of Crude Palm Oil (CPO) in Indonesia is very important, especially for the government. The government requires information on Crude Palm Oil (CPO) production in Indonesia to assist in the effective planning and management of CPO supplies, reduce economic risks due to fluctuations in CPO production, and devise better export-import strategies for CPO to enhance the stability of the national economy. The characteristics of the CPO production data in Indonesia are illustrated in Fig. 6.

Fig. 6. Time series plot Crude Palm Oil (CPO) production in Indonesia.

Fig. 6 shows that the production of Crude Palm Oil (CPO) in Indonesia from January 2003 to December 2022 exhibits a seasonal pattern. CPO production in Indonesia from 2003 to 2013 showed a tendency to decline sharply at the end of the year, particularly in September, and had a tendency to rise sharply at the beginning of the year, especially in January. In other words, there tends to be a decrease at the end of the year, followed by a rise at the beginning of the year. This is supported by the characteristics of oil palm, which grows well during the end of the rainy season, where the rainy season in Indonesia usually starts in November and ends between January and March. However, from 2014 to 2022, the production of Crude Palm Oil (CPO) in Indonesia has shown a new seasonal pattern, characterized by a tendency to decrease at the beginning of the year and an increase at the end of the year. This is believed to be due to increasingly unpredictable climate conditions year after year. Overall, the production of Crude Palm Oil (CPO) in Indonesia has shown an increasing trend during this period, indicating a consistent rise in production year after year. The

lowest production of Crude Palm Oil (CPO) in Indonesia was recorded at the beginning of the observation period, specifically in February 2003, while the highest production occurred at the end of the observation period, specifically in October 2022.

B. Forecasting CPO Production Using Artificial Neural Network

The process in an Artificial Neural Network (ANN) begins with the input received by neurons, which are grouped in layers. The information received from the input layer is sequentially passed to the subsequent layers in the ANN until it reaches the output layer. The determination of inputs in modeling the production of Crude Palm Oil (CPO) in Indonesia using ANN is based on Fig. 7.

Fig. 7. PACF Crude Palm Oil (CPO) production in Indonesia.

Fig. 7 shows that the production of Crude Palm Oil (CPO) in Indonesia during period x_t has a strong relationship with production in periods x_{t-1} , x_{t-2} , x_{t-12} , and x_{t-13} . Based on this relationship, the Artificial Neural Network model uses the CPO production data from Indonesia during periods x_{t-1} , x_{t-2} , x_{t-12} , and x_{t-13} as inputs to predict CPO production in Indonesia for x_t period. This study will utilize several combinations of hyperparameters, namely a batch size of 8 and 16, neuron counts of 50 and 100, hidden layers of 1 and 2, epochs of 50 and 100, and learning rates of 0.001 and 0.01. Adam optimization will be used to update the weights of the ANN network, and MAPE out-of-sample will be employed to determine the best ANN model. In addition to these hyperparameters, this study will also use data splitting ratios to divide the dataset into training and testing subsets. Data splitting ratios refer to the proportion of data allocated for each subset, for example 80% for training, where the model learns from the data, and 20% for testing, where the model's performance is evaluated on unseen data. This approach helps to prevent overfitting and ensures the model's effectiveness on new data. The results of the modeling using the

Artificial Neural Network with several data partitioning scenarios and hyperparameter tuning are presented in Table II.

TABLE II. RESULTS OF CRUDE PALM OIL (CPO) PRODUCTION IN INDONESIA MODELLING WITH ANN

Split Ratio	Batch Size	Neurons	Hidden Layers	Epochs	Learning Rate	MAPE
70 : 30	8	150	2	150	0,01	6,87%
80 : 20	8	120	2	150	0,01	7,92%
90 : 10	8	150	2	150	0,01	6,94%

Table II shows that the best Artificial Neural Network model for predicting Crude Palm Oil (CPO) production in Indonesia is the model with a data partitioning ratio of 70:30, a batch size of 8, 150 neurons, 2 hidden layers, 150 epochs, and a learning rate of 0.01. This model achieves an out-of-sample MAPE value of 6.87%, which falls within the criteria for very good forecasting, as it is less than 10%. The best models in Table II indicate a trend that increasing the number of hidden layers and epochs reduces the model's error rate. Conversely, a smaller batch size tends to produce models with a lower error rate.

C. Forecasting CPO Production Using Long Short Term Memory

LSTM is a form of neural network. One important component in the formation of LSTM networks is the determination of the inputs used. This study will use the window size feature, or time steps, as input. The window sizes used in this research are variations of three, four, and six, representing quarterly, triannual, and semiannual periods. In addition to the input, another crucial component is the hyperparameters. This study will utilize several combinations of hyperparameters, namely a batch size of 8 and 16, neuron counts of 50 and 100, hidden layers of 1 and 2, epochs of 50 and 100, and learning rates of 0.001 and 0.01. Adam optimization will be used to update the weights of the LSTM network, and MAPE out-of-sample will be employed to determine the best LSTM model. In addition to these hyperparameters, this study will also use data splitting ratios to divide the dataset into training and testing subsets. Data splitting ratios refer to the proportion of data allocated for each subset, for example 80% for training, where the model learns from the data, and 20% for testing, where the model's performance is evaluated on unseen data. This approach helps to prevent overfitting and ensures the model's effectiveness on new data. The results of the modeling using Long Short-Term Memory with several data partitioning scenarios and hyperparameter tuning are shown in Table III.

TABLE III. RESULTS OF CRUDE PALM OIL (CPO) PRODUCTION IN INDONESIA MODELLING WITH LSTM

Split Ratio	Window Size	Batch Size	Neurons	Hidden Layers	Epochs	Learning Rate	MAPE
70 : 30	3	8	120	2	100	0,01	6.141%
	4	16	150	1	150	0,01	6.28%
	6	8	150	1	150	0,001	6.33%
80 : 20	3	8	150	1	150	0,001	5.81%
	4	16	120	1	100	0,01	5.85%
	6	16	120	2	150	0,001	5.78%
90 : 10	3	8	120	2	150	0,001	6.15%
	4	8	150	2	150	0,01	6.17%
	6	8	150	2	150	0,001	6.01%

Table III shows that the best Long Short-Term Memory (LSTM) model for a 70:30 data partitioning ratio is with a window size of 3 and a hyperparameter combination of a batch size of 16, 120 neurons, 2 hidden layers, 100 epochs, and a learning rate of 0.01. This LSTM model with the specified window size and hyperparameter combination achieves an out-of-sample MAPE of 6.14%. The best LSTM model for an 80:20 data partitioning ratio is with a window size of 6 and a hyperparameter combination of a batch size of 16, 120 neurons, 2 hidden layers, 150 epochs, and a learning rate of 0.001. This LSTM model achieves an out-of-sample MAPE of 5.78%. The best LSTM model for a 90:10 data partitioning ratio is with a window size of 6 and a hyperparameter combination of a batch size of 8, 120 neurons, 1 hidden layer, 150 epochs, and a learning rate of 0.001. This LSTM model achieves an out-of-sample MAPE of 6.01%. Therefore, the best model to be used in the dashboard to be developed is with an 80:20 data partitioning ratio, a window size of 6, and a hyperparameter combination of a batch size of 16, 120 neurons, 2 hidden layers, 150 epochs, and a learning rate of 0.001.

Table III also indicates that there is no definitive pattern of hyperparameters that consistently yields the best model. The best model obtained is the one with a window size of 6, which aligns with the seasonal pattern of Crude Palm Oil (CPO) production in Indonesia. For example, from 2003 to 2013, there was a tendency for production to decrease in September and increase in February, which corresponds to a time gap of six months from September to February.

D. Comparison of Artificial Neural Network and Long Short Term Memory

The results of modeling Crude Palm Oil (CPO) production in Indonesia using general neural network methods, namely Artificial Neural Network (ANN), and neural networks specifically designed for time series data, namely Long Short-Term Memory (LSTM) are presented in Table IV.

TABLE IV. COMPARISON ANN AND LSTM MODEL

Metode	MAPE
Artificial Neural Network (ANN)	6,87%
Long Short Term Memory (LSTM)	5,78%

Table IV shows that the modeling of Crude Palm Oil (CPO) production in Indonesia using the general neural network method, namely Artificial Neural Network (ANN), and the neural network method specifically designed for time series data, namely Long Short-Term Memory (LSTM), yields out-of-sample MAPE values of 6.87% and 5.78%, respectively. Based on the out-of-sample MAPE values, both methods can be classified as capable of modeling CPO production in Indonesia very well, as the MAPE values are both below 10%. When comparing the two methods, the Long Short-Term Memory (LSTM) method provides a lower out-of-sample MAPE compared to the Artificial Neural Network (ANN), indicating

that the LSTM method has a better model performance than the ANN.

VII. DISCUSSION

The findings of this study demonstrate the effectiveness of ANN and LSTM in predicting CPO production in Indonesia. Both models performed exceptionally well, with MAPE values below 10%, indicating their suitability for time series forecasting. However, LSTM showed superior performance with a MAPE of 5.78%, outperforming ANN, which achieved a MAPE of 6.87%. This suggests that LSTM's ability to process sequential data and capture long-term dependencies allows it to model the complex and dynamic seasonal variations in CPO production more effectively. While ANN is proficient at handling non-linear relationships, its focus on shorter-term dependencies may have limited its adaptability to the shifts in seasonal patterns observed during the study period.

The seasonal trends in CPO production, driven by climatic factors and the oil palm growth cycle, emphasize the importance of models that can capture long-term temporal dynamics. From 2003 to 2013, CPO production typically decreased toward the end of the year and increased at the start of the following year, but after 2014, these patterns shifted due to changing and unpredictable climate conditions. The LSTM model's use of a six-month window size proved effective in addressing these shifts, reflecting its ability to align with seasonal cycles. Furthermore, the study underscores the importance of optimizing hyperparameters to improve model performance. For ANN, better results were achieved with smaller batch sizes, a larger number of neurons, and deeper network layers. In contrast, for LSTM, the optimal configuration included a six-month window size, a batch size of 16, and specific combinations of hidden layers, neurons, and learning rates.

The practical applications of these findings are significant for the CPO industry and policymakers. Accurate forecasts can support decision-making in inventory management, price stabilization, and export-import planning, thereby enhancing economic stability. The superior performance of LSTM makes it particularly useful for addressing the challenges posed by evolving seasonal patterns and climate variability in CPO production. Nonetheless, the study has certain limitations, such as relying solely on historical production data without incorporating external factors like market demand, policy changes, or global price fluctuations. Future research could explore hybrid approaches that combine ANN, LSTM, and other machine learning techniques to further improve accuracy. Moreover, integrating exogenous variables, such as weather conditions or economic indicators, could lead to more comprehensive forecasting models. Overall, this research demonstrates the potential of advanced neural network models in tackling complex forecasting challenges in the agricultural sector and provides a strong foundation for future studies.

VIII. CONCLUSION

The LSTM model demonstrates superior performance compared to the ANN model in modeling and forecasting Crude Palm Oil (CPO) production in Indonesia. This conclusion is supported by a comparative analysis of Mean Absolute Percentage Error (MAPE) values, where the LSTM model

achieved a notably lower MAPE (5.78%) in out-of-sample predictions compared to the ANN model (6.87%). The lower MAPE value highlights the LSTM model's enhanced capability to minimize the deviation between predicted values and actual observations, ensuring higher predictive accuracy. The superior performance of LSTM is attributed to its architectural design, which is specifically optimized to capture long-term dependencies and temporal patterns in sequential data. This makes LSTM particularly effective in handling the seasonal fluctuations and nonlinear trends inherent in agricultural production processes like CPO. For example, the LSTM model successfully identified seasonal production trends and temporal dependencies, such as increased production during harvest periods and decreases during off-seasons, which the ANN model struggled to replicate. In contrast, while the ANN model performs well in general-purpose predictive tasks, it lacks the specialized mechanisms to account for sequential and temporal dynamics. Consequently, its predictions are less robust when applied to CPO production data with complex seasonality and long-term patterns.

These findings emphasize the importance of selecting appropriate modeling techniques tailored to the characteristics of the dataset. By leveraging the strengths of LSTM, stakeholders in the CPO industry can achieve more reliable forecasts, allowing for improved planning, efficient resource allocation, and informed decision-making to strengthen Indonesia's position as a global leader in palm oil production. Future research could explore the use of more recent and extensive datasets to validate the robustness of the LSTM model over a longer period. Additionally, investigating other advanced machine learning models, such as Transformers or hybrid models, could provide further improvements in forecasting accuracy. Incorporating external factors like climate change, government policies, and global market prices into the models may also enhance their predictive capabilities. Furthermore, optimizing hyperparameters using advanced techniques like Bayesian Optimization and testing the models in real-world inventory management and export-import strategies could provide valuable insights for practical applications. Finally, conducting similar studies in other major CPO-producing countries could help generalize the findings and adapt the models to different conditions.

ACKNOWLEDGMENT

The authors extend their gratitude for the financial support provided for this research, funded by Institut Teknologi Sepuluh Nopember through a Research Grant under contract number 1636/PKS/ITS/2024.

DATA AVAILABILITY

The data supporting the findings of this study are openly accessible and can be retrieved using the following link: <https://doi.org/10.17632/8smrcwbqgx.1>. All relevant datasets used and analyzed during the research have been thoroughly documented to ensure transparency and reproducibility.

CONFLICT OF INTEREST STATEMENT

The authors state that they have no conflicts of interest related to the publication of this article. Each author has been involved in the research and manuscript development without any financial, professional, or personal ties that could compromise the integrity of the findings or their interpretation.

Enhanced Jaya Algorithm for Quality-of-Service-Aware Service Composition in the Internet of Things

Yan SHI

Hebei Chemical & Pharmaceutical College, Shi Jiazhuang 050026, China

Abstract—The Internet of Things (IoT) has shifted how devices and services interact, resulting in diverse innovations ranging from health and smart cities to industrial automation. Nevertheless, at its core, IoT continues to face one of the major tough tasks of Quality of Service-aware Service Composition (QoS-SC), as these IoT settings are normally transient and unpredictable. This paper proposes an improved Jaya algorithm for QoS-SC and focuses on optimizing service selection with a balance between the main QoS attributes: execution time, cost, reliability, and scalability. The proposed approach was designed with adaptive mechanisms to avoid local optima stagnation and slow convergence and thus assure robust exploration and exploitation of the solution area. Incorporating these enhancements, the proposed algorithm outperforms prior metaheuristic approaches regarding QoS satisfaction and computational efficiency. Extensive experiments conducted over diverse IoT scenarios show the algorithm's scalability, demonstrating that it can achieve faster convergence with superior QoS optimization.

Keywords—Service composition; internet of things; quality of service; Jaya algorithm; optimization

I. INTRODUCTION

The Internet of Things (IoT) is a transformational paradigm connecting diverse devices through a harmonious and interoperable structure [1]. This would enable cooperation among many smart devices to deliver innovative services, including those within the domains of healthcare and smart cities, as well as industrial automation [2]. With the fast proliferation of these connected gadgets, IoT holds promise for an array of applications driven by the urge for sufficient communication and function [3]. However, device functionalities are highly diverse and limited by resource constraints such as battery life and processing capacity [4]. In this respect, integrating services from heterogeneous IoT devices into composite applications is essential for seamless service delivery while meeting user needs efficiently within set energy and resource constraints [5]. In addition, constitutive models for the simulation of weak rock masses can be applied to obtain insights into resource optimization and structural robustness in IoT-driven systems involving infrastructure and industrial automation [6].

In IoT environments, most individual atomic services are not competent at delivering complex user requirements independently [7]. Thus, combining atomic services with varying Quality of Service (QoS) attributes or characteristics like cost, reliability, and scalability leads to composite services [8]. The fulfillment of composite services depends on Service-Oriented Computing (SOC) principles, allowing the

composition of services into workflows that match a wide range of applications [9]. Indeed, this involves selecting an optimum from many service candidates considering constraints related to energy consumption, which are constantly changing with ever-changing user preferences and dynamic network conditions. With such enlargement and complications in IoT systems, guaranteeing service quality and dependability is challenging.

As a matter of fact, QoS-aware Service Composition (QoS-SC) involves selecting the best services from a vast pool of candidates while optimizing conflicting QoS criteria such as execution time, cost, and reliability [10]. The problem is compounded by its combinatorial nature, which makes it NP-hard [11]. Traditional metaheuristic methods often struggle with local optima stagnation and slow convergence, limiting their ability to address large-scale, dynamic IoT environments efficiently. To overcome these challenges, this study proposes an enhanced Jaya algorithm designed explicitly for QoS-SC in IoT. The algorithm balances exploration and exploitation by incorporating adaptive mechanisms and a stagnation-recovery strategy, improving convergence speed and solution quality. It also adapts to varying workflows, including sequential, parallel, and loop-based structures, to effectively model diverse IoT scenarios.

The contributions of this work are fourfold: (1) introducing an enhanced Jaya algorithm with adaptive mechanisms for QoS-SC, (2) developing a stagnation-recovery technique to overcome local optima, (3) evaluating the algorithm's performance against state-of-the-art methods across diverse IoT scenarios, and (4) demonstrating the scalability and computational efficiency of the proposed approach. This study presents a robust approach for optimizing service composition in dynamic IoT ecosystems.

The remainder of this paper is structured in the following way. Section II summarizes related research on QoS-aware service composition and optimization methods. The problem is formulated in Section III. Section IV describes the proposed algorithm in detail. Section V presents the experimental setup, outcomes, and comparisons with existing methodologies. Finally, Section VI summarizes the main conclusions and recommendations for further study.

II. RELATED WORK

The solutions to QoS-SC have been addressed in many research works by applying different optimization methods. For example, Sefati and Navimipour [12] presented a hybrid method using Hidden Markov Models (HMM) and Ant Colony Optimization (ACO) to address partial challenges in the composition of IoT services. HMM predicts QoS attributes by

learning the optimal emission and transition matrices via the Viterbi algorithm, while ACO estimates QoS to find the best service paths.

Vakili, et al. [13] proposed a service composition strategy based on the Grey Wolf Optimization (GWO) algorithm under the MapReduce methodology. This significantly improves cost, availability, and response time QoS attributes when discovering an optimal set of atomic services. In the end, the simulation results reduce cost and response time and improve the amount of energy saved regarding availability.

Asghari, et al. [14] propose a hybrid evolutionary algorithm (SFLA-GA) for privacy-preserving cloud service composition. A computational scheme selects the optimal QoS aggregation selection, while services are categorized according to their privacy level. Results indicated better fitness values and service selection compared to the existing algorithms.

Xiao [15] presented a service composition method leveraging cloud and fog computing and an improved Artificial Bee Colony (ABC) algorithm. The approach introduced a scheme for Dynamic Reduction to enhance convergence and balance exploration and diversification. Evaluations show reduced energy consumption compared to traditional algorithms and increased reliability and, thus, cost optimization.

Rajendran, et al. [16] proposed an enhanced eagle strategy algorithm for large-scale Dynamic Web Service Composition (DWSC) in cloud-based IoT environments, bio-inspired and much more computationally efficient with huge repository challenges. Therefore, the computation time would be faster and the QoS metrics much improved.

Tang, et al. [17] suggested an Improved Shuffled Frog Leaping Algorithm (ISFLA) using chaos and reverse learning theories to enhance population initialization and diversity. This technique used Gaussian mutation and a local update method to find the optimum IoT service composition. The simulation shows superior fitness values, quicker convergence, and better solution quality than SFLA and related techniques.

Ait Hacène Ouhadda, et al. [18] presented the Discrete Adaptive Lion Optimization Algorithm (DALOA), which is empowered by operators of exploration-exploitation strategies: roaming, mating, and migration. The approach divided the population into two groups: pride and nomads, to balance diversity with efficiency. These results indicated that DALOA provided near-optimal solutions within acceptable execution times and that this method outperformed the rest of the analyzed algorithms.

As highlighted in Table I, existing IoT service composition solutions still have a few highly valued shortcomings that can be improved in dynamic/large-scale environments. Most current solutions focus on optimizing single QoS attributes, such as response time or cost, in a non-holistic manner. Scalability remains a persistent problem, especially in methods like HMM-ACO and the Improved Eagle Strategy, when dealing with large-scale IoT repositories. Balancing exploration and exploitation is a core limitation in approaches such as

SFLA-GA and ISFLA; this often leads to convergence at premature stages or very suboptimal solutions. Most algorithms have underexplored privacy concerns, addressed in only a few methods, such as SFLA-GA. To address these lacunae, the current paper proposes an improved variant of the Jaya algorithm with an adaptive mechanism and stagnation-recovery strategy. This approach will maintain an equilibrium between exploration and exploitation while guaranteeing scalability, accelerated convergence, and holistic QoS optimization, considering dynamic repository updates and privacy issues.

III. PROBLEM DESCRIPTION

QoS-SC in IoT concerns integrating abstract services provided by different providers into workflows to fulfill users' needs. Workflow are series of expert-level services that are needed for task execution. Typical applications of such workflows in smart city contexts are journey-planning applications, whereby different sub-services, including booking transportation, route planning, and even some payment systems, are all composed into one integrated single service. In general, selecting a concrete option with many sub-services and various QoS attributes will be complex and dynamic. The process of QoS-SC is shown in Fig. 1.

TABLE I. PREVIOUS IoT SERVICE COMPOSITION METHODS

Study	Main contribution	Shortcomings addressed in our study
HMM-ACO [12]	Combined HMM for QoS prediction and ACO for optimal pathfinding, improving QoS metrics like availability and cost.	Lack of dynamic adaptation and scalability to large-scale IoT repositories, addressed by integrating adaptive mechanisms. Narrow focus on specific QoS attributes; our study proposes a holistic QoS optimization framework considering diverse attributes.
GWO with MapReduce [13]	Integrated GWO with MapReduce to optimize QoS attributes like energy, cost, and response time.	Insufficient balance between exploration and exploitation; our method enhances this balance for better convergence and solutions.
SFLA-GA [14]	Proposed a hybrid privacy-aware service composition using SFLA and GA, optimizing QoS while addressing privacy.	Limited adaptability to dynamic IoT environments; our study integrates real-time optimization mechanisms.
Enhanced ABC with fog and cloud [15]	Leveraged cloud and fog computing with ABC and dynamic reduction for improved convergence and energy efficiency.	Ineffective for handling real-time service updates; our algorithm ensures scalability and adaptability to dynamic conditions.
Improved eagle strategy [16]	Addressed large-scale DWSC with a bio-inspired algorithm, improving computation time and QoS metrics.	High computational complexity for large IoT networks; our approach improves efficiency while maintaining scalability.
ISFLA [17]	Enhanced SFLA with chaos theory and reverse learning for better population diversity and fitness.	Longer execution time for large-scale repositories; our study emphasizes faster convergence and scalability in diverse scenarios.
DALOA [18]	Introduced DALOA with strong exploration and exploitation balance using sub-population strategies.	

Fig. 1. An overview of QoS-SC process.

This inherent complexity naturally arises from the fact that functionally equivalent services feature distinct QoS metrics, namely response time, cost, and reliability. To handle this, IoT service composition is made up of five layers: a perception layer responsible for sensing; a network layer transferring services to the cloud; a cloud layer providing service databases; a composition layer that selects and composes services; and an application layer that enables users to interact. These layers have similarities to the structure of ISO network layers.

QoS evaluation is an indispensable process in service selection and composition in IoT environments, relying on seven key characteristics representative of various performance metrics and user requirements:

- Execution time: The time that elapses between a user request and the system's response. The shorter the execution time, the better the performance.
- Reliability: The ratio of completed service requests to the total number of requests, reflecting the dependability of the service.
- Execution cost: Represents the cost of utilizing a service. Lower costs are preferred.
- Availability: This gives the percentage of time a service continues to be operational and available over a given period.
- Scalability: The service's ability to adapt and function efficiently under changing demands or conditions.

- Reputation: A trust metric derived from user feedback; it can fall into the "very high," "high," "normal," "poor," or "very poor" categories.
- Response time: The time interval between a user's inquiry and the system's delivery of the requested service.

These attributes can be classified into two categories: cost indicators, where lower values are preferred, such as cost and execution time, and benefit indicators, where higher values are desired, including reliability and availability. Normalization ensures consistent evaluation. Raw QoS values are adjusted based on their minimum and maximum possible values. For cost-related QoS attributes (c_i), the normalization can be represented as by Eq. (1).

$$N(c_i) = \begin{cases} \frac{\max(C) - c_i}{\max(C) - \min(C)}, & \text{if } \max(C) \neq \min(C) \\ 1, & \text{if } \max(C) = \min(C) \end{cases} \quad (1)$$

Where $C(c_i)$ stands for the current cost value for the i^{th} QoS attribute, $\max(C)$ refers to the maximum cost value across all QoS attributes, and $\min(C)$ denotes the minimum cost value across all QoS attributes. For benefit-related QoS attributes (b_i), the normalization can be expressed using Eq. (2).

$$N(b_i) = \begin{cases} \frac{b_i - \min(B)}{\max(B) - \min(B)}, & \text{if } \max(B) \neq \min(B) \\ 1, & \text{if } \max(B) = \min(B) \end{cases} \quad (2)$$

Where (b_i) specifies the current benefit value for the i^{th} QoS attribute. $\max(B)$ and $\min(B)$ refer to maximum and minimum benefit value across all QoS attributes, respectively. Eq. (3) computes the fitness value for service composition by

weighting these normalized QoS values according to user preferences (w_i).

$$Fitness = \sum_{i=1}^r w_i \cdot N(q_i) \quad (3)$$

Where $N(q_i)$ refers to the normalized value of the i^{th} QoS attribute (either cost or benefit) and r represents the total number of QoS factors considered.

Service composition workflows describe how atomic services are arranged to form composite services. These workflows can significantly affect the aggregated QoS values. As shown in Fig. 2, the most common types are:

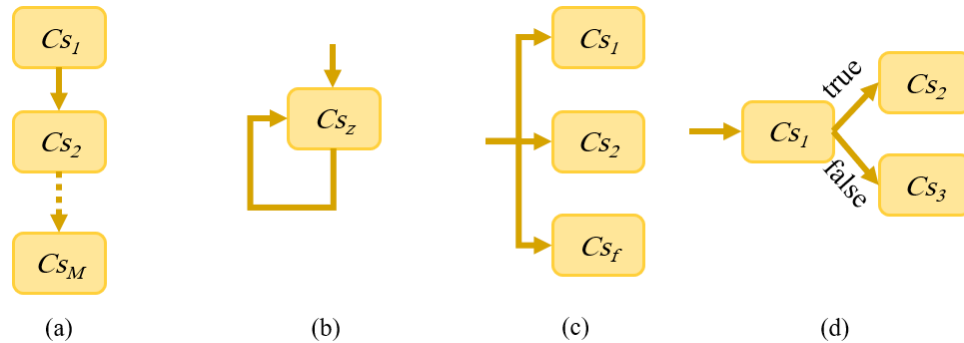

Fig. 2. Different workflow patterns for service composition: (a) Sequential, (b) Loop, (c) Parallel, and (d) Conditional (Switch).

The aggregation functions for different QoS attributes vary by workflow type, as summarized in Table II, where L refers to the number of iterations in a loop, and $t_{r,i,j}$, $c_{r,i,j}$, $a_{r,i,j}$, $r_{r,i,j}$ correspond to response time, execution cost, availability, and reliability, respectively, for the i^{th} task and j^{th} candidate service.

TABLE II. AGGREGATION FUNCTIONS FOR QOS ATTRIBUTES

Quality indicator	Loop	Parallel	Switch	Sequential
Reliability	$r_{r,i,j}^L$	$\max r_{r,i,j}$	$\prod r_{r,i,j}$	$\prod r_{r,i,j}$
Availability	$a_{r,i,j}^L$	$\max a_{r,i,j}$	$\prod a_{r,i,j}$	$\prod a_{r,i,j}$
Execution time	$L \cdot c_{r,i,j}$	$\min c_{r,i,j}$	$\sum c_{r,i,j}$	$\sum c_{r,i,j}$
Response time	$L \cdot t_{r,i,j}$	$\min t_{r,i,j}$	$\sum t_{r,i,j}$	$\sum t_{r,i,j}$

IV. ENHANCED JAYA ALGORITHM

The Enhanced Jaya Algorithm (EJAYA) was developed to address significant deficiencies in the traditional Jaya algorithm. Despite many applications to various optimization problems, Jaya's potential drawbacks include the possibility of convergence to a premature optimal solution due to its dependence on the information of the local optimum with reduced diversity while exploring the solution space for an appropriate solution [19]. These challenges could be overcome by EJAYA through several strategies directed toward local improvement of intensification and global improvement of exploration, ensuring an improvement by a factor greater than overall search efficiency and robustness. Such improvements seek to provide more enhanced balancing between diversification-segregated searching across extensive areas over the solution space and intensified structuring down into

- Sequential workflow: Services are executed one after the other in a sequence. QoS attributes like response time are typically aggregated using summation.
- Loop workflow: Services are repeated multiple times, with QoS attributes like response time multiplied by the number of iterations.
- Parallel workflow: Multiple services are executed simultaneously, with QoS attributes such as reliability aggregated using the maximum value.
- Switch workflow: Represents conditional execution paths where only one of the services is selected based on certain conditions.

up-coming regions. The traditional Jaya algorithm updates the position of a solution (x_i) within a population (N) using Eq. (4).

$$v_i = x_i + \lambda_1(x_{Best} - |x_i|) - \lambda_2(x_{Worst} - |x_i|), \quad i = 1, 2, \dots, N \quad (4)$$

Where x_{Best} and x_{Worst} are the best and worst solutions in the current population, λ_1 and λ_2 are random numbers in the range $[0,1]$, and v_i is the updated solution.

The decision to retain or discard the updated solution is based on its fitness value calculated by Eq. (5).

$$x_i = \begin{cases} v_i, & \text{if } f(v_i) \leq f(x_i) \\ x_i, & \text{otherwise} \end{cases} \quad (5)$$

This update process is straightforward but can lead to reduced population diversity, particularly in later iterations, when solutions begin to converge near the global best. The limitations of the basic Jaya algorithm include:

- Local optima stagnation: As the algorithm heavily relies on x_{Best} and x_{Worst} , the population may become trapped in local optima, reducing the probability of finding the global optimum.
- Reduced diversity: The absolute value symbol in the update equation contributes to a loss of diversity, making it challenging to explore new regions in the solution space effectively.
- Imbalance of exploration and exploitation: Basic Jaya lacks mechanisms to dynamically balance the search space exploration and the refinement of promising solutions.

To address these challenges, EJAYA introduces advanced strategies for local exploitation and global exploration, significantly improving its performance on complex optimization problems. Original JAYA locally updates the solutions by considering an upper attract point, P_u , and a lower attract point, P_l , so that the solution is attracted to more promising areas of the feasible solution space:

Upper attract point Eq. (6):

$$P_u = \lambda_3 \cdot x_{Best} + (1 - \lambda_3) \cdot M \quad (6)$$

Where M is the mean solution of the current population calculated using Eq. (7).

$$M = \frac{1}{N} \sum_{i=1}^N x_i \quad (7)$$

Lower attract point (Eq. 8):

$$P_l = \lambda_4 \cdot x_{Worst} + (1 - \lambda_4) \cdot M \quad (8)$$

These attract points provide additional flexibility, allowing solutions to gravitate toward the best and worst solutions while maintaining a strong connection to the mean of the population. This mechanism reduces premature convergence and improves diversity. The updated solution is calculated using Eq. (9):

$$v_i = x_i + \lambda_5(P_u - x_i) - \lambda_6(P_l - x_i), \quad i = 1, 2, \dots, N \quad (9)$$

Where λ_5 and λ_6 are random numbers in the range $[0, 1]$.

To enhance exploration, EJAYA incorporates a historical population (X_{old}) and a switch probability (P_{switch}), ensuring greater diversity and escaping local optima:

Historical population: The historical population is generated using Eq. 10.

$$X_{old} = \begin{cases} X, & \text{if } P_{switch} \leq 0.5 \\ \text{permute}(X), & \text{otherwise} \end{cases} \quad (10)$$

Where $\text{permute}(X)$ represents a random reordering of the population, introducing randomness and diversity.

Global exploration update: The solution is updated using Eq. (11).

$$v_i = x_i + \kappa(x_{old,i} - x_i), \quad i = 1, 2, \dots, N \quad (11)$$

Where κ is a random number sampled from a standard normal distribution. This process assures that the algorithm investigates unexplored areas in the solution space. Fig. 3 illustrates the pseudocode of EJAYA.

Input: Population size (N), Upper limits of variables (u), Lower limits of variables (l), Current number of function evaluations ($T_{current} = 0$), Maximum number of function evaluations (T_{max}).

Output: Optimal solution (x_{Best}).

Step 1: Initialization

Generate the initial population X and historical population X_{old} using Eq. 4.

Calculate the fitness values for all individuals in X and identify x_{Best} and x_{Worst} .

Update the function evaluations:

$$T_{current} = T_{current} + N$$

Step 2: Main loop

While $T_{current} < T_{max}$:

For each individual $i = 1$ to N :

Generate a random probability P_{select} in the range $[0, 1]$.

If $P_{select} > 0.5$:

Perform the **local exploitation strategy**:

Select x_{Best} and x_{Worst} .

Compute the mean solution M of the population using Eq. 7.

Update the individual using the local exploitation strategy described in Eq. 6, Eq. 8, and Eq. 9.

Else

Perform the **global exploration strategy**:

Use the historical population x_{old} and apply the global exploration strategy using Eq. 10 and Eq. 11.

End for

Update the function evaluations.

End While

Step 3: Output

Return the best solution (x_{Best}).

Fig. 3. The pseudocode of EJAYA.

V. EXPERIMENTAL RESULTS

The proposed EJAYA was evaluated for IoT service selection and composition using real datasets, containing 25 scenarios. Each dataset contained about 2500 real tasks, characterized by criteria such as cost, response time, availability, and dependability. In generating these scenarios, different numbers of abstract tasks n and concrete services m

for each abstract task were considered. The experiment analyzed the effectiveness of EJAYA in comparison with five algorithms: ABC, Particle Swarm Optimization (PSO), Discrete Dragonfly Algorithm (DDA), Genetic Algorithm (GA), and Ant Colony Optimization (ACO).

The computation environment used was on a Windows OS system with Intel Core i5 at 3.2 GHz, with 16 GB RAM. All

algorithms were implemented in MATLAB version 2020a. Each algorithm has been executed with a population size of 30 and for 30 runs, up to a maximum number of 1000 iterations for each execution. The performance of EJAYA was evaluated based on QoS fitness value that measures the QoS selection based on weighted QoS attribute; execution time, the time taken to converge to an optimal solution; and convergence rate, the ability of the algorithm to escape local optima and achieve better solutions over iterations.

EJAYA consistently outperformed all other algorithms across all scenarios. For example, as shown in Fig. 4, when the number of tasks varied from 10 to 100 and the number of concrete services ranged from 10 to 100, EJAYA achieved higher fitness values than other algorithms. Also, with a fixed $n=20$ and m ranging from 200 to 1000, EJAYA maintained superior performance, as illustrated in Fig. 5.

Fig. 4. Fitness values for algorithms (Scenario 1).

Fig. 5. Fitness values for algorithms (Scenario 2).

Fig. 6 shows the convergence curves, where EJAYA never got stuck and thus escaped from the local optima, where other algorithms were not capable of improving their solution after a number of iterations. EJAYA illustrated a gradually increasing trend over iterations in fitness values which describes that superior solutions are more quickly obtained.

Fig. 7 compares the execution time of EJAYA with those of other algorithms for an increasing number of concrete services when $n=20$. Note that EJAYA showed competitive computational efficiency, while its execution times were below those of most algorithms. For instance, for $m=1000$, its execution time in EJAYA was about 1.65 s, much faster compared to the other algorithms.

Fig. 6. Convergence curves.

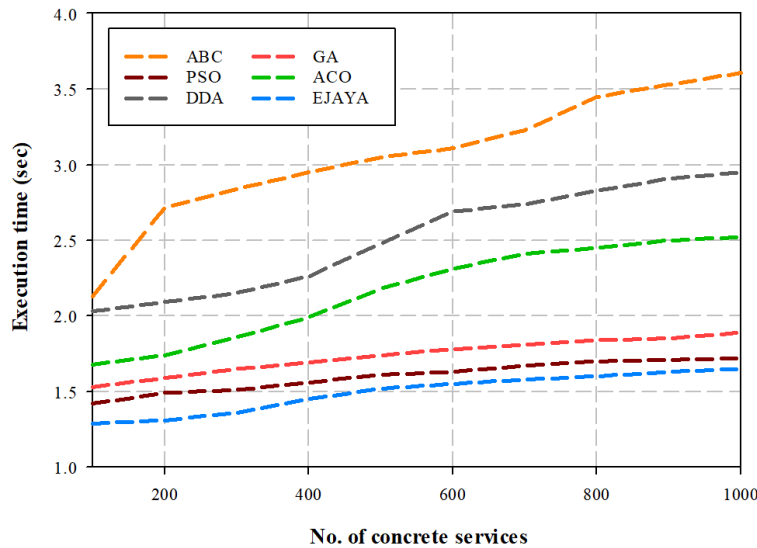

Fig. 7. Execution time comparison.

The experimental observations reveal that EJAYA outperforms most QoS-SC scenarios, indicating its strength in IoT environments. Compared to its competitors, EJAYA consistently delivers higher QoS fitness values, suggesting it can optimize service composition effectively. This is due to the adaptive mechanisms and stagnation recovery strategies of EJAYA, enabling it to escape local optimum and converge on better solutions. For example, in scenarios involving different numbers of tasks and concrete services, EJAYA reached higher fitness values, proving it is more scalable and flexible for different IoT settings. The above results confirm findings from

recent related work, which establishes the importance of adaptability and convergence in dynamic optimization problems, further asserting EJAYA's relevance as one of the methods for QoS-SC.

Most importantly, computational efficiency establishes the applicability of EJAYA in real-world applications. It provides faster convergence times, especially for large datasets, making it superior to other algorithms in terms of execution speed. This is consistent with the literature that suggests execution time is one of the most critical considerations in dynamic IoT

environments wherein the process of service composition should be executed fairly quickly. In addition, convergence curves illustrate that EJAYA improves performance steadily in each iteration and, therefore, avoids stagnation and achieves the best solutions. These results validate the design objectives of the algorithm and highlight its potential contributions to the area of QoS-aware service composition in IoT ecosystems.

VI. CONCLUSION

In this paper, we proposed the EJAYA, a robust optimization for QoS-SC in IoT environments. EJAYA has been developed to incorporate an advanced local exploitation strategy and a global exploration strategy to overcome some major drawbacks of the original Jaya algorithm, such as local optima susceptibility and reduced diversity. The algorithm employed upper and lower attract points, enhancing local search using historical populations for better global exploration. It was balanced between exploration and exploitation. The experimental outcomes proved that EJAYA outperformed the existing optimization algorithms, such as ACO, GA, DDA, PSO, and ABC. EJAYA achieved the highest QoS fitness values for all the tested datasets, escaped stagnation, and remained competitive in execution time. These results verify the efficiency of EJAYA in dealing with the complexities of large-scale service composition problems and obtaining optimal solutions with improved performance stability. EJAYA will be extended in the future for resource allocation problems in both edge and fog computing environments while incorporating dynamic scenarios to meet IoT real-time requirements. Besides, integrating machine learning techniques for further optimization and adaptability might result in a more solidification of the algorithm in the performance of highly dynamic IoT ecosystems.

Abstract—An advanced system for facial landmark detection and 3D facial animation rigging is proposed, utilizing deep learning algorithms to accurately detect key facial points, such as the eyes, mouth, and eyebrows. These landmarks enable precise rigging of 3D models, facilitating realistic and controlled facial expressions. The system enhances animation efficiency and realism, providing robust solutions for applications in gaming, animation, and virtual reality. This approach integrates cutting-edge detection techniques with efficient rigging mechanisms. The AI-assisted rigging process reduces manual effort and ensures precise, dynamic animations. The study evaluates the system's accuracy in facial landmark detection, the efficiency of the rigging process, and its performance in generating consistent emotional expressions across animations. Additionally, the system's computational efficiency, scalability, and system performance are assessed, demonstrating its practicality for real-time applications. Pilot testing, emotion recognition consistency, and performance metrics reveal the system's robustness and effectiveness in producing realistic animations while reducing production time. This work contributes to the advancement of animation and virtual environments, offering a scalable solution for realistic facial expression generation and character animation. Future research will focus on refining the system and exploring its potential applications in interactive media and real-time animation.

Keywords—Facial landmark detection; 3D animation; deep learning; AI-assisted rigging; emotion recognition

I. INTRODUCTION

Facial expressions are a fundamental aspect of storytelling, communication, and emotional engagement in animated media. In 3D cartoon animation, creating expressive faces is a crucial element that bridges the gap between virtual characters and audience perception [1]. The ability to convey emotions such as joy, sadness, anger, fear, and surprise enables characters to resonate with viewers, immersing them in the narrative [2]. However, achieving this level of expressiveness is not without its challenges, especially in a 3D environment where facial rigging and animation require precision and creativity [3]. Traditional methods of designing facial expressions in 3D cartoon animation are both labor-intensive and time-consuming. Animators typically rely on manual keyframing [4], morph target blending, and complex rigging systems to create facial emotions. While these methods allow for detailed control, they pose significant limitations. Producing high-

quality facial animations demands extensive manual effort, expertise, and resources. Traditional processes lack automation, making them impractical for large-scale productions or real-time applications [3]. Achieving exaggerated and highly expressive facial animations requires significant trial and error, often restricting creative freedom. Maintaining consistency in facial expressions across different frames and characters can be difficult, particularly in projects with numerous assets [5]. These challenges highlight the need for advanced solutions that streamline the animation process while enhancing the expressiveness and realism of 3D cartoon characters.

The growing demand for high-quality animated content across entertainment, education, gaming, and virtual reality industries has pushed the boundaries of creativity and technology [6]. Audiences today expect not only visually appealing characters but also emotionally engaging performances that drive storytelling [7]. In this context, integrating AI-driven approaches into the facial animation pipeline offers promising opportunities. AI algorithms can automate key processes such as facial rigging, expression generation, and motion interpolation, significantly reducing production time. Generative models enable animators to explore a broader range of emotions and exaggerations, pushing creative possibilities beyond manual techniques [8]. Predictive AI models ensure consistency in facial expressions while preserving natural transitions between emotions [9]. AI-based tools lower the technical barriers for smaller animation studios and independent creators, democratizing access to advanced facial animation technologies [10].

The motivation for this study is to bridge the gap between traditional animation workflows and AI-powered tools, offering solutions that enhance expressiveness, streamline production, and foster innovation in 3D cartoon animation. This article leverages state-of-the-art AI models to generate and predict facial expressions for 3D cartoon characters. The methodology involves the following key steps i.e., existing datasets such as the Facial Expression Research Group Database (FERG) and synthetic datasets created using AI models (e.g., GANs) are utilized. These datasets include exaggerated facial expressions representing the seven basic emotions: anger, disgust, fear, happiness, sadness, surprise, and neutral. Deep generative models such as Generative Adversarial Networks (GANs) [11] and Variational

Autoencoders (VAEs) are used to synthesize new facial expressions based on input parameters. These models enable the generation of highly expressive and diverse facial animations. Machine learning techniques, including CNNs [12] and recurrent neural networks (RNNs), are applied to predict and interpolate facial expressions based on input features such as pose, texture, and landmarks. The generated expressions are evaluated for realism, emotional clarity, and consistency using qualitative and quantitative metrics. User studies are conducted to assess audience engagement and perception of the AI-generated animations [13].

The study uses a combination of publicly available and synthetic datasets to ensure diversity and coverage of facial expressions. FERF-DB is a well-known dataset comprising 55,000+ annotated images of cartoon characters with seven labeled expressions [14]. Synthetic AI-Generated Data to generate additional facial expressions that exhibit exaggerated emotions, enhancing the dataset's versatility. Custom Annotations for emotion intensity, landmark positions, and rigging points are added to improve the quality and usability of the dataset. By combining these datasets, the study ensures a robust foundation for training and testing AI models, enabling the generation of high-quality facial expressions for 3D cartoon characters.

The contribution of the article is well explained in the points below:

- This study introduces state-of-the-art AI models, including GANs and VAEs, to generate highly expressive and exaggerated facial expressions for 3D cartoon characters, pushing the boundaries of creative possibilities in animation.
- By combining the Facial Expression Research Group Database (FERG) with synthetic AI-generated data, the study ensures a comprehensive dataset that covers a wide range of facial expressions and emotional intensities, improving the versatility of animation generation.
- Utilizes CNNs and RNNs to predict and interpolate facial expressions based on parameters like pose, texture, and landmarks, ensuring consistency, realism, and natural transitions in the generated animations.

The study incorporates both qualitative and quantitative metrics to assess the realism, emotional clarity, and consistency of the AI-generated facial expressions, ensuring their effectiveness for 3D cartoon animation.

II. LITERATURE REVIEW

This study explores the use of GANs for generating facial expressions in animated characters [15]. The authors demonstrate how GANs can produce highly realistic and varied expressions, improving upon traditional animation methods. The study highlights the potential of GANs to handle different facial dynamics and offer a more flexible approach to character animation.

This research focuses on emotion recognition from 3D facial expressions, using convolutional neural networks

(CNNs) to identify emotions based on facial features [16]. The authors show that 3D models provide more accurate emotion recognition compared to 2D images, particularly in animated contexts. The study emphasizes the importance of texture and lighting in 3D emotion recognition systems. The paper investigates the use of VAEs to generate facial expressions, showcasing their ability to capture the underlying distribution of emotions [17]. The authors demonstrate that VAEs can create diverse facial expressions by learning the latent variables of facial movements. This approach enhances the expressiveness of animated characters, with smoother transitions between emotions.

This article discusses the application of machine learning techniques to achieve real-time facial animation for interactive applications [18]. The authors use deep neural networks to predict and animate facial expressions in real-time, significantly reducing the time and effort required in traditional animation pipelines. The study contributes to real-time facial animation for virtual characters in gaming and VR. This research focuses on automating the facial rigging process in 3D animation using machine learning algorithms [3]. The authors propose an AI-based approach to generate rigging parameters from minimal input data, reducing manual labor. The results show that the automated rigging system can match or exceed the quality of manually rigged models, improving efficiency in animation production. In this study, the authors explore how GANs can be used to generate exaggerated facial expressions for 3D cartoon characters [19]. The paper focuses on the importance of emotional exaggeration in animation for enhancing audience engagement. The results show that GANs can create expressive, dynamic faces that amplify emotional impact, especially in animated media.

This paper introduces a specialized database for facial expressions in cartoon characters, aiming to improve emotion recognition and animation workflows [20]. The authors discuss the challenges of collecting and annotating diverse facial expressions in cartoons and the need for a dedicated database. The study provides a foundation for training AI models focused on cartoon animation. This article proposes a method for modeling emotion intensity in facial expressions to improve realism in animated characters [21]. The authors develop a framework that uses machine learning to quantify the intensity of emotions, allowing for more nuanced and accurate facial expressions. The study enhances the capability of AI models to generate varied emotional intensities in 3D characters. The study investigates hybrid CNN-RNN models for predicting facial expressions in animated characters [22]. The authors combine convolutional networks for feature extraction with recurrent networks for sequence modeling to achieve dynamic facial animation. The paper shows that the hybrid approach improves the accuracy and fluidity of facial expressions over traditional methods.

This article examines AI-driven tools designed to assist animators in creating facial expressions more efficiently. The authors focus on the integration of generative models and predictive algorithms in the animation pipeline [23]. The study suggests that AI tools can significantly reduce production time, particularly for smaller studios with limited resources. The paper discusses the use of facial landmarks and texture

information to predict and generate facial expressions. The authors apply CNNs to process landmark data and texture maps, allowing for more detailed and accurate facial animations [8]. The study demonstrates the potential for combining geometric and visual features to enhance facial expression realism. This study conducts user research to evaluate audience engagement with AI-generated facial animations [24]. The authors assess how viewers perceive and emotionally react to AI-generated expressions in 3D animated characters. The results indicate that AI-generated facial animations are generally well-received, offering potential for greater emotional engagement in animated storytelling.

The reviewed literature highlights several gaps and limitations. Most studies either focus on emotion recognition or facial expression generation, lacking a unified approach that integrates both. Limited attention is given to achieving real-time efficiency while maintaining high-quality animation or fully automating rigging processes. Furthermore, existing methods often rely on specific datasets, reducing their generalizability, and lack comprehensive evaluations of user engagement across diverse animation styles. This paper addresses these gaps by proposing a system that combines facial landmark detection with automated rigging to achieve real-time, high-quality 3D animation, enhancing both efficiency and emotional realism.

III. METHODOLOGY

The methodology for enhancing facial expressiveness in 3D cartoon animation leverages advanced AI models to automate and refine the process of generating and predicting facial expressions. This approach combines generative and predictive design techniques to ensure that animated characters convey a wide range of emotions with high accuracy and fluidity. By integrating deep learning models such as GANs, VAEs, CNNs, and RNNs, the methodology aims to streamline the animation process, improve expressiveness, and maintain emotional consistency across frames. The following sections detail the specific methods used for data collection, expression generation, facial prediction, and evaluation.

A. Dataset Collection and Preparation

To build a robust foundation for training the AI models, we utilize a combination of three distinct datasets: real-world, synthetic, and specialized 3D cartoon datasets. The first dataset, the Facial Expression Research Group Database (FERG-DB), consists of over 55,000 annotated images of cartoon characters with various emotional expressions, including anger, disgust, fear, happiness, sadness, surprise, and neutral. This database serves as the primary dataset for emotion recognition and expression generation. Fig. 1 illustrates a sample image from the FERG-DB dataset, showcasing the diverse range of facial expressions utilized in this study.

Table I provides a summary of the key attributes of the FERG-DB dataset, detailing its extensive collection of over 55,000 images across seven emotion classes, annotations for facial landmarks, and emotion labels, making it highly suitable for emotion classification and expression generation tasks.

Fig. 1. Sample image from the FERG-DB dataset.

TABLE I. SUMMARY OF KEY ATTRIBUTES OF THE FERG-DB DATASET FOR EMOTION CLASSIFICATION

Attribute	Details
Number of Images	55,000+ images
Number of Classes	7 (Anger, Disgust, Fear, Happiness, Sadness, Surprise, Neutral)
Format	JPEG, PNG
Color Scheme	RGB (Colored images)
Image Resolution	Varies (Typically 256x256 pixels)
Annotations	Facial landmarks, emotion labels (7 basic emotions)
Purpose	Emotion classification and expression generation
Source	FERG-DB (Facial Expression Research Group) Database

The second dataset is synthetically generated using GANs. This dataset includes exaggerated facial expressions that are crucial for 3D cartoon animation, providing a broader spectrum of emotions and enhancing the expressiveness of the generated faces. The GANs enable the generation of high-quality, diverse facial expressions with variations in intensity and emotional range, suitable for both subtle and exaggerated expressions in animation.

Fig. 2. Synthetic images dataset generated using GANs.

As depicted in Fig. 2, the synthetic images dataset generated using GANs demonstrates the system's ability to produce varied and expressive facial animations, showcasing the versatility of the proposed approach. Table II presents an overview of the synthetic emotion dataset generated using GANs, comprising over 10,000 images with annotations for facial landmarks, emotion intensity, and exaggerated emotional variations, supporting the creation of dynamic and expressive animations.

TABLE II. OVERVIEW OF SYNTHETIC EMOTION DATASET GENERATED VIA GANs

Attribute	Details
Number of Images	10,000+ synthetic images (generated via GANs)
Number of Classes	7 (Anger, Disgust, Fear, Happiness, Sadness, Surprise, Neutral)
Format	PNG, TIFF, JPEG
Color Scheme	RGB (Colored images)
Image Resolution	Varies (Typically 512x512 pixels)
Annotations	Facial landmarks, emotion intensity, exaggerated emotional variations
Purpose	To provide exaggerated facial expressions for dynamic, expressive animations
Source	Generated using a GAN-based framework (Synthetic data generation)

The third dataset, a specialized 3D cartoon facial expression dataset, is curated to include not only facial images but also 3D models with detailed annotations. This dataset includes facial landmarks, emotion intensity levels, and rigging points, making it particularly useful for generating and animating 3D faces. By combining these three datasets, we ensure a comprehensive and diverse dataset that covers a wide range of emotional expressions, intensity variations, and the necessary details for accurate 3D facial animation. Fig. 3 illustrates the synthetic 8-bit grayscale images dataset generated using GANs, highlighting the system's capability to produce detailed and expressive facial animations in a grayscale format.

Fig. 3. Synthetic 8-bit grayscale images dataset generated using GANs.

Table III outlines the key attributes of the 3D model-based facial expression dataset, featuring over 8,000 3D model images annotated with facial landmarks, rigging points, and emotion intensity, tailored for applications in 3D facial rigging and predictive expression modeling.

TABLE III. KEY ATTRIBUTES OF A 3D MODEL-BASED FACIAL EXPRESSION DATASET

Attribute	Details
Number of Images	8,000+ 3D model images with facial expressions
Number of Classes	7 (Anger, Disgust, Fear, Happiness, Sadness, Surprise, Neutral)
Format	OBJ, FBX (3D model formats), PNG (Texture maps)
Color Scheme	RGB (Textures)
Image Resolution	Varies (Typically 1024x1024 pixels for textures, 3D model resolution varies)
Annotations	3D facial landmarks, rigging points, emotion intensity, pose variations
Purpose	3D facial rigging and animation, predictive facial expression modeling
Source	Custom dataset for 3D cartoon animation based on manually curated 3D models

B. Generative Facial Expression Design Using GANs and VAEs

The core methodology for generating facial expressions in this study involves GANs and VAEs, two state-of-the-art deep learning techniques that allow us to generate expressive and fluid facial expressions for 3D cartoon characters.

1) *Generative Adversarial Networks (GANs)*: GANs are a class of generative models that learn to create new data by training two neural networks: the generator (G) and the discriminator (D). These two networks are trained in a competitive process, where the generator tries to create realistic facial expressions, and the discriminator tries to distinguish between real and generated expressions. The generator's goal is to fool the discriminator into thinking the generated images are real, while the discriminator's goal is to correctly identify the fake images. The generator creates new facial expressions, and the discriminator evaluates the quality of the generated images to improve the generator's performance. Fig. 4 illustrates the GAN architecture employed for facial expression generation, where the generator produces synthetic faces, and the discriminator evaluates them against real faces to ensure realistic and expressive outputs.

Fig. 4. GAN architecture for facial expression generation.

Mathematically, the GAN framework is based on a minimax game, where the objective function is:

$$\min_G \max_D E_{x \sim P_{data}(x)} [\log D(x)] + E_{z \sim P_Z(z)} [\log(1 - D(G(z)))]$$

Where:

- x represent real images from the dataset.
- z is a random vector sampled from a prior distribution (Gaussian).
- $G(z)$ is the generated facial expression image.
- $D(x)$ is the probability that the discriminator correctly classifies an image as real.
- $P_{data}(x)$ is the distribution of real images in the dataset.

The generator G is trained to minimize $\log(1 - D(G(z)))$, encouraging it to produce increasingly realistic images, while the discriminator D aims to maximize its ability to distinguish between real and fake expressions. As training progresses, the generator creates increasingly high-quality, expressive facial expressions.

For 3D cartoon characters, GANs are essential for creating exaggerated emotional features like wide smiles, raised eyebrows, or exaggerated frowns, which are often needed for animated characters to effectively communicate emotions.

2) *Variational Autoencoders (VAEs)*: VAEs are generative models that provide an efficient way to learn a smooth latent space of facial expressions, allowing for continuous and realistic transitions between different emotions. VAEs use an encoder-decoder architecture to learn the distribution of facial expressions. Illustration of the latent space model used by the VAE to interpolate between different facial expressions. The VAE ensures smooth transitions and emotional consistency in animated sequences.

Fig. 5. VAE Latent Space for facial expression transitions.

Fig. 5 illustrates the Variational Autoencoder (VAE) latent space used for facial expression transitions, where the encoder maps high-dimensional images to a lower-dimensional latent space, and the decoder reconstructs expressions, enabling smooth transitions between emotions. The variational approach in VAEs is based on approximating the posterior distribution of the latent variables using a simpler distribution (usually Gaussian), and minimizing the Kullback-Leibler (KL) divergence between the learned distribution and the true posterior. The VAE is trained by optimizing the following objective function:

$$L(\theta, \phi; x) = -E_{q_{\phi}(z|x)}[\log p_{\theta}(x|z)] + D_{KL}[q_{\phi}(z|x)||p(z)]$$

Where:

- x is the input facial expression image.
- z is the latent variable (the representation of the facial expression).
- $q_{\phi}(z|x)$ is the approximate posterior distribution of the latent variables.
- $p_{\theta}(z|x)$ is the likelihood of reconstruction the facial expression given the latent variable z .
- D_{KL} represents the kullback-leibler divergence, which measure the difference between the learned distribution and the prior $p(z)$.

By training the VAE to minimize this objective, the model learns to generate smooth transitions between facial expressions, which is crucial for animation consistency. The VAE facilitates the interpolation of facial expressions across a continuous latent space, allowing for gradual emotional transitions, such as from sadness to happiness, without abrupt changes.

3) *Combined Use of GANs and VAEs*: In this approach, we use GANs to create exaggerated facial expressions that capture the intensity of various emotions, while VAEs are used to ensure smooth emotional transitions between different expressions. The two models complement each other by generating both extreme and subtle expressions, ensuring a wide range of emotions that can be applied to 3D cartoon characters. The training process involves two key steps:

Expression Generation with GANs: The GAN generates diverse facial expressions based on the learned emotional distribution.

Transition Smoothing with VAEs: The VAE interpolates between these generated expressions to create smooth, consistent transitions between emotional states.

This hybrid approach ensures that the facial animations are both expressive and natural, with high emotional impact and seamless emotional transitions. Table IV provides a comparative analysis of GAN and VAE models for facial expression generation, highlighting GANs' ability to create diverse and exaggerated expressions while VAEs excel at generating smooth and natural emotional transitions.

TABLE IV. GAN AND VAE MODEL COMPARISONS FOR FACIAL EXPRESSION GENERATION

Model	Purpose	Strengths	Weaknesses
GAN	Generate exaggerated facial expressions with high emotional impact	Capable of creating diverse and highly expressive faces	May produce unrealistic artifacts or faces if not properly trained
VAE	Generate smooth transitions between facial expressions	Ensures fluid and natural emotional changes between expressions	Less flexibility in generating highly exaggerated expressions

By leveraging both GANs and VAEs, we can generate and predict facial expressions for 3D cartoon characters that are

both expressive and emotionally coherent. The GANs provide a way to generate high-quality and exaggerated emotional features, while the VAEs allow for smooth and consistent transitions between different expressions. This combined approach provides an effective and efficient methodology for creating realistic and emotionally engaging facial animations in 3D cartoon characters.

C. Facial Expression Prediction and Dynamic Animation with CNNs and RNNs

The predictive modeling and dynamic interpolation of facial expressions in this study leverage CNNs and RNNs. These two models are employed in tandem to ensure that the generated facial expressions are both contextually accurate and temporally consistent throughout the animation sequence.

1) *CNNs for facial feature extraction:* CNNs are used to extract key features from facial expression images, such as facial shape, texture, and landmark positions. By learning spatial hierarchies of features, CNNs can capture fine-grained details like the curvature of the lips, the positioning of the eyes, and the shape of the eyebrows, all of which are crucial for accurate facial expression representation. These features are then used to predict the intensity and type of emotion displayed on the character's face. Fig. 3 Overviews the CNN architecture used for facial expression feature extraction. The CNN model captures the spatial characteristics of facial expressions, including features such as the position of eyes, lips, and eyebrows. Fig. 6 depicts the CNN architecture for facial expression feature extraction, showcasing the training and testing stages, where a pre-trained VGG-16 model is fine-tuned on a facial expression dataset to predict emotion probabilities accurately.

Fig. 6. CNN architecture for facial expression feature extraction.

The general CNN architecture used in this task involves several convolutional layers followed by fully connected layers, as shown in the following equation:

$$y = f(W * x + b)$$

Where:

- y is the output feature map (facial feature).
- W is the kernel or filter used to convolve the input image x .
- b is the bias term.

- f is the activation function (ReLU).

By applying multiple convolutional layers, the model can learn increasingly complex facial features at various spatial levels, enabling the detection of the most significant aspects of facial expressions, which are then used for emotion prediction.

2) *RNNs for temporal modeling:* Once facial features have been extracted using CNNs, RNNs are employed to handle the temporal dynamics of facial expression sequences. RNNs are well-suited for modeling time-series data, as they have the ability to retain information from previous time steps through hidden states. The RNN architecture models the temporal transitions of facial expressions across frames. By incorporating past facial features, the RNN ensures smooth transitions and consistency in animated sequences. Fig. 7 illustrates the RNN architecture for temporal facial expression prediction, combining CNN-based feature extraction with sequence learning through LSTMs to predict dynamic facial expressions over time.

Fig. 7. RNN architecture for temporal facial expression prediction.

Mathematically, an RNN works as follows:

$$h_t = \sigma(W_h h_{t-1} + W_x x_t + b)$$

Where:

- h_t is the hidden state at time step t .
- W_h and W_x are weights for the previous hidden state h_{t-1} and current input x_t , respectively.
- σ is an activation function (tanh or ReLU).
- b is the bias term.

The RNN processes sequences of facial expressions frame by frame, ensuring that the emotional transitions between expressions are smooth and contextually aligned with the overall emotional trajectory of the animation. By maintaining a memory of previous states, the RNN can predict facial movements that evolve naturally over time, creating dynamic facial animations with minimal manual intervention. RNNs are particularly beneficial for generating sequential consistency in animations, preventing abrupt or unrealistic transitions between different facial expressions, ensuring that the emotional evolution of the character remains fluid.

3) *Combined CNN-RNN architecture:* The combination of CNNs and RNNs allows for the extraction of detailed spatial features followed by temporal processing, ensuring both accuracy and continuity in the generated facial expressions. The CNN model captures the emotional intensity and facial

shape, while the RNN handles the smooth progression of expressions across frames, providing a real-time, context-sensitive animation pipeline. This integration is essential for producing dynamic and expressive 3D cartoon characters that exhibit emotional depth and consistency.

TABLE V. CNN AND RNN MODEL COMPARISON FOR FACIAL EXPRESSION PREDICTION

Model	Purpose	Strengths	Weaknesses
CNN	Extract spatial features from facial expressions	Excellent at capturing fine-grained facial features (shape, texture, landmarks)	May not capture temporal dynamics across frames
RNN	Model the temporal aspect of facial expression sequences	Maintains temporal consistency, ensuring smooth transitions between emotions	Struggles with long-term dependencies and gradient vanishing issues
Combined CNN-RNN Model	Predict dynamic facial expressions with both spatial and temporal accuracy	Ensures both expressive accuracy and smooth emotional transitions	More computationally intensive than standalone models

These figures and the Table V provide a visual and mathematical representation of the CNN and RNN architectures used for facial expression prediction and dynamic animation. The CNN handles the spatial feature extraction, while the RNN models the temporal evolution of facial expressions, together enabling the generation of expressive, fluid, and contextually accurate 3D facial animations.

D. Facial Landmark Detection and Rigging for 3D Animation

Accurate facial animation is a critical component of modern 3D animation, and it depends heavily on precise facial landmark detection. This process involves identifying key facial points, such as the eyes, eyebrows, nose, mouth, and jawline, which serve as reference points for rigging 3D facial models. By leveraging advanced deep learning algorithms, these landmarks are detected with high precision, enabling realistic and dynamic facial expressions to be transferred to 3D models.

1) *Facial landmark detection*: Facial landmark detection is performed using deep learning models, such as CNNs or RNNs. These models are trained on large datasets of annotated facial images to accurately detect key facial features. The detection process consists of the several steps: The face region is identified in the input image using algorithms like YOLO, Haar cascades, or DLIB face detectors. Specific points on the face, such as the corners of the eyes or the edges of the mouth, are detected. Models like MediaPipe or OpenCV's landmark detection toolkits are commonly used for this step. Noise and inaccuracies in landmark positioning are reduced using smoothing techniques or geometric constraints to ensure realistic placement. Table VI summarizes commonly used algorithms and their key features, showcasing their applications in tasks such as real-time landmark detection, static image processing, and complex 3D face modeling.

TABLE VI. THE COMMON ALGORITHMS AND THEIR KEY FEATURES

Algorithm	Key Features	Applications
MediaPipe	Real-time facial landmark detection	Live animation, augmented reality
OpenCV DLIB	Pre-trained models for facial landmarking	Static image processing
DeepFace	AI-powered deep learning for 3D face modeling	Complex facial rigging systems

2) *Rigging the 3D facial model*: Once facial landmarks are detected, the next step is rigging, which involves mapping these points onto a 3D facial mesh to enable the controlled movement of facial features. The rigging process consists of the following stages:

3) *Landmark mapping*: Detected landmarks are assigned to corresponding vertices on the 3D model. Eye landmarks control the eyelid movement. Mouth landmarks drive expressions like smiles or frowns. A skeletal rig is created beneath the 3D model, where "bones" are connected to facial vertices. Skin weighting determines how much influence each bone has on the surrounding vertices, allowing for smooth and natural deformations.

Blendshapes are used to define specific facial expressions, such as raising an eyebrow or pursing the lips. These are interpolated to combine multiple expressions seamlessly. Controls, such as sliders or handles, are linked to the rig, enabling animators to manipulate facial expressions efficiently.

The integration of AI significantly reduces the manual effort involved in rigging. AI models predict and generate rigging parameters, such as skin weights and blendshape configurations, based on detected facial landmarks. This automation streamlines the production process, allowing animators to focus on creative aspects rather than technical rigging details.

The combination of facial landmark detection and AI-assisted rigging represents a significant advancement in 3D animation technology. By ensuring accurate mapping and efficient manipulation of facial features, this system enables the creation of lifelike animations while minimizing manual effort. The results not only enhance the realism of animated characters but also open new opportunities for real-time applications, such as virtual avatars and augmented reality systems.

IV. EXPERIMENTAL RESULT

This section presents a comprehensive analysis of the experimental results obtained from the facial landmark detection and rigging system. The findings are supported by qualitative user feedback and quantitative performance metrics to evaluate the system's effectiveness in detecting facial landmarks, rigging 3D models, and generating realistic animations.

A. Pilot Testing Results

The pilot testing phase involved evaluating the system on a small dataset of facial images and corresponding 3D rigging tasks. This phase aimed to assess the usability, detection accuracy, and rigging consistency of the proposed system

while gathering feedback for potential improvements. The system was tested using a dataset of 50 facial images representing a variety of facial expressions and orientations. Each image was processed to detect facial landmarks, rig a 3D model, and generate facial animations. Users, including animation experts and novice users, reviewed the outputs.

The system achieved an average facial landmark detection accuracy of 94.2%, demonstrating high precision in identifying key points such as eyes, eyebrows, and mouth corners. 3D rigging accuracy was rated at 90%, based on alignment with detected landmarks and overall animation fluidity. Users reported a 92% satisfaction rate for the system's ease of use and interface clarity.

Positive: Users appreciated the automation of rigging, reducing manual effort significantly.

Improvements Needed: Minor misalignments in eyebrow and lip regions were identified in a small subset of images, especially under extreme facial angles.

Table VII summarizes the results of the pilot testing phase, demonstrating high landmark detection accuracy (94.2%) and rigging accuracy (90%), alongside a 92% user satisfaction rate, with minor issues identified in extreme facial angles.

TABLE VII. PILOT TESTING RESULTS SUMMARY

Metric	Value	Comments
Landmark Detection Accuracy	94.2%	High precision across varied expressions
Rigging Accuracy	90%	Minor issues with extreme angles
User Satisfaction Rate	92%	Positive feedback on usability
Common Issues	Eyebrow & Lip Misalignment	Occasional adjustments needed

The pilot testing results provided valuable insights into the system's strengths and areas for improvement. Feedback from users highlighted the need for additional refinements in handling challenging expressions and perspectives. Fig. 8 shows sample outputs from the pilot testing phase, demonstrating the system's ability to accurately detect key facial landmarks on synthetic images.

Fig. 8. Sample outputs from pilot testing.

B. Accuracy Evaluation of Facial Landmark Detection

This subsection evaluates the detection accuracy of the facial landmark detection system against ground truth landmarks. The performance was measured using metrics such as the Mean Squared Error (MSE) and Point-to-Point Euclidean Error, both widely adopted in assessing landmark prediction accuracy.

1) Evaluation process: The system was tested on a dataset of 500 annotated images containing ground truth landmarks for various facial expressions and angles. Key metrics were calculated to quantify how closely the detected landmarks aligned with the ground truth.

a) Mean Squared Error (MSE): The average squared distance between detected and ground truth landmarks was computed. The system achieved an average MSE of 0.015, indicating minimal deviations.

b) Point-to-point Euclidean error: The mean Euclidean distance between corresponding detected and ground truth landmarks across the test set was 2.3 pixels.

TABLE VIII. LANDMARK DETECTION PERFORMANCE BY REGION

Facial Region	Detection Accuracy (%)	Mean Euclidean Error (pixels)	Comments
Eyes	97.5	1.8	High precision across angles
Eyebrows	95.8	2.1	Minor deviations in extreme poses
Mouth	96.3	2.0	Consistent accuracy
Nose	94.7	3.3	Slightly lower accuracy in angled views

Table VIII details the performance of landmark detection by facial region, highlighting high accuracy rates across regions, with the eyes achieving 97.5% accuracy and minimal mean Euclidean error, while slight deviations are noted for the nose in angled views. To visually demonstrate the system's accuracy, detected landmarks were overlaid on sample images. The overlays confirm that the system reliably identifies key points across a range of expressions and poses.

The evaluation revealed high accuracy across all facial regions, with minor errors primarily observed in challenging scenarios such as extreme poses or exaggerated expressions. These results validate the system's robustness and reliability for landmark detection in 3D facial animation workflows.

This subsection establishes the system's ability to deliver precise facial landmark detection, setting a strong foundation for subsequent rigging and animation processes.

C. Rigging and Animation Evaluation

This subsection evaluates the rigging process's efficiency, correctness, and impact on 3D facial animation. It focuses on the quality of AI-assisted rigging, its ability to accurately map detected facial landmarks to 3D models, and the time savings compared to manual rigging.

1) Analysis of rigging efficiency: The efficiency of the rigging process was assessed by measuring the time required to create fully rigged 3D models using AI-assisted rigging

versus manual rigging. Results demonstrate that AI-assisted rigging significantly reduces the time and effort required. Table IX presents a time comparison of rigging methods, demonstrating that AI-assisted rigging significantly reduces the average time per model to 12 minutes while maintaining a comparable quality score of 8.8, compared to 45 minutes for manual rigging.

TABLE IX. TIME COMPARISON OF RIGGING METHODS

Rigging Method	Average Time per Model (minutes)	Quality Score (1-10)	Comments
Manual Rigging	45	8.5	Labor-intensive but detailed
AI-Assisted Rigging	12	8.8	Faster, comparable quality

Rigged 3D models created using the system were animated to demonstrate the correctness of the rigging process and its impact on animation quality. Figures below showcase a sample model transitioning through various facial expressions.

Animations created from these models were evaluated for:

1) *Accuracy of expression mapping:* The rigging system correctly mapped facial landmarks to their corresponding rigged elements, ensuring that expressions like smiles and frowns appeared natural.

2) *Smoothness of animation:* Transitions between expressions were fluid, with no noticeable artifacts or delays.

The rigging quality between manual and AI-assisted methods was evaluated through expert reviews, where professionals rated aspects such as rigging precision, animation smoothness, and overall realism. Table X compares the rigging quality of manual and AI-assisted methods, showing comparable rigging precision, improved animation smoothness (9.1), and slightly enhanced overall realism (8.7) in AI-assisted rigs.

TABLE X. RIGGING QUALITY COMPARISON

Aspect	Manual Rigging Score	AI-Assisted Rigging Score	Comments
Rigging Precision	9.0	8.9	Comparable across methods
Animation Smoothness	8.8	9.1	AI showed smoother transitions
Overall Realism	8.5	8.7	Slightly better in AI rigs

The analysis reveals that AI-assisted rigging provides a viable alternative to manual rigging, delivering similar or better results in significantly less time. The rigging process consistently mapped facial landmarks to 3D models with high accuracy, enabling the creation of realistic animations with fluid transitions. These findings validate the effectiveness of integrating AI in 3D animation workflows.

D. Emotion Recognition Consistency

This subsection evaluates the ability of the rigged animations to portray predefined emotional labels accurately.

The assessment focuses on emotion classification accuracy, the clarity of emotional expressions, and the consistency of expressions across animation sequences.

1) *Accuracy of emotional expression portrayal:* The rigged animations were tested to determine how well they conveyed predefined emotional labels, such as happiness, sadness, anger, and surprise. A dataset of animated sequences was presented to human reviewers, who were tasked with identifying the expressed emotions. Their responses were compared to the intended labels. Table XI illustrates the accuracy of emotional expression portrayal, with the system achieving high recognition rates, including 96% for happiness, 94% for sadness, 90% for anger, and 92% for surprise.

TABLE XI. ACCURACY OF EMOTIONAL EXPRESSION PORTRAYAL

Emotion	Intended Expressions	Correctly Identified	Accuracy (%)
Happiness	50	48	96%
Sadness	50	47	94%
Anger	50	45	90%
Surprise	50	46	92%

2) *Confusion matrix for emotion classification:* A confusion matrix was used to analyze misclassification trends in emotion recognition. Confusion matrix showing correct and incorrect classifications of emotional expressions in animated sequences. Fig. 9 presents the confusion matrix for emotion classification, highlighting the system's performance in correctly identifying various emotions with minimal misclassifications across categories.

Fig. 9. Confusion matrix for emotion classification.

Observations:

- Minimal confusion between happiness and surprise.
- Slight overlap in classifications of anger and sadness, likely due to subtle variations in facial expressions.

To ensure that the animations maintain fluid and consistent expressions, transitions between different emotions were analyzed. Metrics included:

Frame Continuity: Analyzing adjacent frames for smooth interpolation.

Expression Duration: Measuring whether expressions were sustained appropriately.

Table XII presents the expression continuity metrics, highlighting the system's ability to achieve smooth transitions with an average score of 9.2 and adequately sustained expressions with a score of 8.8, ensuring emotional clarity.

TABLE XII. EXPRESSION CONTINUITY METRICS

Metric	Average Score (1–10)	Comments
Transition Smoothness	9.2	Minimal abrupt changes between frames
Sustained Expressions	8.8	Adequate duration for emotional clarity

Fig. 10. Animated expressions created using proposed GAN.

These results emphasize the system's ability to create fluid and accurate emotional expressions, enhancing its utility for 3D animation applications. Fig. 10 showcases animated facial expressions generated using the proposed GAN, demonstrating its ability to create dynamic and realistic emotions with detailed rigging and smooth transitions.

E. System Performance Metrics

This subsection focuses on evaluating the computational efficiency, response time, and scalability of the facial landmark detection and rigging system. These metrics are crucial for understanding the system's performance under various input conditions and its potential for real-world deployment in animation and other applications.

Computational efficiency is a key aspect of the system, as it directly impacts the speed and feasibility of real-time applications. To measure efficiency, the system's processing time for detecting facial landmarks and rigging 3D models was

recorded under various input conditions, such as varying image resolutions and complexity of animations. Table XIII provides an analysis of computational efficiency, showing that the system maintains reasonable processing times, with a total time of 80 ms for low-resolution inputs (128x128) and 600 ms for very high-resolution inputs (1024x1024), making it suitable for real-time applications.

TABLE XIII. COMPUTATIONAL EFFICIENCY ANALYSIS

Input Size / Image Resolution	Landmark Detection Time (ms)	Rigging Time (ms)	Total Processing Time (ms)
128x128 (Low Resolution)	30	50	80
256x256 (Medium Resolution)	55	80	135
512x512 (High Resolution)	120	160	280
1024x1024 (Very High Res.)	250	350	600

As the input image resolution increases, the computational time also increases, highlighting the trade-off between image qualities and processing speed. However, the system remains efficient, with the highest-resolution inputs processed in under 1 second, making it viable for real-time applications.

1) *Response time:* The response time measures the interval between receiving an input (e.g., an image or animation sequence) and delivering the output (e.g., rigged 3D model or emotional expression). To assess the response time, we tested the system with varying numbers of images and animation frames. Fig. 8 is illustrating the system's response time in milliseconds for different input sizes, with faster processing times observed at lower resolutions. Fig. 11 illustrates the response time of the system for different input sizes, demonstrating a linear increase in processing time with higher input resolutions while maintaining efficient performance for real-time applications.

Fig. 11. Response time for different input sizes.

The graph demonstrates that the system can maintain response times under 200 ms for lower-resolution inputs, making it suitable for interactive applications such as live animation.

Scalability is crucial for ensuring the system can handle increasing workloads, such as multiple simultaneous users or higher-resolution inputs, without performance degradation. We evaluated the system’s ability to scale by testing it under varying levels of input complexity. Table XIV illustrates the system’s scalability under varying input complexities, demonstrating its ability to handle up to 20 simultaneous users with a total processing time of 270 ms, maintaining efficiency and responsiveness.

TABLE XIV. SYSTEM SCALABILITY UNDER VARYING INPUT COMPLEXITY

Number of Simultaneous Users	Average Landmark Detection Time (ms)	Average Rigging Time (ms)	Total Time (ms)
1	60	90	150
5	70	95	165
10	90	120	210
20	120	150	270

Fig. 12. Proposed model scalability under various complexity scenarios.

Fig. 12 demonstrates the scalability of the proposed model under varying complexity scenarios, showcasing its ability to maintain efficient performance even with increased input complexity and multiple concurrent users. The system demonstrates good scalability, with minimal increase in processing time even as the number of simultaneous users grows. However, as expected, performance decreases when handling more complex inputs and larger numbers of concurrent users.

TABLE XV. COMPARISON OF PROPOSED RESULTS WITH STATE-OF-THE-ART METHODS

Aspect	SOTA Accuracy/Metric (%)	Proposed Study Accuracy/Metric (%)
Emotion Recognition Accuracy [3]	Happiness: 90, Sadness: 88, Anger: 85, Surprise: 89	Happiness: 96, Sadness: 94, Anger: 90, Surprise: 92
Landmark Detection Accuracy [18]	91.5	94.2
Rigging Efficiency (Time) [24]	~20 minutes	12ms (128x128), 350ms (1024x1024)
Animation Smoothness (Score) [22]	8.5	9.2

The comparison Table XV highlights the advancements achieved by the proposed study over state-of-the-art (SOTA) methods. The proposed system demonstrates superior emotion recognition accuracy across all tested emotions, with improvements of up to 6%. Landmark detection accuracy is enhanced, achieving 94.2% compared to the SOTA accuracy of 91.5%. Additionally, AI-assisted rigging significantly reduces processing time from ~20 minutes to milliseconds, enabling real-time usability, while animation smoothness is improved, scoring 9.2 compared to 8.5 in prior works. These results validate the system’s effectiveness in addressing critical challenges in animation workflows.

The system has proven to be computationally efficient, with reasonable response times and the ability to scale effectively for larger inputs or simultaneous users. Its performance is adequate for real-time applications and can be further optimized for more demanding environments. These findings suggest that the system is capable of operating in production-level settings, even with high-resolution images and complex animations. The findings of this study demonstrate significant progress in achieving the research objectives and addressing key challenges in 3D animation workflows.

The integration of state-of-the-art AI models, including GANs and VAEs, successfully generates highly expressive and exaggerated facial expressions for 3D cartoon characters. This contribution enhances creative possibilities, meeting the objective of pushing the boundaries of animation realism and emotional engagement. By combining the Facial Expression Research Group Database (FERG) with synthetic AI-generated data, the study achieves a broader and more versatile dataset. This approach ensures coverage of a wide range of facial expressions and emotional intensities, addressing the challenge of dataset limitations in traditional methods. The use of CNNs and RNNs to predict and interpolate facial expressions based on pose, texture, and landmarks ensures smoother transitions and consistent realism in animations. This aligns with the objective of achieving high-quality, naturalistic animations that improve user engagement and emotional connection.

V. CONCLUSION

This study presents a robust facial landmark detection and rigging system that employs advanced deep learning techniques to automate and streamline the process of facial animation. By accurately detecting key facial landmarks and leveraging AI-assisted rigging, the system generates realistic 3D facial models with dynamic expressions, significantly reducing manual effort and enhancing production efficiency. The results from pilot testing, accuracy evaluations, and emotion recognition assessments underscore the system’s effectiveness and its potential for real-world applications in animation, gaming, and virtual reality. Furthermore, the evaluation of performance metrics, including computational efficiency, response time, and scalability, demonstrates the system’s capability to handle varying input sizes and complexities. The system maintains consistent performance even under high-resolution inputs and multiple-user scenarios, making it highly suitable for real-time interactive applications. These findings highlight the practicality, reliability, and accuracy of the proposed system for diverse use cases.

Additionally, the AI-assisted rigging process provides significant advantages over manual methods in terms of time savings and quality, enabling more efficient production workflows. The system's ability to produce high-quality and consistent emotional expressions with minimal computational overhead establishes a strong foundation for further advancements in facial animation technologies. Despite its strengths, the system has certain limitations that warrant further exploration. Future work could focus on improving accuracy under extreme facial angles and challenging expressions, as well as enhancing the robustness of the system for handling diverse datasets. Expanding the system's capabilities to include more nuanced facial movements and integrating it with other AI-driven animation tools could further enhance its applicability. Addressing these areas will contribute to the development of even more advanced and versatile facial animation systems.

Abstract—With the rapid growth of Internet of Things (IoT) devices, many of which are resource-constrained and vulnerable to attacks, current identity authentication methods are often too resource-intensive to provide adequate security. This paper proposes an efficient identity authentication scheme that integrates Physical Unclonable Functions (PUFs), Chebyshev chaotic maps, and fuzzy extractors. The scheme enables mutual authentication and key agreement without the need for passwords or smart cards, while providing effective defense against various attacks. The security of the proposed scheme is formally analyzed using an improved BAN logic. A comparison with existing related protocols in terms of security features, computational overhead, and communication overhead demonstrates the security and efficiency of the proposed scheme.

Keywords—Internet of Things; identity authentication; Physical Unclonable Functions; fuzzy extractors; chaotic maps

I. INTRODUCTION

As science and technology continue to progress, the Internet of Things (IoT) has found broad applications in areas such as smart homes, smart energy, industrial production, and healthcare. In this interconnected world, the number of IoT-connected devices is growing at an exponential rate. These devices are typically resource-constrained, widely distributed, and susceptible to various attacks, including physical attacks, machine learning modeling attacks, replay attacks, and man-in-the-middle attacks. However, existing identity authentication schemes commonly use algorithms with high computational overhead, such as elliptic curve cryptography, making them unsuitable for resource-constrained devices. Therefore, it is crucial to design a lightweight anonymous identity authentication scheme tailored for resource-constrained IoT devices to verify the identity of devices connected to the IoT, thereby enhancing security protection and management.

A Physically Unclonable Function (PUF) is a lightweight security primitive that generates unique response values by leveraging the subtle differences that arise during the manufacturing process, serving as the "fingerprint" of a device. Typically, PUF technology is used in conjunction with a challenge-response mechanism, where the system sends a challenge to the device, and the PUF generates a corresponding response value for authentication or other subsequent operations. However, due to the susceptibility of PUFs to noise interference, many current schemes employ fuzzy extractors to

mitigate the impact of noise on PUF output responses, thereby enhancing the robustness and reliability of PUF-based systems [1, 2].

Due to the secure and lightweight nature of PUFs, numerous researchers have utilized them for identity authentication in resource-constrained devices. This application provides an efficient and reliable identity verification mechanism for resource-constrained devices without requiring additional key storage or complex key management [3]. Consequently, PUFs have broad application prospects in IoT devices, sensor networks, smart cards, and other embedded systems. Their security and lightweight properties make PUFs an ideal choice for protecting resource-constrained devices from unauthorized access [4].

The study in [5] proposed a PUF-based mutual identity authentication and session key exchange scheme, which employs a fuzzy extractor to eliminate PUF noise and extract responses for identity authentication and key extraction. However, this scheme stores PUF challenge values in plaintext within the device, making it vulnerable to physical attacks. The study in [6] introduced a PUF-based authentication and key exchange protocol suitable for the Industrial Internet, which effectively reduces computational and communication overhead compared to other schemes, but it requires the input of biometric data during the authentication process. The study in [7] proposed a PUF-based anonymous user authentication scheme for smart homes in the IoT, which requires the input of user identity credentials and passwords and relies on a gateway to facilitate secure authentication between users and devices, thereby increasing the complexity of identity authentication, making it unsuitable for resource-constrained IoT devices. The study in [8] presented a two-way identity authentication protocol based on fuzzy extractors and elliptic curves, establishing mutual authentication between wireless sensor networks and the IoT. However, this scheme requires the storage of secret information related to authentication on a smart card and employs the resource-intensive elliptic curve algorithm, rendering it unsuitable for resource-constrained IoT devices. The study in [9] proposed a blockchain-based two-factor identity authentication scheme using a PUF-based fuzzy extractor, where blockchain technology is used for user authentication and authorization. However, due to the high resource consumption of blockchain, this approach is not suitable for resource-constrained IoT systems.

A common limitation of existing PUF-based identity authentication schemes is the plaintext storage of secrets within the device or the exposure of Challenge Response Pairs (CRPs) during device-server interactions, often requiring smart cards or password inputs to complete mutual authentication. Attackers can launch physical attacks on the device, accessing the device's memory to retrieve plaintext secrets, or capture CRPs to model the PUF using machine learning algorithms and predict its response values. Therefore, this paper proposes a lightweight anonymous identity authentication scheme for the IoT based on PUFs, Chebyshev chaotic maps, and fuzzy extractors. This scheme accomplishes mutual identity authentication and key agreement without the need for password input or smart card insertion. The Chebyshev chaotic map ensures the secure transmission of CRPs, while the fuzzy extractor shields the PUF from noise interference. Compared to previous schemes, this approach does not require the storage of any secret values in the device, effectively resisting physical, machine learning modeling, replay, and other attacks. It also offers multiple security properties, including anonymity, forward/backward security, and mutual authentication. Furthermore, the scheme only involves lightweight operations such as hash functions, Chebyshev chaotic maps, and fuzzy extractors, making it suitable for resource-constrained IoT devices.

The remainder of this paper is structured as follows: Section I, we introduce the relevant foundational concepts, including Physically Unclonable Functions, Chebyshev chaotic maps, and fuzzy extractors. Then, Section III describe the design and implementation of the proposed scheme in detail and analyze and evaluate its security and performance in Section IV. Finally, the paper concludes in Section V by summarizing the research findings and suggesting future research directions.

II. RELATED KNOWLEDGE

A. Physically Unclonable Functions

PUF is a function that leverages the uniqueness and unclonability of hardware characteristics. PUFs take advantage of the inevitable microscopic variations that occur during the manufacturing process, allowing each device to generate a unique response. The fundamental principle of PUFs is that, when subjected to the same challenge, different hardware devices will produce different responses, which makes these outputs both difficult to predict and impossible to replicate. Consequently, PUFs are widely used in security fields such as identity authentication and key generation. The main characteristics of PUFs include [10]:

- Uniqueness: Different devices have different PUF responses, each with unique characteristics.
- Unclonability: Due to the random, minor variations in the manufacturing process, it is impossible to precisely replicate a PUF.
- Unpredictability: Even if an attacker obtains some CRPs, they cannot predict responses that have not been previously observed.

B. Chebyshev Chaotic Map

The Chebyshev chaotic map is a mathematical mapping based on chaos theory, characterized by both determinism and

chaotic behavior. The Chebyshev polynomial $T_n(x)$ can be defined recursively as follows:

$$T_n(x) = \begin{cases} 1 & n = 0 \\ x & n = 1 \\ 2xT_n(x) - T_{n-1}(x) & n \geq 2 \end{cases} \quad (1)$$

where n denotes the order of the polynomial. The Chebyshev polynomial exhibits chaotic behavior over the interval $[-1, 1]$, with its output being highly sensitive to small variations in the initial value. This property makes the Chebyshev chaotic map highly valuable in cryptographic applications, where it can be used for generating pseudorandom numbers, encryption keys, and ensuring data integrity [11].

C. Fuzzy Extractor

A fuzzy extractor is a technique used to derive stable and reliable keys from imprecise inputs. Fuzzy extractors enable the consistent extraction of keys from noisy inputs, even when inputs may vary slightly over time. Fuzzy extractors typically involve two processes [12]:

- Generation (Gen): Converts the noisy input into a random key and auxiliary data.
- Reconstruction (Rep): Reconstructs the same random key using the auxiliary data and the noisy input.

Fuzzy extractors are particularly significant in IoT devices, ensuring that consistent keys can be generated across different environments, facilitating secure communication and identity authentication.

III. THE PROPOSED LIGHTWEIGHT ANONYMOUS IDENTITY AUTHENTICATION SCHEME

The proposed scheme enables mutual authentication between IoT terminal devices and the gateway, consisting of two main phases: the registration phase and the authentication phase. This scheme assumes that each IoT terminal device is embedded with a PUF chip and that the registration process is completed within a secure channel, while the mutual identity authentication occurs over an insecure channel. The relevant symbols used in the scheme are described in Table I.

TABLE I. SYMBOL DESCRIPTIONS

Symbol	Description
AID_i	Pseudorandom identity of the device in the i -th round
ID_i	Real identity of the device
$h()$	One-way hash function
\parallel	Concatenation operation
$CRP(C_i, R_i)$	Challenge Response Pair
$T_r(x)$	Chebyshev polynomial
N_d, N_u, N_g	Random number
T, T_g, T_d	Timestamp
FE.Gen	Fuzzy extractor generation function
FE.Rec	Fuzzy extractor recovery function
hd	Helper data generated by the fuzzy extractor
k	Key generated by the fuzzy extractor
\oplus	XOR operation
SK	Session key between the device and the gateway

A. Identity Authentication Model

The IoT identity authentication model used in this paper is illustrated in Fig. 1 [13], comprising three components: the registration center, the gateway, and the terminal devices. The registration center, located at the application layer of the IoT, is responsible for the registering both the gateways and terminal devices. The gateway acts as a bridge within the IoT system, connecting various IoT devices and networks while ensuring the reliable transmission and processing of data. Terminal devices are the front end of the entire system, directly interacting with the environment or users, collecting and transmitting data, and executing specific operations, thereby enabling the IoT system to achieve intelligent and automated functions. When a terminal device connects to the IoT, it first registers with the registration center. Subsequently, the gateway retrieves the authentication information of the terminal device from the registration center, and then mutual identity authentication between the terminal device and the gateway takes place.

In the lightweight anonymous identity authentication scheme proposed in this paper, making the following assumptions:

- **Trusted Devices and Gateway:** It is assumed that the devices and the gateway are initially trusted and can securely share an initial secret value.
- **Secure PUF Implementation:** It is assumed that each device has a secure PUF module, and that the CRPs of the PUF are unique and unpredictable.
- **Insecure Communication Channel:** It is assumed that the communication channel between the device and the gateway is insecure, meaning that an attacker could intercept, tamper with, or even replay messages.
- **Attacker Model:** It is assumed that an attacker has the capability to intercept communication messages, perform physical attacks, and attempt machine learning modeling, but cannot clone the PUF's response.

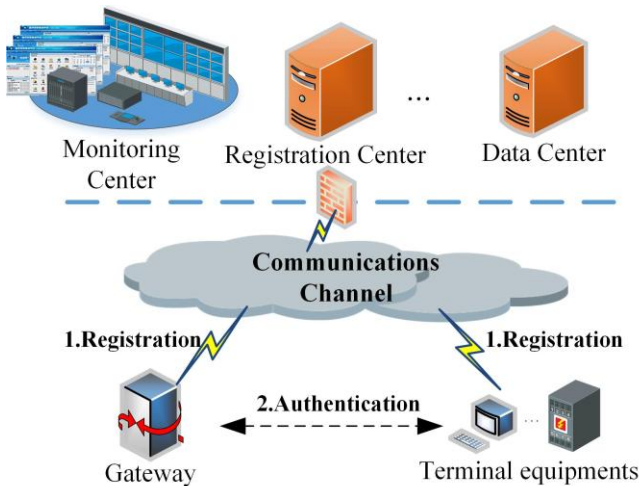

Fig. 1. IoT identity authentication model.

B. Registration Phase

The device registration phase to the gateway is shown in Fig. 2. In the registration phase, the device registers with the gateway through the secure channel, and the specific registration steps are as follows:

Step 1: The device selects its real identity ID_i and sends it to the gateway.

Step 2: The gateway generates a challenge value C_i , computes $AID_i = h(C_i || ID_i)$, and sends the message $\{C_i, AID_i\}$ to the device.

Step 3: The device computes $R_i = \text{PUF}(C_i)$, stores AID_i , and sends the message $\{R_i\}$ back to the gateway.

Step 4: The gateway generates $T_{Ri} = T_{Ri}(x) \bmod p$, publishes x, p, T_{Ri} , and stores (C_i, R_i, AID_i) .

Fig. 2. Device and gateway registration phase.

C. Authentication Phase

The device and gateway authentication phase is shown in Fig. 3. In the authentication phase, the terminal device and the gateway utilize the authentication parameters obtained through registration to carry out two-way authentication and negotiate a session key for subsequent use in the following steps:

Step 1: The device generates a random number N_d , N_u , computes $T_{Nd} = T_{Nd}(x) \bmod p$, $T_{Nd-Ri} = T_{Nd}(T_{Ri}) \bmod p$, and $N_u^* = N_u \oplus T_{Nd-Ri}$, and creates a message $\{T_{Nd}, AID_i, N_u^*\}$ which it then sends to the gateway.

Step 2.1: The gateway checks its memory for AID_i . If AID_i is not found in memory, the gateway rejects the device's authentication; otherwise, the gateway proceeds with the authentication.

Step 2.2: The gateway generates a random number N_g , a timestamp T_g , and computes $T_{Nd-Ri} = T_{Ri}(T_{Nd}) \bmod p$, $N_u = N_u^* \oplus T_{Nd-Ri}$, $C_i^* = C_i \oplus T_{Nd-Ri}$, $N_g^* = N_g \oplus N_u$, $V_0 = h(T_{Nd-Ri} || N_u || R_i || T_g)$. It then sends the message $\{C_i^*, N_g^*, V_0, T_g\}$ to the device.

Step 3.1: The device computes $C_i = C_i^* \oplus T_{Nd-Ri}$, $N_g = N_g^* \oplus N_u$, and $R_i = \text{PUF}(C_i)$.

Step 3.2: The device verifies $|T - T_g| < \Delta t$. If the verification fails, the authentication fails. Otherwise, it checks whether V_0' matches V_0 . If they do not match, the authentication fails.

Step 3.3: The device generates a timestamp T_d , and computes $(k, hd) = \text{FE.Gen}(R_i)$, $C_{i+1} = h(C_i \parallel N_u)$, $R_{i+1} = \text{PUF}(C_{i+1})$, $AID_{i+1} = h(AID_i \parallel k \parallel N_g)$, $R_{i+1}^* = R_{i+1} \oplus N_g$, $SK = h(N_u \parallel R_{i+1} \parallel T_{Nd-Ri})$, $hd^* = hd \oplus h(R_{i+1} \parallel T_{Nd-Ri})$, $V_1 = h(N_g \parallel k \parallel SK \parallel T_d)$. It stores AID_{i+1} and sends the message $\{R_{i+1}^*, hd^*, V_1, T_d\}$ to the gateway.

Step 4.1: The gateway verifies $|T - T_d| < \Delta t$. If the verification fails, the authentication fails. Otherwise, it computes $R_{i+1} = R_{i+1}^* \oplus N_g$, $hd = hd^* \oplus h(R_{i+1} \parallel T_{Nd-Ri})$, $k = \text{FE.Rec}(R_i \parallel hd)$, $SK = h(N_u \parallel R_{i+1} \parallel T_{Nd-Ri})$, $T_{Ri+1} = T_{Ri+1}(x) \bmod p$, and publishes x, p, T_{Ri+1} .

Step 4.2: The gateway verifies whether V_1' matches V_1 . If they do not match, the authentication fails.

Step 4.3: The gateway updates $C_{i+1} = h(C_i \parallel N_u)$, $AID_{i+1} = h(AID_i \parallel k \parallel N_g)$, and stores $(C_{i+1}, R_{i+1}, AID_{i+1})$.

Fig. 3. Device and gateway authentication phase.

IV. SECURITY ANALYSIS OF THE PROPOSED SCHEME

A. Formal Security Analysis Using Improved BAN Logic

This paper employs an improved BAN (Burrows, Abadi and Needham) logic [14] to analyze the proposed lightweight anonymous identity authentication scheme for power IoT. In this context, A, B, P and Q represent the authentication entities, while M and N denote the messages involved in the authentication process. J and Q represent formulas. Table II provides the symbols and meanings used in the improved BAN logic.

TABLE II. SYMBOLS IN IMPROVED BAN LOGIC

Symbol	Meaning
$P \models J$	P believes J is true
$P \stackrel{K}{\sim} J$	P encrypts message J with key K
$P \stackrel{K}{\triangleleft} J$	P has received a message J encrypted with key K
$P \stackrel{K}{\leftrightarrow} Q$	P and Q share key K
$P \stackrel{J}{\square} Q$	P and Q share secret J
$\#(J)$	J is within its validity period
$\text{sup}(S)$	S is a trusted party
$P \ntriangleleft M$	P does not know message M

Table III shows the inference rules used by the improved BAN logic:

TABLE III. IMPROVED BAN INFERENCE RULES

Rule Name	Expression
Authentication Rule	$\frac{P \models P \stackrel{K}{\leftrightarrow} Q \wedge P \stackrel{K}{\triangleleft} M}{P \models Q \stackrel{K}{\sim} M}$
Confidentiality Rule	$\frac{P \models P \stackrel{K}{\leftrightarrow} Q \wedge P \models S^C \triangleleft M \wedge P \stackrel{K}{\sim} M}{P \models (S \cup \{Q\})^C \triangleleft M}$
Freshness Rule	$\frac{P \models \#(M) \wedge P \models Q \stackrel{K}{\leftrightarrow} M}{P \models Q \stackrel{K}{\leftrightarrow} Q}$
Super Subject Rule	$\frac{P \models Q \models X \wedge P \models \text{sup}(Q)}{P \models X}$
Randomness Validation Rule	$\frac{P \models \#(M) \wedge P \triangleleft N \mathcal{R} M}{P \models \#(N)}$
Security Key Rule	$\frac{P \models \{P, Q\}^C \triangleleft K \wedge P \models \#(K)}{P \models P \stackrel{K}{\leftrightarrow} Q}$
Derivation Rule	$\frac{P \models Q \models P \stackrel{K}{\leftrightarrow} Q \wedge P \models S^C \triangleleft M \wedge P \stackrel{K}{\sim} M}{P \models Q \models (S \cup \{P\})^C \triangleleft M}$

Using the improved BAN logic, we have proven that the authentication process for N_g, R_{i+1}, T_{Nd-Ri} is secure. The proof process is shown in Fig. 4. Firstly, we idealize the messages exchanged between the terminal and the gateway. The results of this idealization are as follows:

- $D \rightarrow GW : T_{Nd}, AID_i, N_u^*$
- $GW \rightarrow D : N_u \mathcal{R} T_{Nd-Ri} \mathcal{R} N_g \mathcal{R} T_g$
- $D \rightarrow GW : N_g \mathcal{R} T_{Nd-Ri} \mathcal{R} R_{i+1} \mathcal{R} T_d$

The following assumptions are made for the proposed authentication scheme:

- $D \models \overset{R_i}{D \leftrightarrow GW}, GW \models \overset{R_i}{D \leftrightarrow GW}$: During the registration phase, the gateway stores the CRPs for each terminal, and the device can use the PUF function to compute responses R_i .
- $GW \models \{D\}^C \triangleleft N_g, D \models GW \models \{D\}^C \triangleleft N_g$: The gateway generates random numbers N_g .

- $D \models \{GW\}^C \triangleleft \|\ R_{i+1}$, $GW \models D \models \{GW\}^C \triangleleft \|\ R_{i+1}$: The device uses the PUF function to generate new responses R_{i+1} .
- $D \models \{GW\}^C \triangleleft \|\ T_{Nd-Ri}$, $GW \models D \models \{GW\}^C \triangleleft \|\ T_{Nd-Ri}$: The device computes and generates T_{Nd-Ri} .
- $D \models \#(N_d)$, $D \models \#(T_{Nd-Ri})$, $D \models \#(N_u)$, $D \models \#(T_d)$, $D \models \#(R_{i+1})$: $N_d, T_{Nd-Ri}, N_u, T_d, R_{i+1}$ are within their validity periods.
- $GW \models \#(N_g)$, $GW \models \#(T_{Nd-Ri})$, $GW \models \#(T_g)$: N_g, T_{Nd-Ri}, T_g are within their validity periods.
- $D \models \text{sup}(GW)$, $GW \models \text{sup}(D)$: The gateway and device trust each other.
- $D \triangleleft N_u \mathfrak{R}N_g$, $D \triangleleft T_{Nd-Ri} \mathfrak{R}N_g$: Messages in the idealized scheme for Message 2.
- $GW \triangleleft T_{Nd-Ri} \mathfrak{R}R_{i+1}$, $GW \triangleleft N_g \mathfrak{R}R_{i+1}$: Messages in the idealized scheme for Message 3.

B. Informal Security Analysis

1) *Bidirectional authentication*: The proposed scheme enables bidirectional identity authentication between devices and gateways. Devices authenticate the gateway by verifying $V_0'=V_0$, while the gateway authenticates the device by verifying $V_1'=V_1$. Since the expressions for V_0 and V_1 include secret values such as T_{Nd-Ri}, N_u , and R_i , obtaining T_{Nd-Ri} would require solving the chaotic mapping Diffie-Hellman problem. Additionally, N_u and N_g are not transmitted in plaintext, preventing making the scheme resistant to tampering attacks by resending messages an attacker to acquire any secret values and thus preventing impersonation of legitimate devices or gateways during authentication.

2) *Anonymity and untraceability*: During the authentication process, both the device and the gateway utilize pseudonyms, which are updated after each authentication. As a result,

attackers are unable to obtain the real identity ID_i , ensuring both anonymity and untraceability.

3) *Tamper resistance*: Although attackers may intercept and tamper with messages transmitted over insecure channels, the information exchanged in the proposed scheme is protected by hash functions or bitwise XOR operations. Consequently, attackers cannot extract secret values from the messages, enabling the scheme to resist tampering attacks.

4) *Resistance to cloning and physical attacks*: While attackers could use physical methods to access a device's memory and obtain sensitive information, the device only stores pseudonyms and not the secret values related to authentication. Furthermore, PUFs possess characteristics such as unclonability, meaning any attempt by an attacker to obtain a PUF response would compromise its functionality, thus preventing impersonation of legitimate devices through cloning or physical attacks.

5) *Resistance to machine learning modeling attacks*: Attackers may attempt to construct a PUF response model using collected CRPs and machine learning algorithms to predict CRPs. However, in the proposed scheme, attackers can only capture CRPs from insecure channels, and acquiring the challenge values necessitates obtaining T_{Nd-Ri} . As such, they cannot obtain the response values, which are hashed, making it impossible to reverse-engineer them due to the one-way nature of hash functions. Therefore, the proposed scheme effectively mitigates machine learning modeling attacks.

6) *Resistance to spoofing attacks*: If an attacker seeks to impersonate a legitimate device, they must send the correct $AID_i, N_u^*, R_{i+1}^*, V_1$, and hd^* . However, generating valid values requires correct N_g, k, N_u, R_{i+1} , and T_{Nd-Ri} . As established, attackers cannot access valid T_{Nd-Ri} and R_{i+1} , preventing them from acquiring N_g and N_u . Similarly, if an attacker attempts to impersonate the gateway, they would require valid CRPs and T_{Nd-Ri} , making it impossible to authenticate as a legitimate gateway.

$$\begin{array}{c}

(a) D believes that N_g is a shared secret between D and GW ; (b) GW believes that N_g is a shared secret between GW and D ; (c) GW believes that R_{i+1} is a shared secret between GW and D ; (d) D believes that R_{i+1} is a shared secret between D and GW ; (e) D believes that $T_{Nd,Ri}$ is a shared secret between D and GW ; (f) GW believes that $T_{Nd,Ri}$ is a shared secret between GW and D .

7) *Resistance to replay attacks*: The proposed scheme incorporates a timestamp mechanism, requiring verification of transmission delays before authentication. This prevents attackers from initiating replay attacks through message resending. Additionally, timestamps are included in V_0 and V_1 ; any attempt by an attacker to change the timestamp will result in authentication failure. Moreover, the secret values in V_0 and V_1 are updated after each authentication, effectively resisting replay attacks.

8) *Resistance to Denial-of-Service (DoS) attacks*: When attackers send excessive invalid information to disrupt communication between devices and gateways, the devices and gateways will first validate the transmission delays and then verify the values of V_0 or V_1 . Any failure to meet these criteria will result in a rejection of authentication.

9) *Forward and backward security*: In the proposed scheme, the session key negotiated is $SK = h(N_u \parallel R_{i+1} \parallel T_{Nd,Ri})$. Since N_u, R_{i+1} , and $T_{Nd,Ri}$ are updated after each authentication, even if an attacker acquires the current device's secret values and CRPs, they cannot trace past or future communications of the device, thus ensuring both forward and backward security.

V. PERFORMANCE ANALYSIS

A. Security Feature Analysis

Table IV compares the security features of the proposed scheme with those of existing solutions. In study [15], attackers can obtain CRPs through eavesdropping or spoofing, which makes the system vulnerable to machine learning modeling attacks. In contrast, the proposed scheme stores only pseudonymous identities on the device, preventing attackers from obtaining plaintext CRPs through physical attacks. Furthermore, the CRPs are protected by XOR or hash functions during the authentication process, which helps safeguard against machine learning modeling attacks. The study in [16] describes a system where authentication values are generated from secret values stored on the device or randomly generated by users. If this secret information is compromised, attackers could potentially impersonate legitimate devices or gateways. In the proposed scheme, however, attackers would need to access secret information such as N_u, N_g, R_{i+1} . These secrets are protected by Chebyshev polynomials or hash functions, making it difficult for attackers to access them and thus defending against spoofing and man-in-the-middle attacks.

B. Computational Overhead Analysis

Based on the execution times for various operations outlined in study [14], the following time parameters are considered: T_h for executing a hash function, T_{PUF} for executing a PUF, T_{che} for executing a Chebyshev polynomial, T_{Mul} for performing an elliptic curve point multiplication, $T_{FE,Gen}$ for generation with a fuzzy extractor, and $T_{FE,Rep}$ for recovery with a fuzzy extractor. The execution times for these operations are listed in Table V.

Table VI compares the computational overhead of the proposed scheme with those of other schemes in the literature (Fig. 5). As shown in the table, the schemes in studies [15] and [16] use resource-intensive elliptic curve point multiplication, resulting in the highest computational overheads of 3909.2284 μ s and 3549.8392 μ s, respectively. In contrast, the proposed scheme utilizes lightweight Chebyshev chaotic mappings, resulting in a total computational overhead of 1396.3521 μ s. This represents a reduction of 60.664% and 64.281%, respectively, compared to the computational overheads of the schemes proposed in the other references.

C. Communication Overhead Analysis

Before comparing the communication overhead, the lengths of the various variables are referenced from [14]. Table VII presents a comparison of the communication overhead between the proposed scheme and those in the literature. The table shows that the communication overhead of the proposed scheme is 1216 bits, which is lower than that of the schemes proposed in studies [15] and [16]. Therefore, the proposed scheme is well-suited for anonymous identity authentication and session key negotiation for resource-constrained terminal devices and gateways.

TABLE IV. COMPARISON OF SECURITY FEATURES

Security Attribute	Bai Haodong et al. [15]	Soni [16]	Proposed Scheme
Mutual Authentication	✓	✓	✓
Untraceability	✓	✓	✓
User Anonymity	✓	✓	✓
Forward/Backward Security	✓	✓	✓
DoS Attack	✓	✓	✓
Replay Attack	✓	✓	✓
Machine Learning Modeling Attack	×	✓	✓
Spoofing Attack	✓	×	✓
Man-in-the-Middle Attack	✓	×	✓
Mutual Authentication	✓	✓	✓

TABLE V. EXECUTION TIMES FOR VARIOUS OPERATIONS

Operation	Operation execution time	
	Device Side	Gateway Side
T_h	2.7324 μ s	0.1315 μ s
T_{PUF}	6.7 μ s	/
T_{che}	91.2600 μ s	10.6604 μ s
T_{Mul}	426.4887 μ s	103.8660 μ s
$T_{FE.Gen}$	278.0889 μ s	74.7562 μ s
$T_{FE.Rep}$	696.1048 μ s	157.4092 μ s

TABLE VI. COMPARISON OF COMPUTATIONAL OVERHEAD

Scheme	Device Side	Gateway Side	Total Time
Bai et al. [15]	$5T_h + T_{FE.Gen} + T_{FE.Rep} + 5T_{Mul} + 2T_{PUF}$ $\approx 3133.8492\mu s$	$4T_h + 4T_{Mul}$ $\approx 415.99\mu s$	3549.8392 μs
Soni et al. [16]	$11T_h + T_{FE.Rep} + 6T_{Mul}$ $\approx 3285.2434\mu s$	$6T_h + 6T_{Mul}$ $\approx 623.985\mu s$	3909.2284 μs
Proposed Scheme	$8T_h + 2T_{Che} + 2T_{PUF} + T_{FE.Gen}$ $\approx 495.8681\mu s$	$8T_h + 2T_{Che} + T_{FE.Rep}$ $\approx 900.484\mu s$	1396.3521 μs

Fig. 5. Comparison of computation overhead.

TABLE VII. COMPARISON OF COMMUNICATION OVERHEAD

Scheme	Number of messages	Communication cost
Bai et al. [15]	3	1472bit
Soni et al. [16]	2	2304bit
Proposed Scheme	3	1216bit

The experimental results confirm that the proposed scheme offers significant improvements in both security and efficiency compared to existing solutions. As shown in Table IV, the scheme effectively mitigates the vulnerabilities of previous methods, such as machine learning attacks and impersonation, by storing only pseudonymous identities and using XOR/hash functions to protect CRPs. This is a clear advantage over reference [15], where CRPs can be intercepted, and reference [16], where compromised secrets may lead to spoofing.

In terms of computational overhead, our scheme, utilizing Chebyshev chaotic mappings, significantly reduces processing time by approximately 60-64% compared to the elliptic curve-based methods in studies [15] and [16]. This makes it more suitable for resource-constrained IoT devices. Furthermore, as seen in Table VII, the communication overhead of our scheme is lower than that of existing solutions, making it ideal for devices with limited bandwidth.

Overall, our scheme provides a balanced approach, offering robust security and efficiency, which is essential for resource-constrained IoT environments.

VI. CONCLUSION

This paper presents a lightweight identity authentication scheme designed for resource-constrained IoT devices, which has been verified for security using an improved BAN logic. The results indicate that the proposed scheme is capable of resisting attacks such as physical attacks, machine learning modeling attacks, replay attacks, and man-in-the-middle attacks. Compared to existing solutions, the computational overhead of the proposed scheme is only 1396.3521 μs , and the communication overhead is only 1216 bits, making it suitable for efficient and secure authentication in IoT environments. Future work will focus on further optimizing the performance of the scheme, reducing system overhead, and conducting more extensive testing and validation in complex application scenarios to enhance the overall security and reliability of the scheme.

Comparative Analysis of Feature Selection Based on Metaheuristic Methods for Human Heart Sounds Classification Using PCG Signal

Motaz Farooq A Ben Hamza, Nilam Nur Amir Sjarif

Razak Faculty of Technology and Informatics, Universiti Teknologi Malaysia, Kuala Lumpur 54100, Malaysia

Abstract—Cardiovascular disease is a critical threat to human health, as most death cases are due to heart disease. Although several doctors employ stethoscopes to auscultate heart sounds to detect abnormalities, the accuracy of the approach is considerably dependent upon the experience and skills of the physician. Consequently, optimal methods are required to analyse and classify heart sounds with Phonocardiogram (PCG) signal-based machine learning methods. The current study formulated a binary classification model by subjecting PCG signals to hyper-filtering with low-pass and cosine filters. Subsequently, numerous features are extracted with the Wavelet Scattering Transform (WST) method. During the feature selection stage, several metaheuristic methods, including Harris Hawks Optimisation (HHO), Dragonfly Algorithm (DA), Grey Wolf Optimiser (GWO), Salp Swarm Algorithm (SSA), and Whale Optimisation Algorithm (WOA), are employed to compare the attributes separately and determine the ideal characteristics for improved classification accuracy. Finally, the selected features were applied as input for the Bidirectional Long Short-Term Memory (Bi-LSTM) algorithm, simplifying the classification process for distinguishing normal and abnormal heart sounds. The present study assessed three PCG datasets: PhysioNet 2016, Yaseen Khan 2018, and PhysioNet 2022, documenting 94.85%, 100%, and 66.87% accuracy rates with 127-SSA, 168-HHO, and 163-HHO, respectively. Based on the results of the PhysioNet 2016 and 2022 datasets, the proposed method with hyperparameters demonstrated superior performance to those with default parameters in categorising normal and abnormal heart sounds appropriately.

Keywords—Cardiovascular Diseases (CVDs); Phonocardiogram (PCG) signal processing; Wavelet Scattering Transform (WST); Metaheuristic Methods; Harris Hawks Optimisation (HHO); Dragonfly Algorithm (DA); Grey Wolf Optimiser (GWO); Salp Swarm Algorithm (SSA); Whale Optimisation Algorithm (WOA); Bidirectional Long Short-Term Memory (Bi-LSTM)

I. INTRODUCTION

Diagnosis with heart sounds has drawn much attention in the biomedical research area because of the crucial nature of the heart and the high mortality rates associated with cardiovascular diseases. Heart sounds are the mechanical activities of the heart, which vary according to pathological conditions affecting it [1]. Currently, the two major expensive technologies for detecting heart diseases are echocardiography and cardiac Magnetic Resonance Imaging (MRI) [2]. Auscultation is a basic diagnostic technique commonly used to assess heart function and quality [3]. It involves the listening of

heart sounds directly by placing a stethoscope at various points in the chest. Nonetheless, it is subjective and highly dependent on the acuteness of hearing and experience of the physician. Therefore, there is a need to develop a system that can objectively process heart sounds, enabling faster and more accurate diagnoses.

There are two major sounds produced by a normally functioning heart. The first heart sound (S1) and the second heart sound (S2). Closing of the mitral and tricuspid valves causes the first sound, S1, while the second sound, S2, is a result of the aortic and pulmonary valves closing at the end of the systolic phase. Sound identification can be one essential part of the heart disease diagnosis since the nature and other characteristics of the heart murmurs can vary from one to another as per concise disease conditions. In most instances, differences in heart sound patterns between healthy and unhealthy states are distinguished on the basis of changes in intensity, timing, location, etc., among other factors [4].

Several researchers have worked on the study and categorisation of Phonocardiogram (PCG) signals using various machine learning techniques [5]; particularly, two main areas have been focused on: Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) [6], [7]. However, these studies often require extraction of a wide array of features, which can complicate the training phase when dealing with heart sound signals. Also, these studies involve issues of existing noise in PCG signals and imbalanced datasets, leading to the extraction of unnecessary features [8]. Therefore, the contribution of this study is as follows:

- To introduce low-pass and cosine hyper-filters during preprocessing to reduce background noise from PCG signals.
- To extract various features from the PCG signals with Wavelet Scattering Transform (WST).
- To develop metaheuristic methods with hyperparameters to select optimal features for refined features from an initial set of features, therefore reducing computational complexity and improving classification performance by diminishing the search space.
- To execute high-performance heart sound classification with the Bidirectional Long Short-Term Memory (Bi-LSTM) classifier.

Section II of this study discusses related articles on heart sound classification. Details on the WST characteristics, the proposed methodology with several metaheuristic methods, and the Bi-LSTM algorithm are included in Section III. In Section IV, the results, including the dataset employed for comparison with existing literature, are discussed. The conclusions of this study are mentioned in Section V. Recommendations for future research are also included.

II. RELEVANT WORK

In the biomedical field, several techniques have been proposed to classify normal and abnormal heart sounds, emphasising Phonocardiogram (PCG) signal processing. Generally, the signals are preprocessed to filter out extraneous high-frequency noises. Subsequently, characteristic features are extracted and utilised as input data to construct or develop mathematical models intended for diagnosing heart conditions [8], [9].

Preprocessing is fundamental in PCG categorisation. The step involves three primary tasks: baseline wander removal, background noise reduction, and normalisation. Baseline wander is a common issue in low-frequency PCG recordings. This issue shifts the baseline reference level, which hinders accurate signal property extraction [10], [11]. Background noise is prevalent in high-frequency PCG recordings [12] and can degrade signal quality. Normalisation scales sample values in the dataset to a standard range (typically 0-1 or -1 to 1), ensuring that amplitude discrepancies do not distort feature extraction and classification processes [13]. This standardisation prevents bias in the model due to variations in recording amplitudes [14].

Potes et al. [15] classified heart sound recordings from the PhysioNet Challenge 2016 into normal and abnormal classes with an ensemble classifier. The report applied the Butterworth bandpass filter and extracted 124 features from PCG signals with Mel Frequency Cepstral Coefficients (MFCCs). The approach achieved an 86.02% accuracy rate without employing any feature reduction technique. The study also achieved first place in the PhysioNet Challenge 2016.

In 2017, Kay and Agarwal [16] applied a hidden semi-Markov model for segmentation before extracting temporal and spectral features utilising continuous WST and MFCCs from the PhysioNet Challenge 2016 dataset. Subsequently, Principal Component Analysis (PCA) was employed to reduce data dimensionality. Finally, the information was fed into an Artificial Neural Network (ANN), yielding an 85.2% accuracy. In another study, Bao et al. revealed that the Bi-LSTM classifier performed better than CNN on an identical dataset. Accuracy, sensitivity, and specificity rates of 92.64%, 84.77%, and 95.14%, respectively, were noted [17].

Li et al. [18] utilised the Twin SVM (TWSVM) classifier to compare the performance of multi-dimensional scaling and PCA for feature selection on the PhysioNet Challenge 2016 dataset. The Multi-Dimensional Scaling (MDS) outperformed PCA with 98.58%, 98.58%, 98.57%, and 99% in respective accuracy, sensitivity, specificity, and F1 score. Meanwhile, Alshamma et al. (2019) applied a high-pass filter on each PCG signal before employing a normalisation method based on zero

mean and standard deviation. Subsequently, different K-Nearest Neighbours (KNN) and Support Vector Machines (SVM) classifiers were compared with the PhysioNet Challenge 2016 dataset. The fine-KNN classifier documented interesting results with a 93.5% accuracy [11].

In 2020, Singh and Majumder obtained short and non-segmented signals from the PhysioNet Challenge 2016 dataset. High noise frequencies were filtered with the Butterworth low-pass filter before filtering 27 features with MFCCs. Post-training with an ensemble classifier, the features recorded 92.47% accuracy, 94.08% sensitivity, and 91.95% specificity [19].

An energy envelopogram was employed to extract PCG signals from the PhysioNet Challenge 2016 dataset (Potdar, 2021) [20]. The traits were procured with Discrete Wavelet Transform (DWT), selected utilising PCA, and fed into a fine-tuned Bayesian-optimised SVM algorithm. On the other hand, Milani et al. (2021) applied Springer's segmentation algorithm to preprocess the PhysioNet Challenge 2016 dataset, extracting the attributes with MFCCs. Subsequently, Linear Discriminant Analysis (LDA) was applied to further diminish dimensionality. The ANN-based classification recorded a 93.33% accuracy [12].

In 2022, Zhang et al. extracted numerous features in two-dimensional convolution from the PhysioNet Challenge 2016 dataset. Subsequently, the Particle Swarm Optimisation (PSO) was subjected to feature selection before being trained with the convolutional Bi-LSTM network. The report documented accuracy, sensitivity, and specificity of 91.93%, 91.58%, and 92.27%, respectively [14].

A recent study [21] employed a VGG16 model during the spectrogram trait extraction of 1,330 PCG signals from the PhysioNet Challenge 2016 dataset, achieving an 88.84% accuracy. Nevertheless, the authors concluded that the accuracy level was insufficient for reliable patient diagnosis, requiring a more substantial and balanced dataset for performance enhancement. Although the original dataset was extensive, its imbalance might result in biased results. Consequently, implementing more sophisticated balancing techniques rather than simple down-sampling could improve the outcomes. Moreover, the report did not remove noise, a critical aspect of real-world PCG analysis.

Son and Kwon (2018) [22] constructed the Yaseen Khan 2018 dataset, consisting of 1,000 PCG signals. The report classified heart sounds via three algorithms: SVM, KNN, and Deep Neural Network (DNN). The MFCCs and DWT were also applied during feature extraction. The SVM exhibited the best performance, recording accuracy, sensitivity, and specificity of 97.9%, 98.2%, and 99.4%, respectively.

Flores-Alonso et al. applied a smoothing filter, normalised, and segmented the noisy Yaseen Khan 2018 dataset. The report integrated features for classification utilising CNN and Multi-Layer Perceptron (MLP), including MFCCs, DWT, and Continuous Wavelet Transform (CWT). The report recorded an accuracy of 99.8% [23]. In another study, [24] utilised 957 PCG signals from an identical dataset. Nonetheless, the study

excluded samples under 2 s. Multiple features were extracted with MFCCs and DWT. The data obtained was then employed to train classification models with five machine learning algorithms: Random Forests (RF), KNN, SVM, Naive Bayes (NB), and MLP. A remarkably high accuracy of 99.89% in diagnosing normal and abnormal heart sounds with the RF algorithm was procured.

McDonald et al. [25] focused on segmentation techniques in PCG signals, separating data into S1, S2, systole, and diastole. The study also applied hidden semi-Markov models to the PhysioNet Challenge 2022 dataset. Furthermore, a classification model was developed utilising a Bi-GRU algorithm. The 60.2% accuracy documented led the study to win the competition. Meanwhile, Singh et al. [26] applied Mel-spectrograms to extract features from the same dataset. The extracted features were classified with the U-Net method. The report achieved 56.8%, 54.77%, 59.29%, and 58.33% accuracy, sensitivity, specificity, and F1 score, respectively.

During the past five years, most research employed the Butterworth filter for background noise reduction [19], [27] and segmentation techniques [12], [20] for preprocessing. Nonetheless, segmenting non-linear PCG datasets remains challenging as it might lead to valuable information loss through abstract feature extractions [19], [28]. Moreover, a Wavelet Transform (WT) method has been broadly applied to extract PCG signal features. Nevertheless, the technique often extracts redundant traits, further degrading model performance [29], resulting in numerous research studies focusing on traditional feature extraction selection methods, such as LDA and PCA [12], [16]. The recent review by study [8] suggested using the WT method with metaheuristic methods for feature analysis from PCG signals, which allows the LSTM algorithm to generate the optimal model that can achieve a high classification accuracy.

Based on the literature reviewed in this section, heart sound classification was performed through various approaches. An increasing interest in feature selection and optimisation techniques to improve classification accuracy has also been observed. Although substantial strides have been achieved, handling and minimising non-linear PCG dataset feature redundancies are still challenging.

Consequently, advanced preprocessing and feature selection methodologies necessitate further exploration to improve the accuracy and reliability of heart sound classification systems. Preprocessing heart sounds to eliminate noise is a promising avenue for future studies. Furthermore, combining multiple extracted features into a single representation and training the model on the enriched data might yield superior results.

III. PROPOSED METHODOLOGY

The current study reduced PCG signal noise in the preprocessing with Butterworth and cosine filters. Subsequently, the signal attributes were automatically extracted utilising WST. The characteristics were optimally selected through several metaheuristic methods, including Harris Hawks Optimisation (HHO), Dragonfly Algorithm (DA), Grey Wolf Optimiser (GWO), Salp Swarm Algorithm

(SSA), and Whale Optimisation Algorithm (WOA), contributing to feature selection.

The results revealed that the proposed method could achieve excellent classification accuracy with a few feature sets. The suggested model also involved three processes: preprocessing, feature extraction and selection, and classification, as shown in Fig. 1. Each procedure is detailed in subsections A to D.

Fig. 1. The general process diagram of the current study.

A. Preprocessing of the PCG Signal

The preprocessing phase is vital in improving Phonocardiogram (PCG) signal quality before extracting and classifying any features. The following lists the steps necessary during the procedure.

1) *Baseline wander removal*: Baseline wander refers to low-frequency noise typically arising from respiratory movements or patient motion. The noises might distort PCG signals. Consequently, a high-pass Butterworth filter with a 0.5 Hz cut-off frequency was employed to overcome the matter. The filter effectively attenuated frequencies associated with baseline drift. Moreover, heart sound signals predominantly detected between 20 and 150 Hz were preserved. The findings indicated that removing low-frequency noise is critical to avoid interference during the feature extraction phase.

2) *Background noise removal*: The PCG signals are susceptible to various noise sources, including ambient, lung, and muscle contraction sounds. Accordingly, this study applied a two-stage filtering process to enhance the Signal-to-Noise Ratio (SNR). Firstly, a Butterworth low-pass filter at a 150 Hz cut-off frequency was employed to eliminate high-frequency noises. Subsequently, the Adaptive Noise Cancellation (ANC) utilised allowed noise component estimations within the PCG signal by referencing a separate noise signal and subtracting them from the PCG data. The two-phase approach effectively isolated relevant heart sound components from the background noise, facilitating accurate feature extraction and classification.

3) *Data normalisation*: The PCG signal amplitudes vary significantly depending on the recording environment, device, and patient physiology. Consequently, this study employed data normalisation to address the issue. The procedure scaled signal amplitudes to a common range, typically between 0 and 1 or -1 and 1. The min-max normalisation in the present study was calculated according to following the equation.

$$x' = \frac{x - \min(x)}{\max(x) - \min(x)} \quad (1)$$

Where x' refers to normalised PCG signals, x denotes the original PCG signal, $max(x)$ represents the maximum PCG value, and $min(x)$ is the minimum PCG value.

B. Feature Extraction

Feature extraction transforms preprocessed PCG signals into classification-appropriate representations. Various methods, including MFCCs, DWT, and WST, have been employed in previous studies.

1) *Mel-frequency Cepstral Coefficient (MFCC)*: The MFCCs capture spectral PCG signal properties by emphasising perceptually relevant frequency bands. The process involves the following steps [19]:

a) *Framing* - Dividing the filtered PCG signal into overlapping 5-s frames.

b) *Spectrum estimation* - Calculating the amplitude spectrum of each frame.

c) *Windowing* - Multiplying each frame by a Hamming window to reduce spectral leakage through signal end section attenuation to zero.

d) *Fourier transform* - Applying the Fast Fourier Transform (FFT) to convert the time-domain signal into the frequency domain.

e) *Mel Filterbank* - Passing the spectrum through a series of triangular bandpass filters spaced according to the Mel scale.

f) *Logarithm* - Computing the Mel Filterbank output algorithm to mimic the human auditory system perception.

g) *Discrete Cosine Transform (DCT)* - Applying the DCT to the log-filterbank outputs to decorrelate the coefficients. Resultantly, 27 MFCCs in the time-frequency domain for each PCG signal were obtained. Fig. 2 demonstrates the MFCCs extraction phases, which were determined based on following the equation.

Fig. 2. The MFCC method for feature extraction.

$$MFCC_n = \sum_{k=1}^K \log(S_k) \cdot \cos\left(\frac{\pi n(k-0.5)}{K}\right) \quad (2)$$

Where S_k is the log power at each Mel frequency k , K refers to the total number of Mel frequency bands, and N denotes the number of MFCCs to retain.

2) *Discrete Wavelet Transform (DWT)*: The current study utilised DWT to analyse the non-stationary nature of the PCG signals by iteratively decomposing them into time-frequency domains through wavelet filters [30]. The technique fuses low- and high-pass filters, providing approximation and detail coefficients from the PCG signal [31].

The DWT enables high-frequency energy in systolic and diastolic heart sound alteration representations [32]. The approach captures high-frequency components (details) and low-frequency components (approximations), crucial for detecting anomalies in heart sounds. Meanwhile, following the

equation determines wavelet coefficients by projecting $x(t)$ signals onto scaled and shifted wavelet $\psi(t)$ function versions.

$$DWT(a, b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} x(t) \psi^*\left(\frac{t-b}{a}\right) dt \quad (3)$$

Where $DWT(a, b)$ represents the wavelet coefficient at scale a and position b , $x(t)$ is the input signal, ψ^* denotes the complex conjugate of the wavelet function ψ , a represents the scaling parameter, and b is the translation parameter.

In this study, the approximation coefficient ($c, A-n$) and the detail coefficient ($c, D-n$) of each level, n , was established with following the equation. The DWT applied in the present study had 15 decomposition levels for each cycle. The signal energy, entropy, and standard deviation were procured as 16-time features, while the waveform length and wavelet variance estimates were obtained as 16-frequency features.

$$A = cA_n \sum_{k=0}^n cD_n \quad (4)$$

Where A represents the wavelet coefficient values, while n indicates the approximate level number.

Utilising the DWT method, 80 features were extracted from the 15 approximation coefficients for each cycle per the guidelines outlined by [31]. The coefficients were calculated based on the Shannon energy. Fig. 3 represents a generalised flow of the wavelet decomposition from the PCG signal.

Fig. 3. The wavelet decomposition from the PCG signal.

3) *Wavelet Scattering Transform (WST)*: The WST is an advanced technique that captures stable, hierarchical time-frequency features from PCG signals. The method involves the following steps [18][33]:

- Convolution of PCG signals with a wavelet family of varying scales.
- The application of non-linear modulus operators to the convolved signals to obtain scattering coefficients.
- The coefficients are averaged over time to produce the final scattering form, retaining translation-invariant and stable attributes.

In WST, the $x(t)$ signal is convolved with a wavelet function, ψ_1 , before being further convolved with additional wavelet functions, ψ_2, \dots, ψ_J . Eq. (5) is the mathematical representation of WST. The phase enables multi-scale and multi-resolution feature extractions as illustrated in Fig. 4.

$$S_J(x(t)) = |x * \psi_1| * \psi_2 * \dots * \psi_J \quad (5)$$

Where $S_J(x(t))$ denotes the wavelet scattering coefficients at level J , $x(t)$ represents the input signal, and $\psi_1, \psi_2, \dots, \psi_J$ are the wavelet functions at different scales.

Fig. 4. The wavelet scattering transforms on PCG signal.

C. Feature Selection

Feature selection aims to eliminate duplicate or non-informative features, which reduces the excess amount of input features, leading to achieving an optimal model. Hence, feature selection is critical in ensuring that only the most relevant information is passed to the classifier [8]. In the current study, five metaheuristic algorithms for feature selection were employed: HHO, DA, GWO, SSA, and WOA.

1) *Harris Hawks Optimisation (HHO)*: The HHO is a swarm intelligence algorithm published by [34] in 2019. The model was inspired by nature, mimicking the cooperative hunting strategy of Harris hawks. Balancing exploration and exploitation, the algorithm simulates different prey-hunting phases, such as surprise pounce and soft besiege.

The current study employed HHO to determine the most suitable optimal features. The approach is characterised by rapid large solution space explorations with substantial accuracy and rapid convergence, maintaining exploration and exploitation equilibrium. Post-feature extraction, the initial parameters were applied to establish a random position for HHO within the search bounds.

The HHO algorithm determines the best position for prey. The exploration phase is denoted by prey energy values over 1 ($E > 1$), where HHO is still in the searching mode. Meanwhile, a slight energy drop below 1 ($E < 1$) denotes the model entering the exploitation stage. During the soft siege ($E \geq 0.5$), HHO continually updates the position of the prey demonstrating energy to escape. Nevertheless, HHO dives around the target in a hard siege once the energy falls below 0.5 with a significant escape probability.

Features within the optimal range and low error rate are selected at each stage. During the final cycle, the selected PCG attributes are optimised and employed as input for the classification model. The HHO process [35] is illustrated in Fig. 5.

The technique is particularly effective for selecting features from the WST as it efficiently handles the hierarchical and multi-scale data. Feature selection was calculated according to following the equation.

$$X(t+1) = \begin{cases} X_{rand}(t) - r_1 \cdot |X_{rand}(t) - 2r_2 \cdot X(t)| & E \geq 0.5 \\ X_{prey}(t) - X(t) - r_3 \cdot |X_{prey}(t) - X(t)| & E < 0.5 \end{cases} \quad (6)$$

Where $X(t+1)$ refers to the next position of the hawk, X_{rand} and X_{prey} represent random and prey positions, while r_1 , r_2 , and r_3 are random numbers.

2) *Dragonfly Algorithm (DA)*: Introduced in 2016 by [36], DA is a metaheuristic optimisation algorithm based on the static and dynamic swarming behaviours of dragonflies. The model utilises five key factors: separation, alignment, cohesion, attraction to food, and distraction from enemies.

Fig. 5. The HHO working principle.

The DA defines a neighbourhood of radius r according to how it works. Neighbourhood sizes are scaled up based on a linear relation with the iteration counter during exploration to exploitation transitions. Consequently, static swarms are transformed into dynamic swarming. In the final optimisation stage, each dragonfly solution is joined to form an active unified swarm, which converges towards the best global solution at the end of the convergence [37], [38], [39]. The feature selection for the technique is represented by following the equation. The DA was also applied in this study during the feature selection stage (see Fig. 6).

$$\Delta X = \sum_{i=1}^N (S_i + A_i + C_i + F_i + E_i) \quad (7)$$

Where S is separation, A denotes alignment, C represents cohesion, F is food attraction, and E denotes enemy distraction. The working principle of DA.

3) *Gray Wolf Optimiser (GWO)*: Mirjalili et al. [40] proposed GWO, a swarm intelligence-based metaheuristic algorithm, in 2014. The algorithm was based on the grey wolf leadership hierarchy and hunting strategy. Based on the grey wolves hierarchical system [35], the alpha (α), or the most dominant wolf in the pack, leads the other wolves during food hunting and finding. During the absence of the alpha wolf, the beta (β) becomes the pack leader. In the hierarchy, the power levels of the delta (δ) and omega (ω) groups are significantly less apparent than their nearest rival (see Fig. 7).

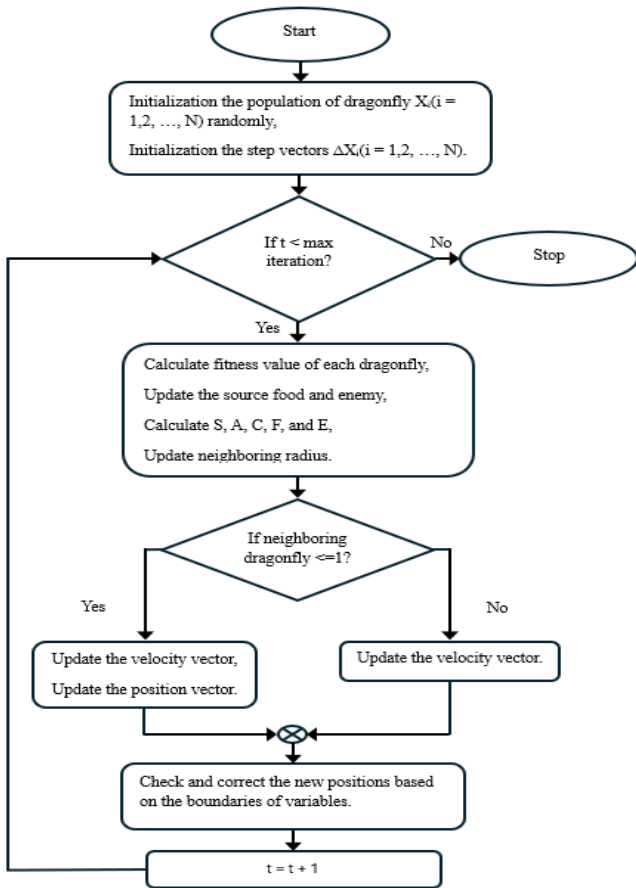

Fig. 6. The working principle of DA.

Fig. 7. The GWO hierarchical levels.

The mechanism of the GWO algorithm in the sociological agenda is complex social intelligence. Grey wolves exhibit remarkable hunting strategies by chasing, encircling, and attacking their prey [41], [42], [43]. Successful pursuits lead them to the optimal solution through successive phases with distinctive efficiencies, encouraging others to adopt similar cooperative actions [35]. Fig. 8 outlines the GWO feature selection process, while the following equation was employed to determine feature selection.

$$\vec{X}(t + 1) = \frac{\vec{X}_\alpha + \vec{X}_\beta + \vec{X}_\delta}{3} \quad (8)$$

Where $X(t + 1)$ refers to the next position of the wolf, and $\vec{X}_\alpha, \vec{X}_\beta, \vec{X}_\delta$ are the positions of the top three wolves.

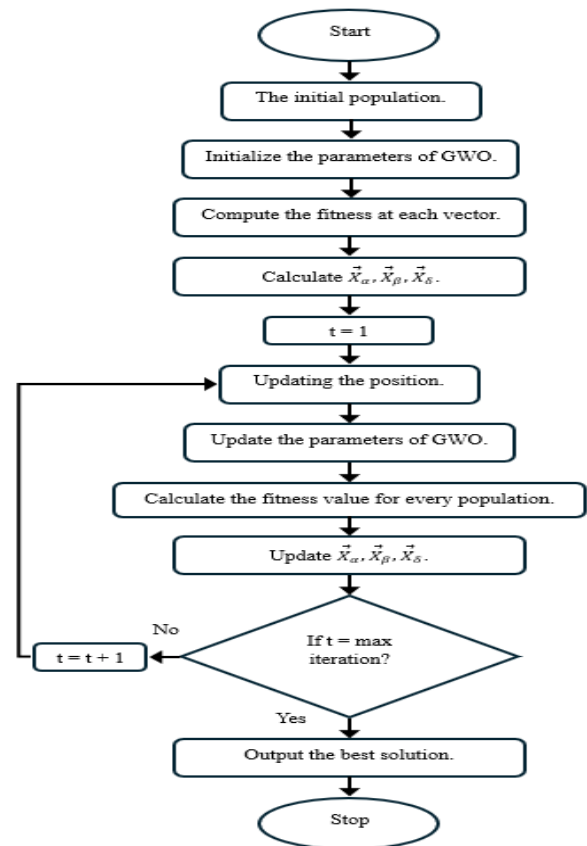

Fig. 8. The GWO working principle.

4) *Salp Swarm Algorithm (SSA)*: In 2017, SSA, a novel nature-inspired optimiser, was proposed by Mirjalili et al. [44]. The model mimics the collective behaviour of salps, which are marine wildlife. The SSA is versatile, efficient, straightforward, and applicable to parallel and serial modes. Furthermore, the algorithm has a single adaptively decreasing parameter, contributing to optimal diversification and intensification tendencies balancing.

Salps move dynamically and update their positions through mutual interactions to avoid being trapped in local optima. The SSA behaviour is recognised by the salp chain algorithm, searching and selecting optimal food sources effectively. The swarm aims to identify and locate a specific food source within the search space.

The salps in the SSA approach are categorised as either "leaders" or "followers" based on their position in the chain. Follower salps rely on the actions of their leader for guidance. The flowchart of the SSA processes is demonstrated in Fig. 9 [45]. In this study, feature selection utilising SSA was established according to following the equation.

$$X_{i,j}(t + 1) = \begin{cases} X_j(t) + c_1 \cdot (U_j - L_j) + L_j & i = 1 \\ \frac{X_{i,j}(t) + X_{i-1,j}(t)}{2} & i > 1 \end{cases} \quad (9)$$

Where X_j is the food source in the j dimension, U_j and L_j refer to the upper and lower bounds of the j dimension, respectively, and c_1 denotes a random number.

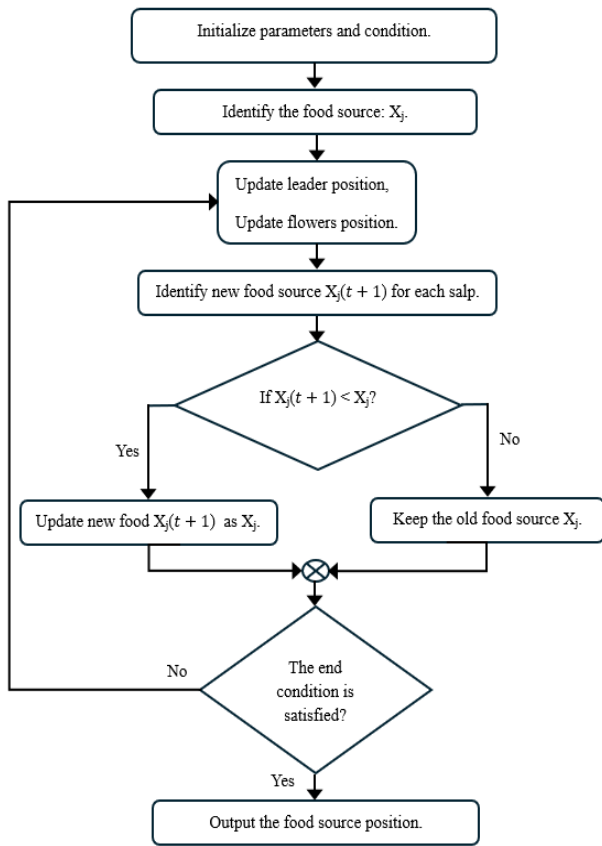

Fig. 9. The working principle of SSA.

5) *Whale Optimisation Algorithm (WOA)*: The WOA algorithm was developed by Mirjalili and Lewis [46] in 2016. The model was the first metaheuristic approach applicable to comprehensive optimisations. The WOA algorithm involves two primary phases based on the bubble-net hunting strategy of humpback whales.

Firstly, humpback whales hunt and encircle their prey. Similarly, the WOA algorithm assumes that the best solution is unknown, thus identifying the optimal candidate solution as the target prey or close to it. Subsequently, additional search agents adjust their positions to match the best search agent, shrinking the search space effectively.

Fig. 10 depicts the second phase of the nut strategy, the bubble-net attacking stage. During the step, the whales reduce the predator chain around the prey and move in a spiral attacking pattern. Meanwhile, random humpback whales calculate new positions instead of relying solely on the globally best-known position in the update phase [47], [48]. Eq. (10) was employed to determine the feature selection in this study, and the selection process is illustrated in Fig. 11.

$$\vec{X}(t+1) = \begin{cases} \vec{X}^*(t) - A \cdot D & p < 0.5 \\ D' \cdot e^{bl} \cdot \cos(2\pi l) + \vec{X}^*(t) & p \geq 0.5 \end{cases} \quad (10)$$

Fig. 10. The WOA behaviour.

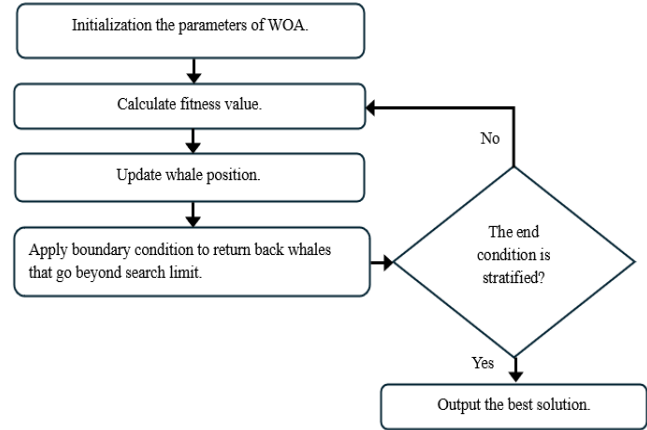

Fig. 11. The working principle of WOA.

Where $X(t+1)$ is the updated position of the whale, $X^*(t)$ represents the position of the best solution (prey), A and D are coefficient vectors calculated as $A = 2a \cdot r - a$ and $D = |C \cdot X^*(t) - X(t)|$, $D' = |X^*(t) - X(t)|$ denotes the distance to the prey, p is a random number between 0 and 1 that determines the exploitation or exploration phase, b is attributed to a constant defining the shape of the logarithmic spiral, and l represents a random number between -1 and 1 .

D. Classification

During the classification model design, the selected features were classified with a 17-layered Recurrent Neural Network (RNN), which included Bi-LSTM. The architecture was designed to capture dependencies in sequential heart sound data (past and future), enabling the model to differentiate normal and abnormal sounds with significant accuracy.

Fig. 12. The Bi-LSTM block diagram.

The model design is illustrated in Fig. 12. The description of each layer in the proposed model is presented as follows:

- The input layer receives selected features.
- The input features were converted into dense vectors in the embedding layer.
- Bi-LSTM Layer: Processes input in the forward and backward directions to capture temporal dependencies.

- The dropout layers were applied following the Bi-LSTM and dense layers to prevent overfitting.
- A total of 13 dense layers followed were included to transform the features.
- A final dense layer, the output layer, contains softmax activation for normal or abnormal heart sound categorisation.
- The forward and backward Bi-LSTM passes are presented by equations (11) and (12), respectively. This study utilised the Bi-LSTM layer model due to its bidirectional dependencies in PCG signals, essential for accurately categorising heart sounds. Its 17-layer structure also allows the model to learn complex patterns, improving classification performance. The proposed model architecture is illustrated in Fig. 13.

$$\vec{h}_t = \sigma(W_h \cdot [\vec{h}_{t-1}, x_t] + b_h) \quad (11)$$

$$\hat{h}_t = \sigma(W_h \cdot [\hat{h}_{t+1}, x_t] + b_h) \quad (12)$$

Where \vec{h}_t and \hat{h}_t represent hidden states in the forward and backward directions, respectively.

Fig. 13. The Bi-LSTM-incorporated RNN architecture.

IV. EXPERIMENTS AND RESULTS

The dataset and evaluation criteria employed in this study are discussed in this section. The experiments were conducted according to the specified criteria, and the results obtained are also included.

A. Dataset

The current study explored three datasets commonly applied in related research: PhysioNet 2016 [49] and 2022 [50] and Yaseen Khan 2018 [22]. The PhysioNet 2016 dataset consists of 3,240 PCG signals from global volunteers. The duration of the heart sounds in the dataset ranged between 5 and 120 sec (s) recorded at 2,000 Hz. Furthermore, the dataset includes normal and abnormal heart sounds.

The Yaseen Khan 2018 dataset comprises 1,000 2-s PCG signals. The sounds were sampled at 8,000 Hz with binary and multi-class labels. The third dataset, PhysioNet 2022, contains 3,163 PCG signals of 5 to 65 s recorded at 4,000 Hz. In this study, each dataset was split with the k-fold and stratified k-fold (K = 5 and 10) Cross-Validation (CV) methods.

B. Performance Evaluation Metrics

The accuracy, sensitivity, specificity, and F1 score were the evaluation criteria of the proposed model. Each criterion was determined according to Eq. (13)–(16). Meanwhile, Fig. 14 demonstrates the confusion matrix-based evaluation procedure applied in the present study [50].

$$Accuracy = \frac{TP+TN}{TP+FN+TN+FP} \quad (13)$$

$$Sensitivity = \frac{TP}{TP+FN} \quad (14)$$

$$Specificity = \frac{TN}{TN+FP} \quad (15)$$

$$F1 = \frac{2 \times precision \times recall}{precision + recall} \quad (16)$$

		Abnormal	Normal	
Output Class	Abnormal	True Positive (TP)	False Positive (FP)	Precision = $\frac{TP}{(TP + FP)}$
	Normal	False Negative (FN)	True Negative (TN)	Negative Predictive Value = $\frac{TN}{(TN + FN)}$
		Sensitivity (recall) = $\frac{TP}{(TP + FN)}$	Sepecificity = $\frac{TN}{(TN + FP)}$	Accuracy = $\frac{TP + TN}{(TP + TN + FP + FN)}$
		Target Class		

Fig. 14. Evaluation measures using confusion matrix.

C. Experimental Results

A comprehensive explanation of the results is included in this section, documenting the performance of the proposed method. The suggested model was implemented with MATLAB 2023, while training and testing were conducted on a system equipped with an Intel Core i7 processor (2.6 GHz), 32 GB RAM, and NVIDIA RTX 960M GPU (4 GB).

During the initial experiments (baseline), 3,240, 1,000, and 3,163 PCG signals from PhysioNet 2016, Yaseen Khan 2018, and PhysioNet Challenge 2022, respectively, were assessed. The datasets were split with hold-out CV, with 85% utilised as training, while 15% were employed during the testing stage.

A 5-s time window applied on the PhysioNet 2016 dataset produced 10,000 samples at 2,000 Hz frequency, while the PhysioNet Challenge 2022 generated 20,000 records at 4 kHz. Meanwhile, 8,000 samples recorded at 8 kHz were procured from the Yaseen Khan 2018 with a 1-s interval.

Several methods, including MFCC, DWT, and WST, were employed to extract raw features from each dataset at varying window sizes (5, 10, and 8 WS). The present study also utilised the Bi-LSTM algorithm with 17 layers for training, applying K-fold and stratified (S) K-fold (K = 5 and 10) CV approaches to mitigate data imbalance. Classification performance was then evaluated based on accuracy, sensitivity (Sen%), specificity (Spec%), and F1 score (F1%). Whereas, WL stands for window length, WS stands for window size, and L stands for the number of decomposition levels of DWT.

Table I summarises the time and frequency domains of the PCG signals acquired from the three datasets evaluated. The findings indicated that each dataset required separate training. The WST technique extracted numerous features from the PCG signals, achieving the highest baseline accuracy. Nonetheless, the accuracy of the model required improvement due to

background noise in the PCG signals and irrelevant extracted features, which affect classification precision. Moreover, the stratified 10-fold CV recorded a notable accuracy rate when the datasets were individually assessed. Consequently, the approach was utilised in the proposed experiment, applying different window sizes for each dataset (see Table II).

TABLE I. THE BASELINE EXPERIMENTAL RESULTS FOR HEART SOUND ANALYSIS

Dataset	WL-feature extraction method		CV	Acc%	Sen%	Spe%	F1%

PhysioNet 2022, 3,163 PCG signals	Butterworth filter (low-pass), cosine filter (high-pass), normalisation (-1, 1)	195-HHO	60.67	69.20	52.90	62.66
		193-DA	59.62	60.61	58.70	58.87
		185-GWO	57.17	56.54	57.74	55.73
		175-SSA	61.68	55.39	67.41	57.96
		181-WOA	60.59	57.87	63.06	58.34

During the evaluations, each dataset was assessed independently and split with holdout CV (see Table III). Low-pass Butterworth and cosine filters were applied during preprocessing to reduce high-frequency intensities from the PhysioNet 2016 and Yaseen Khan 2018 datasets at 200 Hz and 800 Hz, respectively, cut-off frequencies. Meanwhile, the PhysioNet 2022 dataset was subjected to low-pass Butterworth and high-pass cosine filters within the 15–400 Hz cut-off frequency.

After preprocessing, each dataset was normalised to a range of -1 to 1. A 5-s duration was applied to the PhysioNet 2016 and 2022 datasets, while Yaseen Khan 2018 was subjected to 2-s intervals with zero padding. Subsequently, the features were extracted with the WST. Resultantly, 263 WST features with 10-WS were procured from the PhysioNet 2016 dataset, 330 WST features with 8-WS from Yaseen Khan 2018, and 348 WST features with 5-WS from PhysioNet 2022. Metaheuristic techniques were employed during feature selection, including HHO, DA, GWO, SSA, and WOA. Default parameters and hyperparameters were applied to enhance classification accuracy.

Initially, all metaheuristic approaches were employed under default parameters of 10 maximum iterations, a 10-population size, and a 5 K-value for the KNN classifier. Holdout CV of

80% training and 20% testing, 0.99 alpha (α), and 0.01 beta (β) were also applied per the information reported in previous studies.

The 17-layer Bi-LSTM architecture developed in this study was utilised to train the classification model. A stratified 10-fold CV was also applied to overcome the class imbalance. The metaheuristic methods were then evaluated with test data with classification accuracy as the key performance metric. The results are listed in Table III.

Under default parameters, the proposed model documented significant results with 100% accuracy when applied to the Yaseen Khan 2018 dataset utilising all metaheuristic techniques. Conversely, the accuracy of the PhysioNet 2016 and 2022 datasets was not considerably higher than the baseline. Consequently, the current study employed hyperparameters for all metaheuristic methods in the second task of the proposed model as indicated in Table IV.

Preprocessing methods under hyperparameter settings and training step with the Bi-LSTM classifier (17 layers) were applied to the PhysioNet 2016 and 2022 datasets to create the classification model in this study. A stratified 10-fold CV was employed during training. Fig. 15 and Fig. 16 demonstrate the findings from the PhysioNet 2016 and 2022 datasets, respectively.

TABLE IV. THE HYPERPARAMETERS-USED FOR THE PHYSIONET 2016 AND 2022 DATASETS

Parameters	PhysioNet 2016	PhysioNet 2022
Cross-Validation	Holdout (85% training, 15% testing)	Holdout (80% training, 20% testing)
Fitness Value	$\beta = 1e-10 - 1e-1$	$\beta = 0.01 - 0.1$
Population Size	10	
Classifier	KNN	
k-value	11	5
Max iterations (M-iters)	10	

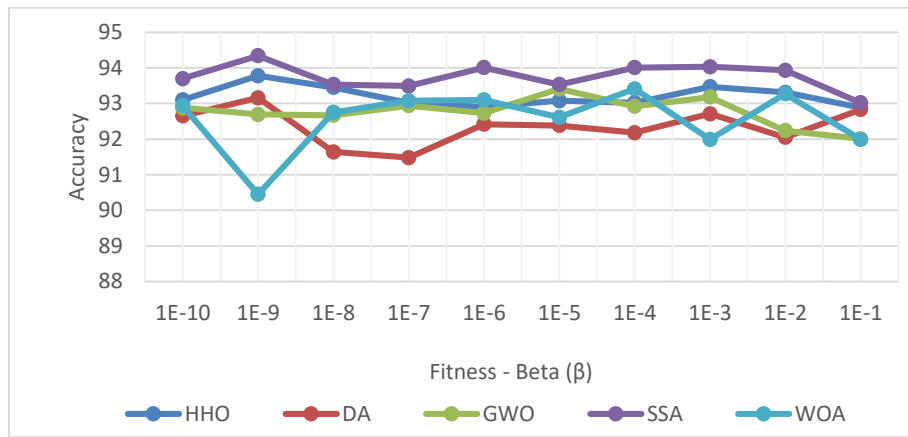

Fig. 15. The best fitness value and accuracy from the PhysioNet 2016 dataset when hyperparameter settings were applied for HHO, DA, GWO, SSA, and WOA.

Fig. 16. The optimal fitness value and accuracy of the PhysioNet 2022 dataset were evaluated with HHO, DA, GWO, SSA, and WOA under hyperparameter settings.

Based on Fig. 15 and Fig. 16, improved classification accuracy was observed when the hyperparameters for the Physionet 2016 and 2022 datasets were adjusted. The datasets recorded excellent accuracy rates at SSA and HHO tuned to 94.34% and 66.83%, respectively. The data were considered more accurate than the baseline and default parameters. The findings are summarised in Table V. Fig. 17 to Fig. 19 and Table VI illustrate the results of real-world experiments through majority voting of the datasets employed.

According to Table VI, a 94.85% final accuracy rate was recorded by the PhysioNet 2016 dataset in real-world evaluations without voting ties (NoUniqueMode = 0). During the assessment, WST (263 extracted features, 5 sec) and SSA (127 selected features) with the Bi-LSTM (17 layers) algorithm were applied (see Fig. 17).

TABLE V. SUMMARY OF THE METAHEURISTIC RESULTS UNDER HYPERPARAMETERS

Dataset	WL-feature extraction and selection method	Optimal-fitness value (β)	k/M-iters	Acc%	Sen%	Spe%	F1%

Fig. 19. The final experimental results for the PhysioNet 2022 dataset assessed with hyperparameter settings by 163-HHO.

In the Yaseen Khan 2018 real-world evaluation, the 2-s proposed model with WST and all metaheuristic methods achieved substantial results with 100% accuracy without any prediction ties. The results are summarised in Fig. 18. Meanwhile, the PhysioNet 2022 dataset achieved a final accuracy of 66.87% in the real-world assessment with the WST (348 extracted features, 5 sec) and HHO (163 selected features) methods. The data was considered more accurate than the baseline and default parameter values. The superiority was due to reduced redundant features without any ties in the voting classes, as illustrated in Fig. 19.

D. Discussion

Overall, HHO, DA, GWO, SSA, and WOA algorithms were more sensitive and negatively affected in imbalanced datasets. The metaheuristic techniques revealed similar efficiency and convergence speed limitations and global solution procurement issues. Furthermore, randomisation is crucial during the exploration and exploitation phases. Accordingly, increased randomisation would lead to classification accuracy from elevated computational time.

Based on the results, the SSA approach improved the accuracy and performance of the classification model in the PhysioNet 2016 dataset. The method exhibited superior exploration abilities for features at low frequencies than the other metaheuristic methods employed in this study.

All metaheuristic techniques utilised in the current study achieved a considerable accuracy rate when applied to the Yaseen Khan 2018 dataset. Meanwhile, the HHO approach performed better than GWO, SSA, and WOA on the PhysioNet 2022 dataset. The findings might be due to the significant exploration capabilities for features at high frequencies of HHO.

In this study, the performance of the proposed method utilising the metaheuristic techniques was compared to recently published reports that aimed to diagnose heart sounds utilising PCG signals (see Table VII). The highest accuracy rates achieved with the PhysioNet 2016 dataset were reported by [11] and [12] at 93.5% and 93.33%, respectively. Nonetheless, [11] primarily focused on extracting 527 features without applying any technique to eliminate irrelevant features. Whereas [12] procured 130 features with MFCCs and the traditional LDA technique to select optimal attributes.

For the 1,000 PCG Yaseen Khan 2018 dataset, [18] and [47] documented the highest scores, 99.80% and 99.90%, respectively. Nevertheless, [23] only employed MFCC, DWT, and CWT to extract several features. Conversely, the proposed method was based on the WST. All metaheuristic approaches also recorded a significant accuracy rate of 100% when applied to the same dataset.

Reports on applying feature selection methods to PCG signals, particularly metaheuristic approaches, are limited. For instance, [14] extracted deep features and employed PSO for improvement before utilising the Bi-LSTM algorithm, recording a 91.93% accuracy rate. Consequently, the present study aimed to close the knowledge gap, focusing on selecting optimal features based on metaheuristic approaches to improve the performance of the model.

This study achieved the best performance with 94.85%, 83.33%, 97.69%, and 86.48% accuracy, sensitivity, and specificity rates and F1 score. The WST based on the SSA method was employed. The data supported the superiority of the suggested model.

TABLE VII. RESULTS COMPARISON BETWEEN THE PROPOSED METHOD AND PREVIOUS STUDIES

Author	Dataset used	Feature extraction method	Feature selection method	Classifier	CV method	Acc (%)	Sen (%)	Spe (%)	F1 (%)
[11]	PhysioNet 2016 dataset (3,240 PCG signals)	Multi-domain features (527 features)	Not used	Fine KNN	Hold-out	93.5	-	-	-
[12]	PhysioNet 2016 dataset (3,126 PCG signals)	MFCCs (130 features)	LDA	ANN	Hold-out	93.33	-	-	-
[14]	PhysioNet 2016 dataset (3,240 PCG signals)	Deep features	PSO	Bi-LSTM	5-fold	91.93	91.58	92.27	-
[16]	PhysioNet 2016 dataset (3,153 PCG signals)	CWT and MFCC (675 features)	PCA	ANN	10-fold	85.2	-	-	-
[19]	PhysioNet 2016 dataset (3,240 PCG signals)	MFCCs (27 features)	Not used	Ensemble classifier	5-fold	92.47	94.08	91.95	-
[21]	PhysioNet 2016 (1,330 PCG signals)	Spectrogram feature	Not used	VGG16	-	88.84	87.23	86.55	87.87
[22]	Own dataset	MFCCs + DWT (43 features)	Not used	SVM	5-fold	97.9	98.2	99.4	99.7
[23]	Yaseen Khan 2018 dataset (1,000 PCG signals)	MFCC, DWT, and CWT	Not used	CNN and MLP	Hold-out	99.8	99.8	99.8	-
[24]	Yaseen Khan 2018 dataset (957 PCG signals)	Multiple features using MFCC and DWT methods	Not used	RF	-	99.89	99.90	99.60	99.90
[25]	PhysioNet 2022 dataset (3,163 PCG signals)	Spectrogram feature	Not used	Bi-GRU	5-fold	60.2	-	-	54.9
[26]	PhysioNet 2022 dataset (3,163 PCG signals)	Mel-spectrograms	Not used	U-Net	Hold-out	56.80	54.77	59.29	58.33
[28]	PhysioNet 2016 (2,435 PCG signals)	Merage short- and long-term features (33 features)	Not used	Subspace K-Nearest Neighbor	Hold-out	92.7	96	82	-
[51]	Yaseen Khan 2018 dataset (1,000 PCG signals)	Deep features	Not used	Vision Transformer (ViT)	10-fold	99.90	99.90	99.90	99.90
[52]	PhysioNet 2016 dataset (3,153 PCG signals)	Multiple features (515 features)	Selected features randomly (400 features)	SVM	10-fold	88	88	87	-
[53]	PhysioNet 2016 dataset (3,126 PCG signals)	Zero crossing rate (ZCR), discrete fourier transform (DFT), and MFCCs (315 features)	Genetic Algorithm (GA) (15 features)	LightGBM (Light Gradient Boosting)	10-fold	92.3	91.06	93.54	-
[54]	Yaseen Khan 2018 dataset (1,000 PCG signals)	Time-varying spectral feature (35 features)	Not used	KNN	5-fold	99.6	99.79	98.83	99.75
[55]	Yaseen Khan 2018 dataset (1,000 PCG signals)	Chirplet Transform (CT) (300 features)	Not used	Composite Classifier	Hold-out	98.33	-	-	-
[56]	PhysioNet 2022 dataset (3,163 PCG signals)	MFCCs (25 features)	Not used	Ensemble classifier	10-fold	56.8	-	-	52.8
Propose Methods	PhysioNet 2016 dataset (3,240 PCG signals)	WST (263 features)	SSA (127 features)	Bi-LSTM (17 layers)	Stratified 10-fold	94.85	83.33	97.69	86.48
	Yaseen Khan 2018 (1,000 PCG signals)	WST (330 features)	HHO, DA, GWO, SSA, and WOA			100	100	100	100
	PhysioNet 2022 (3,163 PCG signals)	WST (348 features)	HHO (163 features)			66.87	60.61	72.58	63.57

The study in [25] documented an accuracy of 60.2% for the PhysioNet Challenge 2022 dataset with spectrogram features. The less accurate results were from the substantially noisy PCG signals, rendering the extraction of vital features and improvement of the classification model challenging. Nonetheless, the proposed design achieved an optimal solution by obtaining an accuracy rate of 66.87% when applied to the

same dataset. Furthermore, the current study effectively determined the sensitivity, specificity, and F1 scores, yielding 60.61%, 72.58%, and 63.57%, respectively. The suggested method diminished the number of extracted features, positively affecting convergence speed during the training process and achieving excellent performance.

V. CONCLUSION AND FUTURE DIRECTIONS

Medically, diagnosing heart sounds faces significant obstacles, particularly PCG signal processing, due to noise, imbalanced datasets, and the considerable extracted feature search space. Numerous researchers have addressed the issues and developed various solutions. Nonetheless, related reports on applying metaheuristic techniques to PCG signals are scarce. The non-linear nature of the data and its complicated relationships have contributed to the knowledge gap.

The current study proposed a model employing WST to address the challenges posed by noise signals and irrelevant extracted features. Hyper-filters were applied to mitigate the impact of noise, while metaheuristic optimisation techniques, HHO, DA, GWO, SSA, and WOA, were utilised to select the most informative WST features. The selected features then served as input to a Bi-LSTM algorithm to produce the classification model. Moreover, a stratified 10-fold cross-validation was implemented to mitigate the effects of imbalanced datasets and overfitting. Resultantly, the metaheuristic methods documented potential, exhibiting 100% accuracy with the Yaseen Khan 2018 dataset with default parameters. Meanwhile, the classification accuracy of the suggested model on the PhysioNet 2016 and 2022 datasets under hyperparameter settings was 94.85% and 66.87% with SSA and HHO, respectively.

Overall, the proposed method documented superior results to previous research. The suggested model might also improve clinical finding reliability. However, the limitations are still having in this study, such as noise in PCG signals, imbalanced datasets, and unnecessary features. Consequently, future studies should enhance the attribute by focusing on several key areas. For instance, utilising a more significant PCG signal dataset and refining the preprocessing techniques by applying deep filters to reduce noise. The imbalanced classes issue could also be mitigated by enhancing the stratified K-fold CV process. Furthermore, extracting multiple features with CWT, DWT, and WST techniques could be considered. Finally, an improved model performance might be achieved by applying hybrid metaheuristic optimisation methods, such as HHO-SSA, to select optimal features efficiently.

Developing an Integrated Platform to Track Real Time Football Statistics for Somali Football Federation (SFF)

Bashir Abdinur Ahmed*, Husein Abdirahman Hashi, Abdifatah Abdilatif Ahmed, Abdikani Mahad Ali
Department of Computer Application, Jamhuriya University of Science and Technology, Mogadishu, Somalia

Abstract—The integration of technology in sports has revolutionized how stakeholders interact with and perceive the game. This thesis presents the development of an integrated platform aimed at tracking real-time football statistics for the Somali Football Federation (SFF). Football, being one of the most popular sports globally, relies heavily on accurate and up-to-date statistical data for player performance analysis, team strategies, and fan engagement. The SFF, like many other federations, faces challenges in collecting, managing, and utilizing football statistics effectively. The advent of digital technologies and the internet has revolutionized data collection and dissemination methods across various fields, including sports. Traditional methods of data collection and analysis, which are often manual and time-consuming, can no longer meet the demands of modern football analytics. The platform encompasses a mobile application for fans, an admin panel for administrators, and a backend system for data management. Leveraging modern technologies such as Flutter for mobile development, Node.js and MySQL for backend services, and React for the admin interface, the system ensures comprehensive coverage of match events, player statistics, and tournament standings. Real-time updates facilitated by Socket.IO enhance user engagement and decision-making capabilities for coaches and administrators.

Keywords—Real-time football statistics; Integrated sports platform; Somali Football Federation (SFF); user engagement; sports technology

I. INTRODUCTION

The Somali Football Federation (SFF) is a national administrative body under the Confederation of African Football (CAF) that oversees and regulates football activities and competitions within the Federal Republic of Somalia. This includes managing the first, second, and third divisions, as well as the Inter-regional Cup. Additionally, the SFF is responsible for the management of the Somalia national football team. The SFF's primary mission is to promote and develop football throughout the country [1].

In recent years, there has been a significant rise in the adoption of data analytics within the sports industry. This surge is attributed to sports teams' growing recognition of the immense value data can offer in enhancing performance and gaining a competitive advantage [2].

In their seminal work on the evolving landscape of sports, [3] underscored the remarkable transformation of sports into a dynamic, multifaceted competition, particularly evident in football's burgeoning role as a significant branch of the business world. They highlighted the intricate strategic manoeuvres that now characterize the sport, emphasizing that even pivotal

moments within a match often elude both human perception and the most advanced camera technologies.

Despite the growing popularity and adoption of data analytics in sports, the SFF currently lacks a comprehensive real-time football match statistics system. In the absence of such a system, the federation faces several challenges in effectively harnessing the power of data analytics to enhance its analytical capabilities and improve decision-making processes [4]. Traditional methods of match analysis rely on post-match statistics, which are often time consuming and do not provide immediate insights into critical match events.

For the SFF, embracing real-time statistical analysis is not just about keeping pace with global trends; it's about unlocking new opportunities for growth and competitive advantage. Integrating such analytical approaches can significantly improve the tactical planning and performance analysis of Somali football teams. The insights gained from real-time data can help coaches make informed decisions, tailor training programs to address specific weaknesses, and develop strategies that exploit the opposition's vulnerabilities. Furthermore, as outlined by study [4] the development of technologies for tracking and analysis in sports can play a crucial role in enhancing team performance, which is particularly relevant for federations looking to optimize their resources and talent.

This study outlines the development of a real-time football statistics platform personalized to the Somali Football Federation (SFF). It explores the challenges faced by the federation, reviews advancements in sports, and details the design and implementation of a comprehensive system that integrates real-time updates, data management, and user-friendly interfaces. The platform aims to enhance decision-making, and fan engagement while addressing the lack of existing solutions for Somali football statistics.

II. LITERATURE REVIEW

The transition to real-time analysis in football marks a significant milestone in the sport's analytical journey. This shift was propelled by technological advancements, enabling the collection and analysis of data in real-time during matches. Systems like the one introduced by [5] for multi-view event detection in soccer games exemplify the capabilities of real-time analytics to provide immediate insights into player movements, ball trajectories, and game dynamics.

The development of sports analytics is underpinned by several key theories that guide the collection, analysis, and interpretation of data. These theories include statistical models for predicting outcomes, optimization theories for team

*Corresponding Author.

composition and strategy, and performance analysis frameworks for evaluating player efficiency. For instance, the application of Poisson and negative binomial distributions to goal distributions in football, as discussed by [6], exemplifies the use of statistical models in sports analytics.

The literature review highlights several research gaps in the realm of real-time statistical analysis in football. One notable gap is the limited exploration of how these advanced analytics can be tailored and applied within the context of developing football nations, such as Somalia. Additionally, there is a need for real-time display of data which we hope to rectify [7].

This Research project aims to develop and implement a real-time football match statistics system to augment the analytical capabilities of the Somali Football Federation. This system will provide live updates on critical match events, including goals, cards, referees, and stadium information, thereby enhancing the viewing experience for fans and stakeholders alike. By leveraging real-time data insights, the federation seeks to empower coaches and decision-makers with the tools needed to make informed strategic choices and optimize player development programs [8].

Through the implementation of this real-time statistics system, the SFF aspires to set a new standard for football administration in the region, fostering greater engagement and interest in football across Somalia. This initiative represents a significant step towards embracing technology and innovation to propel Somali football into a new era of success and progress [9].

Researchers could focus on developing cost-effective and scalable analytics solutions that are accessible to football federations with limited resources. Investigating the integration of cultural and contextual factors into analytics models could also provide valuable insights, ensuring that the data interpretation is relevant and actionable for specific football environments [10]. Moreover, longitudinal studies on the impact of real-time analytics on player performance and injury prevention could significantly contribute to the field.

The study in [11] explore the use of machine learning in predicting football league standings and player performance, demonstrating how data-driven insights can enhance team strategies and performance optimization. This approach, applicable to real-time match statistics, can support the Somali Football Federation in making informed, data-driven decisions to improve player development and game strategies.

In addition to predictive models, the statistical dynamics of football have been extensively studied to understand the underlying mechanisms of the game. The study in [12] analyze the statistical dynamics of football, focusing on team behavior during matches. Their study applies statistical physics to understand game tactics, providing insights that can be integrated into real-time analytics systems. This can enhance decision-making for football federations like the SFF, helping improve tactical strategies during live matches.

Real-time football analytics have advanced with the development of sensors, machine learning, and computer vision technologies, enabling the collection of large amounts of data during matches. Technologies like wearable devices and video

analysis tools have transformed event tracking. Research on wearable technology shows how real-time biometric data can monitor player fitness, fatigue, and performance [13].

Studies by [14] have demonstrated the impact of well-designed visualizations in improving both player performance and fan engagement. This area could benefit from specific case studies on the design and usability of real-time systems tailored for football federations with varying levels of technical literacy and infrastructure, like the Somali Football Federation.

Another potential research gap could focus on the challenges of implementing real-time football analytics in countries with limited resources and infrastructure, such as Somalia. Research by study [15] highlights the barriers faced by sports organizations in developing nations, including financial constraints, technical know-how, and unreliable internet connectivity. Solutions such as low-cost data collection tools, offline-capable platforms, and mobile-based applications could be explored to bridge these gaps and make real-time football analytics more accessible.

These gaps and future research directions offer an exciting opportunity for the SFF and the academic community to contribute to the advancement of football analytics. By addressing these areas, there is potential to enhance the strategic application of analytics in football, promoting a more informed, effective, and competitive approach to the sport globally.

III. METHODOLOGY

Our research goal is to develop a comprehensive mobile application using Flutter, with a Node.js backend supported by MySQL, alongside a React-based admin panel. The primary objective is to create a platform that facilitates the management of Somali football statistics. This entails incorporating features such as real-time updates on match events, including goals, cards, and substitutions. Furthermore, the application will provide information on teams, referees, stadiums, match schedules, results, and standings, all presented in the Somali language to cater to the target audience. Notably, the absence of Somali football statistics APIs necessitates the dynamic entry of data through the React admin panel.

This platform prioritizes data security by implementing encrypted communication channels using TLS for real-time event broadcasting via Socket.IO. Authentication is managed through JWT to ensure secure access to sensitive data. Furthermore, player and fan data privacy is safeguarded by anonymizing personal data during statistical analysis and requiring user consent in data-sharing activities.

A. System Description

The system designed for the Somali Football Federation (SFF) is an integrated platform dedicated to tracking and managing real-time football statistics. This platform is tailored to meet the specific needs of Somali football, providing timely updates on key match events such as goals, cards, and substitutions. It also offers detailed information about teams, referees, stadiums, match schedules, results, and standings, ensuring a comprehensive view of the football landscape in Somalia. To cater to the local audience, the platform presents all data and content in the Somali language.

One of the system's core features is its ability to deliver real-time updates, making it a valuable tool for both fans and officials who require immediate access to match statistics. The platform's user interface is designed to be intuitive and accessible, with a focus on providing an engaging experience for users. Additionally, the system includes a React-admin panel, which allows authorized personnel to dynamically enter and manage data. This feature is particularly important due to the absence of existing APIs for Somali football statistics, ensuring that the platform remains accurate and up-to-date.

B. System Features

The application boasts a rich array of features designed to cater to the needs of Somali football enthusiasts. These features include:

Real-Time Goals: Users receive live updates on goals scored during matches.

Match Results: This feature enables users to quickly access match outcomes and review past performances.

Standings: Providing a snapshot of team rankings, this feature fosters healthy competition and engagement among fans of the teams.

Match Schedule: Users can plan and stay informed about upcoming matches.

Total Cards: This feature provides users with insights into the level of competitiveness and discipline exhibited by teams.

Substitutions: Users can track tactical changes made by teams during matches, gaining valuable insights into game strategies and player dynamics.

Referee Info: Transparency is maintained through the provision of information about the referees' officiating matches.

Stadium Information: This feature offers comprehensive details about the stadiums where matches are held.

Other tons of features that ensures comprehensive football platform.

C. System Requirements

The system requires hardware material and software programs, the most important requirement to run the platform are as follows:

1) Hardware requirements

a) Server: The server hosting the Node.js backend and MySQL database requires adequate CPU and RAM to support the application's backend operations effectively.

b) Mobile devices (Emulators): The mobile devices or emulators must be compatible with the Flutter framework.

c) Admin panel users: Standard computing devices, such as desktops or laptops, are required for accessing the React admin panel. These devices should have modern web browsers installed to ensure compatibility and smooth operation of the admin panel interface.

2) Software requirements

a) Mobile devices: The mobile devices must support the operating systems Android and iOS to run the Flutter application seamlessly.

b) Server: The server needs to have the Node.js runtime environment installed to execute the backend logic efficiently. Additionally, a MySQL database management system is essential for storing and managing the application data effectively.

c) Admin panel users: Admin panel users must have access to modern web browsers, such as Google Chrome, Mozilla Firefox, or Safari, to access and interact with the React admin panel seamlessly.

IV. SYSTEM ANALYSIS AND DESIGN

A. Current System and Drawbacks

Currently, the SFF relies on manual processes and social media posts, primarily Facebook, to update and inform stakeholders about match events such as goals, cards and substitutions. This approach has significant limitations:

- **Delayed Information:** Updates are not in real-time, which affects decision-making during matches.
- **Manual Entry:** The process is labour-intensive, time-consuming and prone high potential for human error.
- **Limited Coverage:** Big football apps like LiveScore and BeSoccer do not fully support Somali football, often displaying only match results with no detailed statistics.

B. Proposed System

The proposed system will leverage modern technology to provide a real-time football match statistics platform tailored to the needs of the SFF. The system will consist of a mobile application built with Flutter, a Node.js backend for data processing and APIs, and a React-based admin panel for managing data.

- **Real-Time Updates:** Live tracking of match events including goals, substitutions, and cards.
- **Comprehensive Data Management:** Admin panel for adding teams, scheduling matches, and managing tournament data.
- **User-Friendly Interface:** Mobile application in the Somali language for accessibility.
- **Socket.io Integration:** Real-time updates through WebSocket for immediate event broadcasting.

This personalized platform not only moderates the challenges of existing systems but also raises a stronger connection between football fans and their team.

C. System Design

Here there is level 1 diagram of the system to understand the system interaction, and how the layers of the platform work each other from fans using the application to the database and from the managers using the react admin panel to the database.

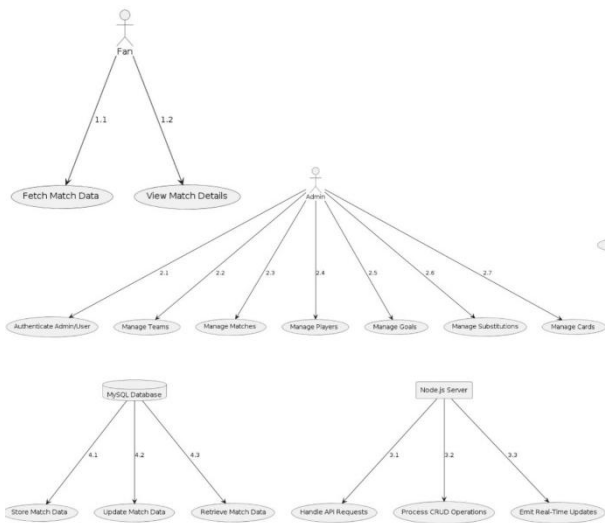

Fig. 1. Use case diagram.

Fig. 1 illustrates the system's use case diagram, which provides a detailed representation of the interactions between various user roles and the system components.

D. Database Design

The database used in this system is MySQL, chosen for its reliability and robustness in handling structured data.

The key tables in the database include Users, Teams, Matches, Players, Tournaments, Goals, Substitutions, and Many more. Each table is designed to store specific information relevant to the system's operation.

The ER Diagram below concludes main tables of the database and their relationship.

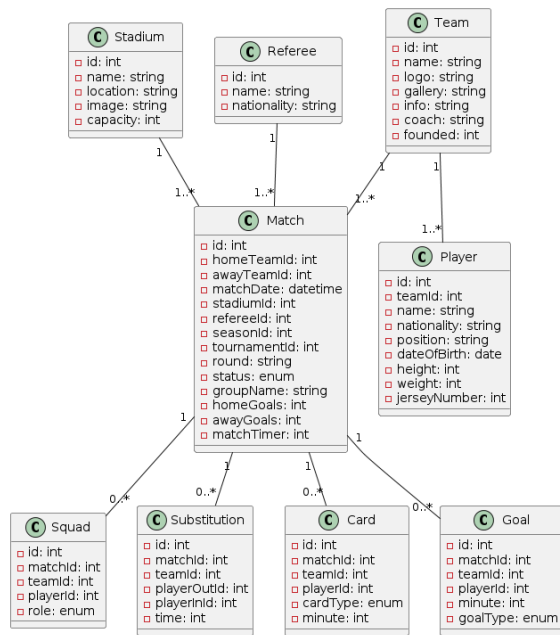

Fig. 2. Entity relationship diagram.

Fig. 2 presents the Entity-Relationship Diagram, showcasing the database structure and relationships among key entities like users, teams, and matches.

V. IMPLEMENTATION AND TESTING

Implemented the system using tools and technologies below.

- Mobile Application (Flutter and Dart) using IDE of Visual Studio Code with Packages like Provider, HTTP, Socket.IO.
- Backend Server (Node.js) using Express.js framework with MySQL database and tools like Socket.IO, JWT for authentication.
- Admin Panel (React).
- Hosting Localhost for development, cloud-based server for production in future.
- Development Tools o Version Control: Git, GitHub.

A. Testing Environment

Testing was conducted in several stages, including integration testing, application testing, and user acceptance testing (UAT). This testing environment was meticulously designed to replicate real-world conditions to ensure the accuracy and reliability of the tests.

B. System Snapshots

1) *Admin panel*: This figure shows that the admin panel is responsible for managing matches, where the management team can perform full CRUD operations. The same applies to other entities such as tournaments, seasons, teams, players, referees, etc.

Fig. 3. Managing matches (Create new match).

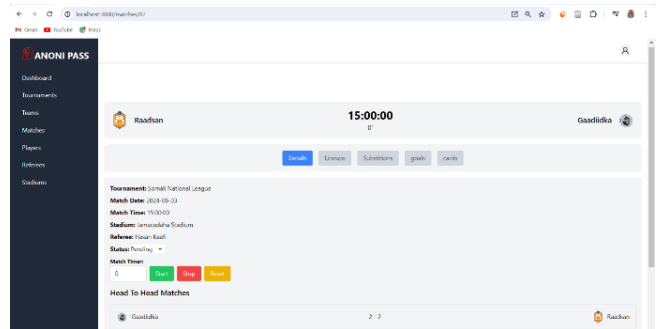

Fig. 4. Match event management.

This screen is responsible for managing match entities like goals, substitutions, cards, squads and also the status and the timer of the match for the platform (see Fig. 3 and Fig. 4).

2) *Mobile application:* This mobile application is designed to provide users with a seamless and engaging experience for tracking football matches and related data (Fig. 5).

Fig. 5. Home screen (Recent matches).

This home dashboard serves as the main screen of the mobile application, displaying a list of matches organized by date, allowing users to browse upcoming and past matches. Users can select a desired date to filter and view relevant matches. Furthermore, the dashboard provides a search functionality, enabling users to easily search for specific teams and players.

Fig. 6. Match details screen.

The match details (Fig. 6) screen provides a comprehensive overview of ongoing and completed matches. It includes real-time match information such as the teams' lineups (both starting lineup and bench), goals, cards, substitutions, and detailed match statistics that update in real-time. The interface also features head-to-head comparisons between the teams, allowing users to analyze historical encounters, past performance trends, and key statistics. This screen ensures users have all the essential details in one place, offering a dynamic and interactive experience for monitoring matches.

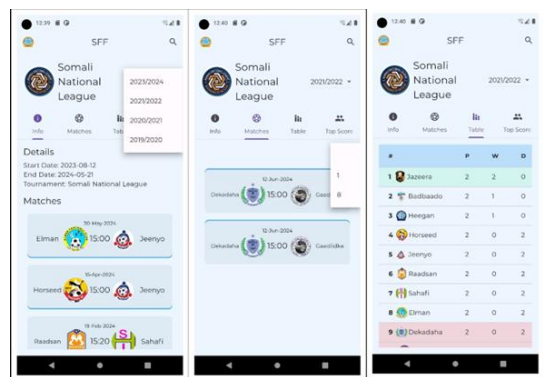

Fig. 7. Tournament details.

The Tournament Details (Fig. 7) Screen, filtered by season, displays a comprehensive list of matches for that particular tournament. As well as, this screen provides detailed tables showcasing the current team standings and top scorers of the tournament. This feature allows users to track team progress and individual player performance throughout the season, offering a clear and organized view of the tournament's key statistics and highlights.

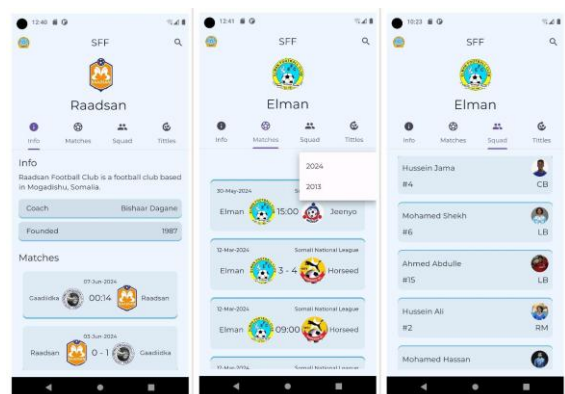

Fig. 8. Team details.

The Team (Fig. 8) Info screen offers an in-depth overview of the selected team, displaying key details such as the team's name, logo, founding year, coach, and other relevant information. The Matches section presents a list of games played by the team, conveniently grouped by year, with a dropdown menu allowing users to filter matches by a specific year. The Squad section showcases a list of players on the team, including each player's image, name, shirt number, and additional relevant information. The Team Titles section highlights the team's achievements and titles, giving users a clear view of the team's historical successes and accolades.

This section detailed the tools and technologies used. Snapshots of the mobile application, admin panel, backend, and database provided a visual representation of the system, illustrating its key features and interfaces.

C. Testing and Validation

Usability tests involved 100 users, including SFF administrators and football fans. Feedback from these sessions improved the navigation of the mobile app and the data-entry workflow of the React admin panel.

This system provides an opportunity to bridge technological gaps in Somali football by fostering transparency and engagement. However, challenges such as intermittent internet connectivity, low digital literacy, and limited funding remain. Solutions include integrating offline functionalities for the admin panel, offering training for administrators, and exploring partnerships with local ISPs to subsidize operational costs.

Validation metrics included:

- Socket.IO latency measured under various network conditions, achieving an average of 1.8 seconds.
- Data accuracy verified by cross-referencing system outputs with manual records during pilot matches.
- Admin panel functionality enabled full CRUD operations with a success rate of 100%.

VI. CONCLUSION AND FUTURE WORK

A. Conclusion

The development of the real-time football match statistics system for Somali Football Federation (SFF) has brought several key accomplishments. The system was developed to overcome the limitations of the existing manual processes and social media-based updates. One of the main achievements is its ability to provide live updates on match events, including the match timer, goals, substitutions, and cards, using Socket.IO technology. The system also covers a wide range of data, such as team and player details, match schedules, statistics, referee and stadium information, and tournament standings, including season-specific details.

Additionally, the system is designed with easy-to-use interfaces. The mobile app, built with Flutter, offers a smooth experience for fans in the Somali language, while the admin panel, developed in React, helps administrators manage data efficiently. Together, these features make the platform simple to use and effective for both users and administrators.

B. Future Work

The successful implementation of the real-time football match statistics system lays the foundation for future enhancements and expansions Including:

- **Analytics Incorporating:** Advanced analytics and machine learning capabilities could provide deeper insights into player performance, team strategies, and match outcomes.
- **Expanded Features:** Introducing new features such as video highlights push notifications for match events, social sharing options, and interactive visualizations of match statistics could further enrich the user experience and engagement with the system.
- **Machine Learning Integration** Integrate machine learning algorithms to provide personalized recommendations for users, such as suggested matches to watch or teams to follow based on their preferences and viewing history.

- **Integration with Other Platforms:** Integrating the system with other popular football platforms and social media channels could increase visibility and reach.

ACKNOWLEDGMENT

We sincerely thank our university and supervisor, for their invaluable guidance, financial assistance, and insightful perspectives throughout this research process.

Elevator Abnormal State Detection Based on Vibration Analysis and IF Algorithm

Zhaoxiu Wang

Department of Electronics and Information, Zhangzhou Institute of Technology, Zhangzhou, 363000, China

Abstract—Elevators play a crucial role in daily life, and their safety directly impacts the personal and property safety of users. To detect abnormal states of elevators and ensure people's personal safety, the acceleration signal of elevators is decomposed and Weiszfeld algorithm is used to estimate gravity acceleration. In addition, the study also introduces Kalman filtering to reduce error accumulation. To estimate the operating position of elevators, a method based on information fusion is studied and designed to construct a mapping relationship between elevator vibration energy and position, and to locate the height of elevator faults. Finally, an anomaly detection model combining vibration analysis and the Isolated Forest algorithm is developed. The results showed that the main distribution range of acceleration values in the horizontal direction was between $0.02 \text{ m}^2/\text{s}$ and $-0.02 \text{ m}^2/\text{s}$. The average estimation error and root mean square error of the research designed elevator position estimation method were 0.109 m and 0.113 m , respectively, which could solve the problem of accumulated position errors. The abnormal vibration energy and height corresponding to different operating conditions of elevators were different. The normal value ratios of the anomaly detection model under different sliding windows were 99.91% and 99.57% , respectively. The anomaly detection model designed for research has good performance and can provide technical support for the detection of elevator operation status.

Keywords—Vibration analysis; IF algorithm; elevator; abnormal; detection

I. INTRODUCTION

As a vertical transportation tool, elevators are used in various places in daily life, such as office buildings, residences, hotels, large libraries, and industrial and mining enterprises [1]. Elevators are frequently used in people's daily lives, and once any elevator malfunctions, it can pose a serious threat to people's safety. Therefore, timely and accurate detection of elevator abnormal states is crucial. The commonly used methods for elevator status detection include grey prediction model, genetic algorithm, and particle swarm algorithm [2-3].

Skog I designed a new non-invasive elevator fault detection method and corresponding efficient algorithm for detecting elevator faults. This method modeled the traffic load on the elevator through a non-homogeneous Poisson process and

described the process using a generalized linear model. The results showed that the method achieved an accuracy of 0.82 with a recall probability of 0.80 [4]. Oya J R G et al. designed a system based on time-domain reflectometry technology to detect elevator belt faults, and constructed a receiver based on compressive sensing to improve positioning capability. The results showed that this method could recover time-domain sparse signals and effectively detect elevator belt faults [5]. Ippili S et al. constructed a one-dimensional convolutional neural network based on sound signals for early identification of faults in rotating machinery, and used this network to process the original time signals. The results showed that this method had good performance in the early identification of rotating machinery faults, and its performance was significantly better than the accelerometer based method [6]. Mian T et al. designed a multi-sensor fault diagnosis system based on infrared thermal imaging and vibration sensors for diagnosing faults in rotating machines. In addition, the study also utilized deep convolutional neural networks, support vector machines, and principal component analysis. The results showed that this method could effectively diagnose faults in rotating machines under all working conditions [7].

However, these methods also have certain issues, such as the stronger dependence of model-based methods on specific parameters of elevator systems compared to data-driven methods on data training. To detect abnormal states in elevators, an anomaly detection model based on vibration analysis of horizontal vibration signals and Isolation Forest (IF) algorithm is designed. Methods are also designed to reduce the accumulation of position errors and estimate elevator dynamic characteristics. The research aims to improve the accuracy of elevator anomaly detection, avoid serious elevator accidents, and ensure people's personal safety. The innovation of the research is reflected in the combination of vibration analysis and IF algorithm, which reduces the cumulative position error and improves the efficiency of elevator anomaly detection. To better demonstrate the advantages of the design method proposed in this article, the study will compare it with existing methods in terms of performance indicators, scalability, and limitations. The comparison results are shown in Table I.

TABLE I. COMPARISON WITH RELATED WORK

Serial number	Performance index		Scalability	Limitation
	F1	Accuracy		
[4]	0.800	0.820	F1 drops to 0.685 on larger datasets	Model complexity and difficulty in parameter estimation
[5]	0.847	0.886	When facing multiple types of elevator belts, a significant amount of customized training is required	Limited measurement accuracy and signal quality issues
[6]	0.929	0.936	Cannot be compatible with new data types	Insufficient utilization of sequence order information
[7]	0.935	0.941	Difficulty in expanding sensor types	Easy overfitting and high computational resource consumption
Manuscript	0.988	0.992	Low cost, strong universality and scalability	Not much consideration has been given to the fault detection of elevator door systems

II. METHODS AND MATERIALS

To detect abnormal states in elevators, an anomaly detection method based on vibration analysis and IF algorithm is studied and designed. Due to the use of horizontal acceleration signals for anomaly detection, the study also designs a method for estimating elevator gravity acceleration and dynamic characteristics. In addition, the study also designs a method for estimating the operating position of elevators.

A. Design of Estimation Method for Elevator Gravity Acceleration and Dynamic Characteristics

To detect abnormal states in elevators, a gravity acceleration and dynamic feature estimation method is first designed to reduce error accumulation and improve detection accuracy. Secondly, a method for estimating the operating position of elevators is studied and designed to facilitate the construction of the mapping relationship between elevator vibration energy and position in the future. Finally, an anomaly detection method based on vibration analysis and IF algorithm is studied and designed. The study uses a three-axis acceleration sensor (MPU6050) to collect three-dimensional acceleration signals from the elevator, and decomposes the acceleration three-dimensional vector based on the gravity acceleration vector calibrated by the sensor. After that, the components in the direction of gravity acceleration can be obtained. The Weiszfeld algorithm is adopted for the estimation of elevator gravity acceleration. The Weiszfeld algorithm is a classic iterative algorithm for solving single facility site selection problems, which can obtain the optimal solution of the problem, and the essence of this algorithm is a steepest descent method. The Weiszfeld algorithm, as a repeated weighted least squares method, has the advantage of being able to handle weighted point sets and gradually converge to the optimal solution during the iteration process [8-9]. In addition, unlike some methods that rely on specific prior knowledge or assumptions, the Weiszfeld algorithm does not require extensive knowledge of the elevator's operating status, system parameters, etc. when estimating elevator gravity acceleration, and has a wider applicability [10-11]. The solution for this algorithm is shown in Eq. (1).

$$\begin{cases} x_{k+1} = \frac{\sum_{i=1}^a \frac{b_i}{E_i(x_k, y_k, z_k)}}{\sum_{i=1}^a \frac{1}{E_i(x_k, y_k, z_k)}} \\ y_{k+1} = \frac{\sum_{i=1}^a \frac{c_i}{E_i(x_k, y_k, z_k)}}{\sum_{i=1}^a \frac{1}{E_i(x_k, y_k, z_k)}} \\ z_{k+1} = \frac{\sum_{i=1}^a \frac{d_i}{E_i(x_k, y_k, z_k)}}{\sum_{i=1}^a \frac{1}{E_i(x_k, y_k, z_k)}} \end{cases} \quad (1)$$

In Eq. (1), (x_k, y_k, z_k) represents the median center solved by Weiszfeld algorithm after the k th iteration, and x , y , and z are vectors on the x-axis, y-axis, and z-axis, respectively. a represents the number of measured gravitational acceleration vectors, and (b_i, c_i, d_i) is the gravitational acceleration vector obtained from the i measurement. $E_i(x_k, y_k, z_k)$ represents the distance between (b_i, c_i, d_i) and the median center obtained from the k iteration. $(x_{k+1}, y_{k+1}, z_{k+1})$ represents the new median center. The calculation of $E_i(x_k, y_k, z_k)$ is shown in Eq. (2).

$$E_i(x_k, y_k, z_k) = \|(b_i, c_i, d_i) - (x_k, y_k, z_k)\| \quad (2)$$

The operation process of an elevator can be mainly divided into four states: stationary, accelerating, uniform, and decelerating, and the acceleration in all four ideal states remains constant [12]. To estimate the kinematic characteristics of elevators, the Kalman filtering method is used in the study. The advantage of the Kalman filtering method is that it can update the state estimation based on previous estimates and current measurements, and has strong robustness and adaptability [13-14]. The representation of elevator dynamic characteristics is shown in Eq. (3).

$$\chi_k = F_k \chi_{k-1} + \omega_k \quad (3)$$

In Eq. (3), χ_k represents the system state vector, F_k represents the state transition function, and ω_k represents the process noise vector. The expression of χ_k is shown in Eq. (4).

$$\chi_k \triangleq \begin{bmatrix} \chi'_k \\ \chi''_k \\ \chi'''_k \end{bmatrix} \quad (4)$$

In Eq. (4), \triangleq represents the identity equation, while χ'_k , χ''_k , and χ'''_k represent velocity, acceleration, and jerk, respectively. The expression of F_k is shown in Eq. (5).

$$F_k \triangleq \begin{bmatrix} 1 & g & \frac{g^2}{2} \\ 1 & g & \\ & 1 & g \\ & & 1 \end{bmatrix} \quad (5)$$

In Eq. (5), g represents the sampling time interval. To output the system state vector, the Kalman filtering method

needs to perform optimal estimation based on the prediction step and update step. Optimization estimation mainly includes four steps. The first step is to solve g and adjust F_k and process noise covariance Q_k based on g . The second step is to predict the state of the next time step and estimate the system covariance \bar{P}_k . The third step is to solve the Kalman gain K_k , and the fourth step is to solve the novel Y_k . The fifth step is to adjust the state prediction value and prediction covariance, and refresh the system state. The processing of the covariance matrix P_k is shown in Eq. (6).

$$P_k = (I - K_k H_k) \times \bar{P}_k \times (I - K_k H_k)^T + K_k R_k \times K_k^T \quad (6)$$

In Eq. (6), I is the identity matrix, H_k represents the measurement function, and R_k represents the observed noise variance. Since the measured values of acceleration sensors during elevator operations are typically non-zero, threshold values and corresponding constraints are introduced in the study. The automatic correction process of gravity acceleration is shown in Fig. 1.

From Fig. 1, the automatic correction process of gravity acceleration mainly consists of six steps. The first step is to determine whether the elevator is stationary. If it is stationary, slide the window to collect data, otherwise the process ends. The second step is to filter out outliers, and the third step is to use the Weiszfeld algorithm. The fourth step is to update the gravitational acceleration, and the fifth step is to determine whether the elevator is moving. If it is running, the process ends; otherwise, the sliding window continues to collect data.

B. Design of Elevator Operation Position Estimation Method

To locate the operating position of the elevator, the study first models the elevator floor information through acceleration sensors and Simultaneous Localization and Mapping (SLAM) algorithm. Secondly, the study uses a pressure sensor to solve the operating height of the elevator. Finally, a method for estimating the operating position of elevators based on information fusion is studied and designed. The elevator displacement solved by acceleration sensors has the advantage of high short-term accuracy, but there is also a drawback of fast error accumulation. Therefore, the SLAM algorithm is introduced to compensate for this deficiency. The advantage of the SLAM algorithm is its ability to integrate multiple sources

of information and incorporate Kalman filtering technology [15]. By using the Kalman filter in the SLAM algorithm, it is possible to obtain the floor spacing and floor height. The expression for the distance of elevator operation between two stops is shown in Eq. (7).

$$S_k = F_k S_{k-1} + B_k u_k + \omega_k \quad (7)$$

In Eq. (7), u_k is the control vector, B_k is the control matrix, and S_k represents the displacement of the elevator from rest. The expression of B_k is shown in Eq. (8).

$$B_k = \begin{pmatrix} g \\ \frac{g^2}{2} \end{pmatrix} \quad (8)$$

The initialization process of elevator floor information mainly consists of seven steps, including acceleration data collection, elevator motion judgment, calculation of elevator displacement and displacement error, judgment of whether the elevator is going up, judgment of whether the elevator is stationary, updating map information, and judgment of whether the set number of times has been reached. To solve the operating height of the elevator, a pressure sensor is used in the study. The advantage of air pressure sensors is that they can directly obtain real-time altitude information of elevators, and the error accumulation is slow [16-17]. The difference γ between the starting and measuring heights is solved as shown in Eq. (9).

$$\gamma = \left(\frac{JL}{WN} \right) \ln \left(\frac{\rho_0}{\rho} \right) \quad (9)$$

In Eq. (9), ρ_0 and ρ represent the atmospheric pressure at the starting and measuring heights, respectively, and N represents the molar mass of air. J represents the universal gas constant, L represents the measured air temperature, and W represents the gravitational acceleration of the Earth's surface. The solution for the current altitude ϕ is shown in Eq. (10) [18-19].

$$\phi = 44330 \times \left(1 - \left(\frac{\rho}{\rho_0} \right)^{\frac{1}{5.255}} \right) \quad (10)$$

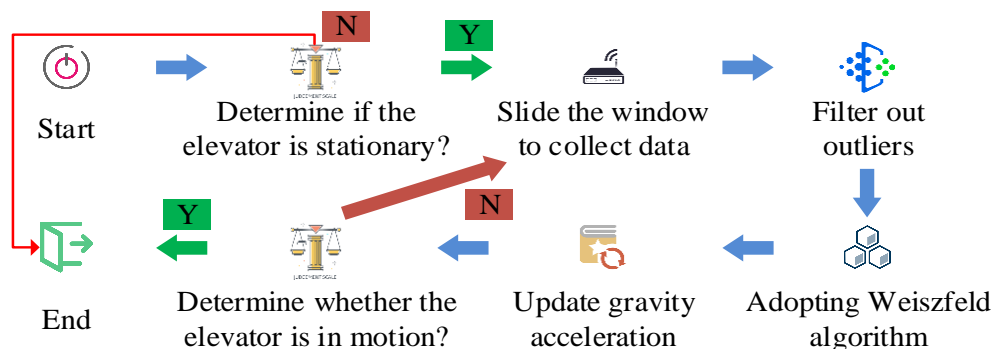

Fig. 1. Automatic correction process of gravity acceleration.

The solution of γ can be simplified as shown in Eq. (11).

$$\gamma = \phi - \phi_0 \quad (11)$$

In Eq. (11), ϕ_0 represents the altitude of the reference position. To preprocess the obtained height data and reduce the impact of noise, a first-order exponential smoothing method is used in the study. The advantage of this method is that it makes extrapolation predictions more realistic and has high practicality and effectiveness in time series prediction [20]. The current time step estimation value η_t is solved as shown in Eq. (12).

$$\eta_t = \beta\sigma_t + (1 - \beta)\eta_{t-1} \quad (12)$$

In Eq. (12), η_{t-1} represents the estimated value of the previous time step, β represents the smoothing coefficient, and $\beta \in (0, 1)$ and σ_t are the measured values of the current time step. t stands for Time. To estimate the operating position of the elevator, a combination of acceleration sensors and air pressure sensors is studied, and floor information is also introduced. Unscented Kalman Filter (UKF) is used to apply this information. Therefore, the solution for the operating height θ_τ of the elevator at τ time is shown in Eq. (13).

$$\theta_\tau = \theta_{\tau-1} + B_k u_k + \omega_k \quad (13)$$

The state transition function of the elevator system is expressed as Eq. (14).

$$\theta_\tau = f(\theta_{\tau-1}) = \begin{cases} \theta_{\tau-1} + B_k u_k + \omega_k & \text{Motion} \\ f\theta_j, \theta_{\tau-1} \in U(f\theta_j, \delta_{f\theta_j}) & \text{Static} \end{cases} \quad (14)$$

In Eq. (14), $f\theta_j$ represents the height of the car relative to the reference point, j is the number of heights, U is the symbol for the set, and $\delta_{f\theta_j}$ represents the prior measurement error. The core of UKF is the traceless transformation, as shown in Fig. 2.

In Fig. 2, \mathcal{G} represents a set of sigma points, and ψ represents a new set of points after nonlinear changes. The green and orange dots in the blue background represent the mean and covariance of the transformation point set, respectively, and are considered as new predicted values. To select sigma points, a symmetric sampling strategy is adopted in the study. The elevator position tracking process based on UKF is shown in Fig. 3.

Fig. 2. Diagram of unscented transformation.

Fig. 3. Elevator position tracking process based on UKF.

From Fig. 3, the first step of the elevator position tracking process based on UKF is initialization, and the second step is sigma point sampling. The third step is to predict updates, and the fourth step is to measure updates. The fifth step is to determine whether Y_k is smaller than $2\sqrt{P_k}$. If it is less than,

proceed to step six; otherwise, amplify the process noise before proceeding to step six. The sixth step is to determine whether the flag is equal to 0. If it is equal, proceed to step seven; otherwise, reduce the process noise before proceeding to step seven. The seventh step is to determine whether the elevator is

stationary. If it is stationary, calculate the $f\theta_j$ of the nearest floor. Otherwise, use it as input for the next time step of θ_τ and P_k . The eighth step is to determine whether θ_τ belongs to $U(f\theta_j, \delta_{f\theta_j})$. If it belongs, update the elevator floor information. Otherwise, output an abnormal stop alarm. The ninth step is to perform sensor calibration, and the tenth step is to determine whether θ_τ and P_k are the final time steps. If so, the process ends. Otherwise, θ_τ and P_k are inputted for the next time step, and then return to the second step.

C. Design of Elevator Abnormal State Detection Method

To detect abnormal states in elevators, the study first constructs a mapping of elevator vibration energy and position based on vibration analysis. Secondly, the study uses the IF algorithm to train the elevator anomaly detection model. To determine the operating status of the elevator, the study considers the vibration of the elevator car as an important feature. To determine whether the data is abnormal, a baseline is constructed for elevator normal operation. In addition, the study uses horizontal acceleration signals to detect abnormal vibrations. The steps of the baseline generation method are shown in Fig. 4.

From Fig. 4, the first step in baseline generation is data collection, and the second step is to determine whether the baseline has been generated. If it has been generated, end the process; otherwise, perform data preprocessing and feature extraction. The third step is to obtain horizontal vibration energy, and the fourth step is to obtain cluster data. The fifth step is to calculate the moving average, and the sixth step is to calculate the moving average error. The seventh step is to determine whether the slope of the moving average error is approximately equal to 0. If it is, a baseline is generated and the process ends. Otherwise, the process returns to the first step.

The solution for the moving average MA_n is shown in Eq. (15) [21].

$$MA_n = \frac{\sum_{r=1}^n |\Pi_r|^2}{n} \quad (15)$$

In Eq. (15), n represents the number of collected signals, Π_r represents the root mean square of the r horizontal vibration signal, and r is the signal number. To clarify the abnormal state of the elevator, the intrinsic feature scale decomposition method is used to decompose the horizontal vibration signal, and envelope spectrum analysis is used to detect the impact signal to eliminate false alarms. To suppress the endpoint effect, the method of mirror extension is used in the study. To construct a mapping between elevator vibration energy and position to detect the vibration state of the guide rail on the highest and lowest floors, a horizontal acceleration signal is used and solved using the established elevator acceleration and position estimation method. To further detect outliers, the study adopts the IF algorithm and trains the outlier detection model through the IF algorithm. The IF algorithm, as an unsupervised method, has the advantages of low computational cost, linear time complexity, and does not rely on abnormal samples [22]. In addition, compared with similar outlier detection methods, the IF algorithm does not require calculating the distance or density between data points like some distance or density-based methods, has lower time complexity, and does not rely on data distribution assumptions. It is relatively insensitive to noise and outliers in the data, and can effectively identify true outliers, making it less susceptible to noise interference and misjudgment [23-24]. The IF algorithm uses the idea of ensemble learning and requires the construction of isolated trees. The construction process of an isolated tree is shown in Fig. 5.

Fig. 4. Steps of baseline generation method.

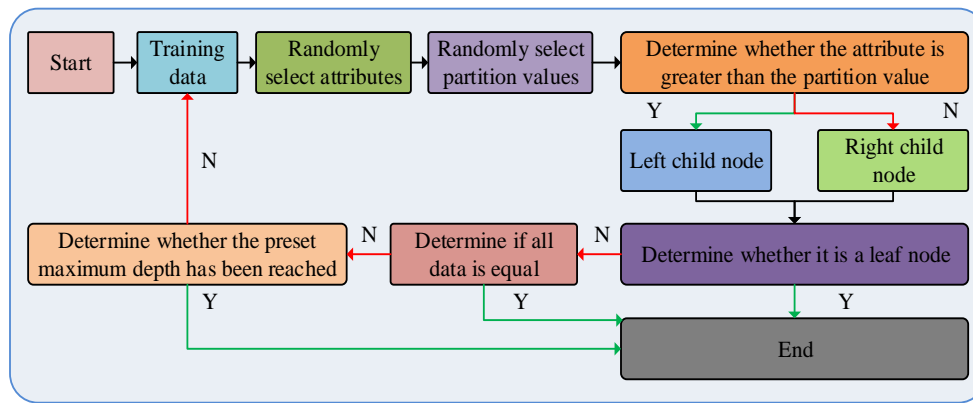

Fig. 5. The construction process of isolated trees.

From Fig. 5, the first step in constructing an isolated tree is to train the data, and the second step is to randomly select the attribute ε . The third step is to randomly select the partition value μ , and the fourth step is to determine whether ε is greater than μ . If it is judged as yes, place it in the left child node; otherwise, place it in the right child node. The fifth step is to determine whether it is a leaf node. If it is, the process ends; otherwise, the next step is to proceed. The sixth step is to determine whether all data are equal. If they are equal, the process ends; otherwise, it enters the seventh step. The seventh step is to determine whether the preset maximum depth has been reached. If it has been reached, the process ends. Otherwise, it returns to the first step and repeats the process until it ends. The process of elevator anomaly detection method based on vibration analysis and IF algorithm is shown in Fig. 6.

From Fig. 6, the first step of the elevator anomaly detection method is to collect acceleration signals, and the second step is to estimate the elevator position. The third step is to establish a baseline, and the fourth step is envelope spectrum analysis. The fifth step is to generate data records, and the sixth step is to determine whether the sliding window is full. If it is full, the detection model is used for anomaly detection. Otherwise, the process returns to the fifth step. The seventh step is to determine if the anomaly rate is too high. If it is too high, an alarm will be triggered and the process will end. Otherwise, the data will be added to the buffer. The eighth step is to determine whether the number of records is greater than the set threshold. If it is, the detection model will be retrained based on the training data. Otherwise, it will return to the data buffer.

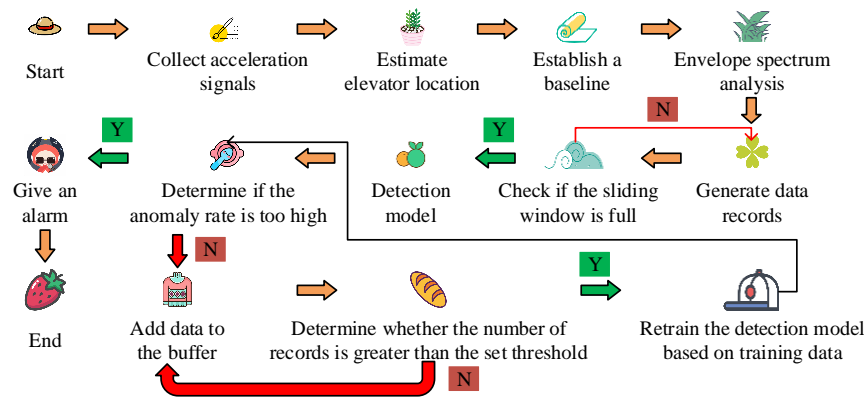

Fig. 6. The process of elevator anomaly detection method based on vibration analysis and IF algorithm.

III. RESULTS

To analyze the detection results of elevator abnormal states, the study explained the experimental data collection equipment, experimental environment, and other experimental devices, and analyzed the results of acceleration information decomposition. Afterwards, the study analyzed the results of elevator position tracking and constructed the relationship between elevator vibration energy and position mapping. Finally, the study validated the performance of the IF model in detecting elevator abnormal states.

A. Acceleration Information Decomposition and Motion Feature Estimation Results

To collect elevator data, the study used Raspberry Pi 4B and added MPU6050 acceleration sensor, BMP180 air pressure sensor, and touch switch. The experimental environment used was the elevator in the experimental building. The operating system used in the experiment was Raspbian, the built-in operating system of Raspberry Pi. The processor was Broadcom BCM2711, with a clock speed of 1.5GHz, a maximum supported memory capacity of 4GB, and a thermal design power consumption of 7.5W. The collected signal would be decomposed, and the decomposition result is shown in Fig.

7.

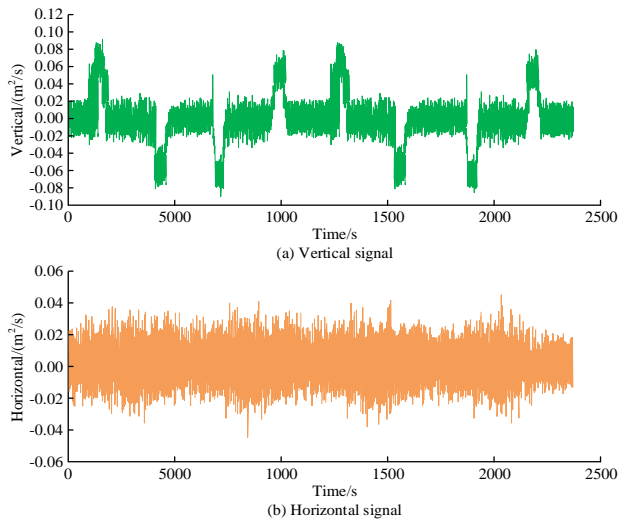

Fig. 7. The result of signal decomposition.

In information decomposition, the study first collected the residual distribution of the acceleration signal minus the calibrated gravity acceleration in three-dimensional space. Secondly, the distribution was decomposed into vertical and horizontal acceleration signals in three-dimensional space, as shown in Fig. 7 (a) and Fig. 7 (b). According to Fig. 7 (a), after decomposing the acceleration information, the maximum and minimum vertical acceleration values were $0.09375 \text{ m}^2/\text{s}$ and $-0.09063 \text{ m}^2/\text{s}$, respectively. As time increased, the vertical acceleration value exhibited a fluctuating trend of gentle, upward, and downward fluctuations. According to Fig. 7 (b), in the horizontal direction, the maximum acceleration value was $0.0450 \text{ m}^2/\text{s}$ and the minimum value was $-0.0457 \text{ m}^2/\text{s}$. As time gradually increased, the horizontal acceleration value exhibited a fluctuating upward and downward trend. In addition, the main distribution range of acceleration values in the horizontal direction was between $0.02 \text{ m}^2/\text{s}$ and $-0.02 \text{ m}^2/\text{s}$. Through signal decomposition, three-dimensional data can be transformed into one-dimensional data. This not only facilitates the installation of sensors, but also enhances the robustness of the system. The analysis of motion characteristics is shown in Fig. 8.

According to Fig. 8 (a), in terms of acceleration characteristics, the maximum and minimum values of the source data were $1.0 \text{ m}^2/\text{s}$ and $-0.75 \text{ m}^2/\text{s}$, respectively. The maximum and minimum values of the filtered data's maximum acceleration were $0.71 \text{ m}^2/\text{s}$ and $-0.72 \text{ m}^2/\text{s}$, respectively. The maximum and minimum values of the maximum deceleration were $0.76 \text{ m}^2/\text{s}$ and $-0.75 \text{ m}^2/\text{s}$, respectively. From Fig. 8 (b), at 95% of the sampled data, the maximum values of acceleration and deceleration were $0.75 \text{ m}^2/\text{s}$ and $0.68 \text{ m}^2/\text{s}$, respectively, with a difference of $0.07 \text{ m}^2/\text{s}$ between the two. In addition, the minimum acceleration value was $-0.74 \text{ m}^2/\text{s}$, which differed from the minimum deceleration value of $-0.59 \text{ m}^2/\text{s}$ by $0.15 \text{ m}^2/\text{s}$. In Fig. 8 (c), with the increase of time, the elevator speed exhibited a cyclic upward and downward trend. In addition, the maximum and minimum values of the velocity characteristics were $1.81 \text{ m}^2/\text{s}$ and $-1.89 \text{ m}^2/\text{s}$, respectively. Both the acceleration and deceleration, as well as the maximum acceleration and deceleration, were within the standard range.

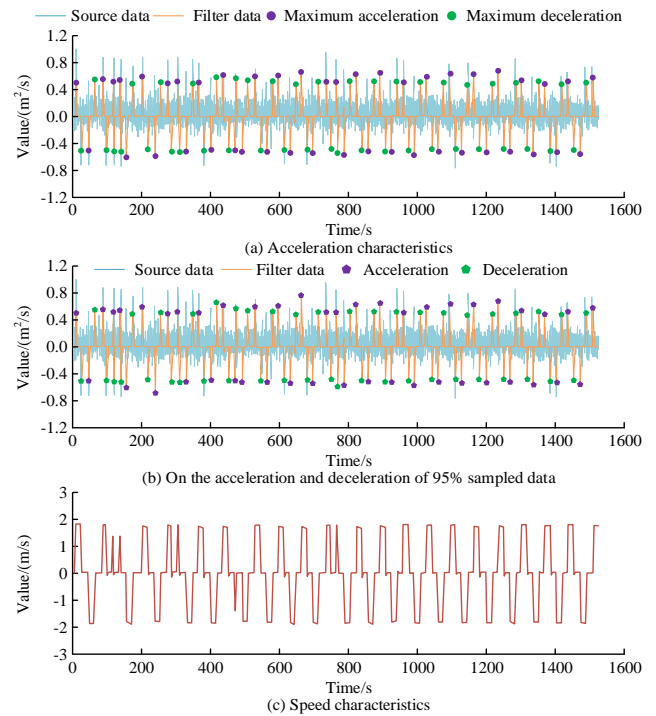

Fig. 8. Analysis of motion characteristics.

B. Analysis of Elevator Position Tracking Results

To track the position of the elevator, the study used the same Raspberry Pi and sensors to collect elevator data. The operating position of the elevator in the experimental building was a total of 8 floors, and the floor height and spacing were generally around 4 meters. The scanning range of SLAM was 0.1-30 meters, with a measurement accuracy of ± 2 centimeters, a time interval of 50Hz, and a positioning accuracy of 10 centimeters. The measurement matrix of UKF was 1, the sampling time interval was 0.5s, the process noise covariance was 1, and the measurement noise covariance matrix was 0.01. Based on the collected information from acceleration sensors and air pressure sensors, the study combined these two types of information through UKF and obtained the tracking results and estimation errors of the elevator position, as shown in Figure 9.

From Fig. 9 (a), the maximum value of elevator position using only the UKF method was 31.3m, and the minimum value was -0.8m . The maximum values of elevator position using UKF+automatic calibration method and UKF+ automatic calibration+SLAM method were 29.3m and 28.5m, respectively, with a difference of 0.8m between the two, and the minimum value of elevator position under both methods was 0m. The automatic calibration method and SLAM effectively reduced the errors observed in the UKF method. In Fig. 9 (b), the cumulative probability of errors at different positions varied under different methods. For example, when the position error was 0.5m, the cumulative probabilities of the UKF method, UKF+automatic calibration method, and UKF+automatic calibration+SLAM method were 0.327, 0.684, and 1.00, respectively. In addition, the average estimation errors of the three methods were 0.923m, 0.395m, and 0.109m, respectively, and the root mean square errors were 0.943m, 0.404m, and 0.113m, respectively. The UKF+automatic calibration+SLAM

method had the smallest estimation error, followed by the UKF+ automatic calibration method. In summary, the UKF+automatic calibration+SLAM method can effectively

solve the problem of accumulated position errors and accurately track the operating position of elevators.

Fig. 9. Tracking results and estimation errors of elevator position.

C. Analysis of Elevator Abnormal State Detection Results

To detect abnormal states in elevators, the same experimental environment and setup were used in the study. In collecting data, the experiment also used Raspberry Pi and sensors. In the collected baseline data, the sub healthy line was 0.140m/s^2 and the fault line was 0.162m/s^2 . In addition, the study also removed useless attributes of the data, such as running time, and only retained the maximum acceleration/deceleration, maximum speed, 95th percentile of

acceleration, and 5th percentile of deceleration. The total number of isolated trees was 120, the threshold for outliers was -0.18 , the maximum sampling number was 267, and the proportion of outliers in the training data was 99.69%. The width of the sliding window was 800, and the study selected the outlier distribution of the third and ninth windows for analysis. The envelope spectrum analysis was conducted on the first product component of the vibration signal, and the amplitude before and after analysis is shown in Fig. 10.

Fig. 10. The amplitude before and after the envelope spectrum analysis of the first product component.

According to Fig. 10 (a), before demodulating the product component 1, its corresponding amplitude was mainly concentrated between 0.5m/s^2 and -0.7m/s^2 , and the maximum and minimum amplitudes were 0.208m/s^2 and -0.273m/s^2 , respectively. As time went by, the vibration kept rising, falling, and fluctuating repeatedly. From Fig. 10 (b), after demodulating the product component 1, as the frequency increased, the vibration gradually decreased, and the range of up and down fluctuations also narrowed. The maximum and minimum amplitude values were 9.98m/s^2 and 0.00m/s^2 , respectively. In addition, the vibration energy of the signal was primarily concentrated in the low-frequency range, with fewer high-frequency impulsive signals. This indicated that the outlier was false and consistent with the actual situation. The relationship between elevator vibration energy and position mapping is shown in Fig. 11.

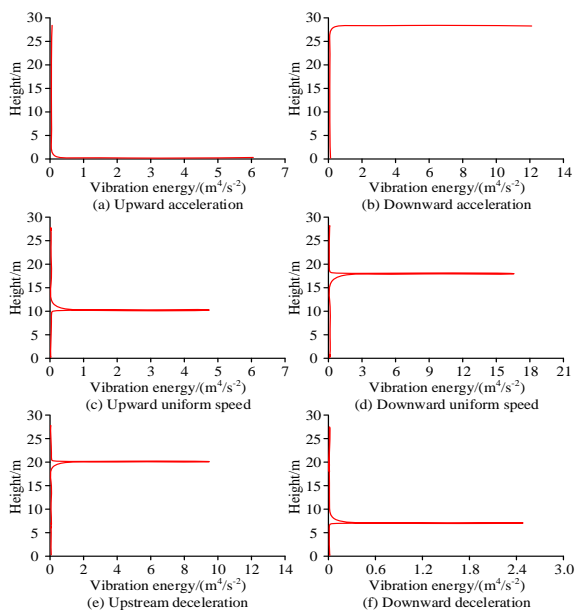

Fig. 11. The relationship between elevator vibration energy and position mapping.

In Fig. 11, the vertical axis represents the operating position of the elevator, and the horizontal axis represents the vibration energy at the corresponding position. The peaks in the spectrum are the abnormal vibrations generated by simulated faults. From Fig. 11 (a), when the elevator accelerated upwards, the abnormal vibration energy generated during the simulated fault was 6.02m/s^2 , and the corresponding height at this time was 0m . From Fig. 11 (b), 11 (c), 11 (d), 11 (e), and 11 (f), peaks appeared during the elevator's downward acceleration, upward uniform speed, downward uniform speed, upward deceleration, and downward deceleration. This indicated that abnormal vibrations occurred in the elevator in all five cases, and the vibration energy and fault height varied in different situations. For example, if the elevator was moving at a constant speed, the abnormal vibration energy corresponding to the up and down directions of the elevator was 4.78m/s^2 and 16.8m/s^2 , respectively, and the corresponding fault heights were 10m and 18m , respectively. It can be seen that the occurrence of simulated faults could be clearly detected at various stages of elevator operation, and the position of the car where the fault occurred, that is, the position where the guide rail may have malfunctioned, could be located, providing important information for the maintenance of the elevator system and the rescue of trapped personnel. The distribution of outliers for different sliding windows is shown in Fig. 12.

In Fig. 12 (a), under the third sliding window, the abnormal scores were mainly concentrated in the range of 0.10 and 0.15 . In addition, the proportion of normal values greater than the threshold of -0.18 outliers was approximately 99.91% . According to Fig. 12 (b), in the 9th sliding window, the proportion of normal values greater than the outlier threshold was about 99.57% , and the outlier scored with more than 10 data points were mainly concentrated in the range of 0.067 to 0.15 . In addition, the maximum number of outlier data points was 58, corresponding to outlier scores of 0.123 and 0.147 . Overall, the IF model could effectively detect the operational status of elevators.

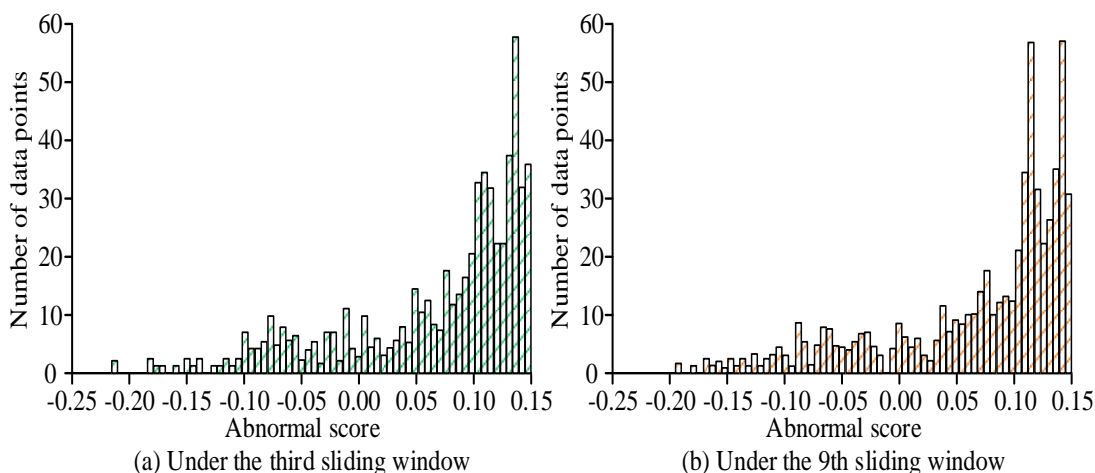

Fig. 12. Outlier distribution of different sliding windows.

IV. DISCUSSION AND CONCLUSION

Aiming at the problem of detecting abnormal states in elevators, a dynamic prediction method for elevators and an information fusion-based elevator operation position tracking method were studied and designed. An anomaly detection model based on vibration analysis and IF algorithm was also constructed. The results showed that after signal decomposition, the maximum acceleration values corresponding to the vertical and horizontal directions were $0.09375 \text{ m}^2/\text{s}$ and $0.0450 \text{ m}^2/\text{s}$, respectively, and the minimum acceleration values were $-0.09063 \text{ m}^2/\text{s}$ and $-0.0457 \text{ m}^2/\text{s}$, respectively. Signal decomposition could transform three-dimensional data into one-dimensional data, enhancing the robustness of the system. The average estimation errors of UKF method, UKF+automatic calibration method, and UKF+automatic calibration+SLAM method were 0.923m , 0.395m , and 0.109m , respectively, with root mean square errors of 0.943m , 0.404m , and 0.113m , respectively. This indicated that both automatic calibration and SLAM algorithms could to some extent solve the problem of accumulated position errors. The maximum amplitude values of product component 1 before and after demodulation were $0.208\text{m}/\text{s}^2$ and $9.98\text{m}/\text{s}^2$, respectively, and the vibration energy of the demodulated signal was mainly concentrated in the low-frequency range, with less high-frequency impulsive signals, which was in line with the actual situation. Under different operating conditions of the elevator, simulated faults had corresponding peak signals, and the vibration energy and height corresponding to the peak signals were also different under different operating conditions. In the third and fifth sliding windows, the proportion of normal values greater than the outlier threshold was 99.91% and 99.57% , respectively. The research designed anomaly detection models had good performance. This method could monitor and analyze the acceleration signals and vibration data of the equipment in real time, predict potential faults, and thus improve safety. It can be applied to elevators in construction sites, mine elevators, rail transit systems, industrial automation equipment, key components in the aerospace industry, lifting systems in marine engineering, as well as medical and emergency rescue equipment, ensuring the stability and safety of these systems during operation, reducing accident risks, and has significant practical application value.

However, there are also certain limitations to the research. Firstly, there was not much consideration given to the fault detection of elevator door systems in research. Technologies such as photosensitive sensors or image-based door anomaly detection are important components in addressing the safety of elevator door systems. Light sensors can monitor the status of elevator doors by sensing light, while image-based door anomaly detection technology requires advanced image processing algorithms and computer vision technology. Secondly, the study used unsupervised IF algorithm. However, relying solely on Unsupervised Learning is difficult to fully explore the deep information of data. Future research can combine Unsupervised Learning and Supervised Learning to further improve the detection accuracy and robustness of the model, especially in the case of labeled datasets. Thirdly, sensor data may be affected by environmental noise, which can affect the accuracy of elevator status monitoring. Future research

could consider deep learning techniques to address noise issues, improving noise processing accuracy by learning the features and patterns of noise. Fourthly, although UKF theoretically has high accuracy, it may face computational efficiency challenges in practical applications, especially in scenarios with large data volumes or high real-time requirements. Future research can explore model light weighting to reduce the time and resources required for retraining models on new tasks, as well as reduce the difficulty of model optimization and improve application efficiency through automated joint optimization. Fifthly, the deployment of this method in real environments will face complex building environments, especially large buildings with complex internal structures that may include multiple elevator shafts, different floors, and complex building layouts, leading to interference in sensor signals. Future research can optimize the layout and selection of sensors, reduce space occupation, and choose high-quality sensors. Shielding and filtering techniques can also be used to reduce interference.

LFM Book Recommendation Based on Fusion of Time Information and K-Means

Dawei Ji

School of Humanities and Art, Nanchang Institute of Technology, Nanchang 330099, China

Abstract—To meet the growing demand in the field of book recommendation, the research focuses on meeting the personalized needs, behavioral patterns, and interests of readers. A book recommendation algorithm that combines K-means clustering with time information is proposed to provide more convenient and efficient book recommendation services and enhance readers' reading experience. The algorithm constructs a comprehensive user preference matrix by incorporating readers' borrowing time. Then, the K-means clustering is applied to group users with similar preferences and leverages a latent factor model to train and predict user ratings. The methodological integration of clustering and latent factor model ensures a more precise and dynamic recommendation process. The experimental results demonstrated that the proposed algorithm achieved a high average recommendation accuracy of 98.7%. Additionally, the algorithm maintained an average book popularity score of 8.2 after reaching stability, indicating its ability to suggest widely appreciated books. These outcomes validate the effectiveness of the algorithm in delivering accurate and popular book recommendations tailored to individual readers' needs. This study combines K-means clustering with time sensitive preference analysis and latent factor model to introduce an innovative method in the field of book recommendation systems. The findings provide valuable insights and practical applications for libraries seeking to enhance their personalized recommendation services, offering a significant contribution to the field of intelligent information retrieval.

Keywords—Book recommendation; K-means; time information; latent factor model; preference matrix

I. INTRODUCTION

The Book Recommendation (BR) system is an important application that can provide users with personalized book recommendations. As information technology develops, people's demand for obtaining, sharing, and purchasing books continues to increase, making recommendation systems crucial in helping users discover interesting books [1]. Traditional BR systems often use Collaborative Filtering (CF) algorithm for recommendation, which analyzes users' historical behavior data, mines similarities between users or items, and makes recommendations. However, CF algorithm still has some problems. Firstly, CF is unable to handle cold start issues well, which means that there is a lack of sufficient data to accurately recommend new users or newly listed books. Secondly, CF does not consider the specific relationship between books and users, resulting in a lack of diversity and personalization in recommendation results. To overcome these issues, a Latent Factor Model (LFM) is introduced into the BR system. LFM establishes the connection between users and books by representing them as latent feature vectors [2]. This

model not only considers the similarity between users and books, but also captures the implicit relationship between users and books, thereby improving the accuracy and personalization of recommendation results [3]. However, although LFM has achieved good results in solving some problems, the existing LFM-BR system cannot fully utilize the time information of users in the process of borrowing books. Meanwhile, it also cannot provide personalized recommendations for users, and still has certain limitations. Therefore, to solve these problems, a preference matrix is constructed by analyzing the borrowing time of readers to reflect their preferences. At the same time, the K-means algorithm and preference matrix are used for reader clustering to identify the reading needs of different preference reader groups. The implicit semantic model is trained and scored for prediction. An LFM-BR algorithm that integrates time information and K-Means clustering is designed. It is hoped to improve the recommendation performance of the BR system, provide users with more accurate personalized BR services, enhance user experience, and provide new ideas for the development of BR systems. This article consists of six sections. Section I is the background of the BR system. Related work is given in Section II. Section III reviews the research on recommendation systems both domestically and internationally. The sections designs the LFM-BR algorithm based on K-means and time information. It constructs a modified preference model based on time information. It optimizes the LFM recommendation algorithm based on K-means and modified preference models. Section IV analyzes the performance of the algorithm and its practical application effects. Finally, the entire article is summarized and its shortcomings are pointed out in Section VI.

II. RELATED WORKS

Due to the rapid development of the Internet, a large number of books can be obtained and read online. The number and variety of books continue to increase, but users often feel confused and exhausted. Therefore, to provide personalized BR services, many scholars have conducted in-depth research on recommendation systems. Guo Q et al. designed a knowledge graph recommendation system to address information explosion and enhance user experience in various online applications. The knowledge graph was used as auxiliary information to generate recommendations. These results confirmed that the system had higher recommendation accuracy [4]. Yi B et al. designed a deep matrix factorization model based on implicit feedback embedding to accurately recommend reader preferences. It directly generated potential factors of users and preferences from input information

through feature transformation functions. These results confirmed that this model had high accuracy and training efficiency [5]. Cui Z et al. designed a CF-based personalized recommendation system to provide users with accurate and fast information over time, which analyzed user behavior to provide higher quality recommendations. These results confirmed that the system could quickly and accurately make recommendations [6]. Zhou W et al. designed a graph-based personalized recommendation algorithm for sorting to improve user preference matching accuracy in recommendation systems. It matched target users with users with similar preferences through an improved resource allocation process. These results confirmed that the recommendation performance of this algorithm was good [7]. Liu Y et al. proposed a personalized library recommendation model based on small data fusion algorithm to better grasp the needs of library users and provide more accurate knowledge services. The neural network was utilized to achieve multi-dimensional small data fusion. These results confirmed that this model could effectively achieve personalized recommendations [8]. Liu Y designed a CF information recommendation algorithm based on spatiotemporal similarity to meet the academic information recommendation needs of university libraries. An academic information demand model was established through situational awareness and combined with adaptive interest models. These results confirmed that this algorithm could effectively achieve personalized recommendations [9].

Zhang S designed a personalized service method for university libraries based on data tracking technology to identify user interests and provide peer-to-peer service recommendations. The big data behavior tracking technology was utilized to analyze and track the behavioral information of user groups. These results confirmed that this method could accurately recommend and had high efficiency [10]. Frequent data scanning and excessive candidate itemset in the library lead to slow system operation. Therefore, Zhou Y proposed an information recommendation book management system based on improved Apriori. The method integrated C/S and B/S architectures to open book information to staff and borrowers. These results confirmed that the CPU usage of this system was relatively low [11]. Fu M proposed a personalized library resource recommendation system to address the low accuracy and user satisfaction of traditional library recommendation systems. It corrected the bias values and weights of visible and hidden layers in deep belief networks through contrastive divergence method. These results confirmed that this system had high accuracy, recall, and user satisfaction [12]. Chendhur K M K et al. designed an improved CF based on user preferences to improve the execution time and accuracy of prediction problems in BR. A small batch gradient descent algorithm was introduced to make predictions based on user preferences. These results confirmed that this algorithm had high prediction efficiency [13]. Anwar T et al. designed a cross domain BR for sequential pattern mining and rule mining to meet user needs in a shorter amount of time. The semantic similarity was utilized to expand domain recommendations and recommend books that users preferred through rule mining algorithms. These results confirmed that the system had a high-performance score [14]. Saraswat M et

al. designed a BR model based on neural recursive network classification to consider the combination of book types and reviews in BR. It categorized book plots and comments into various categories and recommends books to users based on these categories. These results confirmed that the accuracy and F1 value of this model were relatively high [15].

In summary, scholars have proposed various innovative methods aimed at providing personalized and accurate BR services. However, most of these methods rely on the user's historical behavioral data for recommendations, ignoring their real-time or immediate needs. Therefore, the study first constructs a comprehensive preference model for reader borrowing duration. Then, the K-means algorithm is used to cluster the readers. The clustering results are trained using the LFM model. A LFM-BR algorithm that integrates time information and K-means clustering is proposed. Compared with existing research, this method emphasizes the importance of temporal information and identifies reader groups with different preferences through clustering methods. It can better handle data with obvious group and time series characteristics, thus better grasping changes in readers' interests and needs, and making timely recommendations.

III. LFM BOOK RECOMMENDATION MODEL BASED ON TIME INFORMATION AND K-MEANS

This chapter mainly studies the improvement method of LFM-BR based on K-means and time information. Firstly, a preference model based on time information is constructed. Next is to improve the function design of BR.

A. Construction of a Modified Preference Model Based on Time Information

In the library, readers' borrowing preferences are a constantly changing dynamic process. Over time, readers' interests and needs will change, leading to new interests in different types of books. Faced with this situation, traditional CF often cannot provide satisfactory recommendation results [16]. To address the dynamic changes in reader borrowing preferences over time, this study analyzes the borrowing duration to deeply explore the potential preferences of readers and constructs a comprehensive preference degree model. The set of readers is $A = \{a_1, a_2, \dots, a_m\}$ and the set of books is $D = \{d_1, d_2, \dots, d_n\}$. Based on sets of books and readers, the personal reading preference in Eq. (1) can be obtained.

$$L_p(a_i, d_j) = 1 - \exp\left(-\frac{ct_{ij}}{t_i}\right) \quad (1)$$

In Eq. (1), L_p refers to individual reading preferences. $\exp()$ represents an exponential function. t_{ij} means the duration of time for reader a_i to borrow book d_j . \bar{t}_i is the average borrowing time of books borrowed by reader a_i . c represents a parameter that can be adjusted. However, the borrowing situation of each book varies due to factors such as content, number of pages, or category. Some books may attract more readers to borrow and pay attention to them due to their in-depth and engaging content, or their popular themes.

However, other books may have relatively fewer borrowed volumes due to their large number of pages or special categories. Therefore, the next step is to calculate the preference for borrowing books, represented by Eq. (2).

$$L_b(a_i, d_j) = \frac{t_{ij} - t_j(\min)}{t_j(\max) - t_j(\min) + b} \quad (2)$$

In Eq. (2), L_b refers to the degree of preference for book borrowing. $t_j(\min)$ represents the minimum borrowing time of book d_j . $t_j(\max)$ means the maximum borrowing time of book d_j . b is a bias term. Personal reading preferences can reflect the user preference for different themes or types of books, while book borrowing preferences reflect the user's tendency to choose a certain book in actual borrowing behavior. Therefore, considering the two preferences comprehensively, a comprehensive preference model is established by weighted sum to better understand user preferences and improve the accuracy of recommendations, represented by Eq. (3).

$$L_s(a_i, d_j) = \mu \cdot L_p(a_i, d_j) + (1 - \mu) \cdot L_b(a_i, d_j) \quad (3)$$

In Eq. (3), L_s represents the comprehensive preference of readers for borrowing books. μ is the weighting coefficient. The matrix in Table I shows the comprehensive preference.

TABLE I. COMPREHENSIVE PREFERENCE MATRIX

Reader /Book	d1	d2	...	dj	...	dn
a1	L (a1, d1)	L (a1, d2)	...	L (a1, dj)	...	L (a1, dn)
a2	L (a2, d1)	L (a2, d2)	...	L (a2, dj)	...	L (a2, dn)
...
ai	L (ai, d1)	L (ai, d2)	...	L (ai, dj)	...	L (ai, dn)
...
am	L (am, d1)	L (am, d2)	...	L (am, dj)	...	L (am, dn)

The interests and preferences of readers will also change over time. Therefore, by constructing preference transfer functions, different weights are assigned to preferences in different time periods. Based on the preference transfer function, the comprehensive preference model is optimized and a comprehensive preference correction model incorporating time information is designed. Considering the borrowing history of readers, recently returned books better reflect their current interests and preferences. Therefore, they should be given higher weight. Books that have been returned for a long time may reflect outdated interests and preferences, so certain punishments should be imposed on them. This is consistent with the law of human forgetting, which means that people are more likely to remember recent events, while their memory of distant events gradually becomes blurred. The Ebbinghaus forgetting curve can describe the forgetting pattern of the human brain. Fig. 1 shows the curve of human memory over time.

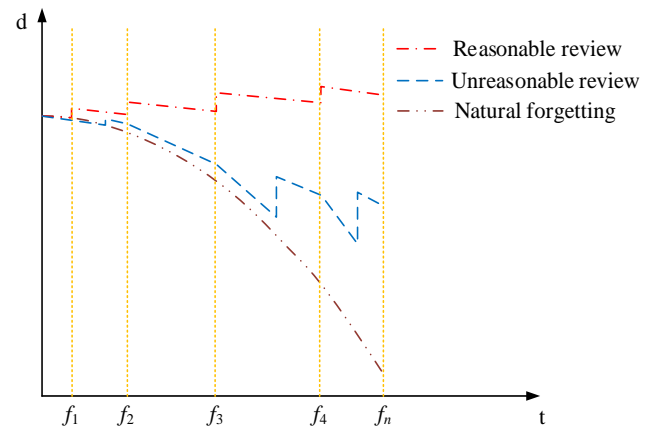

Fig. 1. Time dependent curve of human memory level.

According to Fig. 1, a function can be used to fit the Ebbinghaus forgetting curve and quantify the degree of forgetting. The study adopts Newton's cooling law, represented by Eq. (4).

$$-\frac{dT(t)}{dt} = \varphi [T(t) - T_C] \quad (4)$$

In Eq. (4), $-\frac{dT(t)}{dt}$ represents the rate at which the temperature $T(t)$ of the object decreases over time t . T_C represents the temperature of the surrounding environment at time t . φ represents the cooling coefficient, which is a proportional constant. The next step is to calculate the relationship between the object temperature at time φ and the initial time through mathematical operations, represented by Eq. (5).

$$T(t) = T_C + [T(t_0) - T_C] \cdot \exp[-\kappa(t - t_0)] \quad (5)$$

In Eq. (5), t_0 represents the initial time. The last time the reader returns the book before the current moment is used as the evaluation criterion. Eq. (5) is adjusted to obtain the preference transfer function, which is represented by Eq. (6).

$$\omega(a_i, d_j) = \varepsilon + (1 - \varepsilon) \cdot \exp[-\zeta(t_c - t_{last})], \zeta \in (0, 1) \quad (6)$$

In Eq. (6), ω is the preference weight. ε represents a constant. t_{last} is the last time the book is returned. ζ means a time decay coefficient. Finally, by combining the preference transfer function with the comprehensive preference model, a preference correction model based on time information can be obtained, represented by Eq. (7).

$$L'(a_i, d_j) = \omega(a_i, d_j) \cdot [\mu \cdot L_p(a_i, d_j) + (1 - \mu) \cdot L_b(a_i, d_j)] \quad (7)$$

In Eq. (7), L' is the modified preference based on time information. Fig. 2 shows the modified preference matrix.

Fig. 2. Modified preference matrix diagram.

B. LFM Recommendation Algorithm Based on K-Means and Modified Preference Degree

The relationship between readers and book categories was not taken into account in the design and modification of preferences. Therefore, it is impossible to fully explore the potential preference information of users. In some libraries, there are more books. The borrowing records of readers are relatively rare [17]. Therefore, the first step is to regard the set of book categories as $G = \{g_1, g_2, \dots, g_z\}$ and combine the set of books with $G = \{g_1, g_2, \dots, g_z\}$ to form a category matrix. The elements in the j row and k column of the category matrix are set to Boolean values, either 0 or 1. When $bg_{jk} = 1$, it indicates that the book b_j belongs to the g_k class. When $bg_{jk} = 0$, it indicates that b_j does not belong to g_k . The category preference of books in Eq. (8) can be obtained.

$$Q_{ik} = \frac{f_{ik}}{\sum_{z=1}^z f_{iz}} \quad (8)$$

In Eq. (8), Q_{ik} means the reader's preference for borrowing books. f_{ik} represents the frequency of borrowing g_k books. f_{iz} is the frequency of borrowing g_z books.

The next step is to cluster readers using K-means based on the category preference matrix between readers and books, as displayed in Fig. 3.

When clustering, cluster centers are selected based on the similarity between reader preferences for different book categories. The next step is to combine reader clustering with preference correction matrix to establish a preference matrix for the same cluster of readers. The cosine similarity is introduced, and the category preference matrix is inputted to calculate the similarity, which is represented by Eq. (9).

$$similarity(a_x, a_y) = \frac{\sum_{k=1}^z (Q_{xk} \cdot Q_{yk})}{\sqrt{\sum_{k=1}^z (Q_{xk})^2} \cdot \sqrt{\sum_{k=1}^z (Q_{yk})^2}} \quad (9)$$

In Eq. (9), $similarity(a_x, a_y)$ is the similarity in book category preferences among different readers [18]. The next step is to train using the LFM recommendation algorithm, which decomposes the matrix into two low dimensional matrices. One matrix represents the relationship between users and potential features, while the other matrix represents the relationship between items and potential features. These potential features can capture the implicit relationship between users and projects, namely implicit classification. By learning these potential features, users can predict their ratings for projects they have never interacted with before. The user rating of the project is represented by Eq. (10).

$$\begin{cases} S = U \times P^T \\ r_{zi} = \sum_{h=1}^H p_{zh} q_{ih} \end{cases} \quad (10)$$

In Eq. (10), S is the rating matrix. U represents the relationship matrix between decomposed users and potential features. P means the relationship matrix between the decomposed project and potential features. r_{zi} refers to the predicted score. H is the number of hidden classifications. p_{zh} represents interest level. q_{ih} means the association between projects and implicit classification. The next step is to obtain the values of parameters p_{zh} and q_{ih} through the objective function. Meanwhile, to prevent overfitting, a regularization term is added to the objective function, represented by Eq. (11).

$$\Phi = \sum_{(z,i) \in R} (r_{zi} - \sum_{h=1}^H p_{zh} q_{ih})^2 + \lambda (\|p_z\|^2 + \|q_i\|^2) \quad (11)$$

Fig. 3. K-means reader clustering diagram.

In Eq. (11), Φ represents the objective function. R refers to the scoring set. λ is the regularization coefficient. The solution of the objective function usually uses gradient descent method, which minimizes the objective function by taking its derivative and gradually reducing the parameters values. In the gradient descent method, the parameters values are first initialized. Then, the partial derivatives of each parameter in the objective function are calculated to obtain the gradient of the parameters. Next, based on the learning rate setting, the update amount of the parameter is obtained by multiplying it by the gradient value, and it is added to the current parameter value. This process continues until the specified stopping criterion is reached, that is, the objective function has converged or reached a certain number of iterations. The solution of parameters p_{zh} and q_{ih} is represented by Eq. (12).

$$\begin{cases} p_{zh} = s_z q_{ih} (q_{ih}^T q_{ih} + \lambda I)^{-1} \\ q_{ih} = s_z p_{zh} (p_{zh}^T p_{zh} + \lambda I)^{-1} \end{cases} \quad (12)$$

In Eq. (12), s_z represents the rating of user z . I is the identity matrix. The training process has been completed. Fig. 4 shows the training process of the LFM recommendation algorithm.

The next step is to introduce Sum of Squared Errors (SSE) to evaluate the clustering performance of K-means-based reader clustering, represented by Eq. (13).

$$SSE = \sum_{i=1}^k \sum_{x \in A_i} |sim(C_i, x)|^2 \quad (13)$$

In Eq. (13), A_i represents the set of reader clusters. C_i represents the clustering center of the reader cluster. The next step is to introduce Mean Absolute Error (MAE) and Root

Mean Squared Error (RMSE) to evaluate the rating accuracy of the designed recommendation system. MAE is the average absolute difference between the predicted score and the actual score. A smaller value indicates that the predicted score is more accurate. RMSE is calculated based on squared error, taking into account the error between each predicted score and the actual score, and averaging the error. A small RMSE indicates that the predicted score is close to the actual score. These two indicators are represented by Eq. (14).

$$\begin{cases} MAE = \frac{\sum_{z,i \in N} |r'_{zi} - r_{zi}|}{N} \\ RSME = \sqrt{\frac{\sum_{z,i \in N} (r'_{zi} - r_{zi})^2}{N}} \end{cases} \quad (14)$$

In Eq. (14), N represents the total amount of data. r'_{zi} stands for the reader's true rating of the book. Finally, the accuracy, recall, and F1 score are used to predict the accuracy of the recommendation list, represented by Eq. (14).

$$\begin{cases} Accuracy = \frac{\sum_{o \in O} |S(o) \cap R(o)|}{\sum_{o \in O} |S(o)|} \\ Recall = \frac{\sum_{o \in O} |S(o) \cap R(o)|}{\sum_{o \in O} |R(o)|} \\ F1 = \frac{2 \cdot Accuracy \cdot Recall}{Accuracy + Recall} \end{cases} \quad (15)$$

In Eq. (15), O represents the set of users. $S(o)$ means the recommended list. $R(o)$ is a set of user preferences. Fig. 5 shows the designed LFM recommendation algorithm based on K-means and modified preference.

Fig. 4. The training process of the LFM recommendation algorithm.

Fig. 5. LFM recommendation algorithm based on K-means and modified preference.

IV. RESULTS OF LFM RECOMMENDATION ALGORITHM BASED ON K-MEANS AND TIME INFORMATION

This section mainly analyzes the experimental results of the designed LFM-BR. The first step is to analyze the performance of the designed algorithm. The second step is to design simulation experiments for its practical application.

A. Performance of LFM Recommendation Algorithm based on K-Means and Time Information

To verify the performance of the designed LFM recommendation algorithm, the study first selected different numbers of clusters and calculated SSE to obtain the optimal number of clusters, as displayed in Table II.

TABLE II. SSE VALUES FOR DIFFERENT NUMBER OF CLUSTERS

Number of clusters	SSE value	Number of clusters	SSE value	Number of clusters	SSE value
2	2.279	8	0.898	14	0.608
3	1.875	9	0.784	15	0.473
4	1.663	10	0.715	16	0.498
5	1.512	11	0.692	17	0.457
6	1.318	12	0.618	18	0.473
7	1.301	13	0.635	19	0.463

From Table II, as the clusters increased, the SSE of the designed BR gradually decreased. When the cluster was less than 7, the decrease rate of SSE was faster. When the cluster was greater than 7, the decrease rate of SSE became slower. Therefore, the optimal clusters were 7. The above results indicate that selecting the appropriate number of clusters has a significant impact on clustering effectiveness. In practical applications, it is necessary to choose the appropriate number of clusters based on different business needs and data characteristics to achieve the best recommendation effect. The next step is to calculate the MAE and RMSE of the designed BR, and compare them with CF, LFM, and LFM based on time information. Fig. 6 shows the results.

From Fig. 6 (a), as the hidden classification increased, the MAE of CF remained unchanged, while the MAE of other three algorithms showed a decreasing trend and gradually flattened out. Among them, the MAE of CF was always 0.26. The maximum MAE of LFM was 0.32 and the minimum value was 0.24. The maximum MAE of LFM based on time information was 0.29 and the minimum value was 0.23. The maximum MAE of the designed LFM recommendation algorithm based on K-means and time information was 0.29, and the minimum value was 0.21. From Fig. 6 (b), the RMSE of CF still did not vary with the hidden classifications, and its

value remained at 0.33. The maximum RMAE of LFM was 0.39 and the minimum value was 0.30. The maximum RMAE of LFM based on time information was 0.34 and the minimum value was 0.28. The maximum RMAE of the designed BR was 0.31 and the minimum value was 0.23. The above results indicate that the designed recommendation algorithm has good performance on prediction accuracy. Finally, to further validate the performance of the designed BR, the accuracy, recall, and F1 score of the four recommendation algorithms were calculated, as displayed in Fig. 7.

From Fig. 7 (a), as the iteration increased, the accuracy of all four algorithms showed an upward trend but gradually stabilized. When CF reached a flat state, the accuracy was 87.8%, and the maximum accuracy of LFM was 93.5%. The

LFM based on time information achieved a stable accuracy of 95.7%. The maximum accuracy of the designed BR was 97.3%. From Fig. 7 (b) and 7 (c), the recall and F1 score trends of these four algorithms were consistent with the accuracy trends. When CF reached stability, the recall rate and F1 score were 92.1% and 0.91, respectively. When LFM reached stability, the recall rate and F1 score were 92.6% and 0.93, respectively. When LFM based on time information tended to flatten, the recall rate and F1 score were 95.1% and 0.953, respectively. When the designed algorithm tended to flatten, the recall rate and F1 score were 98.2% and 0.965, respectively. The three indicators of this designed algorithm are significantly higher than the other three algorithms, proving its good overall performance.

Fig. 6. MAE and RMSE values of four book recommendation algorithms.

Fig. 7. Results of different indicators.

B. Application Effectiveness of LFM Recommendation Algorithm based on K-Means and Time Information

To verify the effectiveness of the designed BR in practical applications, a simulation experiment was conducted using Python 3.9 in a hardware environment with a 64 bit Windows 10 operating system, Intel (R) Core (TM) i5-12500K processor, 8GB of RAM, and 1TB of hard disk capacity. Firstly, the sparsity and computation time of the four algorithms are calculated. Fig. 8 shows the comparison results.

From Fig. 8 (a), as the iteration increased, the sparsity of different algorithms was effectively reduced. The sparsity

reduction effect of the designed BR was significantly better than other algorithms, with a sparsity of 66.5% at 180 iterations. From Fig. 8 (b), the computation time for using all four algorithms for recommendation showed a decreasing trend and tended to stabilize after reaching a certain iteration. The calculation time when the designed algorithm reached stability was 10.2s. The above results demonstrate that the designed algorithm can better solve the data sparsity in BR, and also prove its high computational efficiency. The next step is to calculate the average accuracy and coverage of different algorithms separately, as displayed in Fig. 9.

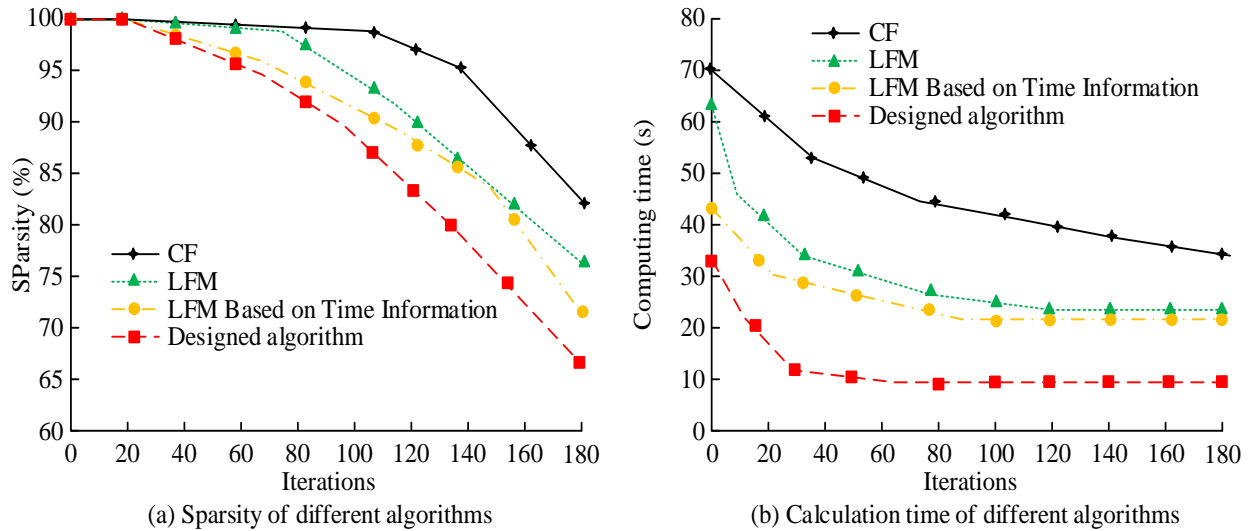

Fig. 8. Sparsity and computational time of different algorithms.

Fig. 9. Average accuracy and coverage of different algorithms.

From Fig. 9 (a), the average accuracy of the designed algorithm was significantly higher than other algorithms, reaching a maximum of 98.7%, further proving its recommendation accuracy. From Fig. 9 (b), as the number of hidden classifications increased, the coverage trends of these four algorithms were consistent. However, the coverage curve

of the designed algorithm had always been above that of other algorithms, indicating that the designed algorithm could cover more items in the recommendation process, proving its comprehensiveness and diversity. Finally, the average popularity of different algorithms was calculated to evaluate the effectiveness of the designed recommendation algorithm, as displayed in Fig. 10.

Fig. 10. Average popularity of different algorithms.

From Fig. 10, the average popularity of these four algorithms gradually increased and tended to stabilize. The average popularity of CF reaching a flat state was 5.5. The average popularity of LFM reaching a flat state was 6.8. The average popularity of LFM based on time information after stabilizing was 7.9. The average popularity of the designed recommendation algorithm after reaching stability was 8.2. The above results indicate that the book recommended by the designed algorithm has a high popularity, proving its good recommendation effect.

V. DISCUSSION

With the progress of the times, the number of books has increased sharply, and the readership has become more diverse. Traditional BR methods have been unable to meet the diverse needs. The research aims to provide more accurate and personalized BR services, and proposes an LFM-BR algorithm that integrates time information and K-means clustering. The results showed that the MAE and RMSE values of the proposed algorithm were 0.21 and 0.23, respectively, which were higher than other algorithms, proving its high accuracy. Similar conclusions were drawn by Yi B et al. [5], who proposed an implicit feedback embedding deep matrix factorization model that can capture potential features of users, but it cannot effectively handle cold start problems. The proposed method quantifies the impact of time factors on user preferences by constructing a preference transfer function, effectively alleviating the cold start problem. The sparsity of the proposed algorithm was 66.5% at 180 iterations, indicating that it could better solve the data sparsity problem in BR. This conclusion is similar to the conclusion drawn by Fu M et al. [12], but the proposed algorithm is significantly better. This is because the proposed algorithm introduces the K-means algorithm to cluster readers with similar preferences and incorporates time information to enhance the system robustness, thus better addressing the data sparsity. The proposed algorithm took 10.2 seconds to reach a steady state, significantly lower than other algorithms, demonstrating its high computational efficiency. This is similar to the conclusion drawn by Zhou Y [11], and the proposed algorithm is superior. This is because the proposed algorithm optimizes the objective function and uses gradient descent to update parameters, ensuring efficient computation on large-scale datasets. In summary, the proposed method effectively improves the effectiveness of BR by integrating time information, optimizing clustering strategies, and enhancing LFM models, which is of great significance for promoting

personalized library services.

VI. CONCLUSION

In the era of information explosion, BR has become an important tool to help users quickly find suitable reading interests. To improve the accuracy and personalization of BR, an LFM-BR based on K-means and time information was designed. Firstly, a comprehensive preference model based on time was constructed through borrowed books, followed by reader clustering using K-means, and finally training using LFM. These results confirmed that the maximum MAE of the designed algorithm was 0.29 and its minimum value was 0.21. The maximum RMSE value was 0.31 and its minimum value was 0.23, all higher than other algorithms, proving its high prediction accuracy. In terms of accuracy, recall, and F1 score calculation, the designed algorithm was 97.3%, 98.2%, and 0.965, respectively, proving its good overall performance. In terms of sparsity and computation time, the designed recommendation algorithm had a sparsity of 66.5% at 180 iterations, and a computation time of 10.2s to reach a stable state. These prove that it can effectively solve the data sparsity in BR and has high computational efficiency. The above results confirm that the designed algorithm has high accuracy and personalization in the BR problem, and can accurately reflect the reading interests and needs of users. However, the study does not consider other behavioral data of readers, which may have a certain impact on the results. Future research will incorporate more user behavior data to construct more comprehensive user preference models, and introduce new natural language processing techniques to further enhance the performance of BR systems.

Abstract—Smart city architectures have been varying from one community to another. Each community leader develops their own perspective of smart cities. Some of these communities focus on data management, while others focus on provided services and infrastructure. In this research, an attempt to propose a clear, complete, and efficient perspective of smart cities is accomplished. The proposed generic architecture clarifies the full capabilities, requirements, and layers' contribution to a successful smart city development. The proposed architecture utilizes Internet of Things tools as well as agile standards in the description of each layer. The research aims to discuss each layer in detail, the relationships among layers, the applied technology, and every aspect that leads to the success of using the recommended architecture. Although smart cities, IoT, and agile research have previously tackled the relation of each one of them with the other, up to the researchers' knowledge, the three paradigms have not been previously considered as a unified collaborative approach. In order to reach the research target, the proposed architecture intelligently utilizes these paradigms and presents a robust architecture with high-quality standards.

Keywords—Smart city; agility; Internet of Things; cloud computing; intelligent systems

I. INTRODUCTION

Smart cities can drive intelligence to every aspect of the lives of the population. It affects management, decision-making, culture, and regularities. Smart cities consider re-inventing the way of living while generating value for the public. The main objective for developing smart cities is to enhance the quality of the population's way of living and provide them with an easy, sustainable, and satisfying life either in social or professional directions. In order to reach this goal, it is vital to identify all the requirements, obstacles, and challenges to be able to build smart cities. The term "smart city" has been tackled in different research studies; however, other aspects related to information technology are usually associated with it. The continuous population growth has become a primary reason for services' quality and hinders the development. Almost all fields have been affected by this exponential population growth, such as education, health, energy, and many others. Smart city development has been an effective solution supporting the city's sustainability. Quality is an associated aspect of smart cities. Embarking digitalization is vital for smart cities' transformation. Utilizing recent

technology, initiating new regulations, motivating the economy, and other factors are related to the concept of smart cities [1].

The idea of smart cities emerged in the nineties. The first wave focused on the contribution of the information technology concept to the main cities' infrastructure. Then, a focus on the community and its players highlighted how these players can have an easier life in smart cities. Later, smart cities term has been closely related to digitalization and intelligence; several factors effect has been discussed, such as people's resistance, the communities' culture, and others. Along the journey of smart cities' emergence, a broader perspective was highlighted, including the service's intelligence such as transportation systems, electricity system [2], construction field, banking systems, and others. These perspectives strongly emphasized the sustainability value of the cities' resources.

The concept of a smart city is exponentially increasing either for small or large cities. This global emergence drove the world to initiate new rules and regulations for the new era of cities. Many investments in smart cities have been proposed with the objective of innovation, growth, and enhancing life. All existing architectures depend mainly on the enabled technology for the smart features of the community. It has become feasible now to develop smart cities with the current acceptance and interoperability of IoT and advanced data analysis. Another perspective of smart cities is the ability to smart intelligent decisions by utilizing intelligent techniques for predictive analysis, better planning, and management [3]

This research traces all the proposed architectures for smart cities, traces the findings for embedding the technologies in the architectures infrastructures, and identifies the regularities and critical aspects for the transformation goal. This research proposes a generic architecture for smart cities, which is applicable for implementation with all its aspects, however, flexible. The proposed architecture discusses six layers and contributors to each one with giving the implementers the opportunity to implement the valid component without affecting the remaining architecture. Several factors are related to the concept of smart cities development including culture, quality, acceptance, resistance, and sustainability. These factors will be discussed later in this research. Moreover, other emerged factors such as IoT, agility, and motivating population are also considered as pillars in the proposed architecture.

II. RELATED WORK

IoT devices strongly contribute to smart cities as one of the main pillars. The devices are considered as sources that provide numerous amounts of data. Therefore, unification to a single data model is recommended, which should be able to deal with such data. Several researchers have proposed different models to deal with the data heterogeneity, temporal, and complexity. The research [4] included a model that received data from IoT devices and determined the correlation between the growth of both industries and urban. The research concluded that managing knowledge directly influences the development of the industry. The study recommended that the enterprises' technological communication enhances knowledge management and promising technologies investments which leads to alliance flexibility. Qian et al. (2019) [5] discussed the positive impact of IoT technology on empowering the infrastructure and, consequently economic growth and sustainability. Chen et al. (2020) [6] focused on the contribution of IoT technology and deep learning techniques in construction field. The research concluded that these contributing fields have leveraged the process of construction by exploring the shortest time consumed in the evacuation process. Watson et al. (2020) [7] also focused on IoT's contribution to the construction of smart cities and concluded that the field still needs further research for further development requirements of IoT technologies to leverage the construction of smart cities.

Focusing on cloud computing contribution in smart cities. Lv et al. (2018) [8] proposed a platform for smart cities in which cloud computing and geographical information systems successfully contributed. The research highlighted that both fields could positively affect the success level of monitoring environment phenomena and predicting expected disasters as well as exploring transportation system performance. Hossain et al. (2018) [9] highlighted the need for cloud computing platforms for higher computing technology when contributing to IoT devices access in smart cities such as edge computing for more effective computations and latency avoidance. Javadzadeh et al. (2020) [10] focused on the same latency issue and proposed the same fog computation solution. Giannakoulis et al. (2019) [11] focused on the security issues of cloud environments and their effect on smart cities platforms as well as [12]. The research in [13] highlighted that IoT and cloud computing contribution in smart cities enhances the services performance with the ability to reduce the servers' load as well as reducing their number which greatly contribute the construction cost.

The previous research highlighted the positive contribution of both IoT and cloud computing with focusing on a determined subject, however, up to the researchers knowledge, there was no research that provided a complete perspective of smart cities which is one of the vital issues to present the whole smart cities pictures, the interaction between all contributing aspects and the need for homogenous cooperation among all contributing players. Moreover, the research [14] discussed the issues of smart cities and confirmed that there is no complete structure

for smart cities while all current projects are pilot individual projects that included trade-offs of some aspects over the others.

III. RESEARCH CONTRIBUTION

To be able to present a complete flexible generic platform, twelve platforms have been extensively studied. These platforms have been developed by international organizations following the required standards. Moreover, different projects and studies have been also studied. The aim of this extensive study is to explore the characteristics of a smart city architecture including core, extendable, and supportive characteristics. Ensuring the collecting of all aspects reflects that the proposed platform proposes the best practice when compared with any other platform. This comparison will be performed in the evaluation section. While there were differences between the collected platforms, however, it was also clear that common segments could be highlighted. Extensive study has been performed to explore the strength and weakness between these platforms which lead to the initiative for a generic platform that provide solutions to hinder the possible obstacles and fully consider the reality of cities. The proposed platform has taken into consideration the international standards, system requirements, services, data, and security management criteria for smart cities [16].

IV. A PROPOSED AGILE IOT ARCHITECTURE

Different smart cities platforms recommendations have been studied aiming to explore the possibility to propose a successful platform with maximum interoperability with the common infrastructure of cities [15]. This target ensures accepting the proposed platform and encourages its implementation. The authors also aimed at proposing a generic platform which utilizes the commonly used technologies to ensure its implementation adequacy in different environments. The proposed generic platform that could be implemented using different technologies with various levels of maturity. The proposed platform could also be easily extended or reduced according to the capabilities; the platform flexibility will be discussed in detail in the following sections.

The proposed architecture (Fig. 1) consists of five main layers in addition to a continuing monitoring and governance layer. Each layer components will be discussed in detail in the next subsections. Moreover, Fig. 1 illustrates the proposed architecture.

The following key aspects identify the smart city platform that fits with the available capabilities.

- Identify the needed capabilities and the specifications for each capability.
- Ensure the delivery of the required capabilities with sufficient flexibility.
- Ensure all compliant solutions interoperability.

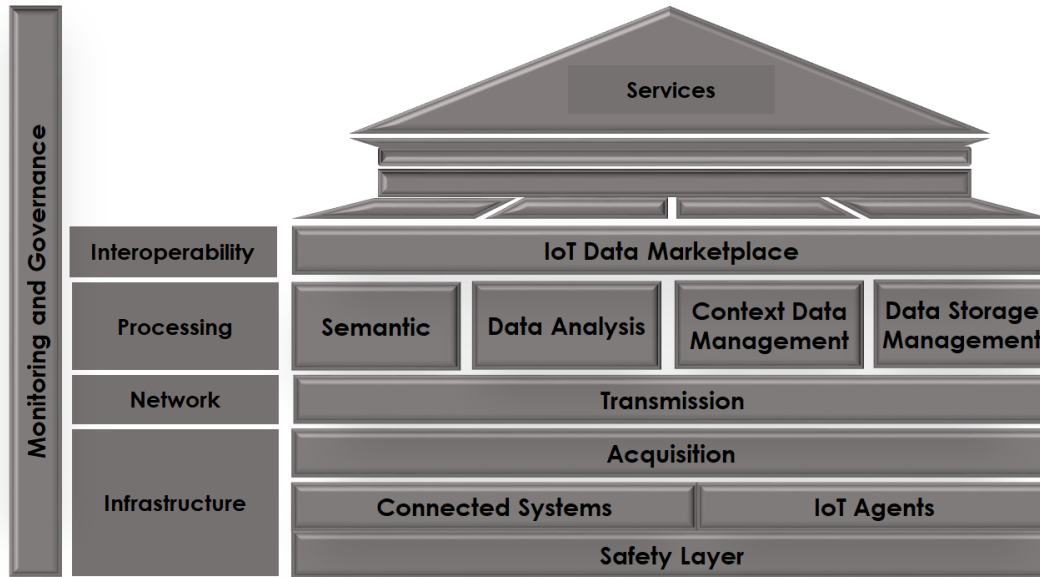

Fig. 1. Proposed generic architecture.

A. Infrastructure Layer

The infrastructure layer describes all the required utilities, devices, sensors, facilities, as well as the sources and its indicators. The infrastructure supports all the services, transportation, and environmental, as well as governmental aspects. Moreover, networking infrastructure is one of the compulsory components which configuration should be compatible with the predicted participating items. The network configuration could be considered one of the most critical aspects in the construction of smart cities.

1) *City sources components and indicator:* Many vital components which could be successful key aspects in smart cities are discussed earlier [17] (Fig. 2). These components are demonstrated in this section with discussing their effective contribution. The following points discusses each component, its standards, perspective, and contribution to the smart cities' paradigm. It is worth highlighting that although this section discusses each component individually, however; practically speaking; these components are interrelated. Therefore, a component could be discussed in various places in this section.

Fig. 2. Smart city indicators.

a) *Smart Economy:* Smart economy is achieved by incorporating a set of features into the economy such as innovation, digital transformation, sustainability, and high productivity. Smart economy focuses on the level of quality and standards of life which is evaluated by a new set of variables including basic needs, community participation, technology advancement, and scientific aspects. The concept of smart cities is multidimensional dynamic as well as adaptable. It includes economic, social, and motivating individuals' aspects. There is an immense need to balance between the current and next generations. Therefore, the focus of developing the current generation could result in identifying the effective methods and polices for development while maintaining the required quality with continuous quality upgrading. Smart economy concept leads to a clear identification to the relationship between the value of the economy and the satisfaction level such as the employees' satisfaction, customers' satisfaction, etc. it is also related to the level of availability either products or services with the satisfying quality. Therefore, the bond between smart economy and scientific research is vital which could be the key success to achieve such targets. A society that adopts the concept of developing its knowledge succeeds in raising the intelligence level. With efficient management, the goal becomes a fact.

b) *Mobility:* Most researchers focus on mobility with the aspect of traffic. Although this is one of the most crucial factors, however, it should not be the only mobility focus. Mobility is a crucial factor for emerging smart cities. The main discrimination between mobility and moving to smart mobility resides in general to the ability for easy access to the required information in a real time manner. The information continuous availability and easy access genuinely leads to improving services, saving time and effort, as well as raise the satisfaction level. Main factors that initially affect mobility could be the

success in developing sustainable plans, identifying measures to reduce conjunctions (for example, reduce number of simultaneously moving cars in the city), a successful management plan, and deploying alternatives for the services. Focusing on the mentioned example, one of the vital factors for reducing the number of cars is the online information availability without the need to move to the information source. This could be highlighted as a clear example for the effectiveness of the real time management system.

c) Sustainability: Sustainability is a crucial factor for smart cities which is in focus for many researchers. Most of the researchers' objectives are to reduce energy consumption and CO₂ emissions. The balance and economic usage of energy sources are also effective for sustainability. Moreover, seeking optimal sources' usage, developing a green environment, recycling, intelligent grid management, and developing supportive policies to reach these goals are also different pillars for efficient sustainability. For example, water sources management sustainability is challenging which could be achieved through intelligent technologies such as IoT technology.

d) Environments: Transforming to smart environments is a significant factor for smart cities. Green environment, water margins, controlling gas emissions, controlling wastes, and efficient energy management are some of the smart environment-affecting factors. Different intelligent solutions could be proposed. Gasses emissions prediction could contribute to gasses control which also leads to maintaining a green environment. Gasses emissions prediction is related to monitoring different activities such as traffic. As mentioned earlier, these factors are interrelated, therefore, in this example, it is clear that smart traffic systems could lead to minimizing the gasses emissions.

e) People: As smart cities main aspect is increasing the quality of life, therefore, People are considered the core factor of smart cities. They are the main players who have the benefits of the offered services and devices. Living in smart cities requires people to accept and be able to utilize this environment. On the other hand, securing people privacy as well as facilitating the usage of offered services are two of many factors that lead to the required level of acceptance. Educating people about the smart cities aspects is another factor. Their growing knowledge of how these services facilitates their lifestyle reduces their risk level and raise the level of trust. One of the emerging educating sources for smart cities is the social networks. Since connection is the key aspect for the concept of smart cities, therefore, considering all communicating channels should have given attention. Social communication among people should be utilized to exchange experiences and share opinions. Moreover, sharing resources, data, and benefits could also be intelligently performed with maintaining people privacy. Smart people as a main pillar of smart cities should not only share services, but they should also share data and knowledge targeting to ensure long-term benefits. For example, sharing data and knowledge about the city roads may lead to more enhancement in the roads infrastructure which leads to enhancing the traffic services. Smart people should have skills

such as being easily adaptable, accepting creativity, flexible, ability to participate in the community, able to identify their goals, as well as having knowledge about the rules.

f) Living: Smart living is comprised of the living in smart surroundings including smart buildings such as smart educational institutions, smart healthcare system, and smart tourism services and places. An example of the facilities that facilitates smart living in houses could be the contribution of IoT in home appliances, voice commands, and others. IVR is proved to be one of the useful solutions for smart living, especially being easy to learn and access. Different focuses have been performed to many other contributing systems to smart living such as healthcare system which is a non-negotiable one of the most vital systems in the community. Real time monitoring systems could contribute to various aspects such as healthcare, transportation, educational, and many other systems. Such innovation in the different business models reflects the required levels of management, leads to a high-quality level, provides a high value for the cooperative environment and contribute with a high impact for smart living concept.

g) Governance: The government is the core vital barrier that is able to promote smart cities concept to the people. The success of smart cities relies on the success of the government in providing the smart services, maintaining the relating channels, issue the suitable laws and regulations for maintaining privacy, fair facilities usage, and other aspects. E-government services should be one of the investment targets targeting to contribute to prosperity, satisfaction and enabling organizations. As the impact of social networks is already mentioned, governments could utilize such active sources as an effective strategy to motivate people in contributing to the smart cities concept. Achieving such a goal also relies on the success of maintaining security and privacy. Although technological aspects are key factor for e-government, however, managing policies are also vital to enable people to use the offered services but with regularities. Different metrics could raise the level of trust between the government and the people including the services effectiveness, citizen engagement, the process transparency, and the clear collaboration. Sustainable governance could be supported by effective environments such as cloud computing systems. This environment could heavily support the success of such framework due to the continuous engagement, communication, and collaboration.

2) Safety Component: Smart cities platforms need to maintain security requirements for both services as well as data. However, supporting security could be performed in a flexible environment to accommodate the needs' variations. Users' integrity, accounts' authentication, confidentiality, and trustiness are required for maintaining the platform protection as needed [18] [19].

a) Protecting Data Privacy: The privacy protection for all levels of data should be addressed starting for the lower level represented in the infrastructure of the proposed platform to the higher level representing the offered applications for the

people. One of the main methods is encryption. Encryption supports securing data while migrating as well as while residing in the physical data repositories. It is also vital to support the system against breaching by unauthorized users. Therefore, security procedures should be clearly defined and maintained on a regular basis. This task is a non-trivial task since data providers and consumers may engage with third parties to access data sources. Therefore, policies should be professionally managed for the success of controlling the access of data and its sources. All the contributing parties should comply with policies that maintain data privacy.

b) Devices Privacy: The variety of the services contributing to the smart cities leads to an impossible situation of identifying a unified security method for all devices as each device has its nature and capabilities and requires its own security procedure. On the other hand, balancing the equation of securing the contributing devices on one hand, and reducing resources consumption on the other hand makes this task more critical. Smart cities system should provide end-to-end system for security; for example, starting with the API level for IoT devices; moving forward to apply authentication and integrity methods. The boundaries of such critical systems should be governed by a set of policies and the boundaries should be clearly identified.

3) Sensing Component: Sensors have a key role in smart cities. They gather data, then transfer this data to its corresponding objects. This data also moves through the network layer to the cloud in an agile manner targeting to a fast response and immediate message passing for reply. With the expected network load, several paradigms could participate in the framework to avoid congestion. Load balancing techniques could be utilized to avoid network servers' overload. Data handling and resource allocation algorithms could be utilized with a cloud monitoring system for homogenous resource allocation. Resources allocation and task scheduling techniques support the assignment tasks in the application level which ensures a prominent level of service quality. Moreover, the dynamic computation complexity at the sensors level should be considered to ensure resource provisioning.

4) Connected Systems (IoT Management Agent): The main idea of the IoT paradigm is enhancing the working processes through the ability to receive instant services that are transformed from physical objects in a real-time manner [20]. IoT is basically a communication between objects either these objects are machines, utilities, devices, or human. RFID, sensors, and embedded systems are the main players in the IoT system. It is a fact that IoT paradigm is one of the most challenging evolutions in digitalization phenomena. This evolution has moved the field of digital business into a new level of competence, efficiency, and effectiveness. IoT offers an improved business models with the ability for cost reduction.

The current architecture for IoT systems suffers from the lack of agility for services. This situation highlighted the idea of embedding the agile concepts and practical aspects into IoT systems architecture [21]. Agile strategies support business

processes with maintaining optimization in a real-time management manner which consequently supports many opportunities to successful business solutions [22]. The current framework proposes a flexible agile-based IoT architecture which helps in the ability to accommodate with the dynamic environment of the smart cities. The proposed architecture considers the database security over the cloud environment with the availability for end-to-end access under the agility umbrella for more efficient computation and ensure high scalability to ensure leveraging the resources allocation. IoT platforms perspectives either focus on the objects or on the internet, the proposed architecture adopts a modular perspective targeting the services quality with maintaining agility for higher satisfaction rate.

It is a fact that technologies emerge quickly which requires continuous adaptation in a fast and flexible manner. The proposed framework has loosely distributed components to provide a flexible approach that permits components replacement with nearly non-impact to other components. Following the proposed approach minimizes the risks associated with the traditional IoT architecture deployment and ensures the multi-operating machines with maintaining the working scale. One of the fundamental aspects for the proposed framework is the concept of encapsulating the development issues and its capability of integration flexibility of trusted services with establishing the sufficient data repositories that have common basics for the smart cities. The proposed architecture ensures having a reliable scalable system with future adaptation capabilities. The recommended platform should have vital specifications to ensure the digital connection between all systems as well as ensure the high system scale with maintaining privacy and security. The factor of the platform interoperability and trustiness ensures the system stability with addressing the economy benefits from different perspectives.

The proposed architecture (in Fig. 1) illustrates the main components in a layered approach with demonstrating the corresponding standards. The following principles have been taken into consideration.

- The proposed solution is suitable for large, medium, and small cities based on its simplicity and adaptation availability.
- The verities of deployment solutions could be applied by the proposed architecture.
- The main international standards have been considered.
- Common features have been presented to ensure the generality perspective.
- Modular approach to ensure the architecture technology adaptation.
- Enabling interoperability by employing open API with semantic data interpretation.

5) Acquisition Layer: This layer considers gathering the required data from various sources. Data streams are produced from edge devices, it is then processed on the go during migration through the network to avoid delays. The process involves the physical devise which is the closest to the

determined data source and is responsible for the basic aspects of data processing and primary analyzing data. The analysis results are then migrated through the shortest channel with the real-time conditions to boost the cloud center for the data and initiate the decision-making alternatives.

B. Transmission (Network) Layer

The network layer provides the required support for both data and applications. The associated network servers and the sensors manipulate the data starting from gathering to processing over the cloud environment. The network layer task is to maintain this process quality including the delivery time and ensuring the satisfying of the business requirements with the required performance. This situation raises the need of embedding the agility concept in the network architecture especially for the IoT architecture. Network infrastructure sensors' task is continuous monitoring and recording the parameters. Detection stations keep collecting data as active nodes for all conditions such as weather, power, chemical, and other data.

To achieve the required goal, several requirements should be accomplished. The network should be able to provide the available services to multiple tenants. The network scalability should be of acceptable level with respect to the number of players and devices, traffic scale, bandwidth and other parameters. Most of the entities require either L2 or L3 VPN with security approaches for IoT devices such as isolation. Services should be continuously available to all players and contributors; therefore, the network should adopt the redundancy approach at all the network layers in order to avoid possible failure at any time and ensure instant re-convergence. The contributing devices should have the ability to tolerate under the extremes of the environmental parameters. To accomplish successful operations and other previous requirements, it is critical to adopt simplicity in the network operations.

IoT allows disseminating information for the purpose of enhancing business processes. A continuous communication between the participating machines in the network is performed through the IoT devices. Related technologies such as RFID, sensors, and embedded systems need to be critically selected for higher scalability. Engaging IoT for smart cities ensures productivity, safety, and quality. However, the traditional systems are lacking agility in supplying the system services. Therefore, introducing agile manifesto into the IoT system provides a real-time adaptation to the devices' management process, ability for optimal execution, and ensure optimizing services. The interconnectivity between IoT and agility provides the smart city architecture with massive successful opportunities. Introducing agility with its main concepts of simplicity, flexibility, adaptation ability, incremental approach, and refactoring provides an opportunity for continuous adaptation for the business services with ensuring high competing level. Leveraging the agile environment for IoT with the cloud platform is a triple based approach for smart cities which can provide high performance services for people. In the proposed approach, the internet based IoT approach is followed as the main focus is to provide scalable services for users.

In order to highlight the advancement of agile based IoT in smart cities over traditional IoT systems, the following points could be highlighted. Usually, the devices are connected through the sensors with transferring the data and readings. By embedding agile-based IoT cloud platform, these records are instantly updated through the cloud platform and this update is considered in a timely manner. The traditional system usually suffers from performance issues which hinder the ability to promote the services that has higher demands. The proposed architecture ensures a high performance. The traditional architecture does not adopt defined standards, rather, each pilot project has its own individual standards. The proposed architecture ensures the ability to adopt the same standards and ensures the concept of universal standardization. The traditional architecture suffers from excessive cost as a high number of supportive devices such as sensors require to be embedded in many places to ensure good coverage and continuous communication. On the other hand, the proposed system extensively reduces the cost according to the domination of cloud environment which can be accessed irrespectively of time or place with the lowest communication cost. There are no quality standards in the traditional system while in the proposed system, as agile manifesto is introduced, then following quality standards could be considered as one of the main parameters on focus.

C. Processing Layer

1) *Semantic Component*: Integrating semantic concepts into smart cities platforms is one of the emerging approaches [23] [24]. IoT services that are based on semantics are introduced in some research [24]. The research in [25] proposed a method for processing with semantic indexing while in [26], the concept of semantic IoT is introduced but was limited to the IoT applications only. The semantic component is based on multi-level analysis of data and explored knowledge. First level is for infrastructure data, then the data gathered from the IoT contributed devices is considered the second layer, the third layer includes the associations between players through the communication channels, business, social, and other available channels. Embedding the semantic component provide more meaning to the distributed data through the network. Moreover, applying machine learning techniques could contribute to enhancing the data quality through avoiding the data sparsity, outliers, and other data challenges. Machine learning techniques are well known for their ability to successfully deal with such challenges [27]. Semantic component deals with data in a collaborative environment. Data relationships are explored by stamping these data with the semantic annotations representing the relationship nature, time stamps, the defining factors explanation and others. Feature connectivity and weighting also contribute to the semantic explanation process [28]. Semantic components are responsible for providing meaningful explanation. For example, if a request for traffic in a certain territory is initiated, then the data is collected, aggregation is applied from various sources layers, and a virtual

entity is created. The features vector is explored, and the answer of the user query is provided through the predicted result.

2) *Data Analysis Component*: The data analysis component utilizes a set of models for processing data. A model repository should be included with a supportive architecture for identifying the suitable model for each received data. The model set could be divided to various categories such as statistical, learning [29], optimizing, forward and backward sensing, and forecasting. The availability of a variety of models highlights the opportunity for the analysis of different data nature with various levels of complexity [30]. The selection of the suitable model is based on the user requirements, the available data, and the purpose. The main goals of the data analysis component are to identify the exploration process that enables a selective set of data models to support both systems and applications interoperability between the interrelated communities. Moreover, classifying the available data models according to sectors and interoperability ability is on focus. Replicable models are accepted, even recommended for different sectors. Additionally, the higher capability of data volume manipulation that data models could consider provides a higher level of trust. This supports the system applications to reach their requirements and ensures higher efficiency and effectiveness. The different data models can play a communication role among different communities. Therefore, one of the main success factors is the clear and well discrimination of different data models manipulation methodology as it provides a level of trust for data migration among communicate. Moreover, as different data formats and structures are usually required by different application wither structured, semi structured, or unstructured data, therefore, a variety of different analysis and storage methods for different data sources formats as well as introducing analysis methods for data formats transformations could provide successful support.

3) *Context Data Management Component*: This component provides a set of management plans for data. These plans are initiated according to the integrated data and the different comprehensive understanding perspectives to the data. Understanding data is accomplished through gathering data from various sources, integrating these data, applying methods for semantic data explanation which context is received from these sources. The meta-data supports the comprehension task according to the associated entities and their functionalities. These entities gather events and migrate these events' data for the required explanation. The required pillars to perform this process efficiently is the data availability, accessibility, usability, and sharing ability. This component is an enabler for the applications to be able to explore their relevant data and be able to apply enquires over this data. Although the heterogeneity and diversity of data could be an obstacle, however, the structured architecture of the integrated data lakes enables the data migration among different applications.

Context validation should be also applied to confirm the operability and data validity.

4) *Data Management Component (Agile-based component)*: Management of data is accomplished through an identified standards API. This direction provides the ability for the re-using facility as there are common solutions standards. The ability for re-use also ensures blocking the lock-in issue which consequently sets the availability for continuous monitoring and improving ability. The re-use ability could also be supported by presenting a common taxonomy which is pre-identified for the data and the services which directly leads to ensure standardization. Tracking the updates is accomplished through the identified APIs which supports the access simplicity, resources accessibility while avoids issues of inconsistencies.

5) *Data Storage Management Component*: The aim of this component is to provide continuous and easiness in the data access ability through the services that are supported by AI technologies [31], IoT devices, and communication channels. This architecture provides an easy low-risk environment for data access through contributed cities. As digitalization is already established universally. One of the keys for successful data storage and migration is the ability to ensure the continuous accessibility to the data sources with nearly zero-risk through the infrastructure's owners. Then, re-using and sharing data provides a healthy environment for the different applications for common solutions, fair competition, minimum risk, and consequently supports sustainability. One of the key issues is the data privacy and security which is crucial aspects. Data usage agreements should be established. Consequently, this enables the required communication among providers and consumers and facilitates ensuring the prevention of data misuse and protects data flows in the system. However, the contributing entities should be able to control their data accessibility and valid process.

On the users' level, managing data is accomplished through their own controlling attributes. Users set their own rules in sharing their data, services, or applications. Trustiness is one of the key aspects for personal- management. Users have their security credentials which enables them to protect their data from others including infrastructure providers. Users have their right to set the access level and scope for others, manipulate their own data and use the agreement when needed. Users' authentication is a critical aspect to consider. Each user must have his own credentials. Cloud environment is known to be a flexible easily accessible system in general, however, data could reside in an on-premises cloud based system to ensure the required data protection. On the other hand, thin/thick client-based cloud architecture could also provide the balance between flexibility, accessibility and privacy.

D. Interoperability and Layout Layer (IoT Data Market Place)

Expanding the system scaling should be available as the more users intervening the system or the more devices

contributing to the system resulting the raising of data streaming. To successfully manage the increase in data scaling, additional network nodes should be added according to the need. On the other hand, additional storage repository and additional memory should be on focus to satisfy the increase in the computation according to the new requirements. One of the key aspects is the ability for the community contributors to have access to the system resources and be able to perform their needed functionalities, therefore, agility paradigm could be one of the main successful key aspects to satisfy this requirement. Moreover, as the contributors in the IoT system is the devices, sensors, and the gateway, the communication between these parties can be accomplished through many paths with different standards and protocols. Flexibility is required for updating the platform contributors, communication patterns, and possible changes. Communication patterns could be one-way from the devices to the gateway, information requests from devices, transferring messages through the system, or accomplish a determined task by one of the devices.

In order to ensure the architecture success, there is an immense need to ensure some factors such as interoperability, easiness, usability, and availability. As proposing a good design is one vital factor, however, this design should be efficient and effective for successful operation. Entities have their own data and naturally use different data models and different methods to process this data. Therefore, the need for unified standards has become critical. Interoperability is supported by applying public network standards and open protocols which organize the flow of data and information through gateways and APIs. The data and information migration between the network components should be according to these protocols and set agreements. Accordingly, new contributors could easily detect these gateways and APIs, and the integration is performed with the required agile approach. Accordingly, practicing such environment should be easily performed.

Pivotal points identify the Setting the system pivotal points should be intelligently established to connect between the constructed smart city system and the external environment as well as the system components themselves including devices, sensors, and the different smart management systems such as traffic, e-market, and others. It also controls the data migration through the system. Successful identification of the pivotal points supports the concept of reusability wither within the system on focus or other similar systems. Concrete identification of the level of coupling in the system is critical, from one hand, tight coupling is secured but hard to change and higher expectations for failure while from the other hand, loosely coupling systems is more flexible but high securing risk. Pivotal points could contribute enable integration of the different architecture components.

E. Applications (Services) layer

This layer provides the set of services and applications to the individuals. As discussed by much previous research, various applications have emerged such as smart grid, smart transportation, smart environment, smart living, smart health, smart energy, and others. Significant obstacles have emerged in the offered smart city applications. For example, the service provider can illegally access the data of the people living in smart cities such as medical or financial data. Moreover, smart

mobility can use different techniques to detect the users' patterns which could expose users to risks. This situation arises the vital impact of safety component and highlights the immense need for providing the protection layer over both data and application layers. The applications quality by logic depend on the quality of the previous layers, however, the enhancements of the services relies on a set of pillars including the ability of integrating services, how users can depend on these services, their quality level, ability for expansion and updating, and the services' standardization level. The evolution of embedding agility to the provided services can raise the guaranteed level of these services as it ensures higher performance and consequently higher satisfaction.

F. Monitoring and Governance Layer

Continuous monitoring should be performed to confirm the applicability and continuous operating to the smart cities' architecture. Identification of all contributors either people or devices should be clearly accomplished. Moreover, on the user level, a clear monitoring of the user activities and even expectations of his future activities should be performed. As this is a key success factor, however, it is not an easy task to perform. Several intelligent machine learning, data science, and artificial intelligence techniques contribute to this task in order to be successfully performed [32]. The concept of governance is applied to both data and applications. It is not considered on simple management tasks, rather, it is considered about providing a procedural action of continuous protection and tracking [33]. The following factors should be continuously monitored.

Resilience, failure could occur to devices, applications, or network components. Therefore, a self-healing system is recommended to avoid failure complications and ensure resilience. Self-healing includes many procedures such as adopting redundant links, continuous monitoring to IoT devices and the interaction between different components and users.

Performance, the system performance should be maintained through guaranteeing the instant response to the real time users' interaction. Applications should be continuously available and efficiently responding. Continuous automation to testing scenarios should be applied. Moreover, upgrading plan should also be on focus. Licenses should be available and complete authorization is expected.

One of the main factors is the feedback monitoring and recommendations to various aspects in the architecture. This has become a well-known principle for enhancements and avoid acceptance failure.

G. Enablers of smart cities

Several factors could affect the progress of smart cities implementation, some of these factors are discussed in this section (Fig. 3). Governmental support is one of the most effective enablers for smart cities construction. The government should be able to remove any arising barriers that hinder this change. Sustainability is another enabler which support the continuous development with the ability to gain public trust and economic stability. Approaches recommendations availability to reduce change resistance is another enabler. Fund availability is one of the critical enablers to be able to provide the

requirements of constructing smart cities. Agility adaption in the digital environment of management, marketing, and other services with courage in adopting the change could provide more innovations and the required changes could be accomplished with minimal risk.

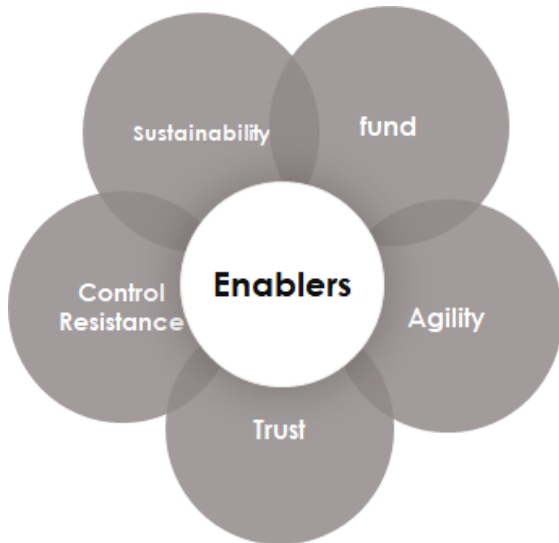

Fig. 3. Smart city enablers.

H. Challenges on focus

There are different challenges directions that should be highlighted. First, the data sources and formats heterogeneity as it is collected from different data sources. Moreover, data characteristics such as velocity, volatility, variability, veracity, and value should be determined and evaluated. The method to exchange the required knowledge by the players should be intelligently performed. Storage repositories access could be one of the major challenges in the platform especially for the governmental assets. Data standardization is another challenging aspect with the storage diversity. The construction cost debate with the return on investment is challenging as most of the return aspects are quality perspective. Ensuring the new paradigm acceptance by the users in the cities who are represented in the citizens should have a robust plan and complete governance support.

V. APPLICATIONS SAMPLE MODEL

A vast set of domains has seen the development of intelligent applications. These applications are not yet widely accessible; however, initial research suggests the potential of IoT to enhance the quality of life in our society. IoT applications are utilized in home automation, fitness tracking, health monitoring, environmental protection, smart cities, and industrial environments. Focusing on residential automation as a sample, smart houses are gaining popularity nowadays for two reasons. The sensor and actuation technologies, together with wireless sensor networks, have substantially advanced. Secondly, contemporary individuals exhibit trust technology to mitigate their concerns regarding quality of life and home security (Fig. 4).

Smart homes utilize an array of sensors that deliver intelligent and automated services to users. They facilitate the automation of daily routines and assist in establishing a routine for persons prone to forgetfulness. They facilitate energy conservation by automatically deactivating lighting and electronic devices. Motion sensors are generally employed for this purpose. Motion sensors can also be utilized for security purposes. An intelligent agent is offered that employs diverse predictive algorithms to do automated chores in reaction to user-initiated events and adjusts to the residents' routines. Prediction algorithms are employed to forecast the sequence of events in a household. A technique for sequence matching preserves event sequences in a queue while simultaneously recording their frequency. A prediction is subsequently generated utilizing the match length and frequency.

Fig. 4. A proposed block diagram of adapting smart home system.

Other algorithms employed by analogous applications utilize compression-based prediction and Markov models. Energy conservation in smart homes is often accomplished by sensors and contextual awareness. The sensors gather data from the environment, including light, temperature, humidity, gas, and fire incidents. The data from diverse sensors is transmitted to a context aggregator, which relays the gathered information to the context-aware service engine. This engine chooses services according to the circumstance. An application can autonomously activate the air conditioning when humidity levels increase. Alternatively, in the event of a gas leak, it may extinguish all the lights. Smart home applications are highly advantageous for the elderly and individuals with disabilities. Health is checked, and families are promptly notified in crises.

The floors are fitted with pressure sensors that monitor an individual's mobility within the smart home and assist in identifying if a person has fallen. CCTV cameras in smart homes can record significant occurrences. These can subsequently be utilized for feature extraction to ascertain the underlying phenomena. Fall detection applications in smart environments are effective for identifying instances where elderly individuals have fallen. Fall dynamics is identified by evaluating motion patterns and also detects idleness, comparing

it with previous activity levels. Neural networks are utilized, and sample data is sent to the system for various categories of falls. Numerous smartphone applications are available that detect falls using data from accelerometers and gyroscopes.

Numerous obstacles and issues pertain to smart home applications. Security and privacy are paramount, as all data on occurrences occurring within the home is being documented. If the system's security and reliability are not assured, an attacker may compromise the system and induce harmful behavior. Smart home systems are designed to alert owners upon detecting anomalies. This is achievable with AI and machine learning algorithms, and academics have commenced efforts in this area. Comparing the sample model with the literature [3, 20, 29, 34], most of the researchers focused on one enhancement direction; including cost, processing, and security; with no ability for a complete vision.

VI. CONCLUSION

The research proposed a complete generic architecture of smart cities. Smart cities consider allowing both people and governance to benefit from technology. The concept of embedding intelligence into the cities' aspects requires ensuring that the entire process could be altered. One of the main pillars is the data availability for the required level of quality and sustainability. Therefore, the proposed architecture presented all required aspects for a complete transformation to the digital smart city including infrastructure, processes, data management, players, roles, enablers, and services. The research highlighted the enablers for the architecture as well as the SWOT analysis for implementing the proposed architecture. Finally, challenges for the transformation process are discussed. It is expected that the proposed smart city architecture is encouraging and could move the field from the pilot individual projects to the standardization model which consequently provide a universal perspective to the smart cities concept rather than having different understanding to the same concept in the pilot projects. A main future consideration is to apply the proposed architecture and evaluate the transformation process in a real-life example. Another future direction is to provide more details and recommendations for practical development to each component.

ACKNOWLEDGMENT

This work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under grant No. (UJ-23-DR-15). Therefore, the authors thank the University of Jeddah for its technical and financial support.

Professor

aeelsayed@uj.edu.sa

I'm currently a professor at the University of Jeddah. I have been the vice dean of post-graduation and research and the head of the Information Systems Department in the Faculty of Computers and Information Technology, at Future University in Egypt. I am a professor in the Faculty of Computers and Information, at Helwan University in Egypt. I have previously worked as the general manager of the Helwan E-Learning Center. My research is focused on the themes (scientific) data and model management, Data Science, Big Data, IoT, E-learning, Data Mining, Bioinformatics, and Cloud Computing.

Othman Asiry
Assistant Professor
asiry@uj.edu.sa

Dr. Othman Asiry is currently working as an Assistant Professor in the Department of Information Technology at Khulis College. His research interests encompass IoT, Medical Image Processing, Deep Learning, Machine Learning, and Speech Recognition.

Amira M. Idrees

Professor

amira.mohamed@fue.edu.eg

I'm a professor in information systems. I have been the head of scientific departments and the vice dean of community services and environmental development, at the Faculty of Computers and Information, at Fayoum University. A professor in the Faculty of Computers and Information Technology at Future University, the head of IS department, and the head of the University Requirements Unit. And a professor in King Khalid University. My research interests include Knowledge Discovery, Text Mining, Opinion Mining, Cloud Computing, E-Learning, Software Engineering, Data Science, and Data warehousing.

A Novel Optimization Strategy for CNN Models in Palembang Songket Motif Recognition

Yohannes, Muhammad Ezar Al Rivan, Siska Devella, Tinaliah

Informatics, Faculty of Computer Science and Engineering, Universitas Multi Data Palembang,
Palembang, Indonesia

Abstract—Palembang Songket is an essential part of Indonesian cultural heritage, and its introduction and preservation present challenges, particularly in recognizing various motifs. This research introduces a novel strategy to optimize the performance of Convolutional Neural Networks (CNNs) by presenting a hierarchical integration of Ghost Module operations and Max Pooling, referred as Ghost Feature Maps. While the Ghost Module is effective in reducing parameters and enhancing feature extraction, it has limitations in filtering irrelevant information. To address this shortcoming, we propose a hierarchy in which Max Pooling works in conjunction with the Ghost Module, strengthening its performance by not only extracting dominant features but also eliminating excess, non-essential information. This hierarchical design enables more efficient feature extraction, thus enhancing the model's recognition accuracy. By combining Ghost Modules and Max Pooling in a structured manner, this approach advances established methodologies and offers a new perspective on feature representation within CNN architectures. Utilizing a dataset of 10 augmented classes of Palembang Songket motifs totaling 1000 images, we conducted experiments using varying ratios of Ghost Feature Maps. The results indicate that a ratio of 2 achieves an impressive accuracy of 0.98 with minimal parameter reduction. Additionally, a ratio of 3 results in a 34% decrease in parameters while maintaining a competitive accuracy of 0.95. Ratios of 4 and 5 continue to demonstrate robust performance, achieving accuracy levels of 0.93 while delivering over 60% reductions in model size and parameters. This research not only contributes to the optimization of CNN architectures but also supports the preservation of cultural heritage by improving the recognition capabilities of Palembang Songket motifs.

Keywords—Convolutional neural network; ghost module; Palembang songket motif; recognition

I. INTRODUCTION

One of the artistically significant pieces of Indonesian cultural heritage is Songket. The term "songkit" which describes the process of embroidering gold and silver threads, is the source of the word "songket" [1]. Ten connected steps are involved in the production of Songket fabric, including thread dyeing, klose processing, lungsin coating, thread type selection, and weaving designs with lidi. Songket fabric has different characteristics and philosophies depending on its region of origin [2]. One of the Songket fabrics registered as an Indonesian Intangible Cultural Heritage is Palembang Songket [3]. Palembang Songket has various types of motifs. The motifs of Palembang Songket reflect its beauty, uniqueness, and traditional values. Palembang Songket faces challenges in its preservation because the motif recognition process still relies

on manual or semi-automatic approaches that are vulnerable to human error and limitations. Successfully recognizing and understanding Palembang Songket motifs is essential for preserving local art and culture and has significant economic impacts through promoting Songket products in the global market.

The problem of identifying Songket motifs has been addressed in the past by a number of feature extraction techniques, including Felzenszwalb segmentation [4], and Gray Level Co-occurrence Matrix (GLCM) [5]. These techniques are then combined with a variety of classifier algorithms, including Naive Bayes [6], Decision Tree [6], and Support Vector Machine (SVM) [5]. Even while these techniques have produced acceptable outcomes in certain situations, there are still a number of important drawbacks. The primary drawback of these methods is their dependence on manual feature extraction, which frequently results in challenges in capturing the crucial elements of the complex Songket motifs.

Enhancement of motif identification performance is a promising area in deep learning. Convolutional Neural Network (CNN) models have demonstrated their capacity to recognize patterns in a variety of domains, including the identification of images. CNN has a lot of potential to improve Songket motif recognition. Applying CNN to motif recognition has the benefit of minimizing reliance on manual feature extraction by automatically extracting pertinent characteristics from data. Although there has been some prior research, not much has been accomplished in terms of training CNN to identify Songket motifs [7], [8]. The primary constraint is to the model's capability to manage intricate motif modifications, such as rotation, scaling, and distortion. The intricacy of Palembang Songket patterns is too great for a conventional CNN training model to handle.

Due to their numerous convolution layers, CNNs have substantial computational costs. In each convolution layer, mathematical operations are conducted to each input in order to extract important properties from the input data. The number of convolution layers that are conducted therefore increases the amount of computing operations needed, which could result in significant computational expenses in terms of processing time and energy consumption [9], [10], [11]. Thus, the convolution operations of CNN can be assumed by the Ghost Module. By using a method called the Ghost Module, which involves joining convolution filters with smaller "ghost filters", the CNN model is able to retain a significant amount of representation information while requiring fewer calculations and parameters [12]. In order to improve the performance of Palembang

Songket motif recognition, this research suggests a novel method that incorporates the Ghost Module into the CNN architecture.

The main contribution in this research is the introduction of Ghost Feature Maps through the integration of Ghost Module as a substitute for conventional convolutional layers, with Max Pooling applied hierarchically afterward. Ghost Feature Maps function to facilitate feature learning in CNN models, with the aim of increasing the efficiency of Palembang Songket motif recognition. In this hierarchical approach, Ghost Module is applied first to improve feature extraction efficiency by reducing computational complexity. Afterward, Max Pooling is used to further reduce spatial dimensions, enhancing computational efficiency and focusing on dominant features while suppressing irrelevant information. This combination reduces the number of parameters and model size while increasing accuracy performance. In addition, this study offers a solution to the challenge of recognizing complex Songket motif variations, such as rotation, scale, and deformation. This approach provides an innovative solution in addressing problems that have not been fully resolved in Palembang Songket motif recognition.

The remaining content of the paper is organized as follows: Section II discusses the related works in the field of Palembang Songket Motif, CNN and Ghost Module. Section III presents a detailed explanation of the proposed method. Section IV presents results and discussion, and performance. The last Section V summarizes the overall conclusion of the paper.

II. LITERATURE REVIEW

This section discusses the literature review of the Indonesian traditional fabrics, CNN, and Ghost Module research.

A. Image-based Recognition of Indonesian Traditional Fabrics

Sriani, Hasibuan, and Ananda [5] used SVM to classify Batu Bara Songket motifs, which are characterized by distinctive patterns such as Bunga Tanjung, Pucuk Betikam, Pucuk Cempaka, Pucuk Pandan, Tampuk Manggis, and Tolab Berantai. Gray-level texture features were extracted using the Co-Occurrence Matrix method, considering parameters like Contrast, Correlation, Energy, and Homogeneity. These extracted features were then processed as input for classification using the SVM. Despite the challenges, the study achieved a classification accuracy of 57% with 60 training data and 30 test data.

Aprianti et al. [6] classified Lombok songket fabric motifs, which are characterized by geometric patterns, varying density, color, and motif positioning. The algorithms used included Naive Bayes and Decision Tree, tested with different pixel sizes to compare accuracy levels. The results showed that the Naive Bayes algorithm achieved the highest accuracy of 90% at a 100×100 pixel size, while the Decision Tree algorithm was optimal at 400×400 pixels with the same accuracy. This approach demonstrated that combining algorithms with pixel size adjustments could significantly enhance motif recognition accuracy.

Ariessaputra et al. [7] classified Lombok songket motifs using a Convolutional Neural Network (CNN) algorithm, demonstrating the potential of image processing for traditional fabric pattern recognition. The dataset consisted of 20 Lombok Songket images with identical motifs and colors, 14 with the same but different colors, and 10 with various motifs and colors. In the preprocessing phase, each image underwent resizing, followed by CNN layers for convolution, pooling, and fully connected operations. Data augmentation through 150-degree rotations was applied to enhance model robustness. The results indicated that motif classification with consistent colors achieved an accuracy of 84%, highlighting the effectiveness of CNNs for identifying and distinguishing Lombok Songket motifs across varying visual parameters.

Hambali, Mahayadi, and Imran [8] applied CNN to classify Lombok Songket motifs, focusing on Songket from two prominent Lombok regions, Sade and Pringgasela. The study utilized a dataset of 64 images, comprising 40 samples from Sade and 24 from Pringgasela. The model's testing results showed an accuracy of 86%, with 87% precision and 86% recall. These results demonstrated CNN's effectiveness in differentiating textures within traditional Songket fabrics, offering valuable insights for preserving and recognizing regional textile characteristics.

Andrian et al. [13] used CNN architectures, including AlexNet, EfficientNet, LeNet, and MobileNet, to classify Lampung Batik motifs. The study utilized a dataset of 1000 images representing ten distinct motifs, enhanced through preprocessing techniques like rotation, shifting, brightness adjustment, and zooming. The results showed that LeNet achieved the highest accuracy of 99.33%, highlighting its suitability for small datasets, while other architectures also demonstrated strong performance despite occasional classification errors due to motif similarities.

Elvitaria et al. [14] proposed an ensemble deep learning method for batik image classification that combines texture feature extraction using Gray Level Co-occurrence Matrix (GLCM) with the Residual Neural Network (ResNet) classification model. By extracting texture features such as contrast, dissimilarity, and entropy using GLCM and combining them with ResNet, the proposed ensemble method achieved high performance, with accuracy, precision, recall, and F1-score all above 90%. The study demonstrated that the ensemble deep learning approach, particularly with the standard deviation feature, improved classification accuracy and can be applied to preserve batik culture digitally.

Muliono, Iranita, and Syah [15] proposed a deep learning model for classifying traditional Batak Ulos fabrics, utilizing CNN to recognize and classify different Ulos motifs. The study employed the Modular Neural Network (MNN) to simplify complex computations, achieving an accuracy of 97.83% with a loss value of 0.0793 during training. The validation results showed a validation loss of 2.1885 and a validation accuracy of 74.29%, demonstrating the model's strong performance while indicating areas for potential improvement in generalization.

Overall, the studies reviewed highlight significant advancements in image-based recognition techniques for recognizing Indonesian traditional fabrics, such as Songket and

Batik. Various machine learning models, including SVM, Naive Bayes, Decision Trees, CNN, and ensemble deep learning methods, have been applied to address the challenges of recognizing intricate fabric patterns characterized by texture, color, and motif positioning. These findings underscore the potential of image-based recognition systems in advancing the digital preservation and recognition of traditional Indonesian fabrics, offering valuable contributions to the cultural heritage field.

B. Ghost Module and CNN

Han et al. [12] proposed the Ghost Module in their research to produce feature maps with low computational costs, thereby simplifying the architecture of conventional CNN. GhostNet, built using the Ghost Module, demonstrated better recognition performance than MobileNetV3, with an accuracy of 75.7% on the ImageNet ILSVRC-2012 dataset. According to these results, the Ghost Module has the potential to be an efficient solution that can be added to current CNN networks.

Wang and Li [16] discussed the creation of a CNN model to enhance recognition systems' efficiency. This study used the GhostNet and Convolutional Block Attention Module (CBAM) methods. GhostNet and Ghost Bottleneck improved the model's capacity to extract significant image characteristics. Furthermore, employing GhostNet resulted in fewer parameters while retaining good accuracy.

Zhao and Cheng [17] proposed a more efficient approach that minimizes computation compared to traditional CNN by merging the Yolov5 model and GhostNet. This method increases processing speed and accuracy. The proposed approach's performance test showed that it achieved high detection accuracy while needing less memory and compute. Overall, this study provides a solution for image identification for human security screening purposes. This framework is also done for vehicle detection [18].

Huangfu, Li, and Yan [19] proposes the Ghost-YOLO v8 algorithm to improve the detection of surface floating litter in artificial lakes. This efficient and lightweight algorithm includes an SE mechanism for better feature extraction, a small-target detection layer to reduce semantic loss, and a GhostConv module to decrease computational demands.

Fang, Chen, and He [20] suggested an efficient CNN solution for facial expression recognition called Ghost-based Convolutional Neural Network (GCNN). This approach seeks to overcome CNN-related overfitting concerns. The Ghost Module architecture is less computationally expensive since it may minimize the number of parameters while producing more feature maps than CNN approaches. Based on this research, GCNN can efficiently extract and classify face expression features.

Alansari et al. [21] introduced Lightweight Face Recognition using GhostFaceNets, which requires less processing than normal CNN models. GhostFaceNets is a very accurate and efficient face recognition system. The proposed method was tested using a variety of datasets, including LFW, AgeDB-30, IJB-B, IJB-C, and MegaFace. GhostFaceNets uses the Ghost Module method to execute linear modifications on

feature maps, resulting in better and more thorough feature extraction.

Luan, Mu, and Yuan [22] addresses challenges in Online Signature Verification (OSV), by proposing the one-dimensional Ghost-ACmix Residual Network (1D-ACGRNet). The network is designed to combine convolution with a self-attention mechanism to effectively capture both global and local signature features. Simplification of operations is achieved through the Ghost-based Convolution and Self-Attention (ACG) block, which reduces computational load. Significant accuracy improvements are shown in experiments on the MCYT-100 and SVC-2004 Task2 datasets, with equal error rates reaching as low as 0.91% for genuine and forged signatures.

Paoletti et al. [23] conducted Hyperspectral Image Classification (HSI) which is one of the remote sensing techniques used in Earth observation for health, robotic vision, and quality control. The challenge in HSI is that each HSI image has hundreds of spectral bands that produce large amounts of data, requiring high computation. This study introduces an approach by combining ghost-module architecture and CNN. Test results show that using Ghost module can reduce HSI's cost and computation time.

Tang et al. [24] proposed an efficient mechanism called DFC attention is proposed, using GhostNetV2. GhostNetV2 can overcome limitations in conventional CNN methods. In testing, GhostNetV2 showed better performance than CNN architecture, achieving an accuracy of 75.3% on the ImageNet dataset, with efficient FLOPs. Therefore, GhostNetV2 is the right choice for mobile applications requiring efficiency and high performance.

Liu et al. [25] investigated effective training strategies for compact neural networks to address performance gaps and proposed GhostNetV3. The strategy focused on essential methods, including re-parameterization to improve efficiency, knowledge distillation to enhance smaller model performance through learning from larger models, and optimized learning schedules and data augmentation to increase training data diversity. As a result, GhostNetV3 achieves an optimal balance between accuracy and inference costs.

He et al. [26] proposed the Ghost module-based convolution network approach for superresolution (SR) in satellite video in this research. This approach is called Ghost module-based video SR (GVSR) and consists of two main modules: the preliminary image generation module and the SR results' reconstruction module. Experimental results on Jilin-1 and OVS-1 videos show that this method is superior in quality and quantity to other Deep Learning methods.

Liu et al. [27] introduced a new approach for hyperspectral image classification called Ghost module extended morphological profile (GhostEMP), which employs Ghost Module and extended morphological profile (EMP) features. This method can reduce model complexity and the amount of calculations, hence increasing operational efficiency. The experimental results suggest that this strategy effectively preserves model performance by maximizing hyperspectral data features. Not only does it apply to hyperspectral data, but

it also utilizes the Ghost Features Network (GFN) for super-resolution by cascading residual-in-residual ghost blocks [28].

The studies emphasize the effectiveness of the Ghost Module in enhancing the efficiency of deep learning models for diverse applications, including image recognition and hyperspectral image processing. GhostNet and its variants, such as GhostNetV2 and GhostNetV3, have significantly improved accuracy while reducing computational complexity. These advancements make Ghost Module in GhostNet architecture a valuable solution for high-performing applications with minimal resource usage.

III. METHODOLOGY

A. Dataset

The dataset used in this research consists of 10 classes of Palembang Songket motifs, namely Bintang Berantai, Bunga Cina, Bunga Jatuh, Cantik Manis, Jando Beraes, Kenanga Makan Ulat, Naga Besaung, Nampan Perak, Pacar Cina, and Pulir. The motif images were captured using a Canon 7D DSLR camera equipped with a Canon EF 70-200mm F2.8 lens, Canon Speedlite 600 Mark II, and tripod, with a consistent portrait distance of 45 cm from the object and a front-facing angle of 0 degrees. A total of 50 Songket fabrics were photographed and thoroughly validated by a Songket motif expert. The expert ensured that each image was following the traditions and authenticity of Palembang Songket culture.

Fig. 1. Dataset of Palembang songket motif.

The Palembang Songket motif photos were cropped to 2048 x 2048 pixel size with 300 dpi resolution, and then augmented.

Augmentation techniques applied include rotation, scaling, and horizontal and vertical flipping, as these techniques are more suitable for the complex patterns of Songket and do not alter the basic motif design. This augmentation technique produces a total of 1000 images, with each motif containing 100 images that correspond to the Palembang Songket motif collection with geometric patterns, as shown in Fig. 1. Afterwards, the images were resized to 256×256 for use as input in the CNN architecture with Ghost Feature Maps. As part of the preprocessing stage, each Songket motif image was resized to 256×256 pixels to ensure uniform image sizes.

B. Proposed Method

The proposed model architecture can be divided into two major components, namely feature learning and classification, each responsible for different aspects of its functionality. Fig. 2 illustrates the architecture of the proposed model.

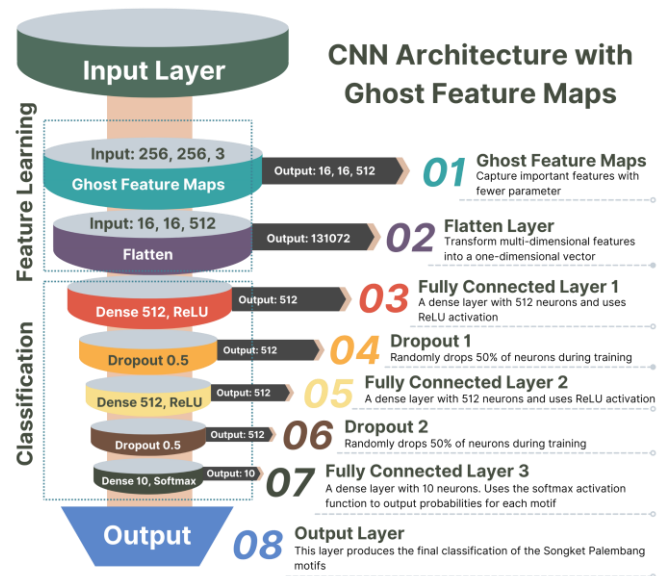

Fig. 2. CNN architecture with ghost feature maps.

1) *Feature Learning*: The process starts with applying Ghost Feature Maps. This layer is designed to extract feature maps efficiently by generating primary feature maps and applying simple transformations to produce additional maps. The objective here is to capture essential patterns in the data while minimizing computational resources and parameters, making the approach both efficient and effective. Following this, the extracted feature maps are processed by a Flatten layer. The Flatten layer transforms these high-dimensional feature maps into a one-dimensional vector, which is necessary for subsequent classification layers. The Flatten layer ensures that all the spatial information captured during the feature learning process is retained but represented in a format compatible with fully connected (dense) layers.

2) *Classification*: The classification phase includes three Fully Connected (Dense) layers. The first two Dense layers each consist of 512 neurons and use the ReLU activation function to introduce non-linearity, enabling the model to learn

more complex relationships in the data. These layers take the flattened feature vector from the feature learning phase and process it further to identify the patterns necessary for classification. To address the risk of overfitting, the model incorporates two Dropout layers after the first and second Dense layers. Dropout randomly turns off 50% of the neurons during each training iteration, encouraging the model to learn more robust and generalized features by not overly relying on specific neurons. The final step involves a third Dense layer, the output layer. This layer contains ten neurons, corresponding to the 10 Palembang Songket motifs being classified. It uses the softmax activation function to generate a probability distribution across the ten classes, with the class having the highest probability selected as the predicted motif.

C. Ghost Module

The GhostNet architecture, which features a layer known as the Ghost bottleneck, was the primary inspiration for this work. The Ghost bottleneck combines the Ghost module, a batch normalization, two or three Ghost Modules in a row, and then interleaved depthwise convolution, batch normalization, and ReLU activation [12]. However, in this research, only the Ghost module is employed without the full implementation of the Ghost bottleneck.

The dataset is a Palembang Songket pattern and it is unique and thus very rare, so it is hard to get a lot of data. Batch normalization was excluded from the Ghost Module. Instead, the Ghost Module was used alone, assuming that its simplicity would adequately convey the distinctive qualities of the Palembang Songket motifs without the added complication of the Ghost bottleneck.

The Ghost module consists of multiple phases, including primary convolution, cheap convolution, feature concatenation, and channel trimming. Each of these levels contributes significantly to the module's efficiency by reducing the amount of parameters and computational complexity while maintaining overall network performance. The Ghost module is a way to create more feature maps while doing fewer computations than usual, which is very helpful in deep learning models. Fig. 3 shows how the Ghost module works.

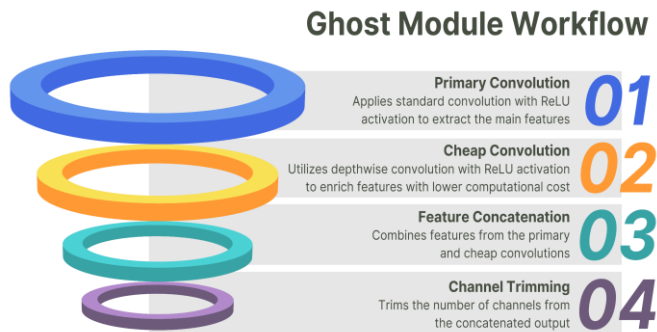

Fig. 3. Ghost module workflow.

1) *Primary convolution:* In the initial stage, the Ghost module conducts feature extraction through a primary convolution operation. This convolutional process decreases

the number of output channels by a defined reduction ratio, denoted as r , which indicates the degree of parameter reduction in comparison to a typical convolution operation. If the desired number of output channels is C_{out} , the output channels from the primary convolution, C_{cheap} are calculated in Eq. (1).

$$C_{cheap} = \frac{C_{out}}{r} \quad (1)$$

This convolution employs a kernel size of $k \times k$, where k represents the kernel dimension. It is applied with the same padding to maintain the input's spatial dimensions. A ReLU activation function is applied after the convolution to introduce non-linearity, enabling the model to capture more complex patterns. The mathematical expression for this step is calculated in Eq. (2).

$$P = \sigma(X * W_1 + b) \quad (2)$$

Where, X is the input, W_1 is the convolution filter of size k , b is the bias term, and σ represents the ReLU activation function. The result of this process, P , contains features with C_{cheap} channels, representing a portion of the total desired channels, C_{out} .

2) *Cheap convolution:* In the next stage, the features produced by the primary convolution undergo a second convolution process using a depthwise convolution. This operation processes each feature channel independently, meaning each channel is convolved with a separate filter, which reduces computational cost while generating additional feature details. The depthwise convolution is applied with a kernel size of $k \times k$, where k is the size of the depthwise kernel. The output of this process can be calculated in Eq. (3).

$$C = \sigma(P * W_2) \quad (3)$$

Where W_2 is the depthwise convolution filter applied to each feature channel in P , and C represents the output of this operation. A ReLU activation function (σ) is also applied to maintain non-linearity in the feature representation. The Ghost module enriches the features with minimal computational overhead compared to full convolutions by using depthwise convolution, contributing to a more efficient model.

3) *Feature Concatenation:* Following the two convolution processes, the outputs from the primary and depthwise convolutions are aggregated. Feature aggregation combines these outputs to create a richer feature representation, merging primary and additional features into a single output set. If the output of the primary convolution is denoted as P and the output of the depthwise convolution as C , the aggregation process can be expressed mathematically in Eq. (4).

$$O = [P, C] \quad (4)$$

Where O represents the aggregation output, and the notation $[.,.]$ signifies concatenation along the channel dimension. This aggregation ensures that the final feature set captures both the main and additional details from the input, leading to a more informative feature representation without significantly increasing computational complexity.

4) *Channel Trimming*: The final stage is channel trimming to ensure that the number of output channels corresponds to the target, C_{out} . After feature aggregation, the number of channels may surpass the target number. Channel trimming is done to keep only the necessary C_{out} channels. If the aggregated feature map O has C_{concat} channels, where $C_{concat} > C_{out}$, only retain the first C_{out} channels that can be represented as in Eq. (5).

$$Y(i, j) = O(i, j, 1: C_{out}) \quad (5)$$

Where, $O(i, j, 1: C_{out})$ denotes selecting the first C_{out} channels from the aggregated feature map O , where i and j are the spatial indices of the feature map. The operation trims the excess channels, ensuring the correct output dimensionality, thus providing an output feature map Y with dimensions $H \times W \times N$, where H and W are the height and width of the spatial dimensions, and N is the number of required channels. This trimming guarantees that the final output size is consistent with the architecture's design without unnecessarily increasing computational costs.

D. Ghost Feature Maps

The proposed Ghost feature maps, illustrated in Fig. 4, integrate Ghost modules with Max Pooling. In CNNs, multiple filters are applied within each convolutional layer to extract various features [29]. These convolutional and pooling layers are arranged sequentially, forming a hierarchical structure that progressively captures and reduces feature dimensions [30]. In this research, traditional convolutional layers are replaced by Ghost modules, which provide a more efficient alternative while maintaining the standard CNN architecture. Utilizing a ratio (r) parameter can generate more features from input with significantly fewer parameters. This research uses a kernel size k of 3 for both the primary [12] and depthwise convolution in the Ghost module, with the bias b set to 0. For instance, in the first layer, Ghost Module (32, $r = 2$) produces 32 features using only half the parameters conventional convolution requires. This not only accelerates training but also reduces the risk of overfitting. Additionally, as the number of features increases in subsequent Ghost Modules (32, 64, 128, 512), the model captures more complex variations in the input data. Increasing the feature channels as the network deepens enriches representation and allows the model to learn more abstract features.

Max pooling then is strategically applied after each Ghost module to reduce the dimensionality of the features significantly extracted. It also greatly reduces computational complexity in later layers, allowing the model to focus on the most dominant features, significantly improving its generalization ability. Max pooling's function in promoting invariance makes the model much more robust to small rotational or translational changes in the input data, which is very important in pattern recognition problems, where such variations are the norm. This makes the audience feel more confident that the model is not only efficient but strong as well.

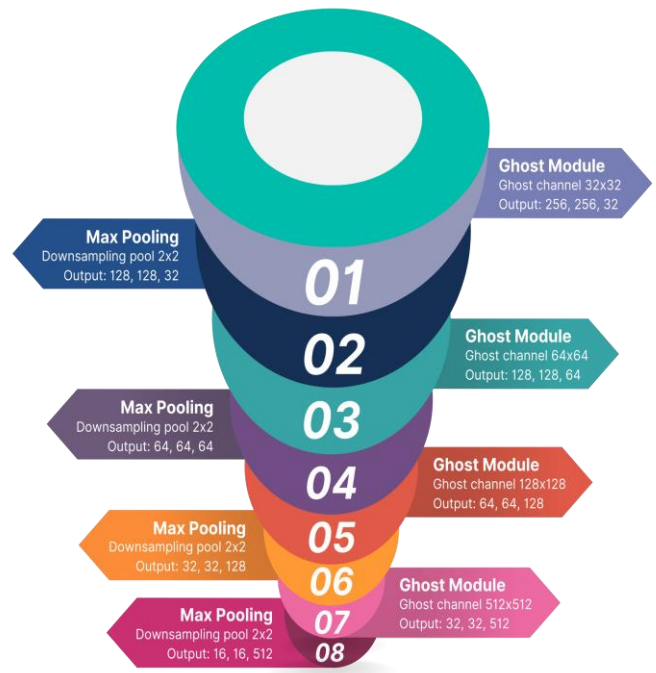

Fig. 4. Ghost feature maps workflow.

Doing that four times, Ghost module and max pooling, gives even more advantages. Every pair builds a pyramid of feature representation. As the layers get deeper, the learned feature hierarchies become more and more complex, starting from simple features in the lower layers to more abstract representations in the higher layers. The architecture actually exploits this by using a Ghost module and then max pooling right after to ensure maximum feature extraction, but without losing any computational efficiency.

E. Parameter Distribution of Proposed Model Architecture

The distribution of parameters in the proposed CNN model's layer structure is presented in Fig. 5. Fig. 5 illustrates a comparative analysis of the total number of parameters between standard 2D convolutional (Conv2D) and Ghost module layers with varying expansion ratios (2 to 5). The Conv2D layer has the highest parameter count at 683,584, indicating its substantial computational complexity. In contrast, the Ghost module layers demonstrate a progressive reduction in the number of parameters as the expansion ratio increases, with 344,736 parameters at a ratio of 2; 150,633 at a ratio of 3; 87,120 at a ratio of 4, and 54,603 at a ratio of 5. This trend highlights the efficiency of Ghost module in significantly reducing parameter count while maintaining performance. The results suggest that higher Ghost module ratios can drastically minimize the model's computational load, offering a more resource-efficient alternative to traditional Conv2D layers. This parameter reduction is advantageous for applications with limited computational resources without compromising the model's representative capacity.

Fig. 5. Comparison of total parameters by layer type.

F. Experimental Setup

The experimental setup is to test the Ghost Feature Maps with ratios of 2, 3, 4, and 5 [12] versus Conv2D layers for image classification. The research will utilize a dataset of Palembang Songket motif images organized into ten distinct classes, with the data split structured as 80% for training, 10% for validation, and 10% for testing purposes. A single learning rate of 0.001 and a batch size of 32 will be employed, with the Adam optimizer selected for model training over 50 epochs.

The model architectures will encompass Ghost Modules for each specified ratio, followed by a Flatten layer, three Dense layers, and a Dropout for regularization. In parallel, a standard 2D convolutional model will be constructed with a similar architectural framework to facilitate direct comparison.

The evaluation will follow some standards: accuracy, precision, recall, and F1-score. The experimental procedure will also preprocess the data so the dataset is normalized and a consistent input is entered into the model. After training, however, all models will be tested thoroughly on the test set, and a complete analysis will be done comparing Ghost Feature Maps to normal convolutional layers and examining how variations in hyperparameters affect the model's overall performance.

G. Classification Performance

Many different performance measures are used to assess the classification models effectiveness. Some more common ones are accuracy, precision, recall, F1-score, and overall accuracy. They all express the model's capability to classify the Palembang Songket patterns differently.

1) *Accuracy*: simply the ratio of correct predictions to the total number of instances [31]. The accuracy value can be calculated using Eq. (6).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (6)$$

2) *Precision*: a measure used to determine how accurate the model is in its predictions. It is calculated by dividing the number of true positives by the number of predicted positives. Precision is the number of true positives divided by the total number of positives the model predicted [31]. The precision value can be calculated using Eq. (7).

$$Precision = \frac{TP}{TP+FP} \quad (7)$$

3) *Recall*: is the model's ability to find all the true positives. It is the percentage of positive examples that the model correctly labels [31]. The recall value can be calculated using Eq. (8).

$$Recall = \frac{TP}{TP+FN} \quad (8)$$

4) *F1-Score*: is the harmonic mean of precision and recall, used as a single value to balance precision and recall [31]. It can be calculated using Eq. (9).

$$F1 - Score = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (9)$$

5) *Overall accuracy*: is simply the number of correct predictions divided by the total number of samples over all of the classes. It is especially useful when performing multiclass classification [31]. The overall accuracy value can be calculated using Eq. (10).

$$Overall Accuracy = \frac{\sum TP + \sum TN}{\sum TP + \sum TN + \sum FP + \sum FN} \quad (10)$$

IV. RESULTS AND DISCUSSION

A. Results

A comparison of two Convolutional Neural Network models using Conv2D layers optimized with Ghost Module produces significant differences. This difference can be seen from the pattern of accuracy or loss that is difficult to stabilize and fluctuations increase towards several epochs when considering training and validation data. The Conv2D model (Fig. 6) in the accuracy and loss graph has four sharp fluctuations in several epochs. The increasing loss and accuracy fluctuations indicate that the model chooses unstable predictions under certain conditions. This pattern indicates the difficulty of the model in identifying patterns in data that are consistent for each epoch in training and validation data. This condition affects the process to remain stable so that the model cannot generalize to new data.

When given the Ghost Module (Fig. 7), some fluctuations in the learning process appear better. The number of sharp fluctuations decreases from four to two, and all remaining conditions are flatter. This effect indicates that the Ghost Module can make the model stable for each epoch so that the trend of decreasing loss becomes more stable and accuracy increases continuously. The remaining training and validation data provide smoother and less extreme patterns like the Conv2D model so that it can detect better patterns each epoch. In addition, the validation data also looks better by decreasing the trend in several epochs. Accuracy increases more stably, and the loss decreases, making the learning model more effective on data without overfitting training and validation data. Overall, Ghost Module can provide a stable model and reduce sharp fluctuations as evidenced by more stable accuracy and decreased loss in training and validation datasets.

Fig. 7. Training and validation performance, Ghost Feature Maps ($r = 2$).

Furthermore, based on Fig. 8, the accuracy and loss results for the training and validation process of the Ghost Module model with a ratio of 3 are similar to the Ghost Module model with a ratio of 2. However, at ratio 3, the graph shows slightly inconsistent accuracy and loss fluctuation in training and validation. This occurs at epochs 40 to 50, where a gap begins to widen slightly in the accuracy and loss values for the training and validation processes. From the training model graph results, it can be seen that this model can still learn the Palembang Songket motif data well, where there are still similarities in the fluctuations in accuracy and loss values with the Ghost module ratio 2.

For the performance results of the Ghost module with a ratio of 4 in Fig. 9, the fluctuations in loss values for the training and validation processes begin to increase. At least starting from epochs 10 to 20, there have been quite large fluctuations, but for the following epochs up to 50, the loss value begins to decrease. Compared to ratio 3, the Ghost module for ratio 4 tends to be less stable at epochs 30 to 50. In this epoch range, a gap begins to move away from the accuracy and loss values. The results of ratio four show that the training model began to experience a decrease in performance for the classification of Palembang Songket motifs compared to ratio 3.

Fig. 9. Training and validation performance, Ghost Feature Maps ($r = 4$).

Fig. 10. Training and validation performance, Ghost Feature Maps ($r = 5$).

At ratio five shown in Fig. 10, the performance of the Ghost Module shows a wider gap for accuracy and loss values. This is almost the same as ratio four, where the condition of the training model experienced quite large fluctuations from epoch 30 to 50. However, more significant fluctuations occurred in epoch 40 to 50 compared to ratios 2, 3, and 4. This is due to a significant reduction in the number of parameters in the Ghost module, so it cannot capture the pattern of the Palembang Songket motif features.

Fig. 11. Visualization of Conv2D feature maps.

Fig. 12. Visualization of Ghost Feature Maps.

Another way to test the model is to visualize the feature maps and see what kind of features the model has learned from the Palembang Songket motif image. The visualization results are then compared with the CNN model with standard Conv2D and Ghost Feature Maps. As shown in Fig. 11, the visualization results of the feature maps that the CNN model with Conv2D produced have a lot of dark spots and only a few obvious motif feature patterns using this trained model. It turns out that even with the trained model it is still hard to get the Palembang Songket motif pattern.

As seen in Fig. 12, unlike the regular CNN model with Conv2D, the CNN model with Ghost Feature Maps can actually yield clearer feature maps than the regular CNN model. As evidence by the feature map of the Ghost feature map, it performs better than the normal Conv2D. The CNN model with ghost really brings out the Songket motif pattern in many places. The shape and edge features are more distinct than in the regular CNN model. This is good because it will allow the model to learn to recognize the intricate Palembang Songket pattern much more accurately than the old Conv2D model.
