Fig. 2 shows the autoencoder, a network that encodes raw input data through a series of hidden layers. The input layer receives unprocessed data, and its dimensionality is continuously reduced by the hidden layers, which identify significant patterns and characteristics. The last hidden layer, or bottleneck layer, is an indication of the input data's compressed encoding. The reconstructed output is created by the output layer, hopefully coming as near as feasible to the original data. at order to force the network to extract the most crucial features from the input data at the bottleneck layer, the autoencoder learns to reduce the reconstruction loss during training. Only the encoder portion of the autoencoder is kept after training in order to encode data that is comparable. The network is limited by regularization, denoising, short hidden layers, and activation function tuning. While adding a loss factor to the cost function encourages training in ways other than replicating the input, keeping each hidden layer as thin as feasible requires the network to take up only representative aspects of the data. Convolutional autoencoders enhance transmission and storage efficiency by reducing the dimensionality of high-dimensional image data. They are able to manage small alterations in object location or orientation and recreate missing components. Nevertheless, they have a tendency to overfit and may result in data loss, which compromises the quality of the reconstructed image. Proper regularization techniques are needed to address these issues.

The study focuses on improving colon cancer detection using CapsNets. Autoencoders play a crucial role in feature extraction from histopathological images. They reduce excessive-dimensional records to a lower-dimensional latent space, simplifying it for evaluation. The autoencoder extracts meaningful capabilities from the pics, identifying patterns, textures, and structural information indicative of cancerous and non-cancerous tissues. It also reduces noise by means of filtering out noise from histopathological pix. The autoencoder's potential to address records versions enhances the version's robustness. The autoencoder's preprocessing ensures the Capsule Network gets the maximum informative enter, improving its potential to correctly hit upon and classify cancerous tissues. This integration improves model accuracy and efficiency, leading to higher sensitivity and specificity. The autoencoder's position on this examine is to enhance early prognosis of colon most cancers through making sure specific and consultant features. Overall, the autoencoder enhances the accuracy, efficiency, and reliability of the most cancers detection model.

D. Capsule Network

A CapsNet is an artificial neural network (ANN) that imitates hierarchical connections through gaining knowledge of from the organizing concepts of biological mind systems. CapsNets are designed to mimic the hierarchical business enterprise of organic mind circuits. Basic building blocks known as tablets are used in a CapsNet to recover from regulations determined in conventional neural networks. Because tablet neurons consider each the spatial connections and the activation facts, they may be greater geared up to address changes in posture and hierarchical systems than normal neurons. Each capsule creates a collection of pose residences, consisting of orientation and position, collectively with an activation that represents a selected entity or part of an item. By enabling the network to iteratively modify the connection coefficients between them in response to the agreement of their posture parameters, capsules enable dynamic routing. Because of its ability to remember intricate spatial hierarchies and recognize subtle patterns in input, CapsNets enhance generalization. Capsules process inputs by affinely transforming the outcome into informative vectors, as opposed to neurons. Neurons function using scalars, whereas capsules use vectors. The processes involved in making artificial neurons include weighted connections, scalar activation, and sum computation. Capsules, on the other hand, undergo additional processes: input vectors are multiplied by weight matrices recorded with spatial relationships, further weight multiplication, weighted sum of input vectors, and vector output application of activation function.

1) Input vectors multiply with spatial-relationship-encoded weight matrices: The neural network's input vectors reflect the initial input or data from a previous layer. Weight matrices are multiplied across these vectors to change them. These weight matrices encode the geographical relationships within the data. When two objects are symmetrically positioned around each other and have similar dimensions, for example, the product of the input vector and weight matrix captures a high-level feature that describes this spatial arrangement. The neural network may identify and capture important correlations and features as it goes through its levels. In this instance, the weight matrix is being multiplied by the input vector.

2) Further multiplication with weights: In this phase, a capsule network's outputs from the preceding step undergo a weighted correction. While typical ANNs utilize error-based backpropagation to update weights, CapsNets use dynamic routing. The weights assigned to the synapses between neurons are determined by this unique procedure. CapsNets provide robust connections between nearby high-level and low-level capsules by dynamically changing their weights. The computation involves figuring out the precise distance between dense clusters indicating low-level capsule predictions and the outputs of the affine transform. These clusters develop and become closer together when low-level capsule predictions are comparable. As seen by the table, the high-level capsule nearest to the current prediction cluster has a bigger weight than the other capsules, which have smaller weights based on their distances.

3) Activation function application for vector output: Capsule activation functions ensure that vector outputs are dynamic and vividly represented. Squashing functions are a common choice since they preserve the vector's direction while restoring its length. The symbol for the Squashing Function is given in (8),

$$U_j = \frac{\|s_j\|^2}{1+\|s_j\|^2}\frac{s_j}{\|s_j\|} \tag{8}$$

where U_j is the output that results from applying the non-linearity function, and s_j is the sum of the input vectors. The vector s_j is compressed to a magnitude ranging from 0 to 1.

Because of this, strong hierarchical representations may be created by allowing capsules to record complex feature relationships. Because the squashing function normalizes data, it enhances resilience to changes and allows capsules to carry nuanced information necessary for complicated pattern detection in jobs like computer vision.

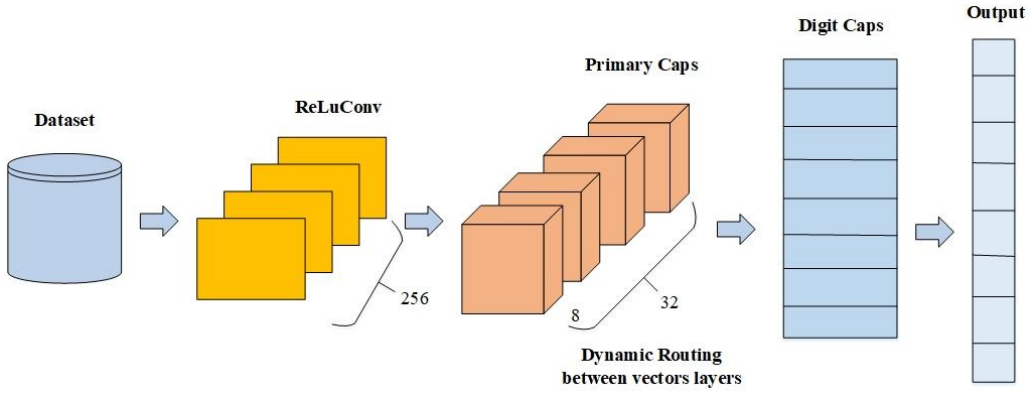

Fig. 3. Architecture of capsule networks.

Fig. 3 presents a simplified architecture of a capsule network that emphasizes the digit capsule and main layers. The input layer receives raw visual data and uses a convolutional layer to extract low-level features. After that, the main capsule layer processes the output and separates it into capsules. Each capsule produces an activation vector that indicates the existence of a particular characteristic or factor within its receptive field. The digit capsule layer, which represents a selected magnificence, is in rate of item popularity. The activation vector that every capsule produces indicates the likelihood that the class will seem in the photograph as well as its spatial connection to other components. An essential idea in CapsNets is dynamic routing, in which the primary pill layer casts votes to determine which digit pill it most carefully matches. This strengthens the settlement among compatible capsules and weakens the connections among incompatible drugs. Shooting the spatial hierarchy among functions, CapsNets are a type of neural community design that improves getting to know approximately representations. Because of dynamic routing, which makes it less complicated to attain an agreement on instantiation settings, they frequently require less information augmentation than conventional CNNs. Because CapsNets constitute vectors and routing systems, they're also more proof against adverse attacks. Additionally, they incorporate posture statistics, which complements structured representation for obligations like location estimation and item reputation.

CapsNets do have several drawbacks, though, including a lack of empirical assist, computational complexity, a probable tendency to overemphasize capsules, and intrinsic complexity. Given their latest age, CapsNets have not gone through calla lot checking out. Further research and evaluation are required to illustrate their typical effectiveness. Furthermore, due of dynamic routing, CapsNets may additionally require more processing power, main to longer training periods and better resource wishes. Applications for CapsNets may be observed in numerous domain names, which includes as clinical imaging, self-reliant vehicles, and visual anomaly detection. They are helpful in scientific imaging, assisting with troubles like organ segmentation and tumor identity. They also are useful in photograph popularity, item detection, region estimation, cybersecurity, and self-riding cars. Nevertheless, extra research and comparison are required to validate their ordinary effectiveness in diverse assignments.

The accuracy and robustness of histopathological image type are greatly improved with the aid of CapsNets inside the proposed study on boosting colon most cancers prediction the usage of CapsNets and Autoencoder-based totally function choice. CapsNets are particularly properly at retaining spatial hierarchies and connections within the image facts, which is vital for effectively recognizing difficult patterns that may be signs of malignant tumors. In evaluation to traditional CNN, which could have trouble processing orientation and attitude changes, CapsNets make better use of clusters of neurons called pills to capture and encode these spatial connections. As a result, they are able to discover characteristics at diverse abstraction stages and offer a greater complex interpretation of the photo statistics. The proposed examine makes use of CapsNets in conjunction with Autoencoders to extract features. This permits the Autoencoder to lessen dimensionality and emphasize pertinent features, whilst additionally utilising CapsNet's higher spatial awareness and sample popularity capabilities. This mixture improves the model's predictive potential, which might result in a greater specific and trustworthy categorization of histopathological photos for the identity of colon most cancers.

Algorithm 1: Algorithm for the Proposed study

Step 1: Data Collection and Preparation

- Load dataset of histopathological images
- Preprocess images

Step 2: Auto encoder for Feature Extraction

- Define Autoencoder architecture
  a. Input layer: X
  b. Encoding layers: progressively reduce dimensions
  c. Bottleneck layer: Z
  d. Decoding layers: progressively reconstruct dimensions
  e. Output layers: X’
- Split dataset into training and testing sets
- Train Autoencoder using mean squared error loss

- Extract compressed features Z from the bottleneck layer

Step 3: Capsule Network for classification

- Define Capsule network architecture
  a. Input layer: Z
  b. Convoutional Layer: extract local feature
  c. Primary Capsule Layer: convert features into capsules
  d. Digital Capsule Layer: from higher-level capsules
  e. Output layer: Class probabilities
- Combine Z with original image data
- Split combined dataset into training and testing sets
- Train capsule network using margin loss

Step 4: Integration

- Integrate Autoencoder and capsule network by feeding Z into the capsule network
- Fine-tune integrated model on training data

Step 5: Evaluation

- Validation and Testing
- Calculate Performance Metrics

V. Result and Discussion

The results of the advanced colon cancer prediction approach, which combines CapsNets with autoencoder-based feature selection, are shown in this section. The results show that this hybrid approach greatly improves the performance and reliability of the classification when compared to traditional techniques. The model makes the evaluation of histopathology images more reliable and consistent using the Autoencoder-based feature extraction with the help of the Capsule Network for determining the complex spatial relations. More details concerning the performance measures, benefits as well as the demerits of the model and how such developments aids in the early detection of colon cancer are demonstrated in this segment.

E. Training and Testing

The Fig. 4 shows the training and testing accuracy of a model over 100 epochs. The X-axis represents the number of training iterations the model has undergone, while the Y-axis represents the accuracy percentage. The figure shows the model's training accuracy on the training dataset and its testing accuracy on the testing dataset. The model's initial phase (0-20 epochs) shows rapid growth in both accuracies, indicating learning and improving performance on both datasets. The middle phase (20-60 epochs) shows slower growth in training accuracy, approaching a plateau around 60 epochs. Testing accuracy additionally improves but starts to lag behind the training accuracy, suggesting overfitting. The later phase (60-a hundred epochs) indicates an excessive schooling accuracy close to 100%, indicating superb performance on the schooling statistics. However, the trying out accuracy stabilizes at 85.9%, indicating overfitting. To cope with overfitting, techniques which include early stopping, regularization, or pass-validation could be implemented. The model's testing accuracy stabilizes at a high stage, indicating top overall performance, but there may be room for development in generalization. To deal with overfitting, techniques which include early preventing, regularization, or go-validation can be applied.

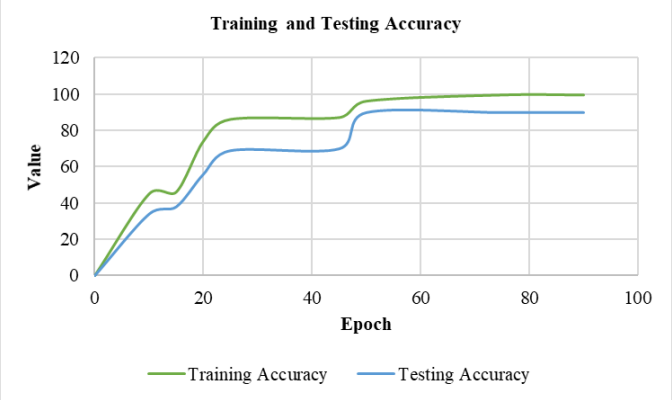

Fig. 4. Training and testing accuracy

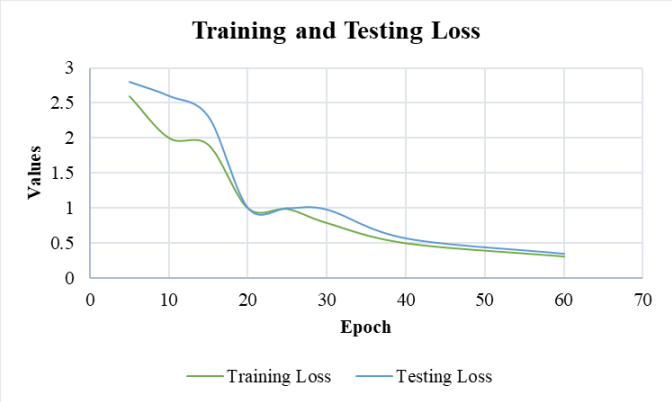

Fig. 5. Training and testing loss.

The Fig. 5 shows the training and testing loss of a version over 60 epochs. The X-axis represents the variety of schooling iterations, at the same time as the Y-axis represents the loss cost, which measures the error between anticipated and real values. The figure shows the lack of the model at the dataset and the loss at the testing dataset. The analysis shows that the version is getting to know efficiently and both training and trying out losses are decreasing, indicating top generalization overall performance. The initial phase (0-20 epochs) shows fast decreases in both losses, at the same time as the center phase (20-40 epochs) indicates a gradual lower in schooling loss and a slow lower in testing loss, indicating accurate generalization but signs of overfitting. The later phase (40-60 epochs) shows a solid and convergent loss, suggesting that the model has reached a superior point wherein further schooling does no longer significantly improve performance or motive overfitting. The graph concludes that the model is nicely-trained, achieving low mistakes charges on each schooling and trying out datasets. The near convergence of training and checking out loss in later epochs shows that the model isn't overfitting notably, maintaining true generalization performance. The stability and convergence of loss values in later epochs recommend an awesome balance among bias and variance, minimizing underfitting and overfitting.

F. Performance Metrics

Performance metrics are numerical measurements which are used to evaluate how a model or gadget plays in achieving its goal. These measures, which are relevant to ML and diagnostic

model, consist of F1 rating, accuracy, precision, and recall. TP as true positive, TN as true negative, FP as false positive, and FN as false negative are represented.

1) Accuracy: A performance statistic called accuracy counts how many of a model's predictions are accurate out of all the predictions it has made. It is computed in (9),

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (9)$$

2) Precision: A performance indicator called precision counts the percentage of accurate positive predictions among all the positive predictions a model makes. It is computed in (10),

$$Precision = \frac{TP}{TP+FP} \quad (10)$$

3) Recall: Recall quantifies the percentage of real positive cases that a model accurately detects; it is sometimes referred to as sensitivity or true positive rate. It is computed in (11),

$$Recall = \frac{TP}{TP+FN} \quad (11)$$

4) F1 score: The F1 score is a performance statistic that offers a fair assessment of a model's accuracy by combining recall and precision into a single number. This provides a more thorough understanding of a model's performance, particularly when working with unbalanced datasets. It is the harmonic mean of accuracy and recall. The F1 score is calculated in (12),

$$F1 = \frac{Precision.Recall}{Precion+Recall} \quad (12)$$

Table I show that colon most cancers prediction with CapsNets and Autoencoder-based feature selection has extraordinary model performance. The model efficaciously classifies 99.2% of the cases with an accuracy of 99.2%, indicating its efficacy in distinguishing among samples which are malignant and people that aren't. The model's 99% accuracy suggests that it could reliably pick out affirmative conditions with few fake positives. The model's capacity to minimize fake negatives while catching the majority of real occasions is demonstrated with the aid of its 98.3% recall. The alternate-off among accuracy and reminiscence is balanced by means of the F1 score, that is 98.6% and represents the harmonic suggest of precision and recall. The resilience and dependability of the model in processing histopathological images are highlighted by those sturdy metrics. Specifically, the accuracy validates the effectiveness of merging Autoencoders with CapsNets, which effects the cautioned observe. It attests to the model's capability to both recognize the complex styles seen in the education set and generalize successfully to new units of records. Because of its brilliant accuracy, the version may be carried out nearly in clinical settings and can assist identify colon cancer early on, growing patient consequences and remedy options.

TABLE I. PERFORMANCE METRICS OF THE PROPOSED STUDY

Metrics	Efficiency
Accuracy	99.2%
Precision	99%
Recall	98.3%
F1 score	98.6%

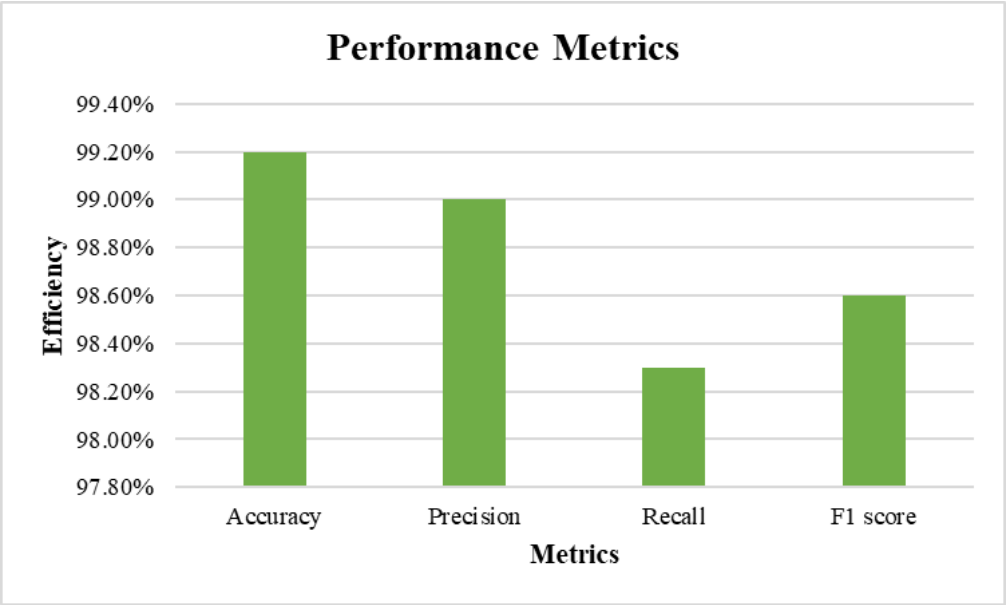

Fig. 6. Performance metrics of the proposed study.

The accuracy, precision, recall, and F1 score of the suggested colon cancer prediction model are highlighted in the Fig. 6 that displays its performance measures. At around 99.2%, the accuracy is the greatest, meaning that 99.2% of all cases are accurately classified by the model, demonstrating its overall efficacy. With 99% precision, only 99% of cases accurately categorized as positive are actually positive, reducing the number of false positives. With a little reduced recall of 98.3%, the model reduces the amount of false negatives by capturing 98.3% of all real positive cases. The F1 score, which is 98.6% and represents the harmonic mean of precision and recall, is a balanced measure of the model's accuracy that accounts for both precision and recall. Taken together, these parameters demonstrate the model's accuracy in colon cancer prediction from histopathological images as well as its dependability. The model's excellent accuracy confirms that it can generalize from training information to unseen test data, which is necessary for its application in real-world clinical settings. In clinical circumstances, it might be advantageous to prevent needless treatments by emphasizing the reduction of false positives over the capture of all real positives, as indicated by the minor decline in recall when compared to precision. The model's well-balanced performance is shown by the F1 score's proximity to both accuracy and recall. The model is robust in learning and identifying complex patterns in histopathological images, and it is also dependable in making accurate predictions, which may lead to improved early detection and diagnosis of colon cancer. This is indicated by the high accuracy and balanced precision-recall performance. Better patient outcomes and more effective clinical decision-making procedures might result from this.

The efficacy metrics of many colon cancer detection techniques are displayed in Table II. With 85% accuracy, 80% precision, 75% recall, and 77% F1 score, logistic regression offers a basic method but falls short in terms of sensitivity and overall effectiveness. Decision trees perform better but still fall short when compared to more advanced techniques, with 87% accuracy, 83% precision, 80% recall, and an 81% F1 score. Results are further improved by Random Forests, which show good overall performance with 90% accuracy, 87% precision, 85% recall, and an 86% F1 score. Gradient Boosting Machines show notable advances in identifying and categorizing malignant cells, achieving superior performance metrics with 93% accuracy, 90% precision, 90% recall, and a 91% F1 score. On the other hand, the suggested approach, which combines autoencoder-based feature selection with CapsNets, yields remarkable outcomes with 98.6% F1 score, 99% precision, 98.3% recall, and 99.2% accuracy. This strategy uses cutting-edge ML algorithms to improve feature extraction and pattern recognition, outperforming all other approaches and demonstrating its improved capacity to consistently and effectively diagnose colon cancer.

TABLE II. COMPARISON OF PROPOSED METHOD WITH DIFFERENT METHODS

Method	Accuracy	Precision	Recall	F1 Score
Logistic Regression [17]	85%	80%	75%	77%
Decision Trees [18]	87%	83%	80%	81%
Random Forest [19]	90%	87%	85%	86%
Gradient Boosting Machines [20]	93%	90%	90%	91%
Proposed Method	99.2%	99%	98.3%	98.6%

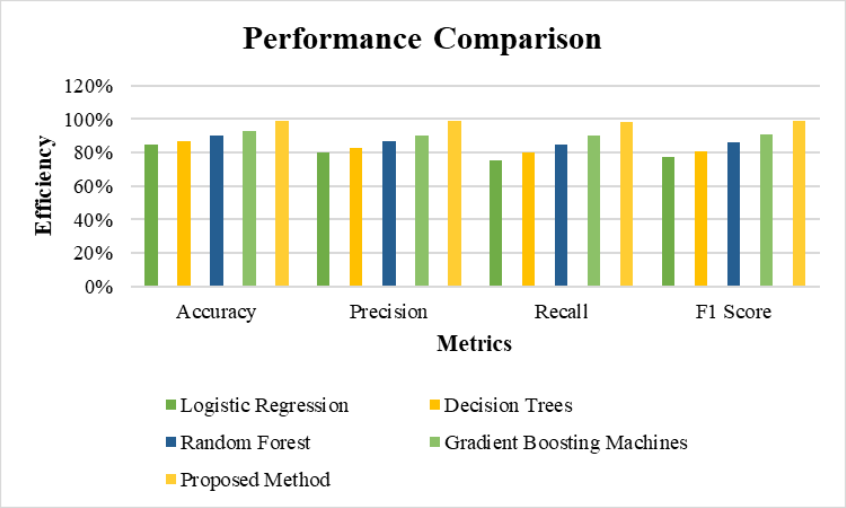

Fig. 7. Performance comparison of the proposed method with different methods.

Fig. 7 showcases a performance comparison of ML algorithms, including Logistic Regression, Decision Trees, Random Forest, Gradient Boosting Machines, and the Proposed Method. The x-axis displays metrics like accuracy, precision, recall, and F1 Score. The Proposed Method have the highest accuracy, precision, recall, and F1 Score and consistently performs well across all metrics, while Random Forest also shows strong performance in most metrics. However, it is challenging to provide a definitive interpretation without specific values and context. The visualization suggests the Proposed Method might be a promising approach, but further analysis and understanding of the data are necessary. The exact

meaning of Efficiency on the y-axis is unclear, and the dataset and problem domain used for this comparison are unknown, limiting broader conclusions.

TABLE III. COMPARISON OF PROPOSED DATASET WITH DIFFERENT DATASETS

Dataset	Accuracy	Precision	Recall	F1 Score
Gapminder Colon cancer [21]	85%	80%	75%	77%
Colon cancer [22]	87%	83%	80%	81%
Multi Cancer Dataset [23]	90%	87%	85%	86%
ICMR Dataset [24]	93%	90%	90%	91%
Lung and Colon Cancer Histopathological Images	99.2%	99%	98.3%	98.6%

The Table III compares many datasets that have been used to assess alternative approaches to the diagnosis of colon cancer. An F1 score of 77%, recall of 75%, accuracy of 85%, and precision of 80% were attained using the Gapminder Colon cancer dataset. With an F1 score of 81%, accuracy of 87%, precision of 83%, and recall of 80%, the Colon cancer dataset demonstrated increased performance. The metrics were further improved by the Multi Cancer Dataset, which achieved an F1 score of 86%, 90% accuracy, 87% precision, and 85% recall. With an F1 score of 91%, accuracy of 93%, precision of 90%, recall of 90%, and recall of 90%, the ICMR Dataset performed even better. With an amazing accuracy of 99.2%, precision of 99%, recall of 98.3%, and an F1 score of 98.6%, the suggested technique surpassed all other methods when evaluated on the Lung and Colon Cancer Histopathological Images dataset, demonstrating its better capabilities in diagnosing colon cancer.

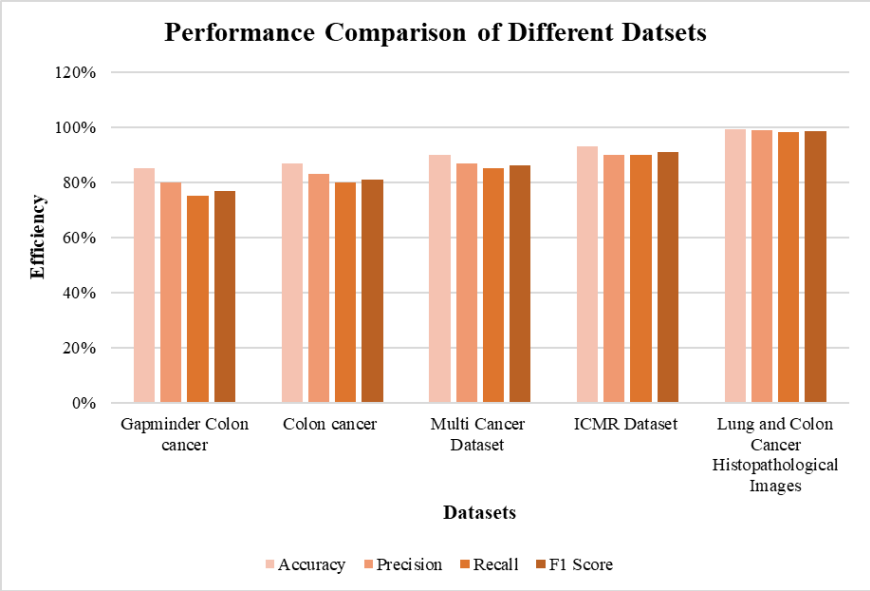

Fig. 8. Performance comparison of the proposed dataset with different datasets.

Accuracy, precision, recall, and F1 score are the four main metrics that are highlighted in the Fig. 8, which presents a visual comparison of the performance of different datasets used in colon cancer diagnosis. The least successful dataset is the Gapminder Colon Cancer dataset, which has an F1 score of 77%, recall of 75%, accuracy of 85%, and precision of 80%. With the Colon cancer dataset, performance somewhat increases to 87% accuracy, 83% precision, 80% recall, and 81% F1 score. These measures are further improved by the Multi Cancer Dataset, which achieves an F1 score of 86%, 90% accuracy, 87% precision, and 85% recall. With 91% F1 score, 90% precision, 90% recall, and 93% accuracy, the ICMR Dataset shows even better efficiency. With accuracy at 99.2%, precision at 99%, recall at 98.3%, and an F1 score of 98.6%, the suggested method which makes use of the Lung and Colon Cancer Histopathological Images dataset achieves the best results in terms of all metrics, demonstrating its better capacity to identify cancer accurately.

G. Discussion

Previous studies of colon cancer detection often struggled with the accuracy and reliability of their models. Although, traditional methods such as decision trees and logistic regression had stability and accuracy problems that increased the number of false negatives and positives Strong models needed for the accuracy of the analysis cannot be fully captured and often requires significant feature engineering [25]. The proposed method uses auto-encoder-based feature selection combined with CapsNets to address these limitations. The ability of CapsNets to preserve spatial structure and detect small patterns is essential for accurate cancer diagnosis. On the other hand, autoencoders enhance feature extraction by reducing noise and compressing high-dimensional data into a feasible hidden area that highlights some important features and most of them were captured there with significant improvements occur in accuracy, precision, recall, and F1 scores It occurs as analyzed hereafter. This approach addresses and improves the weaknesses of

existing methods, thereby providing more accurate and rapid detection of colorectal cancer that can change clinical diagnosis.

VI. Conclusion and Future Work

Research suggests that the combination of autoencoder-based feature selection and CapsNets might greatly improve the accuracy of colon cancer prediction using histopathological images. Because of the CapsNets' spatial hierarchy learning and autoencoders' strong feature extraction capabilities, this model is more successful in correctly identifying malignant tissues. Using a hybrid technique, frequent problems like overfitting are successfully reduced, classification accuracy is increased, and the model's ability to generalize from training to new data is encouraged. The findings imply that this sophisticated machine learning model has great promise for clinical use, where accurate and prompt diagnosis of colon cancer is essential for efficient treatment planning and better patient outcomes. This effective use of contemporary deep learning architectures highlights how various methods may be used to address difficult classification problems in medical image analysis.

Improving the model's flexibility and reactivity to various clinical settings should be the main goal of future research. This involves looking at cutting-edge data augmentation methods to strengthen the model's resistance to changes in the quality and quantity of histopathology images. Furthermore, investigating the incorporation of additional datasets, such genetic data or patient medical history, may provide a more thorough method of cancer diagnosis and prognosis. To fully assess the model's performance and potential, it is also crucial to apply it in actual clinical situations. Extending the study's reach will showcase the adaptability and usefulness of the concept. Lastly, to guarantee that the model satisfies clinical requirements and keeps improving patient outcomes and care, continuous cooperation with healthcare professionals is crucial.

Revolutionizing AI Governance: Addressing Bias and Ensuring Accountability Through the Holistic AI Governance Framework

Ibrahim Atoum
Department of Artificial Intelligence-Faculty of Science and Information Technology,
Al-Zaytoonah University of Jordan, Amman, 11733, Jordan

***Abstract*—Artificial intelligence (AI) possesses the capacity to transform numerous facets of our existence; however, it concomitantly engenders considerable risks associated with bias and discrimination. This article explores emerging technologies like Explainable AI (XAI), Fairness Metrics (FMs), and Adversarial Learning (AL) for bias mitigation while emphasizing the critical role of transparency, accountability, and continuous monitoring and evaluation in AI governance. The Holistic AI Governance Framework (HAGF) is introduced, featuring a comprehensive, five-layered structure that integrates top-down and bottom-up strategies. HAGF prioritizes foundational principles and resource allocation, outlining five lifecycle-specific phases. Unlike the OECD AI Principles, which offer a general ethical framework lacking holistic perspective and resource allocation guidance, and the Berkman Klein Center's Model, which provides a broad framework but omits resource allocation and detailed implementation, HAGF offers actionable mechanisms. Tailored Key Performance Indicators (KPIs) are proposed for each HAGF layer, enabling ongoing refinement and adaptation to the evolving AI landscape. While acknowledging the need for enhancements in data governance and enforcement, the embedded KPIs ensure accountability and transparency, positioning HAGF as a pivotal framework for navigating the complexities of ethical AI.**

***Keywords*—Artificial intelligence; framework; bias; discrimination; governance; key performance indicators**

I. Introduction

The iterative process of AI model development is crucial for enabling machines to perform human-like tasks such as problem-solving, learning, decision-making, and perception. This process enhances technological systems by developing algorithms that process large datasets, recognize patterns, and make predictions. A critical step is training, which uses labeled data to adjust model parameters and optimize performance. Therefore, the quality and quantity of data are vital for success [1]. Accurate and representative training data directly impacts model performance; biased data can lead to errors, particularly in critical fields like healthcare, finance, and criminal justice [2].

In AI, bias refers to systematic prediction distortions arising from training data and model design, while discrimination involves unfair treatment based on characteristics such as age, race, or gender. Although bias can contribute to discrimination, they are not synonymous; discrimination can occur independently of bias, and reducing bias may not eliminate discrimination [3]. Data labeling and algorithm design biases can perpetuate discriminatory patterns, and a lack of diversity in development teams can hinder identifying and mitigating these biases.

To promote fairness and equity in AI, it is essential to ensure diverse and representative training data, fair feature selection, rigorous evaluation strategies, and effective governance frameworks. These frameworks should include policies and guidelines for safe and ethical AI development, emphasizing auditing, transparency, and stakeholder collaboration [4]. Data augmentation and synthetic data generation are necessary to ensure data accuracy and representativeness, as high-quality data is crucial for avoiding biased AI models.

Four key components support responsible AI development: XAI, FMs, AL, and ongoing M&E [5]. While XAI enhances transparency, it faces challenges such as computational costs. FMs may conflict with accuracy, necessitating a holistic approach. AL can mitigate bias through adversarial examples, and continuous M&E is vital for detecting biases over time. Integrating these elements is essential for developing fair and accountable AI systems.

Governments play a critical role in promoting AI's safe and responsible implementation [6]. They can establish ethical guidelines, engage stakeholders, and enforce principles addressing bias, privacy, safety, and security. Regulation in sensitive areas like healthcare and criminal justice ensures adherence to ethical standards. Governments can also promote industry self-regulation through voluntary codes of conduct and support international cooperation to establish common standards.

This paper compares the Holistic AI Governance Framework (HAGF) with the OECD AI Principles [7] and the Berkman Klein Center's Model for AI Governance [8], focusing on the HAGF's unique contribution to AI governance. The HAGF offers a holistic, cyclical approach to resource allocation, structured around five interconnected components: establishing standards, regulating adherence, promoting AI advancement, fostering transparency and accountability, and encouraging a voluntary code of conduct. Each component includes defined roles and theoretical weights, reflecting a vision for responsible AI development and providing enhanced strategic guidance. The HAGF emphasizes the need for formal

guidelines and policies to ensure ethical AI deployment and effective resource allocation for research and development.

While the OECD AI Principles provide foundational ethical guidelines, they have been criticized for lacking a holistic approach to implementation and sufficient guidance on resource allocation, leading to potentially inconsistent interpretations and inadequate stakeholder engagement [7]. Similarly, though comprehensive, the Berkman Klein Center's Model is criticized for its breadth and lack of specific implementation measures and clear metrics for evaluating effectiveness [8]. The HAGF addresses these shortcomings by focusing on resource allocation and integrating top-down and bottom-up strategies to foster ethical AI practices. Furthermore, this paper examines key technical approaches to mitigating bias and enhancing ethical AI development, proposing KPIs for each phase to monitor effectiveness and facilitate continuous improvement.

Section II presents related work, Section III outlines the importance of gathering diverse data, Section IV explores methods for identifying bias in AI, Section V discusses the management of ethical AI practices, Section VI demonstrates study results, and Section Seven summarizes conclusions.

II. Related Work

Ethical AI frameworks are increasingly recognized for guiding responsible AI development and deployment. Notable frameworks, such as the OECD AI Principles [9, 10] and the Berkman Klein Center's Model for AI Governance [11], provide essential high-level guidance but are often criticized for lacking specific implementation details. Key shortcomings include inadequate resource allocation and insufficient stakeholder engagement, complicating the translation of principles into practice, especially regarding diverse participation [12, 13, 14, 15, 16, 17, 18].

Effectively addressing bias and discrimination in AI systems necessitates implementing concrete strategies. As highlighted by study [19] in the context of surgical care, a comprehensive approach is essential for achieving equity in sensitive areas such as healthcare [1, 5, 6]. This approach should go beyond general data-centric efforts and incorporate targeted interventions at each stage of the AI development lifecycle.

To effectively mitigate bias and discrimination, various strategies can be employed, as illustrated in Fig. 1, including enhancing data quality through data augmentation and bias detection [19, 20, 21], promoting transparency via model interpretability and audit trails [22, 23, 24], and utilizing XAI to build trust [25, 26, 27, 28, 29, 30, 31, 32]. Additionally, continuous monitoring processes and implementing fairness-aware algorithms and metrics are crucial for developing fairer AI systems and reducing discriminatory outcomes [33, 34, 29, 3, 4, 36].

Implementing these technical solutions requires integration into a comprehensive governance framework that articulates ethical principles and offers actionable steps, including resource considerations and stakeholder involvement. The growing use of AI across various sectors—such as healthcare, finance, education, and the judiciary—highlights the necessity for robust governance frameworks to tackle unique ethical challenges [1, 5, 6, 37, 38, 39, 40, 41, 42].

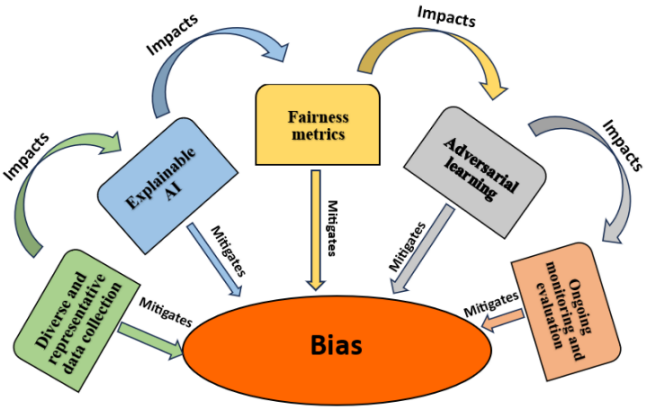

Fig. 1. Strategies for mitigating bias in AI systems.

The HAGF is proposed, which builds on existing efforts by offering a cyclical and interconnected approach to AI governance. HAGF emphasizes resource allocation and combines top-down policy development with bottom-up self-regulation, ensuring continuous refinement. Its focus on resource allocation at each phase, with specific weights assigned to sub-phases, effectively addresses implementation challenges. Critical areas include risk identification, data protection, transparency, and oversight mechanisms.

HAGF's cyclical nature facilitates continuous adaptation to the evolving AI landscape, while KPIs measure effectiveness and progress in ethical AI development. Unlike broader frameworks, HAGF offers specific guidance on data protection, providing organizations with concrete compliance mechanisms. While HAGF has notable strengths, it also recognizes limitations, including the need for deeper guidance on specific ethical issues and implementation challenges; these will be addressed through ongoing refinement and the inclusion of KPIs to track progress. Furthermore, the growing emphasis on auditing AI systems for fairness and bias aligns with HAGF's focus on continuous monitoring, addressing implicit bias, and promoting inclusivity as essential components of the framework.

III. Inclusive Data Collection

Diverse data is essential for developing fair and inclusive AI. Collecting information from various sources and involving multiple stakeholders helps identify potential biases during design and training, enhancing AI accuracy and fairness. In contrast, limited data diversity can lead to overfitting, reduced performance, and the perpetuation of biases against marginalized groups, as illustrated in Fig. 2. The figure underscores these interconnected challenges, including ethical concerns. Therefore, addressing these issues requires careful attention to data collection, model development, and evaluation.

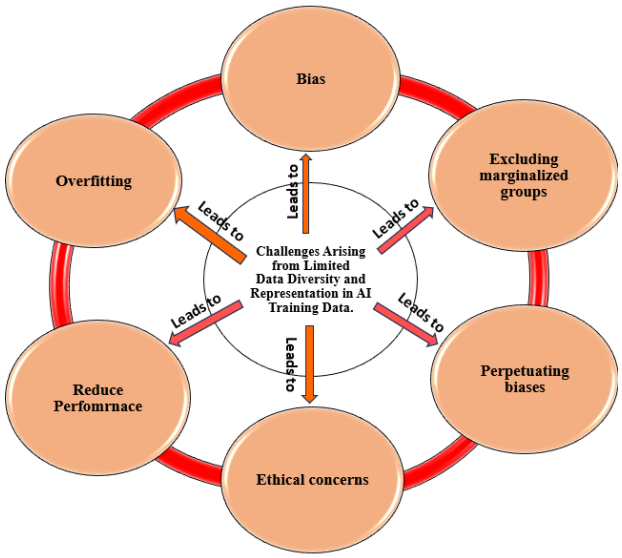

Fig. 2. Challenges arising from limited data diversity and representation.

To address these problems, carefully curating the data to ensure accuracy and representativeness and using techniques such as data augmentation and synthetic data generation to increase diversity and representation. Data curation, the practice of meticulously selecting, organizing, and maintaining data for long-term quality and usability [40], encompasses collection, validation, transformation, integration, and archiving activities. This ensures a trustworthy and well-documented resource for effective analysis and reuse. Building on this foundation, data augmentation transforms existing data to create new, diverse examples, ultimately enhancing model accuracy and robustness [20]. These transformations, tailored to the data type and the problem at hand, can help reduce overfitting and address imbalanced datasets by generating new examples for underrepresented classes, thereby improving overall model performance.

High-quality data is essential for training AI models (as discussed earlier), but challenges arise in acquiring diverse data [40]. Synthetic data generation can address limited or biased training data by creating variations from existing information to improve model fairness and robustness [20]. However, collecting representative data poses difficulties [21, 24, 26, 43, 44]. Biased training data leads to biased AI models, a significant concern for critical applications [45]. Data governance efforts, like audits and fairness benchmarks, aim to ensure the use of representative data, promoting fair and inclusive AI decision-making [46].

IV. Unveiling Bias in AI: XAI, FMs, AL, and M&E

As AI permeates our lives, ensuring fairness and trust is paramount. Three guardians stand watch over responsible development: XAI acts as a transparency lens, revealing how AI makes decisions. FMs, watchful guardians, identify potential biases for equal treatment by AI. Finally, AL strengthens models by mimicking real-world challenges. M&E continuously safeguards against bias creep, ensuring ongoing fairness through regular checks. This ensures AI remains fair and accountable. Despite the oversight role of these guardians, they come with challenges, as outlined in Table I.

Opaque AI systems can lead to biased decisions. XAI cuts through this, revealing AI's reasoning and becoming a powerful tool for fighting bias in critical healthcare fields [27]. Fig. 3 illustrates a typical AI model's limitation: it does not explain its predictions. XAI addresses this by adding an explanation layer and building trust through transparency.

TABLE I. Summary of the Challenges of AI Bias Mitigation Technology

Diverse and representative data collection	***XAI***	***FMs***	***AL***	***On-Going Monitoring***
Data may be incomplete or biased	Computationally expensive	contextual challenges and considerations.	Resource intensive	Resource-intensive.
difficult and computationally expensive	Explanation-challenged	Trade-offs between fairness and performance	limited efficacy	Data bias and incompleteness.
The potential for privacy concerns arises from biases and power imbalances in data collection	Explanations bias	vulnerability to manipulation	over-specialization	Limitations in detecting emerging issues
Potential biases and power imbalances in data collection	Privacy implications	Fairness checklist pitfall	Ethical concerns arise from the possibility of malicious use of AI	The opacity of AI systems limits transparency and interpretability, raising privacy concerns.

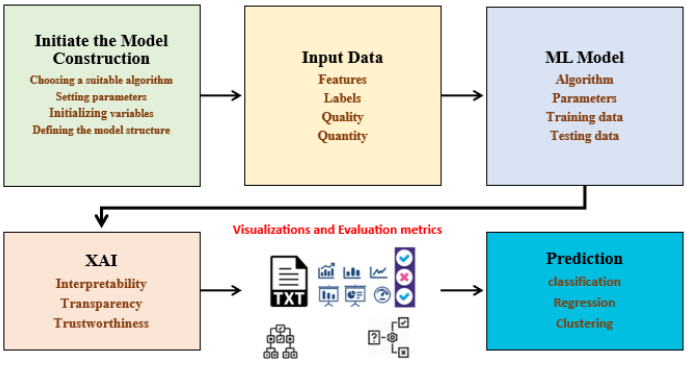

Fig. 3. The placement of XAI in AI model construction.

The National Institute of Standards (NIST) defines transparency, interpretability, explicability, and fairness as key principles for trustworthy AI [28]. These principles are essential for fostering user trust and ensuring AI systems operate ethically and accountable. They align with XAI, which employs techniques like decision trees and other methods to make AI reasoning more transparent for users [29]. By providing clear insights into how decisions are made, XAI helps demystify complex algorithms, enabling users to understand better and challenge AI outputs. This transparency is crucial for individual users, regulatory compliance, and societal acceptance of AI technologies, as illustrated in Fig. 4.

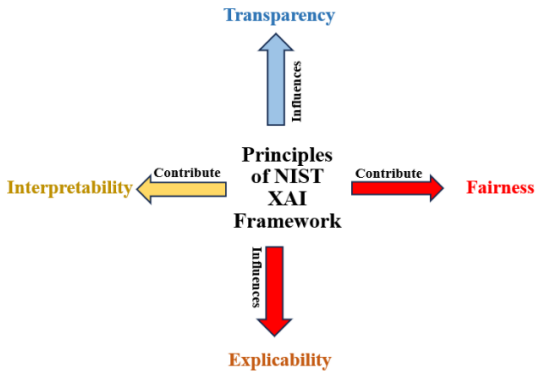

Fig. 4. NIST Key components of AI governance.

However, XAI faces challenges like computational cost, limited explanations, privacy concerns, and unclear explanations that hinder adoption [30]. A multi-disciplinary approach combining machine learning, human-computer interaction, psychology, and ethics is crucial. Balancing technical progress with societal needs and ethics is key to successful XAI [30]. This means developing transparent, interpretable, and ethical XAI solutions prioritizing fairness, accountability, and privacy. A multi-stakeholder approach involving users, experts, and marginalized groups is necessary. Only then can the potential of XAI for trusted and inclusive AI that benefits society be unlocked.

FMs like Equal Opportunity (EO) ensure fair and unbiased AI [31, 32]. These quantitative measures assess bias by examining how AI models treat different groups. For example, EO focuses on consistent True Positive Rates (correct identification of true positives) across groups. Other metrics like Demographic Parity (DP) ensure similar positive outcomes across groups, while Sufficiency (Calibration/Predictive Parity) checks for accurate positive probability predictions [47]. However, FMs face challenges. Defining and measuring them can be difficult; they might conflict with accuracy, and focusing solely on them can lead to a rigid fairness approach. Despite these limitations, FMs are essential for promoting fairness, transparency, and accountability in AI development. It must be recognized that FMs are not a standalone solution [47]. Over-reliance on them risks oversimplification, and manipulation is a potential concern. A balanced approach that considers FMs within a broader fairness definition and measurement framework is necessary. This collaborative effort, acknowledging trade-offs and integrating fairness throughout the AI lifecycle, is key to building more equitable and trustworthy AI systems.

AL tackles bias in AI by introducing cleverly crafted training data designed to fool the system and expose its weaknesses [48, 49]. These examples, like images or text, are false positives during training. By encountering these errors, AI models learn to become more robust against mistakes caused by biased data. AL offers benefits like improved accuracy and reduced cyberattack vulnerability [50]. However, it's not a silver bullet. While promising in improving AI robustness and reducing bias, AL's effectiveness depends on context. It can be computationally expensive and may not address all biases, particularly those rooted in deeper societal issues [51].

Moreover, concerns about overfitting and potential misuse exist. Therefore, AL is most effective as part of a broader strategy for fair AI, alongside continued research focused on responsible innovation and ethics [51]. This combined approach unlocks AL's potential while mitigating risks, allowing AI to harness adversarial training responsibly to create fairer and more trustworthy technologies.

AI systems require continuous M&E to prevent bias from creeping in and ensure ongoing fairness. Regular audits, testing, and user engagement are crucial to identifying and addressing potential biases [36]. FMs, like demographic parity and equal opportunity, can track how outcomes are distributed across different groups and highlight any disparities [36]. Human oversight, through approaches involving humans in the decision-making loop, can help review and intervene in potentially biased decisions [36].

However, challenges exist, including resource-intensive monitoring, requiring expertise and time to analyze data [42]. Biased or incomplete surveillance data can lead to inaccurate conclusions [37]. New biases that emerge over time or issues not present in the training data may also be missed [38]. The lack of transparency in some AI systems can make it challenging to identify bias [52].

Finally, the lack of transparency in some AI systems can make it challenging to identify bias [52], and privacy concerns arise when collecting and analyzing sensitive data [52].

V. Ethical and Responsible AI Management

Governments can promote the safe and responsible implementation of AI by establishing ethical guidelines and standards [54] [55] [56], consulting experts, engaging stakeholders, and formulating clear ethical principles, all of which monitor compliance and implement sanctions to build public trust and ensure the usefulness of AI. Ethics, in general, is a set of principles that help us distinguish between right and wrong. AI ethics is the process of studying how to improve the beneficial impact of AI while minimizing negative consequences. Rapid changes in AI systems raise profound ethical concerns by embedding biases, threatening human rights, and more.

Different international organizations [57] have issued some basic requirements for an AI system to be considered trustworthy. These organizations initially define values necessary for an ethical AI model and move beyond this towards an actionable policy. The most common requirements are explainability, reliability, robustness, security, accountability, privacy and data governance, human agency,

and oversight, legality, fairness, and safety, as shown in Fig. 5; all of these requirements should be evaluated throughout the life cycle of designing an AI model.

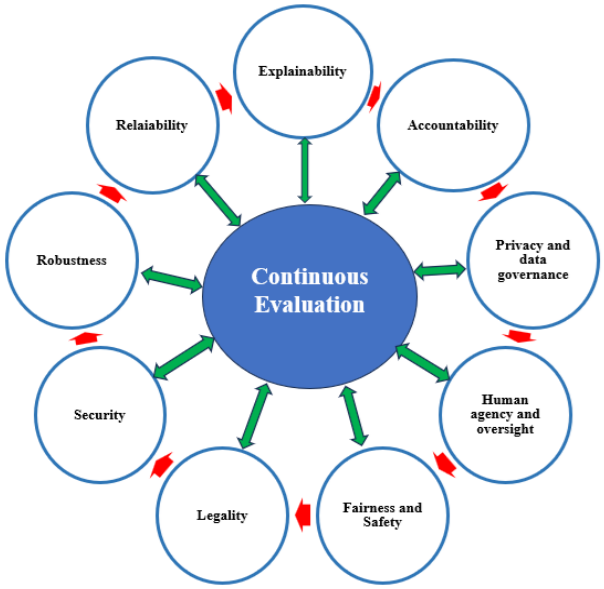

Fig. 5. Basic requirements for an AI model to be considered trustworthy.

Governments play a crucial role in shaping AI's responsible development and use. This includes establishing regulations to address data protection, privacy, and the use of AI in sensitive areas like healthcare and criminal justice. These regulations would focus on data protection, transparency, accountability, and ethical AI use, mitigating potential risks.

These regulations would focus on data protection, transparency, accountability, and ethical AI use, mitigating potential risks. Furthermore, governments can encourage industry self-regulation through voluntary codes of conduct and oversight mechanisms, potentially overseen by regulatory bodies that conduct audits. International collaboration can further solidify these efforts by establishing common standards.

However, responsible AI development shouldn't stifle innovation. Governments can promote AI advancement by investing in research and development, funding academic research, and fostering public-private partnerships. Additionally, supporting educational and training programs equips the workforce with the skills to navigate this evolving technological landscape [41]. This multifaceted approach ensures responsible AI development while fostering innovation and economic growth.

VI. Results

HAGF, presented in Fig. 6, offers a cyclical and interconnected approach to AI governance, emphasizing resource allocation and a multi-faceted strategy combining top-down policy development, bottom-up self-regulation, and continuous refinement. This comprehensive framework establishes a unified approach to AI governance, incorporating a coherent set of definitions and principles for responsible AI utilization. HAGF aligns with both model governance and rights-based models, focusing on ethical AI development, stakeholder engagement, and accountability. It provides a systematic approach to overseeing AI systems throughout their lifecycle.

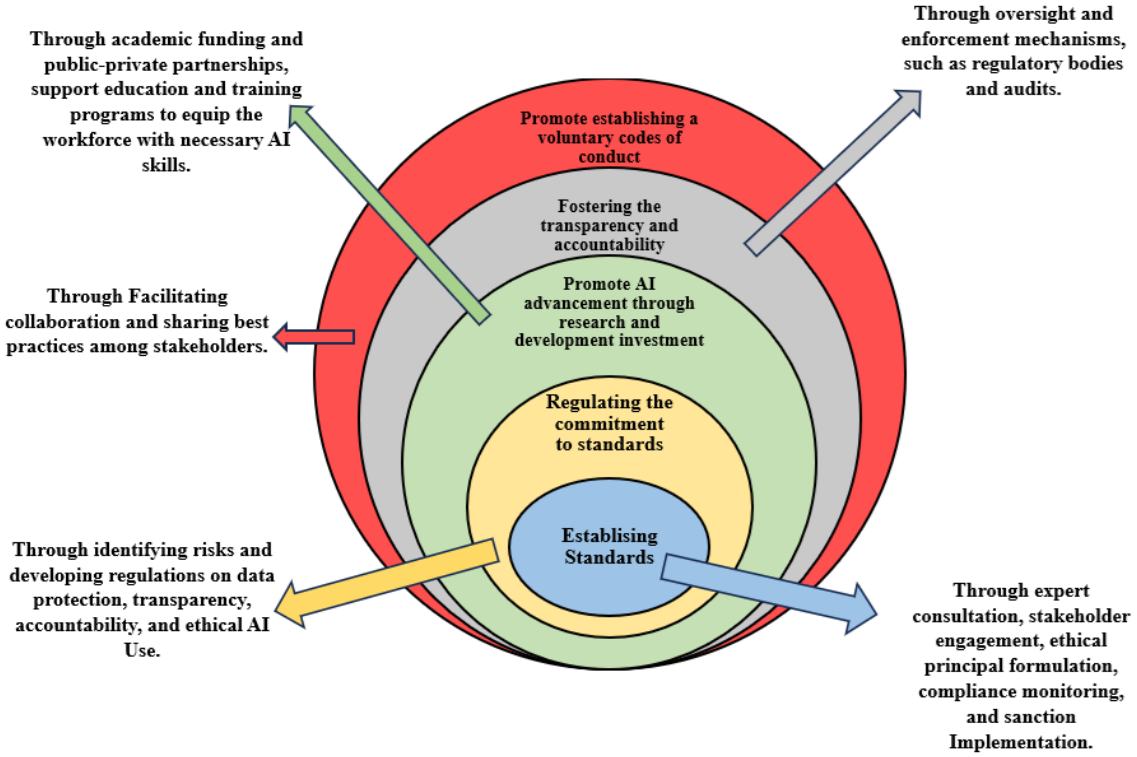

Fig. 6. HAGF – AI Governance framework.

The HAGF framework consists of five interconnected and cyclical components: establishing standards, regulating commitment to those standards, promoting AI advancement, fostering transparency and accountability, and encouraging a voluntary code of conduct. Each of these components plays a specific role in advancing ethical AI governance.

The phases are assigned theoretical weights, as illustrated in Fig. 7, to clearly convey the authors' prioritized vision for responsible AI development and deployment. These weights act as a powerful tool for clarifying the conceptual relationships between the components, providing strategic guidance for implementation, and stimulating discussion and debate regarding prioritization.

These assigned weights enhance the rigor and transparency of the HAGF framework, moving beyond abstract principles to deliver a concrete, actionable, and transparent representation of the authors' vision for ethical AI governance. By emphasizing these weights, the framework illustrates the importance of each component and fosters a deeper understanding of how they interconnect to promote a responsible AI ecosystem.

Phase 1 allocated 20%, focusing on developing a strong foundation for ethical guidelines for AI. This moderately resource-intensive phase involves forming a steering committee, conducting comprehensive research, formulating clear standards, and gathering feedback from diverse stakeholders. Notably, the sub-phase weights prioritize core values, with the highest allocation to formulating ethical guidelines (6%). Furthermore, stakeholder engagement (5%) was emphasized, recognizing the importance of engagement from all stakeholders. In addition, expert consultation (4%) informs the guidelines on best practices, while compliance monitoring (3%) and sanctions enforcement (2%) focus on developing the framework. It is important to note that implementation and enforcement will be addressed in subsequent phases.

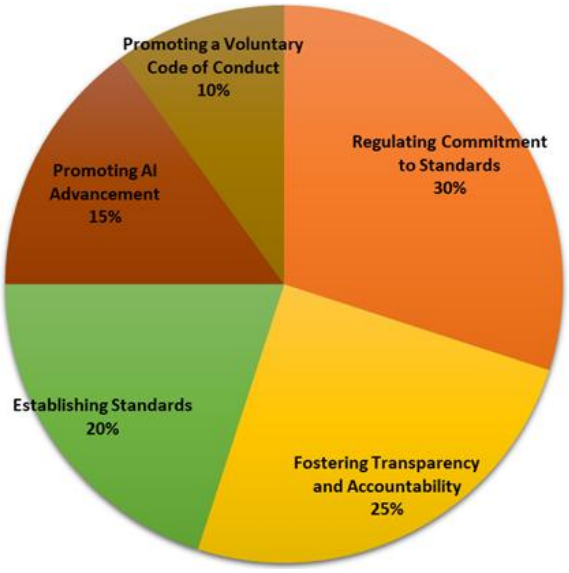

Fig. 7. HAGF phase weights.

The second phase has been assigned the highest weight, with 30% dedicated to translating ethical guidelines into action through robust compliance mechanisms. This resource-intensive phase emphasizes risk identification and the development of regulations for data protection, transparency, accountability, and ethical AI use. Due to the complexity of compliance, ongoing monitoring, regular audits, and potential legal action are necessary. Key focus areas in this phase include risk identification and assessment (9%), data protection regulations (8%), transparency and explainability regulations (7%), accountability mechanisms and sanctions (4%), and collaboration with authorities and dispute resolution (2%). This distribution effectively reflects the relative effort and significance of ensuring compliance with ethical AI standards.

15% has been allocated to the third phase, which aims to foster AI innovation through targeted investments. Notably, Funding Allocation (6%) is the primary focus, receiving the largest share, highlighting the importance of strategically distributing financial resources. In addition, Public-Private Partnerships (4%) leverage both resources and expertise, while Talent Development (3%) works to build a skilled workforce. Ethical Research Practices (1%) ensure that ethical standards are maintained throughout the research process, and Evaluation and Impact Assessment (1%) facilitate continuous learning and improvement. As a result, this distribution emphasizes funding while also recognizing the significance of partnerships, talent, ethics, and evaluation.

In the fourth phase, 25% of the weight is allocated, shifting the focus to building trust through responsible AI practices. Oversight and Enforcement Mechanisms (10%) are essential for ensuring compliance with established guidelines. Furthermore, Regular Audits (8%) assess adherence to these guidelines and pinpoint areas for improvement, while Public Disclosure (7%) enhances transparency by making information about AI systems accessible. This distribution prioritizes oversight and audits, highlighting their importance for accountability, and acknowledges the role of public disclosure in fostering trust.

Finally, 10% of the weighting is allocated to the fifth phase, which emphasizes encouraging self-regulation and best practices in AI. Facilitating Collaboration Among Stakeholders (5%) is vital for uniting diverse perspectives and fostering consensus. Additionally, Sharing Best Practices (3%) allows organizations to learn from each other and implement effective strategies. Promoting Inclusivity (2%) ensures that the codes encompass a broad range of viewpoints. Consequently, this distribution prioritizes collaboration and sharing best practices as essential drivers for developing and adopting meaningful voluntary codes of conduct.

A summary of the weighting assigned to each sub-phase within HAGF is provided in Fig. 8. This figure illustrates a project prioritizing compliance, risk management, and transparency, with Oversight & Enforcement (10%) and Risk Identification (9%) receiving the heaviest weight. Data Protection and Regular Audits (8% each) are also strongly emphasized. Transparency & Explainability (7%) and Ethical Principles and Funding (6% each) are moderately weighted. Stakeholder Engagement (5%), Accountability & Sanctions, Public-Private Partnerships, and Expert Consultation (4% each) are important but less emphasized. Supporting activities

include Talent Development (3%), Public Disclosure (3%), Collaboration (2%), Ethical Research (1%), Evaluation (1%), and Inclusivity (2%). The focus is on robust mechanisms and ongoing monitoring of ethical AI practices.

HAGF aligns with several emerging best practices in AI governance. Its emphasis on ethical development, stakeholder engagement, and accountability resonates with the principle of human-centered AI. The framework prioritizes transparency and accountability, addressing the growing demand for explainable AI (XAI). Furthermore, it implicitly considers risks at various stages of the AI lifecycle and acknowledges the importance of diverse stakeholder involvement, promoting a multi-stakeholder approach. Its cyclical nature facilitates continuous refinement, ensuring the framework remains relevant and effective.

Model Governance Frameworks, including HAGF, the Berkman Klein Center's framework, and the OECD AI Principles, provide blueprints for organizations seeking to implement responsible AI practices. These frameworks offer structured, principled approaches to governance, applicable across various contexts, and serve as models for navigating the complex challenges of ethical AI. While not legally binding or technically specific, they share a commitment to fostering ethical AI practices, each with unique attributes, as highlighted in Table II.

HAGF, in particular, offers significant ethical guidelines for AI development, emphasizing interconnectedness and resource allocation. It promotes stakeholder collaboration and underscores the importance of transparency and accountability, laying a solid foundation for responsible AI practices and positioning HAGF as a valuable contributor to the field.

HAGF framework offers significant advantages through its actionable implementation, breaking down ethical AI governance into specifically weighted sub-phases that prioritize critical areas and inform resource allocation. This explicit weighting compels strategic thinking, clarifying the relative importance of each component. Unlike other frameworks that provide broad guidance, HAGF delivers detailed direction, particularly in data protection, equipping organizations with concrete mechanisms for compliance. Its cyclical and adaptable nature fosters continuous improvement, ensuring relevance in a rapidly evolving landscape.

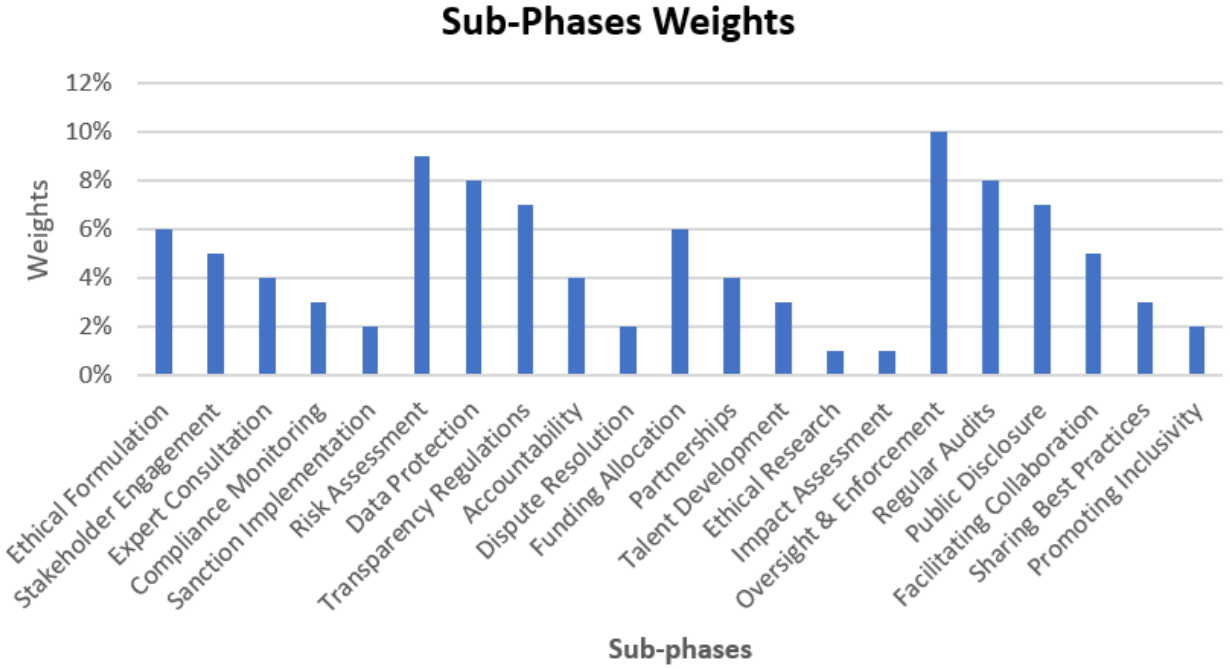

Fig. 8. Percentage weighting of sub-phases in HAGF.

TABLE II. COMPARING AI GOVERNANCE FRAMEWORKS: HAGF, OECD, AND BERMAN KLEIN

Framework	*Scope*	*Focus*	*Holistic Approach*	*Resource Allocation*	*Practical Focus*
HAGF Framework	Provides ethical guidelines for AI development and use, may offer more specific guidance	Interconnectedness and resource allocation.	Yes, it considers various interconnected components	Emphasizes the importance of funding and support	Provides a more concrete and actionable framework
OECD AI Principles	Provides general ethical guidelines for AI development and use	A general approach to ethical considerations	No	It does not explicitly address resource allocation	It gives more general principles
Berkman Klein Center's Model	Provides a comprehensive framework for AI governance	A holistic approach, considering various aspects of AI governance	Yes	It does not explicitly address resource allocation	Provides a general framework with guidance on implementation

However, HAGF has areas for potential improvement. It would strengthen its applicability by providing more detailed guidance on specific ethical issues, such as enhancing its focus on data governance with clear directives for responsible data practices. While its current complexity may pose challenges for some organizations, these issues are manageable and can be addressed through further refinement. HAGF's reliance on consistent funding and expertise highlights its potential for growth and adaptation. Measuring the effectiveness of its ethical guidelines and fostering public trust will enable it to evolve with rapid technological change.

Improvements in its enforcement mechanisms, particularly concerning voluntary codes of conduct, are also essential. As illustrated in Table III, a comprehensive set of KPIs has been developed to facilitate ongoing improvement by measuring the effectiveness of each HAGF phase and tracking progress toward ethical AI development. These KPIs cover critical aspects such as standards development and adoption, regulatory compliance, AI research investment, public trust, stakeholder engagement, and workforce impact. This clear mechanism for monitoring HAGF's performance helps identify areas for enhancement and ensures continuous progress in ethical AI practices, fostering accountability and transparency.

This holistic, cyclical approach, coupled with its emphasis on resource allocation and integration of top-down and bottom-up governance strategies, positions HAGF as an effective tool for promoting responsible AI development and use. Addressing the identified weaknesses and aligning more closely with best practices will further enhance HAGF's effectiveness in fostering ethical AI practices. Recognizing these limitations, as reflected in the insights from Table III, offers a balanced perspective on HAGF's potential and challenges.

TABLE III. KPIS FOR EVALUATING AN AI GOVERNANCE FRAMEWORK

Phase	***Key Performance Indicator (KPI)***
Establishing standards	- Number of AI-related standards and guidelines developed and published. - Level of stakeholder engagement in the standard-setting process. - Clarity and Comprehensibility of the established standards. - Adoption rate of the established standards by AI developers and users. - Number of revisions made to the standards. - Time taken to develop and publish the standards
Regulating the commitment to standards	- Compliance rate with established AI standards. - Number and severity of non-compliance incidents. - Effectiveness of enforcement mechanisms (e.g., audits, sanctions). - Level of public trust in the AI governance framework. - Number of AI-related regulations enacted. - Time taken to resolve non-compliance incidents. - Level of industry engagement in the regulatory process.
Promoting AI advancement through research and development investment	- Amount of funding allocated for AI research and development. - Number of successful AI research projects funded. - Number of new AI-based products or services developed. - Growth of the AI industry in revenue, employment, and innovation. - Collaboration rate between academia and industry on AI projects. - Number of AI-related patents filed. - Return on investment (ROI) for AI research funding.
Fostering transparency and accountability	- Number of AI systems with publicly available information on their algorithms and data sources. - Level of public trust and confidence in AI systems. - Number of successful cases of AI-related accountability measures (e.g., investigations, legal actions). - Frequency and quality of AI impact assessments. - Number of AI explainability tools or frameworks developed. - Number of AI bias detection and mitigation strategies implemented. - Level of public awareness and understanding of AI systems.
Promoting establishing a voluntary code of conduct.	- Number of organizations that have adopted voluntary codes of conduct for AI. - Level of adherence to the codes of conduct by organizations. - Positive impact of codes of conduct on ethical and responsible AI development. - Public perception of the effectiveness of voluntary codes of conduct. - Number of industry-led initiatives promoting responsible AI. - Level of diversity and inclusion in the development and governance of AI systems. - Number of self-assessments or audits conducted by organizations to ensure compliance with codes of conduct.

VII. CONCLUSION

Bias and discrimination in AI systems present significant challenges; however, emerging technologies such as Explainable AI (XAI), Fairness Metrics (FMs), and Adversarial Learning (AL), combined with robust governance frameworks, offer promising solutions. This article introduced the Holistic AI Governance Framework (HAGF), a comprehensive and cyclical approach to ethical AI governance. HAGF comprises five interconnected components: establishing standards, regulating adherence to those standards, promoting AI advancement, fostering transparency and accountability, and encouraging voluntary codes of conduct. By prioritizing resource allocation and integrating top-down policies with bottom-up self-regulation, HAGF addresses the complexities of

AI governance. Its emphasis on expert consultation, stakeholder engagement, and ethical principle formulation lays a strong foundation for effective standards. Additionally, focusing on risk identification, data protection, and accountability through regulation and oversight cultivates a culture of compliance. Investment in AI innovation and the promotion of voluntary codes of conduct supports both responsible practices and technological advancement. To ensure HAGF's effectiveness and adaptability in an evolving AI landscape, a robust suite of Key Performance Indicators (KPIs) is proposed, measuring standards, regulatory effectiveness, public trust, societal impact, and research advancement. Ongoing research, stakeholder engagement, and continuous evaluation and refinement of HAGF—particularly regarding data rights and algorithmic accountability—will be crucial for realizing a just and equitable AI future.

Enhanced Early Detection of Diabetic Nephropathy Using a Hybrid Autoencoder-LSTM Model for Clinical Prediction

U. Sudha Rani[1], Dr. C. Subhas[2]
Research Scholar, JNTUA Ananthapuramu, India[1]
Professor, JNTUA CEK[2]

***Abstract*—Early detection and precise prediction are essential in medical diagnosis, particularly for diseases such as diabetic nephropathy (DN), which tends to go undiagnosed at its early stages. Conventional diagnostic techniques may not be sensitive and timely, and hence, early intervention might be difficult. This research delves into the application of a hybrid Autoencoder-LSTM model to improve DN detection. The Autoencoder (AE) unit compresses clinical data with preservation of important features and dimensionality reduction. The Long Short-Term Memory (LSTM) network subsequently processes temporal patterns and sequential dependency, enhancing feature learning for timely diagnosis. Clinical and demographic information from diabetic patients are included in the dataset, evaluating variables such as age, sex, type of diabetes, duration of disease, smoking, and alcohol use. The model is done using Python and exhibits better performance compared to conventional methods. The Hybrid AE-LSTM model proposed here attains an accuracy of 99.2%, which is a 6.68% improvement over Random Forest (RF), Support Vector Machine (SVM), and Logistic Regression. The findings demonstrate the power of deep learning in detecting DN early and accurately and present a novel tool for proactive disease control among diabetic patients.**

Keywords*—Autoencoder-LSTM; Diabetic nephropathy; early disease detection; machine learning; clinical data analysis; hybrid models

I. Introduction

Diabetes is a serious issue for general health. Approximately millions of individuals worldwide suffer with diabetes. Globally, there were 463 million diabetics in 2019, and 700 million are predicted by 2045 [1]. Kidneys, eyes, nerves, skin, and heart can all be harmed by it. The most frequent cause of kidney failure in diabetic people is diabetes nephropathy (DN)[2]. DN patients have surged in tandem with the exponential rise in the frequency of diabetes patients. Consequently, the mortality rate of DN has also gone up. Consequently, it's critical to identify DN patients early in order to prevent the related illnesses. Early detection of DN by diagnostic markers is crucial, as it might impede the loss of renal function and mitigate unfavorable consequences. Micro albuminuria, or the presence of minute quantities of protein albumin in the urine, is recognized as the first indication of the onset of diabetes mellitus. On the other hand, a significant amount of renal damage has been documented to occur even prior to the development of micro albuminuria [3]. A number of complicating factors, including exercise, urinary tract infections, acute illnesses, and heart failure, are linked to albuminuria. Moreover, it has been documented to transpire in the urine of individuals following a regular diet, suggesting that albuminuria is not a reliable indicator for precisely forecasting diabetic kidney disease.

Elevated blood vessel glucose levels are critical to the development of diabetic neuropathic pain. Through an excess of reactive oxygen species (ROS), hyperglycemia causes problems with metabolism in mitochondria and the sugar metabolic pathway [4]. Glycation at high glucose concentrations creates adducts that are covalent with plasma proteins. AGEs, or advanced glycation end products, are one of these events and a significant risk factor for complications from diabetes. Podocytes are an essential component of the glomerular filtration barrier, and they may become aberrant after extended exposure to hyperglycemia. The loss of podocytes is one of the earliest glomerular morphologic alterations, and it is essential to the emergence of DN. Clinically speaking, diabetic individuals with DN have proteinuria and decreased kidney function [5]. DN patients can be maintained with blood pressure and glucose management, but many eventually develop renal failure [6]. Therefore, it will be crucial to comprehend the pathophysiology of DN and create novel biomarkers in order to diagnose DN early. Nowadays diagnostic methods for conditions such as DN present various issues that stem from the reliance on clinical sign and/or biomarkers associated with the late stage of the disease. Such reliance can lead to lack of timely treatment/fulfillment of early milestones/health concerns prevention. Also, there are other diagnostic tests whereby biopsy or blood samples are taken and this causes discomfort or is risky and therefore people are discouraged from frequent checkup. These traditional tools may also be insensitive and non-specific and therefore result in false positive or negative results as the traditional biomarkers may not necessarily mimic the early stages of DN. Secondly, certain diagnostic techniques for instance, specialized imaging may be expensive as well as unavailable in most health facilities and more so in developing countries. There is also a certain degree of subjectivity and variability in diagnostics, this is due to the facts that using subjective methods such as clinical impression or an interpretation of test results the results of the diagnostics can be significantly different depending a healthcare provider's experience.

However, current approaches of advanced diagnostic targets do not seem to have a perfect solution to these

challenges; but, the machine learning (ML) models for medical diagnostic are a potential solution to these challenges [7]. The large volume of complex data gathered in every healthcare practice may be analyzed by an ML model to search for patterns that can be missed by a clinician and that can predict DN and its development even before its first clinical manifestation. They also enable constant, non- invasive monitoring through trailing with wearable devices or EHR, which offer an instant read out of the patient's status. Through utilization of big and heterogeneous databases, it is possible to enhance the diagnostic precision and increase the abilities to distinguish between the diseases that are similar and make more accurate prognosis depends on the individual parameters of the patient [8]. Due to scalability and cost implications, ML models provide coherent diagnosis support irrespective of the healthcare facility, hence the need to employ specialized personnel and equipment especially in setting with limited accessibility to the same [9]. Moreover, a model for prediction based on the DN-related parameters must be created. As an automated model construction method, ML-based approaches have taken the lead in the domains of medical imaging, human interaction, and healthcare. ML-based approaches are mainly employed for early identification and prediction/detection of different healthcare conditions, such as diabetes, carcinoma, and kidney damage, in order to increase classification accuracy. The popularity of ML-based approaches has skyrocketed recently. While a significant amount of research has been conducted and newly created ML-based algorithms have garnered attention, the hunt for ways to improve classifier accuracy has never ended [10]. Thus, one of the key elements that will determine how accurate the classifiers are is the selection of an ML-based model. Over many years, researchers have worked very hard to create useful models to enhance precision of categorization. Medical data categorization remains a difficult problem for machine learning-based classifiers, despite the quick advancement of computational intelligence theories.

Furthermore, with the use of ML models, patients can be diagnosed and treated, based on the specific characteristics like genetics, lifestyle, and presence of a variety of diseases. It can also take disparate data from clinical, genomic and environmental domains and make application of the data to provide new and unique insights into the disease causes, drivers and therapeutic outcomes. Taken together, the existing diagnostic practices have certain drawbacks, whereas the machine learning models open a vast range of possibilities that help improve the detection rates at the initial stages, refine the diagnostics, and transform the healthcare services to be more individualized and easily scalable. These ML-based classifiers, however, are still unable to categorize patients accurately due to their unsatisfactory accuracy. But the goal of this work is to use ML-based approaches to create a prediction model based on the risk variables associated with DN. Feature extraction techniques also identify DN risk variables. Here are four primary contributions of the proposed Hybrid Autoencoder-LSTM model for detecting Diabetic Nephropathy (DN).

- The study introduces the use of an Autoencoder for effective dimensionality reduction, which helps in isolating essential features. This step not only simplifies the dataset but also enhances the model's ability to focus on the most relevant information, thereby improving the overall accuracy and interpretability of the model.
- The combination of Autoencoder and LSTM architectures leverages the strengths of both models. The Autoencoder efficiently handles feature learning and noise reduction, while the LSTM network excels at sequential data analysis. This hybrid approach provides a comprehensive framework for DN detection, offering improved prediction accuracy compared to conventional machine learning models.
- The study provides a comprehensive performance evaluation of the AE-LSTM model, including metrics such as reconstruction loss, classification accuracy, precision, recall, and F1-score. The comparative analysis with other methods highlights the AE-LSTM model's superior performance and its potential advantages in handling complex, high-dimensional healthcare data.
- The use of advanced optimization techniques like the Adam Optimizer, along with appropriate loss functions (MSE for the Autoencoder and binary/categorical cross-entropy for the LSTM), ensures efficient and effective training of the model. This contributes to achieving high performance metrics, such as accuracy and precision, in the detection and diagnosis of DN.

The rest of the contents are listed in the following order. An introduction is given in Section I. The literary portions are shown in Section II. This is the problem statement found in Section III. The hybrid model-based modeling and analysis approach is covered in Section IV. The results are compiled and the performance indicators are shown in Section V. Section VI offers further research and a conclusion.

II. Related Works

Kim et al. [11] developed the initial stages diagnostic biomarkers to detect DN as a means of DN intervention. In the investigation, Zucker diabetes-related fatty rats were used to model the DN phenotype. The results showed that in addition to significantly raised serum levels of blood glucose, BUN, and creatinine, DN rats also exhibited severe renal injury, fibrosis, and microstructural changes. Moreover, the urine of DN rats emitted higher concentrations of kidney injury molecule-1 (KIM-1) and neutrophil gelatinase-associated lipocalin (NGAL). New DN biomarkers were discovered by transcriptome analysis. Moreover, they were discovered in DN patients' urine. The findings showed that the onset of diabetic nephropathy was associated with an up-regulation of CXCR6 expression levels in rat urine, renal tissue, and clinical samples. In essence, our discovery offers direct evidence that CXCR6 was elevated in urine as diabetic nephropathy progressed. The results therefore imply that the CXCL16/CXCR6 pathway may be involved in the development of end-stage renal disorders. Using these results, a unique therapeutic approach to treating renal fibrosis can be developed. It is unclear, therefore, how CXCR6 contributes to the development of diabetic nephropathy. To investigate the underlying process in DN, more research is needed.

A new deep learning model is presented by Singh et al. [12] for the early identification and prediction of chronic kidney disease. This project aims to construct a DNN and evaluate its performance relative to other state-of-the-art machine learning techniques. Any information that were absent from the database during testing were substituted with the mean of the relevant attributes. The optimal parameters of the neural network were then established by configuring them and carrying out several trials. The most important characteristics were selected using Recursive Feature Elimination (RFE). Hemoglobin, specific gravity, serum creatinine level, blood vessel count, albumin, packed cell volume, and high blood pressure were important features in the RFE. To categorize them, machine learning models were given a range of attributes. The technique could be useful to nephrologists in detecting CKD. The model's testing on limited data sets was one of its limitations. In the future, large amounts of more complex and representative CKD data will be gathered to determine the severity of the illness and enhance the model's performance.

The goal of the Kang et al. [13] study was to create and assess a DL model that uses retinal fundus images to identify early renal function deterioration. This retrospective analysis includes patients who had color fundus imaging and renal function testing. From the images, a DL model was built to identify renal impairment. An estimated rate of glomerular filtration of less than 90 mL/min/1.73 m2 was considered early renal function impairment. The AUC and ROC curve were used to assess the performance of the model. For the whole population, the model's AUC was 0.81.Using retinal fundus images, the deep learning algorithm in this work makes it possible to identify early renal function deterioration. Only for individuals with increased blood HbA1c levels, the model demonstrated greater accuracy is the drawback.

A unique ML model for CKD prediction was put out by Arif et al. [14] It included a number of pre-processing stages, selection of features, a hyper parameter optimization method, and ML algorithms. In order to tackle the difficulties encountered with medical datasets, we utilize sequential data scaling along with robust scaling, z-standardization, and min-max scaling, as well as iterative imputation for missing values. The Boruta method is used for feature selection, while ML algorithms are used to create the model. The model performed exceptionally well with good accuracy when assessed on the UCI CKD dataset. The method, which combines novel pre-processing techniques, the Boruta feature selection, the k-nearest-neighbour algorithm, and grid-search cross-validation (CV) for hyper parameter tuning, shows promise in improving the early identification of CKD. This study emphasizes how machine learning approaches might enhance therapeutic support networks and lessen the influence of ambiguity around the prognosis of chronic illnesses. The study's primary drawback was its dependence on a single dataset the UCI CKD dataset, which has a significant number of missing values.

By combining a number of easily accessible clinical variables with retinal vascular measures, Shi et al. [15] developed a new DKD diagnostic approach for individuals with type 2 diabetes. Xiangyang Central Hospital's 515 consecutive type-2 diabetes mellitus patients were included. Patient diagnoses of DKD were used to separate patients into two groups: the training and testing set, with a random seed of 1. While the ML was developed using data from the training set, the MLA was validated using data from the testing set. The model's performances were assessed. When compared to other classifiers, the random forest classifier-using MLA performed at its best. Verified, the accuracy was 84.5%. Retinal vascular alterations may help in DKD screening and identification, according to a novel machine learning method for the disease's diagnosis that was constructed using fundus images and eight readily accessible clinical data. The sample used in the study limits the generalizability of the model to broader and more diverse populations.

In the Zhang et al. [16] study, membranous nephropathy was diagnosed by combining deep learning techniques with blood and urine Raman spectra. Following baseline correction and data smoothing, the training set was supplemented with Gaussian white noise at varying decibel levels to enhance the data. The assessment results of the ResNet, AlexNet, and GoogleNet models for membranous nephropathy were then obtained by feeding the amplified data into them. As per the experimental findings, AlexNet emerged as the most proficient deep learning model for both samples. All three models were able to attain an accuracy of 1 in classifying serum data pertaining to patients with membranous kidney damage and the unaffected group, and above 0.85 in differentiating urine data. The test results described above show how powerful deep learning methods can be when used in combination with serum- and urine-based Raman analysis to accurately and quickly diagnose individuals with membranous nephropathy. The limitation is the high accuracy reported would not be achievable in a more diverse and unstructured clinical environment, where data quality and characteristics can vary widely.

Several limitations to the application of ML and DL models in diagnosing kidney related diseases are presented in the reviewed literature. A typical issue is that the number and types of datasets are often limited and often only a single dataset may be used in developing the model and hence the range and the variety of data populations might not be very wide. Also, some research works' drawbacks were associated with data quality and data loss, where data missing was a major issue that came up to a need of imputation or data augmentation. In this case, the models' applicability for different conditions or groups may be limited since the improvement was noted only in patients with raised HbA1c levels. In addition, the very high levels of accuracy found in this and similar studies, again in precise experimental settings, may not be highly representative of the variability and range of clinical datasets, again influencing the model's results in the clinic. Lastly, the strong focus on concrete characteristics that include the use of retinal fundus images or Raman spectra may also suggest the models' drawback in conditions when such data is irrelevant or missing.

III. Problem Statement

DN is categorized as a usual complication of diabetes the result of which may culminate into end-stage renal disease if not diagnosed. The current diagnostic processes that are based on biomarkers and imaging oftentimes diagnose DN at the most severe stages, thereby limiting the interventional and treatment

procedures[16]. The reason why diagnosis is usually made later in the course of DN is partly attributed to the slow and progressive nature of kidney damage in such patients when conventional techniques are used. Thus, addressing the mentioned problem of the shortage of diagnostic techniques, this paper proposes and compares an Autoencoder-LSTM model for the diagnosis of diabetic nephropathy. The proposed hybrid model intends to integrate the autoencoder' s ability of decreasing the dimensionality of data and finding hidden beneficial aspects as well as the feature superior to recognizing temporal relations in the series data which is LSTM network. Using this model for Clinical and patient data analysis, the study aims at finding the feeble signs of DN that are masked normally. The latter goal is to create a less invasive and more precise diagnostic tool for early identification of DN, which in turn will allow for proper treatment to be given, enhance the patient's outcomes, and perhaps decrease the likelihood of transitioning to the more significant level of nephropathy.

IV. Proposed Methodology of Hybrid Autoencoder-LSTM model for Early Detection of Diabetic Nephropathy

For the detection of DN, this study uses the Hybrid Autoencoder-LSTM model that uses feature learning and temporal pattern analysis. The methodology encompasses several key stages: acquisition of data as well as preparation, designing the model as well as learning rate schemes for the model. First, the input dataset is formed by using clinical data of patients with diabetes, retrieved from prior researches. This dataset must then be cleaned to deal with any issues pertaining to missing values as well as the normalization of its features, and where needed, feature selection. The Autoencoder component accomplishes the Dimensionality reduction of the input data for the aim of segregating necessary features from the noisy ones. These condensed features are then passed to the LSTM network which learns on the sequences to identify relationships with time of DN. The connection of these two parts is to improve the accuracy of the model through the application of the advantages of the architectures of deep learning. When training the model, several loss functions are used; MSE for autoencoder and binary or categorical cross-entropy for LSTM based on the classification task. The Adam Optimizer helps in achieving the steady state for the value and the model goes through epochs for the optimization. The DN diagnosis and accurate identification of patients with the condition is sought through this integrated, extensive methodological approach that aims to enhance the optimality of the model. It is demonstrated in Fig. 1 given below.

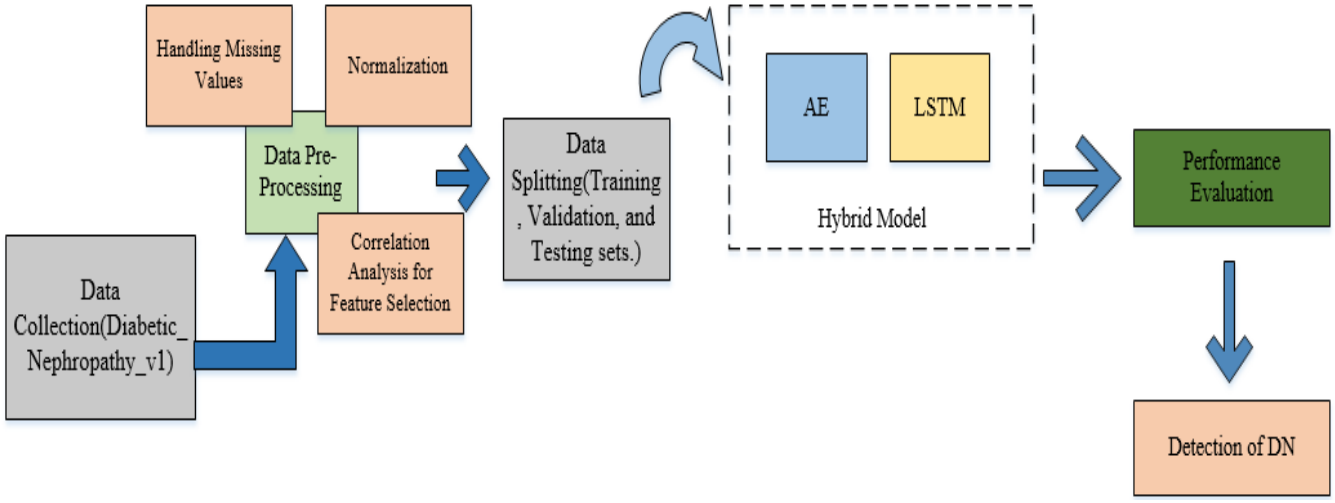

Fig. 1. Hybrid AE-LSTM model block diagram.

A. Dataset Collection

The dataset which is "Diabetic_Nephropathy_v1" contains clinical and demographic data of DN and related diseases[17]. The dataset consists of 767 patient records. These variables involve the patient's sex, age, type of diabetes, duration of the disease, DR and DN, and smoking and drinking habits; as well as glucose levels, HbA1c, body mass index (BMI), and blood pressure. These parameters include height, weight, body mass index, systolic blood pressure, diastolic blood pressure, glycated haemoglobin, fasting blood glucose, blood triglycerides, C-peptide, total cholesterol, high-density lipoprotein cholesterol and low-density lipoprotein cholesterol respectively. More so, details on medication use including insulin, metformin, as well as lipid-lowering drugs among others are incorporated. These variables are expected to be used for analyzing the associations between them and the development of diabetic nephropathy, the results of which are planned to be used for developing better predictors of the disease and increasing the general knowledge on the subject.

B. Data Pre-processing

1) Handling missing values: It is essential to manage the cases of missing values because, for example, they affect the accuracy of a machine learning model, as well as the results of making predictions. It is recommended to impute the missing values with the median or mode of the particular columns for numerical variables since median imputation is less influenced by outliers than the mean imputation. For categorical features it is optimal to use simple form of imputation for the missing data, which is to replace it with the most frequently used category. This approach ensures that the employed dataset is also strong and minimizes the chances of a mistake being made on the

model. Feature selection was performed using correlation analysis and domain knowledge to identify the most relevant clinical variables, discarding those that were redundant or had low significance for DN.

2) Normalization: Most preprocessing acts like standardization on the input variables are significant for models like Autoencoder and LSTMs as they are dramatically affected by the scale of input variables needed. This process helps to make all features at a similar scale to make better and more accurate models and avoid instabilities in the model. Min-Max Scaling standardizes the features to a range of 0 to 1, which is a good practice in terms of equal scaling of features and can contribute to the enhancement of the model's performance and convergence. The formula for Min-Max Scaling is

$$Y_{Scaled} = \frac{Y - Y_{min}}{Y_{max} - Y_{min}} \quad (1)$$

Where Y is the original feature value, Y_{min} is the minimum value of the feature, and Y_{max} is the maximum value. This normalization ensures that all features contribute equally to the model, which is crucial for algorithms sensitive to feature scaling.

3) Correlation analysis for feature selection: Begin by examining the correlation between each feature and the target variable, which in this case is diabetic nephropathy. This analysis helps in identifying features that have a strong relationship with the target variable. Features that exhibit high correlation with the target are likely to provide significant predictive value. For example, if one use correlation coefficients or statistical tests to quantify these relationships. Features with low or negligible correlations can be discarded to simplify the model and improve its interpretability.

C. Integration of Hybrid AE-LSTM Model for the Detection of Diabetic Nephropathy

A multilayer neural network called an auto encoder produces desirable outputs that are similar to inputs with less modification—that is, results that are similar to inputs that have some reconstruction error [18]. Generally, autoencoder is applied in dimensionality reduction since it provide efficient dimensionality reduction in cases of large and more specifically medical data sets due to its high dimensionality reduction rate yet efficiency in preserving important features of the data. In contrast to model like PCA it is capable of learning local non-linear manifold structure of data and thus is more appropriate for high dimensional clinical records. Further, it aids in the reduction of noise to ensure the model concentration on the most important characteristic which is important for tasks such as DN development prediction. It is the same case with autoencoder as they also function in an unsupervised way, which can be useful when processing big data with little or no labels at all. The auto encoder encrypts the input and then utilizes unsupervised learning to reconstruct or decode the output.

The encoder, reconstruction loss, bottleneck, and decoder are the four main parts of a generic auto encoder. The encoder helps to remove characteristics from the input by shrinking the data into an encoded form. The bottleneck layer is the layer that has the fewest characteristics and compressed incoming data. The decoder makes sure that the input and output are the same by helping the model to rebuild the result from the encoded representation. The last metric used to evaluate the decoder's performance and determine how closely the output resembles the original input is Reconstruction Loss.

Additionally, training is done using back propagation, which further minimizes reconstruction loss. This minimum loss serves as an example of the goal that AE aspires to accomplish. The input y that the encoder will compress Eq. (2).

$$y = E(x) \quad (2)$$

Decoder will make an effort to replicate the input. D as x' = D (E (x)).

$$loss(E, D) = \frac{1}{n}\sum_{j=1}^{n} x^i - D(E(x^i)))^2 \quad (3)$$

In this instance, the reconstruction loss equals the difference between the encoded and decoded vectors. The MSE is one method for calculating the reconstruction loss. It is stated in the above-mentioned Eq. (3). The hybrid AE-LSTM's architectural diagram is shown in Fig. 2.

LSTM was created using sophisticated recurrent neurons. In an LSTM, every recurrent neuron may be thought of as a single cell state [19]. For the temporal analysis, the study use LSTM since it is capable of processing sequential data and it can capture long term dependencies, this is because tracking the health status of the patients require tracking their status over a period of time. The LSTMs are built in a way that they do not suffer from vanishing gradient problem and this makes the model to retain information from the previous time step, which is extremely important when predicting medical conditions. For hyper-parameters, learning rate, batch size and number of hidden units were appropriately selected from cross-validation in order to achieve high learning rate but low over-fitting. These choices were further optimized to make sure that the model does well as far as the training data is concerned as well as the unseen data. An LSTM determines its current state by using its data from the previous state, much like a conventional RNN does. The LSTM uses three gates to control the current neuron: the forget gate, update gate, and output gate.

A LSTM can connect current data with historical knowledge. An LSTM is coupled to three gates: an output gate, an input gate, and a forget-about gate. The new and last states are represented by the symbolsQ_t andQ_{t-1}, respectively for the input, and p_t and p_{t-1} for the existing and prior outputs.

Eq. (4), Eq. (5) and Eq. (6) explain the LSTM input gate idea.

$$j_t = \sigma(\mathrm{Z}_j \cdot [z_{t-1}, y_t] + b_j) \quad (4)$$

$$\tilde{Q}_t = \tanh(Z_j \cdot [p_{t-1}, \mathrm{p}_t] + \mathrm{b}_j) \quad (5)$$

$$\mathrm{Q}_t = f_t \mathrm{Q}_{t-1} + j_t \tilde{Q}_t \quad (6)$$

To decide which of the data points y_t and p_{t-1} should be added, where Eq. (4) use a sigmoid layer to filter them. Combining the long-term storage data,$\tilde{Q}_t$ with the present moment informationQ_{t-1}, results in Eq. (6). $\tilde{Q}_t$ Displays a tanz

output, whereas $Z_j$indicates a sigmoid results. The bias of the LSTM input gate is denoted by $b_j$in this instance, while Z_j denotes the weight matrices. Consequently, because of the LSTM's forget gate, the dot product and sigmoid layer may pass information selectively. A certain probability is used to decide whether to delete relevant data from a previous cell.

Use Eq. (7) to determine whether to preserve relevant data from an earlier cell with a particular option. Z_f Represents the weighted matrix b_f the offset, and σ the sigmoid term.

$$f_t = \sigma\left(Z_f \cdot [c_{t-1}, y_t] + b_f\right) \quad (7)$$

The states needed for the following equations are determined by the output gate of the LSTM Eq. (8) and Eq. (9) states provided by the inputs y_t and p_{t-1} .After the final output is produced, it is multiplied by the state decision vectors Q_t that transmit new data via the tanz layer.

$$R_t = \sigma(Z_o \cdot [P_{t-1}, y_t] + b_o) \quad (8)$$

$$p_t = R_t \tanz(Q_t) \quad (9)$$

When using the Autoencoder-LSTM, the transition from the Autoencoder to LSTM is carried out systematically with regards to features and sequence. First, the bottleneck layer of the autoencoder, which contains the compressed and the higher level features of the input is used as input to the LSTM network. This transfer of feature favours LSTM to process data that has undergoes post processing hence removing noise and unnecessary details. Since these are the features passed to the LSTM network, the LSTM makes its computations in a sequential manner which is vital in the learning of temporal characteristics and structures that are useful in diagnosing Diabetic Nephropathy (DN). The last state of the LSTM network is used for the purpose of predicting the probability of DN or for distinguishing between the patients who have DN and those who do not have DN based on temporal pattern learning integrated into the model from the sequences.

The integration of the hybrid model has the following advantages. Thus, by reducing the dimensionality of input data, the first stage of the autoencoder employs a K value to facilitate the LSTM's identification of relevant patterns to the task. This organizational improvement make the model lighter and thus enhances its functionality. Second, the temporal features as processed by the LSTM show important sequential characteristics that can indicate early signs of DN that are not observed by simpler models, allowing for a better understanding of the diseases' evolution.

Optimizations of the autoencoder and LSTM network is done during the training phase so as to get the best performance. In the autoencoder, mean squared error (MSE) loss function is used to minimize the errors in data reconstruction; this way, only the noise is eliminated, and important details are preserved. With relation to the LSTM network, the selection of the loss function is contingent upon the nature of the classification; in cases where the classification is categorically classified as several classes, as opposed to binary cross entropy, which is utilized in cases where the classification is either true or false, the binary cross entropy loss function is employed. For optimizing weights in the model and to make enhancements, specialized algorithms like Adam is used. The training process takes several epochs; the used number of epochs and the batch size is defined depending on the data volume and available computational power. Syllable stress and domains' size tuning makes sure that the model properly learns and functions well in regard to new data.

This detailed approach will assist in established structure to enhance the Autoencoder-LSTM model, by having dimensionality reduction then LSTM in achieving accurate Diabetic Nephropathy prediction. Fig. 2 illustrates the architecture of proposed hybrid AE-LSTM is given below.

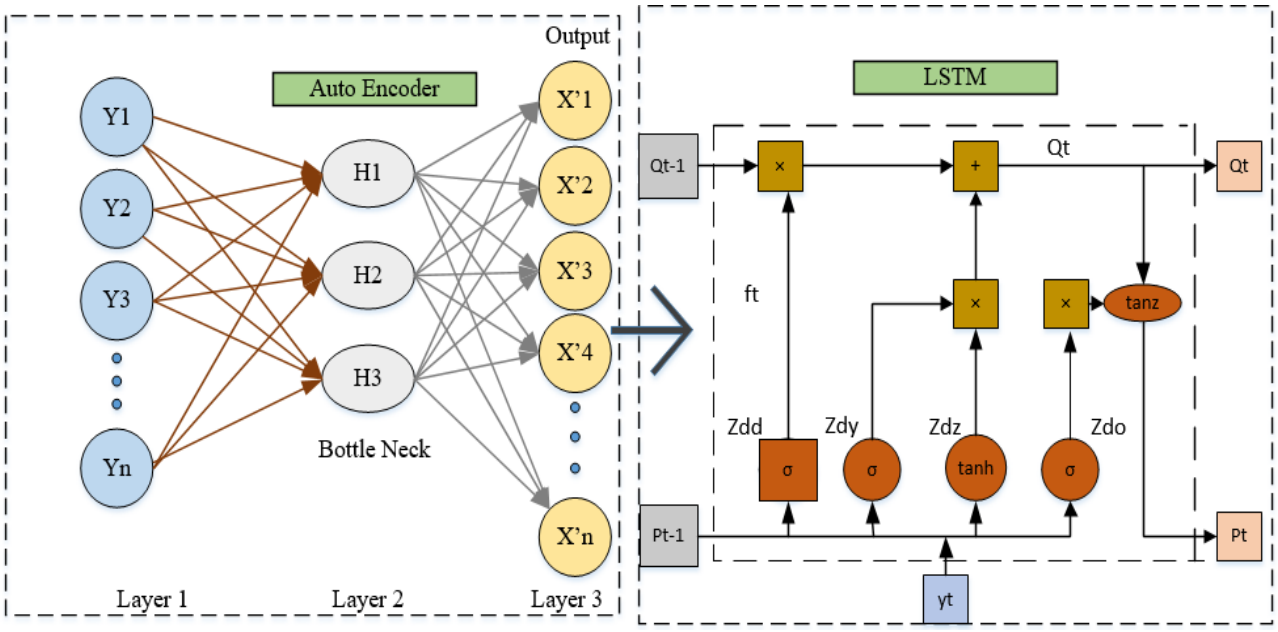

Fig. 2. Hybrid AE-LSTM architecture.

V. Results and Discussion

The results section of the study, the authors provided distilled information about the results from the predictive modeling and disease detection study using the proposed Hybrid Autoencoder-LSTM model. The accuracy of the presented model was compared to several simple and complex models based on the sub belongs and more traditional machine learning as well as deep learning techniques. The performance evaluation was based on the model's metrics as the model successfully predicted the occurrence of DN. The methodology employed data from clinical records and qualified the model implementation and analysis on a Windows 10 environment using python programming language. In line with such findings, the model excels in the identification of the DN onset; this is due to the utilization of the autoencoder dimensionality reduction and the LSTM network with the capability of recognizing temporal patterns. The following variables were used in a measure of the efficiency and predictive capability of the specified model.

A. Auto Encoder's Reconstruction Loss

Reconstruction Loss is one of the ways of evaluating a model particularly an autoencoder to whether compress the data and then decompress it to get the preservation quality. It measures the degree of distortion of output signal in comparison with the input signal end product. It is then computed by comparing the two, sometimes via calculating MSE or Binary Cross-Entropy, etc. Hence, reconstruction loss defines how much information has been lost during the encoding and decoding process, and lower value of it would mean better reconstructions and therefore a better performance of the model in terms of preserving important features of the input data. Eq. (10) expressed it.

$$\text{Reconstruction Loss} = \frac{1}{N}\sum_{i=1}^{N}(x_i - \hat{x_i})^2 \qquad (10)$$

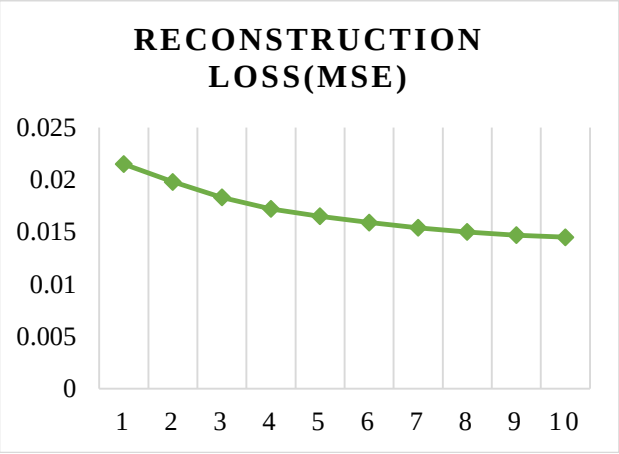

Fig. 3. Reconstruction loss of the proposed AE-LSTM approach.

The Fig. 3 will indicate the reconstruction loss in the Autoencoder, which should decrease over time, thus demonstrating the Auto encoder's ability to learn how to encode and decode the data. The gradual reduction in MSE shows that the present Autoencoder component continues to reduce the dimensionality of the data and retain crucial characteristics efficiently.

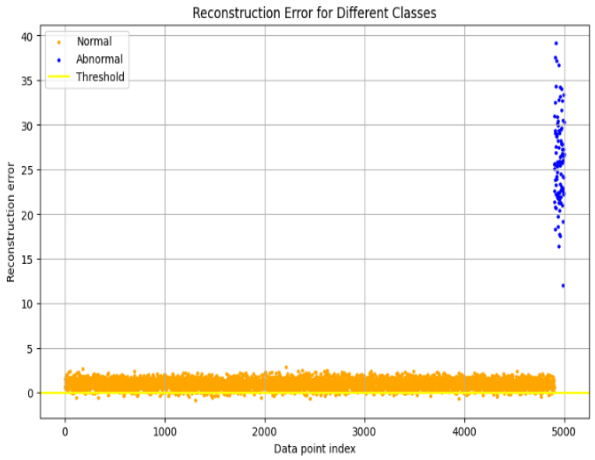

Fig. 4. Reconstruction error for different classes.

Fig. 4 shows the reconstruction errors for normal and abnormal classes, with normal data points clustered around a value of 1 and abnormal points centered around 25. The threshold line, set at 0, visually separates the error ranges for both classes. Fig. 5 shows the histogram of reconstruction error is given below.

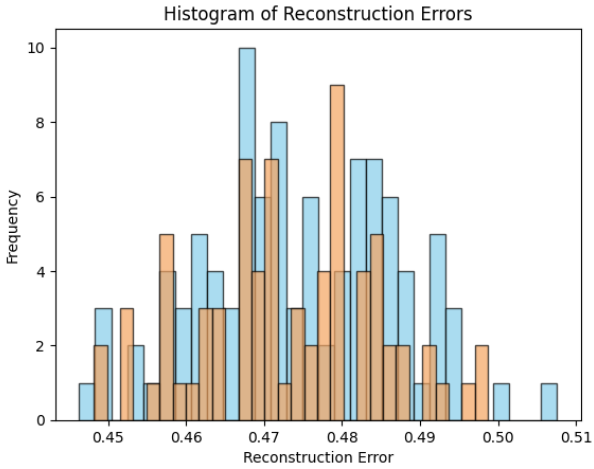

Fig. 5. Histogram of reconstruction error.

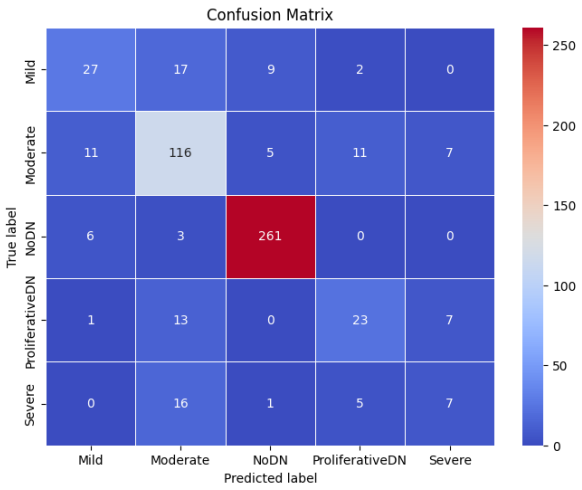

Fig. 6. Confusion matrix.

Fig. 6 shows a heat map of the confusion matrix, displaying the performance of a classification model across five categories: It includes Mild, Moderate, No DN, Proliferative DN and Severe. The diagonal values are the correctly predicted patterns giving high accuracy for some of the top categories such as "No DN" (261 instances correctly classified). Other discrepancies such as the 17 Mild examples classified as Moderate as well as the 16 Severe specimens also classified as Moderate can also be observed from off- diagonal values. Different colors define importance of the data and stress on the distribution of errors and correct predictions.

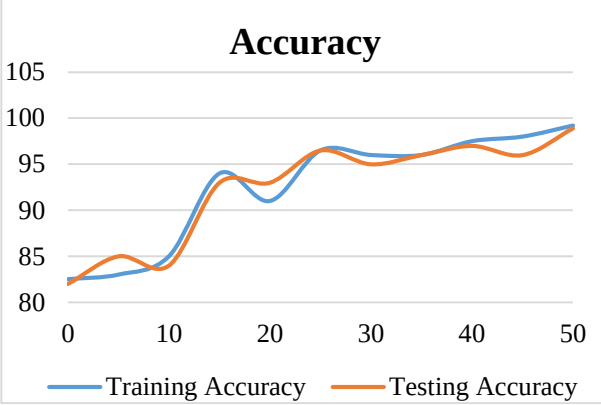

Fig. 7. Training and testing accuracy of the proposed AE-LSTM approach.

Fig. 7 shows that the performance metrics indicating the increase in model's ability to identify relevant patterns for DN detection have escalated exponentially. Thus, it is not surprising that the accuracy recorded during this study was a phenomenal 99.2%% shows that the model is very well trained and is in condition to be able to make sound predictions with the help of encoded features and temporal data. The training accuracy graph shows them gradually rising up to a certain point proving that the model gains better and better understanding of the training data set during the training process. The testing accuracy curve is also smooth and similar to the training accuracy which might depict a good generalization of the model with unseen data. Hence the little difference between the training and testing accuracy shows that the model performed very well by reducing the risk of over fitting as well as improving the robustness of the model.

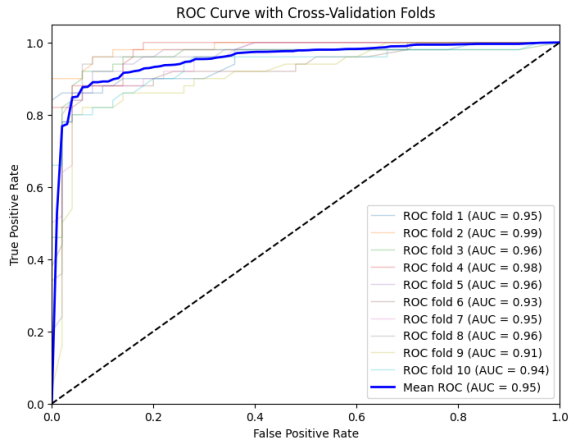

Fig. 8. ROC of the proposed approach.

Fig. 8 shows the ROC curve for the proposed AE-LSTM approach, illustrating how well the model distinguishes between positive and negative cases. The high AUC suggests that the AE-LSTM approach is effective in correctly classifying the data, making it a reliable method for early detection and diagnosis. The results demonstrate that using autoencoder for feature extraction combined with LSTM for classification is a successful strategy in this study.

B. Performance Metrics

1) Accuracy: A method's accuracy is measured by the proportion of test cases it can identify correctly on a certain test set. It is computed as follows in Eq. (11)

$$Accuracy = \frac{RN+RP}{RP+AP+RN+AN} \quad (11)$$

2) Precision: Precision is the ratio of all positively recognized cases to the total number of properly identified positive occurrences by the model. It is quantified in Eqn. (12) is as follows.

$$Precision = \frac{True\ Positives}{(True\ Positives+False\ Positives)} \quad (12)$$

3) Recall: Recall is the idea of the positive cases that the framework correctly detects. It is calculated as follows in Eq. (13).

$$Recall(sensitivity) = \frac{True\ Positives}{True\ Positives+False\ Negatives} \quad (13)$$

4) F1-Score: When there is a large difference in the number of students in one class compared to the other, the F1 score might be helpful. To access the F1 score is apply the Eq. (14) as follows.

$$F1\ Score = 2 \times \frac{(Precision*Recall)}{(Precision+Recall)} \quad (14)$$

When assessing someone, one should consider their F1 score as it provides a useful and unbiased means of gauging recall and accuracy.

C. Consideration with Other ML Approaches

Table I concern the relative comparison of the overall effectiveness of the considered classification algorithms. It can also be seen that, the proposed AE+LSTM method has the maximum accuracy of 99%. 2%, and the EWs are 98. 75%, 98. 92%, with an excellent SW of 98. 79%. These results indicate that the AE+LSTM is not only able to pinpoint the true positive instances but it also keeps a good harmony between Precision and Recall. On the other hand, the Accuracy index of the SVM is fairly impressive recording a 98. Achieves a 96% level of accuracy, solid values for the precision and recall rates, however has a slightly lower F1-score. The same can be said about the Multivariate Logistic Regression method, which also yields the 0.95 of accuracy, but does not rank as high as the AE+LSTM. RF method also behaves well, but has the lowest performance indicators with accuracy equal to 85%, and less TS, PR, and F1-MACV. Thus, it is established that the AE+LSTM approach performs better as compared to the other methods studied for the classification of the data, especially with reference to precision and recall, which are quite

significant signs of how effectively the model is useful for a wide range of data patterns. It is illustrated in Fig. 9. The proposed Hybrid Autoencoder-LSTM model significantly improves early DN detection by enhancing feature extraction and temporal pattern learning. Its ability to reduce dimensionality while maintaining critical diagnostic information ensures higher accuracy than traditional methods. This advancement enables timely medical intervention, improving patient outcomes. The study highlights AI's potential in transforming predictive healthcare with scalable and reliable diagnostic models.

TABLE I. EXISTING METHODS AND SUGGESTED METHOD COMPARISON

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1Score (%)
RF[20]	85	81.60	82.24	81.42
SVM[21]	98.96	91.78	94.08	90.21
Multivariate Logistic Regression[22]	95	92.78	90.82	90.21
Proposed AE+LSTM	99.2	98.75	98.92	98.79

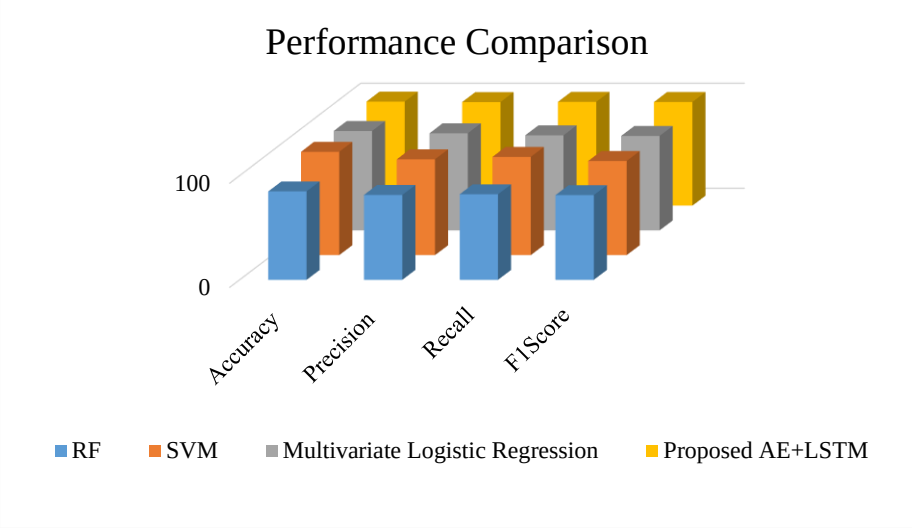

Fig. 9. The performance evaluations of AE+LSTM with conventional approaches.

D. Discussion

The findings showed that one of the better ways of early prediction of DN has been established to be the Hybrid Autoencoder-LSTM model given its efficiency in handling the otherwise elaborate medical diagnoses. Autoencoder whose function here is to decrease the dimensionality of the image data leaving vital features intact and removing background noise; this improves LSTM's ability to learn and identify temporal features essential for DN diagnosis. The LSTM's sequences and the capability to store information from the previous states also enables it to follow the advancement of DN in time. Compared to other classical machine learning systems like RF[20], support vector machines[21], and logistic regression[22], this hybrid model has better result. This benefit derived from Autoencoder dimensionality reduction becomes very useful in helping LSTM isolate on the most significant features, thus lowering the levels of computationally intensity and enhancing model analyzability. The reduction in reconstruction loss over time reflects the autoencoder' s capability to efficiently compress and reconstruct the data while preserving important features. This capability is crucial for enhancing the LSTM's performance by focusing on relevant temporal patterns without being overwhelmed by irrelevant data. The successful reduction in reconstruction errors, particularly the distinction between normal and abnormal classes, further validates the effectiveness of the autoencoder in filtering out noise and emphasizing critical features. Such findings imply that deep learning architectures are more valuable for the intricate medical diagnosis. In a clinical sense, the predictability of DN would definitely alter decisions that are made on a patient as this would enable the clinicians to prevent or at least delay the occurrence of the disease since there would be time to plan on how to handle the situation. Since the proposed model has achieved good values for precision and recall, it means that the identified patients might indeed be at high risk of developing DN, and therefore, timely intervention might help improve the patient's condition. The Hybrid Autoencoder-LSTM performs efficiently in facilitating early Diabetic Nephropathy (DN) prediction through dimensionality reduction and temporal pattern discovery. Autoencoder removes noise and retains core features, improving LSTM's potential for DN progress tracking. Its accuracy is superior compared to RF, SVM, and Logistic Regression with reduced complexity. The decrement in reconstruction loss reflects its optimization in feature extraction, which makes it perform classifying tasks with better efficiency. High recall and precision values validate its feasibility for actual clinical use, allowing for prompt interventions to enhance patient outcomes.

VI. CONCLUSION AND FUTURE SCOPE

In conclusion the findings and analysis of the Autoencoder-LSTM model for the identification of DN in the early stages have shown the prospect of strengthening diagnostic performance. It is suggested that integration of an autoencoder with an LSTM network reduces the dimensionality and contains profitable sequential pattern understanding for the later

component in improving the identification of early signs of DN. The study's results underscore the model's potential for early detection of DN, which could lead to improved patient outcomes through timely medical intervention. Despite these achievements, future work should focus on several key areas to further enhance the model's applicability and performance. This includes validating the AE-LSTM model on diverse datasets to ensure generalizability across different populations, exploring additional feature extraction techniques to improve model robustness, and investigating the integration of the model into clinical decision-support systems for real-time applications. It is suggested that in future studies, the sample ought to be diverse, and the data collected should be followed up over time to see how to improve on the given model. Further, it may be beneficial to experiment with state of the art methods like incorporating attention mechanism, or integrating hybrid model with other modalities of data like genomics or Imaging data to enhance the diagnostic accuracy for early detection. Practical emphasis and the integration of technological innovations into clinical practices will also play an important role in converting these progressive changes into valuable outcomes for patient and stakeholders' experiences.

***Abstract*—With the continuously increasing demand for new technologies, many concepts have emerged in recent decades and the Internet of Things is one of the most popular. IoT is revolutionizing several aspects of human life with a large range of applications including the transportation sector. Based on IoT technologies and Artificial Intelligence, new-generation vehicles are being developed with autonomous or self-driving capabilities to handle transportation in future smart cities. Regarding human-based errors such as accidents, traffic congestion, and disruptions, autonomous vehicles are presented as an alternative solution to increase traffic safety, efficiency, and mobility. However, by transferring from a human-based to a computer-based driving style, the transportation area is inheriting existing cyber-security challenges. Due to their connectivity and data-driven decision-making, the security of autonomous vehicles is a high-level concern since it involves human safety in addition to economic losses. In this paper, a comprehensive review is conducted to discuss the security threats and existing solutions for autonomous vehicles. In addition to that, the open security challenges are discussed for further investigations toward trusted and widespread deployment of autonomous vehicles.**

Keywords*—Internet of Things; smart transportation; autonomous vehicles; cybersecurity

I. Introduction

Ashton, in 1999, introduced the idea of connecting Radio Frequency Identification (RFID) Tags to the Internet which enabled the interconnection of conventional objects to handle autonomous tasks, and therefore, led to the new concept of the Internet of Things (IoT) [1]. With the help of IoT technologies, the transportation area is having a significant evolution from conventional mechanical vehicles to next-generation smart vehicles capable of collecting environmental data, process and communicating them, to make intelligent driving decisions without human assistance [2], [3]. Due to this new orientation toward intelligent transportation systems (ITS), the transport sector has become attractive for various interdisciplinary researchers and industries to work in the industrialization and deployment processes of autonomous vehicles (AV).

An AV is a computer on wheels that is equipped with a multitude of software and electronic components (such as sensors, processing units, and transmission modules), and capable of performing driving tasks on its own. In 2021, the Society of Automotive Engineers (SAE) provided an official updated reference which describes the evolution of vehicles in five automation levels, known as Level 1: driver-assistance; Level 2: partial-automation; Level 3: conditional-automation; Level 4: high-automation; and Level 5: full-automation [4]. In level 1, the human driver has full control over the vehicle's driving mode, but some computing systems are embedded to assist the driver in monitoring the environment (e.g. measuring of distance between vehicles to produce collision alerts, over-speeding alerts, …). In level 2, the human driver has partial control over the vehicle's driving mode, where some vehicular functions are controlled by automated systems (e.g. executing steering and acceleration functions). In level 3, most of the vehicle's driving functions are automated to enable a self-driving mode, but the human driver must necessarily respond to feature requests and take driving control in some situations. In level 4, the vehicle is highly automated and capable of handling driving functions without requiring much intervention from the human driver. In level 5, the human driver has no control over the vehicle's driving mode, and all the driving functions are performed by computing systems in all situations.

The main objective of introducing AVs is to avoid human-based errors that are mostly the cause of traffic issues like accidents, and therefore, to increase traffic safety, mobility, and efficiency [5], [6]. However, the transfer of the driving mode from human hands to computer systems also exposes vehicles to existing cybersecurity challenges, where attackers can gain access to AVs and control them for malicious ends making it urgent to consider their security at a high level for trustworthy developments and deployments. In this paper, a comprehensive review is conducted to give a state of the art of vehicular security, which provides the following key contributions:

- First, it describes the architecture of AVs, highlighting the role of different components, their security and privacy requirements, and the threats and vulnerabilities that can affect their normal operations.
- Second, it explores the literature to identify the reported attack methods against AV components as well as existing solutions that can be used to mitigate attacks.
- Third, it discusses the existing countermeasures to highlight their advantages and limitations, points out open challenges then proposes research directions for further investigations.

In the rest of this paper, Section II provides an overview of the architecture of AVs. The literature review is reported in Section III. Section IV discusses the existing security methods

for AVs. Section V proposes new research directions that can be considered to provide efficient security methods for AVs. The paper is concluded in Section VI.

II. Architecture of Autonomous Vehicle: Overview

The internal components of AVs can be classified into three main layers including the input layer, processing and control layer, and communication layer as depicted in Fig. 1. The input components collect data from the environment which are used by processing components to make decisions for controlling the vehicular functions. The communication components serve as interfaces allowing the interaction between different internal components and also between the vehicle and external entities such as other vehicles, personal devices, and infrastructures.

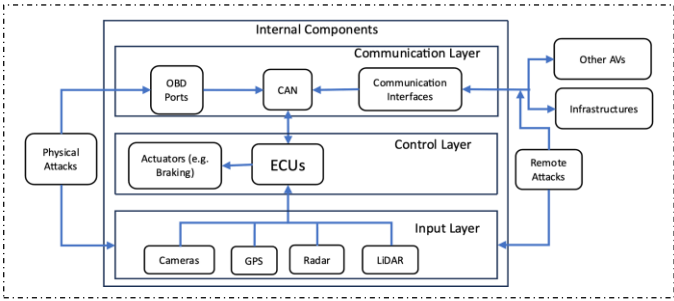

Fig. 1. Components of autonomous vehicles.

A. The Input Layer

AVs are equipped with a large number of sensors to collect specific data from the environment serving as input for control units [7]. Some commonly used sensors are Cameras, "Light Detection and Ranging (LiDAR), Global Positioning System (GPS), Radio Detection and Ranging (Radar), Ultrasonic", etc.

LiDAR sensors are used to detect surrounding objects by sending light waves and calculating the distance based on reflected signals [8]. In the same logic, Radar sensors measure the distance and speed of objects by sending electromagnetic waves in the radio domain and sense the reflected signals. Used for obstacle detection, the Radar works better in bad weather compared to the LiDAR and both are most used for long-range detection whereas ultrasonic sensors are preferable for short-range measurements based on sound waves. No matter the performance of obstacle detection sensors, they cannot identify the colour of a traffic light. Therefore, image sensors (cameras) are used to provide vision capability to the AV and identify different entities in the environment. GPS sensors operate by receiving radio signals from three or more satellites to determine the geographical location [9]. Therefore, GPS sensors are necessary for AVs to localize them and find routes between different locations. These sensors are useful in many applications and serve in AVs to observe the environment and make intelligent decisions to control the vehicle for safe driving and efficient navigation as illustrated in Fig. 2.

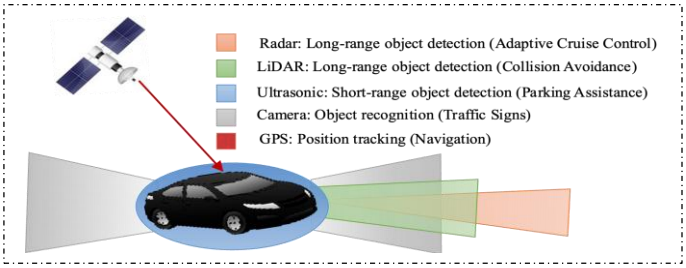

Fig. 2. Use of sensors in AVs.

B. The Control Layer

Electronic Control Units (ECU) represent the brain of AVs. ECUs are embedded systems that receive input signals from other components mainly sensors, process them, and decide the behaviour of vehicular functions [10]. As illustrated in Fig. 3, several types of ECU are used in AVs to perform specific tasks ensuring that vehicular functionalities are well-controlled and operational [11]. These include engine control, speed control, body control, tire-pressure monitoring, transmission modules also called telematics ECUs, and other internal measurement systems [12]. The ECUs can work together or independently based on the required action to take. For example, after detecting a pedestrian or other obstacles, the braking and speed control systems can collaborate to avoid collisions.

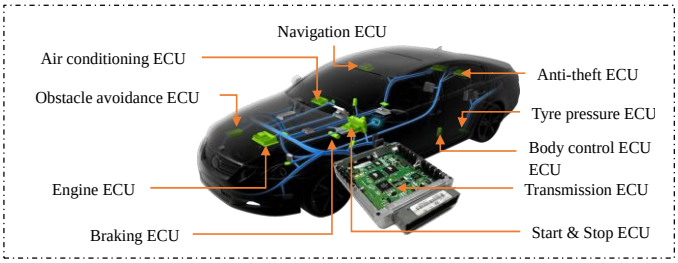

Fig. 3. Embedded ECUs in AV.

C. The Communication Layer

The internal components of AVs such as sensors, ECUs, and actuators, are interconnected through the in-vehicle network also known as "Controller Area Network (CAN)", where they exchange data to perform tasks together [7]. Short-range technologies are mostly privileged for in-vehicle communications to establish wireless connections between sensors and ECUs to reduce complex wiring. Also, external devices can be physically connected to the vehicle through onboard diagnostic (OBD) ports to access the CAN data for diagnostics on components or firmware updates [13]. The OBD ports can be found in any modern vehicle including existing AVs and are commonly used to access and update embedded software in the vehicle's control units.

For external communications, multiple AVs can form a network following the paradigm of vehicular ad-hoc networks (VANET) [14], where each AV can communicate with others and with surrounding communications infrastructures such as roadside units (RSU) as illustrated in Fig. 4.

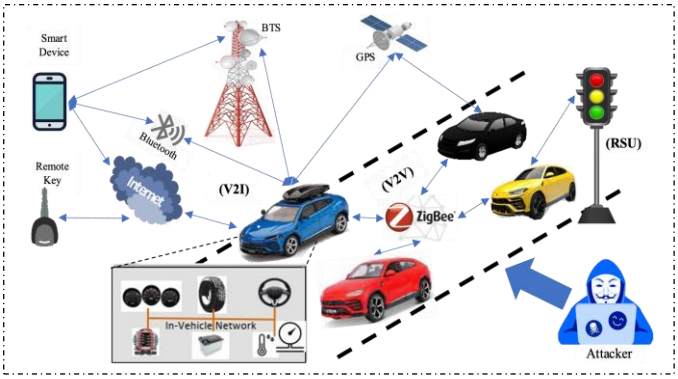

Fig. 4. Network of autonomous vehicles.

Typically, VANETs achieve four main types of communication listed as follows:

- Vehicle-to-Vehicle (V2V) communication: This allows vehicles to share traffic safety information and their status information like speed, position, and direction, to maintain good and safe driving conditions [15].
- Vehicle-to-Infrastructure (V2I) communication: This allows vehicles to interact with RSUs (V2R) for traffic safety information such as accidents, congestion alerts, and various warning messages. In this phase, vehicles can also communicate with other infrastructures such as satellite and Cellular for receiving their navigation-related data and other remote communications [16].
- RSU to RSU (R2R) communication: This allows nearby RSUs to interact and share network status information.
- Vehicle to Everything (V2X) communication: The V2X represents all the vehicular interactions with a large range of communication entities, such as smart devices, smart homes, pedestrians, clouds, computers, cellular networks, etc. [17]. This also includes V2V and V2I.

The vehicular interactions use different types of wireless communications protocols including short-range technologies (e.g. ZigBee, Bluetooth, and ultra-wideband (UWB)); medium-range technologies (e.g. Wi-Fi and "dedicated short-range communication (DSRC)"); and long-range technologies (e.g. Cellular Communications) [18]. The DSRC also known as "Wireless Access in Vehicular Environments (WAVE)" is adopted for V2V and V2R communications whereas cellular technologies are preferable for other V2I communications [19]. In addition to that, the AV uses the WIFI interface to interact with cloud and mobile applications for remote control [20].

D. Security and Privacy Requirements for AVs

The input, processing, and communication layers work together to create a well-functioning driving capability for AVs and their communication environments [21], but compromising any layer can destabilize the vehicle leading to harmful damage with direct consequences on human safety and economy [22]. Therefore, the security of AVs is a high priority and should cover all their internal and external interaction aspects. Some common security requirements are given as follows:

1) Availability: The internal components of AVs must remain accessible for collecting, processing, or transmitting data to ensure continuous operability. Also, the vehicular networks must stay available for receiving and sending safety-related information even during critical conditions such as high mobility. Therefore, AVs must be secured against attacks that can result in availability issues.

2) Authentication: This is a primary security measure where each node must be able to identify the source node that has sent a given message before going through further interactions. Therefore, vehicular networks must be secured against intrusions of malicious nodes to prevent attacks. For the sake of real-time requirements, rapid authentication methods are preferable to minimize communication delays.

3) Confidentiality and integrity: The exchanged messages between different nodes must only be accessible by the authorized members and each node must be able to verify that the received message was not modified or altered during transmission. The cryptographic algorithms are commonly used to achieve confidentiality and integrity requirements, but again, rapid encryption methods are necessary for vehicular applications to avoid added communication delay.

4) Privacy and anonymity: As a large amount of data is collected by AVs, processed, or transmitted over the network, the private information of users must not be exposed to unauthorized parties. This requires strict protection of identification information against potential privacy leakages.

5) Monitoring: In presence of multiple attacks, vehicular networks must be controlled to identify malicious nodes and actively remove them from vehicular communications through an appropriate authority. Therefore, real-time monitoring methods are required to efficiently prevent potential attacks.

E. Security and Privacy Threats Against AVs

Depending on the attack opportunity, attackers can reach AV components using remote interfaces or through physical access [23]. In the remote attack, any component capable of interacting with the surroundings can be vulnerable where an attacker can perform different types of attack aiming to steal information, to control a vehicular function, or to interrupt an operation [9]. In the physical access attack, the attacker can inject malicious codes into the vehicle's system using the onboard ports, physically damage a component, or insert an additional fake component to transmit wrong data into the vehicle's system [24], [25]. Some common attack vectors on AV components and communications are given as follows:

1) Sensor spoofing: The attacker manipulates and generates fake signals stronger enough to force sensors to detect and transmit wrong data [26]. This attack aims to control the decision-making of a targeted ECU which will receive the collected data and make wrong decisions. For example, if the GPS sensor detects stronger signals from the attacker, the navigation ECU of the vehicle can decide to

follow a different trajectory which is intended by the attacker as illustrated in Fig. 5.

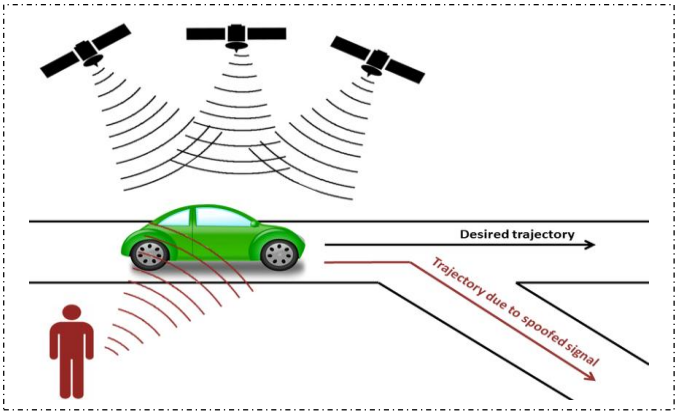

Fig. 5. Illustration of AV's GPS spoofing attacks [27].

2) Sensor jamming: It consists of blocking the sensor's perception by sending noise signals to interfere with normal signals [28]. This attack can interrupt operations of an ECU that depends on data from the targeted sensor. For example, if obstacle detection sensors are not able to collect data, the speed control ECU can decide emergency braking which can lead to accidents and traffic congestion as illustrated in Fig. 6.

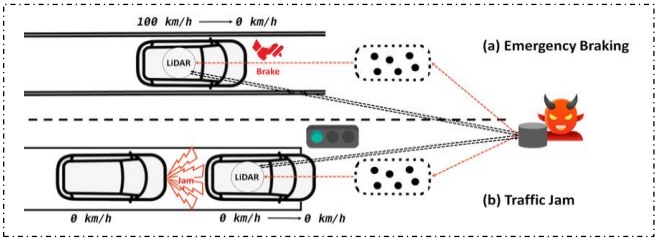

Fig. 6. Illustration of AV's sensor jamming attacks [29].

3) Blinding and adversarial images: The attacker can use strong light beams to blind or confuse the perception of the targeted camera [22]. Adversarial images generally target the machine learning models that are used for image recognition, where attackers manipulate images with adversarial samples that appear to be normal to human eyes but can cause huge confusion to the model producing incorrect outputs [30]. For example, if the attacker manipulates a stop road sign, the vehicle can misinterpret the captured image as a speed limitation and therefore speed up instead of slowing down, which can lead to harmful accidents as illustrated in Fig. 7.

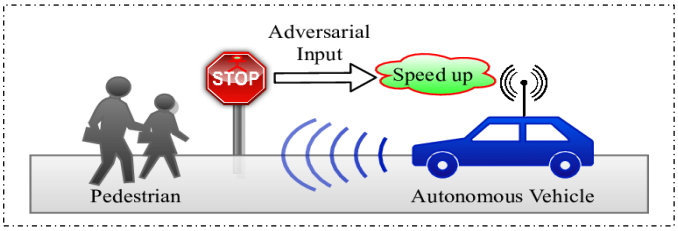

Fig. 7. Illustration of AV's camera attacks [31].

4) Malware and message injection: The attacker runs malicious code in the AV's system using the OBD ports, by flashing into its memory or through the process of firmware updates [32]. Also, the attacker can inject fake information through vehicular communications and force vehicles to take action on wrong data performing the intended activities [33]. These attacks aim to execute a specific task in a targeted ECU or interrupt its normal functionality as illustrated in Fig. 8.

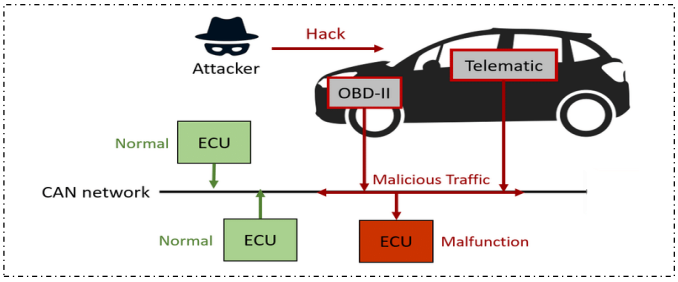

Fig. 8. CAN network attacks [34].

5) OBD Attack: Historically, dedicated handheld tools are used to scan information through OBD ports but most modern OBD devices such as Telia Sense [35] and AutoPi [36], allow connection with personal computers and smartphones for self-diagnostics purposes. As shown in Fig. 9, an attacker can use a compromised OBD device to access the vehicle's system which can allow executing a malicious program in targeted ECUs to control the vehicular functions.

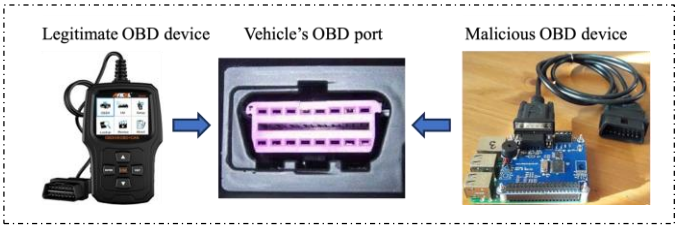

Fig. 9. OBD attacks.

6) DoS (Denial of Service) and DDoS (Distributed DoS): This attack aims to create unavailability of a service. It can target protocols and networks by sending excessive bad traffic packets to disrupt communications [37]. This attack can isolate a targeted vehicle from communicating with others or block the entire vehicular network leading to unwanted traffic conditions. The DoS and DDoS attacks can target AVs in both the internal and external communication aspects.

7) Eavesdropping: The attacker can intercept the exchanged information between different entities and secretly analyse or modify them to serve a malicious goal [37], [38]. The Man in The Middle attack is a typical example where the attacker modifies data between different entities and lets them believe that they are communicating with each other. This attack aims to access private information or to gain control over the vehicle's behaviour.

8) Message replay: The attacker can retransmit the past traffic status information in the vehicular network to mislead vehicles into believing that the action is currently happening

[28]. This attack can create traffic disorder and allow attackers to attempt their goal causing accidents or congestions.

9) Black hole: The attacker can manipulate the network informing other nodes that the malicious node has the shortest path to their destination [39]. After receiving packets, the malicious node will drop all of them to cause data loss blocking other nodes from receiving safety information. This attack can disrupt vehicular communications with the illusion of a normal driving environment.

10) Sybil: This attack consists of creating multiple fake identities in the network known as Sybil nodes which are used to transmit fake information to other nodes [28], and therefore, provoke the illusion of a busy network.

11) Physical damage: The attacker can target a specific component in the vehicle and destroy it [21]. This attack aims to interrupt the normal operations of the targeted component.

III. Literature Review

With the rapid development of connected and autonomous vehicles, several studies and hypothetical demonstrations in the literature have raised security weaknesses. In recent studies reported in [40] and [41], connected vehicles were targeted by more than 1300 reported cyberattacks from 2010 to 2023 and the analysis has shown that the attack frequency increased by 225% from 2018 to 2021, where 85% of attacks used remote interfaces and 54.1% were done by malicious actors leading to system control, vehicle theft, and unauthorized access to private data of users. This section exposes attack methods against AVs and the proposed countermeasures.

A. Sensors: Attacks and Defences

In general, sensors simply collect data and transmit them for further processing without authentication [21]. This fact makes sensors vulnerable to spoofing and jamming attacks.

1) LiDAR Sensors

Attacks: Authors in study [42] reported a successful jamming attack on a LiDAR sensor, the "ibeo LUX3 model", which consisted of sending higher intensity light to the LiDAR and blocking the acquisition of legitimate reflected light waves. Two variations of attack against LiDAR sensors were also demonstrated in study [43], where authors first showed the possibility of manipulating different LiDAR sensors of the same AV to perceive objects farther or closer than their real locations, by recording signals sent from one LiDAR sensor and then relaying those signals to the other LiDAR sensor. The second attack was to send fake signals to the targeted LiDAR sensor and make the vehicle believe that it was approaching a large obstacle. Authors in study [44] also performed this second attack on a LiDAR sensor, the "VLP-16 model", and explained that most LiDAR sensors are vulnerable to this attack especially those with large receiving angles.

Defences: Authors in study [45] proposed a new LiDAR scheme to detect jamming attacks based on random modulation of light waves. This modulation creates four polarization states (horizontal, vertical, diagonal, and anti-diagonal) for the photon and the jamming attack is detected based on a comparison of distances measured from the states. However, the authors acknowledged that their proposed scheme cannot filter jamming signals out of legitimate signals. Authors in study [46] proposed a method to detect fake input signals from LiDAR sensors by using the previous data frames to build a momentum model. However, building this model would require high computational power and time which is not adequate for real-time and resource-constraint applications such as AVs. The use of multiple LiDAR sensors was proposed in [44], to have overlapping views of the vehicle's surroundings or to reduce the signal-receiving angle for each sensor. This technique can reduce attack chances by preventing spoofing attacks on all the sensors at the same time, but requires a high number of LiDAR devices to cover all the vehicle's surroundings and therefore increases the cost. Authors in study [47] also proposed embedding identification data onto LiDAR's light waves by modulating them together, which allows sensor nodes to authenticate the received signals and therefore prevent LiDAR spoofing attacks. An experiment was conducted in [48], and the authors concluded that it becomes more difficult to succeed in LiDAR spoofing attacks when object detection is based on machine learning (ML) models. Authors in study [49], also confirmed the effectiveness of using ML models to detect LiDAR spoofing attacks. A LiDAR spoofing mitigation algorithm was proposed in [50] to detect adversarial objects and non-existing obstacle attacks where authors claimed correct attack detection based on simulation results.

2) Radar sensors

Attacks: A spoofing attack on a Radar device, the "Ettus Research USRP N210 model", was experimented with [51], by recording the broadcasted Radar signals to modify their phases and re-broadcast them to Radar sensors. This caused incorrect distance calculations and resulted in perceiving objects at a 15-meter distance while the real distance was 121 meters. Authors in study [52] demonstrated that it was possible to manipulate an object's velocity together with distance using spoofing attacks on FMCW Radar sensors, by designing an adversarial Radar to simulate two scenarios of attack provoking emergency braking and acceleration in a victim vehicle. Authors in [53] performed a similar attack on an FMCW Radar using a semi-passive modulated transponder and reported that it is possible to confuse a radar perception with ghost targets at different distances and velocities by simply changing the modulation frequency of the transponder without the need to use complex techniques. Also, authors in [54] demonstrated a jamming attack on Radar sensors for manned and unmanned aerial vehicles (UAV) where the attacker can modify the amplitude and the frequency of the recorded signals and then re-broadcast them to the Radar sensor to cause failure in object detection.

Defences: To mitigate spoofing and jamming attacks, a "physical challenge-response authentication (PyCRA)" was proposed in study [55], which sends random signals called challenging signals in the Radar sensing environment and detects fake signals based on a noise threshold. The PyCRA shuts down the sensing signals at random times, which was criticized to potentially affect AV safety-critical components by the authors in [56], who proposed an alternative method

called "Spacio-Temporal Challenge-Response (STCR)" and claimed to achieve better performance by transmitting challenging signals in random directions together with sensing signals instead of shutting them down. Once a malicious signal is detected, the reflected challenging signals are used to identify the attack directions and exclude them. Authors in [57] experimented with an unsupervised deep-learning method on Radar system data to detect manipulation attacks and found an accuracy of 88% detection rate. They defended that their technique could be used in AV's Radar systems to mitigate spoofing attacks, by learning the correlation between categorical and numerical features from Radar signals.

3) GPS Sensors

Attacks: The GPS spoofing attacks were analysed in study [58], where authors explained how it can be easy for an attacker to carry out GPS spoofing attacks by using hardware capable of generating stronger GPS signals, broadcasting them to GPS receivers in a chosen environment to force them to switch from legitimate satellite signals and manipulate their location calculations. In 2013, a man was arrested in New Jersey for using a GPS device that was interfering with GPS ground-based receivers of Newark's Liberty Airport [59]. This device was able to block surrounding GPS receivers from receiving legitimate GPS signals and he claimed using it in the company truck simply to hide from his employer. In [60], authors demonstrated a successful GPS attack using a low-cost device assembled from conventional components and were able to manipulate the navigation data of 38 real cars out of 40 participants to follow a wrong predetermined destination without being noticed. The authors discussed that this attack may not succeed when the driver is familiar with the location but it represents a high risk for self-driving vehicles. Authors in study [61] also demonstrated a new approach to GPS attacks that can succeed in manipulating navigation routes on vehicles where security mechanisms are used such as internal navigation system (INS). The technique consists of exploiting existing navigation data between the vehicle's start and destination points to identify similar routes with the original trajectory using an algorithm and then forcing the vehicle to follow the most similar trajectory. The authors claim that this attack can be successfully executed due to the negligible inconsistencies between the original and the spoofed routes. Also, authors in study [62] proposed a spoofing generator that cancels all legitimate GPS signals and allows surrounding GPS receivers to collect the attacker's generated signals. The authors defended that their spoofing generator can cover all open-sky satellites making this attack difficult to detect based on a comparison of signal consistency from different GPS receivers.

Defences: To prevent GPS attacks, the use of multiple antennas was proposed in study [63], to receive GPS signals and measure their phase differences to detect spoofing attacks but this technique would be inefficient under attack methods as presented in study [62]. Authors in study [64], proposed the use of coding in GPS systems to reduce jamming attacks where GPS signals are encoded and modulated by the satellite before transmitting to receivers that will then demodulate and decode to recover the original GPS signals. However, this method requires changes in GPS satellites which is very difficult and also, the authors acknowledged that their method is less effective when the jamming signals are too strong than the legitimate ones. In many applications, a technique known as "Receiver autonomous integrity monitoring (RAIM)" is used in which, the observed GPS signals are compared with the expected signals to determine the integrity of the received signals [65]. The RAIM uses a pseudo-ranging measurement to produce several GPS positions based on redundant signals [66]. However, the Advanced RAIM (ARAIM) used as an extension for other navigation systems beyond GPS, was criticised in study [67], for having availability issues when one or more satellites cannot be reached. Later, authors in [68] proposed a solution to improve the availability of ARAIM up to 98.75%. Authors in study [69], proposed integrating transmission signatures into GPS satellites which will allow GPS receivers to authenticate the received signals. This method can easily help to detect spoofing attacks but it would involve higher costs for changes in satellites. A rotation-based technique was proposed in study [70], for GPS receivers that can help to determine the angle of arrival of GPS signals from different satellites and compare them to detect spoofing attacks. Authors in study [71], proposed a GPS spoofing detection technique for vehicular GPS receivers based on the Doppler Shift associated with them. In their approach, authors intentionally perturbed the vehicle's velocity and observed the changes in Doppler Shift value if they were consistent with velocity variations or not. Due to the unpredictability of these variations, spoofing signals cannot follow the changes. A GPS spoofing mitigation technique was proposed in study [72], based on the Isolation Forest that consists of detecting the attack and isolating the compromised GPS receiver before correcting it using the location data of roadside units. The authors claimed to achieve good results but this method would require the use of multiple GPS receivers to avoid service interruption. Authors in study [73] and study [74], demonstrated through simulation that machine learning and deep learning algorithms can achieve detection of both GPS spoofing and jamming attacks with high accuracy.

4) Image Sensors (Cameras)

Attacks: A blinding attack was experimented in study [43], on a car's camera (MobilEye C2-270) where authors projected different light beams on it. First, an LED matrix of 940nm 5*5 and an LED spot of 850nm were used and able to blind the camera from perceiving images which took 5 seconds to recover later. A 650nm laser was then used on it to achieve the same results but the camera never recovered again. Authors in [75] conducted similar experiments to permanently blind a camera and concluded that both LED and Laser beams can blind cameras with enough intensity but infrared beams can make exceptions due to their narrow frequency band. Attackers can also use other methods such as manipulating images to cause incorrect predictions of road signs by ML-based algorithms as described in studies [76], [77], [78], [79]. In 2017, Google researchers created stickers with patterns and attached them to some important road objects such as speed limitations and stop signs [80]. The authors claimed that the stickers were able to provoke incorrect predictions in the used algorithms. Authors in study [81], experimented with similar attacks by decorating stop signs with many black-and-white stickers and found a failure of 100% of the algorithm to

recognize the stop signs with a fixed camera and 84.8% with a moving camera on a vehicle. Authors in study [82], experimented with a blinding attack using electromagnetic waves to interfere with cameras and were able to cause incorrect observation of stop signs. This attack is hard to detect because it does not require a physical modification. A similar experiment was conducted in study [83], using invisible infrared lights which affected the captured image's pixels with a magenta colour in ambient light. The authors succeeded in perturbating cameras on the Tesla Model 3 using off-the-shelf IR light sources and confirmed the effectiveness of their attack in various settings.

Defences: To mitigate camera blinding attacks, the authors in [43] proposed two solutions. The first consists of using multiple cameras in the AV to capture redundant images and avoid single-camera failure. This strategy makes it difficult to attack all cameras simultaneously due to the limited beam widths of LED and Laser spots but can increase the cost according to the number of cameras. The second solution is to integrate a light filter into cameras that can cut near-infrared lights. This strategy can be implemented at a low cost but lacks experiments to confirm its effectiveness. The authors in [83], proposed to implement infrared light filter-based software on cameras as mitigation to their attack. Authors in [84], proposed the use of ML algorithms to predict images and compare them with the captured images and claimed that this technique can help to detect blinding attacks and take the required actions before any damage. The use of machine learning models as a solution against adversarial image attacks has also been discussed in the literature. In these models, three major aspects are considered including pre-processing input images as detailed in [85], [86], [87], [88], training with adversarial image samples as proposed in [89], [90], [91], and detecting adversarial inputs using run-time information as described in study [92]. These models can be integrated into ECUs which receive their input images from cameras for the AV's vision.

B. Control and Processing Units: Attacks and Defences

The internal components of the AV can exchange information through the CAN network, where ECUs receive their input data from the different sensors, communication interfaces, and/or other ECUs [93], [94], [95]. Therefore, any failure from the input source can directly influence the ECU to give incorrect output. Also, attackers can observe the CAN messages and inject malicious data through OBD ports or telematic interfaces to target a specific ECU.

1) ECU Attacks: Authors in study [96] experimented with an attack by connecting a laptop to a vehicle's OBD port to access the CAN network and run a custom code named CarShark in targeted ECUs, which was able to compromise their initial functions. They warned that no security measures were applied during vehicle software updates through the OBD port. Authors in study [97] have also shown that an attacker can develop a malicious program and let a vehicle owner download it as a self-diagnostic application which will allow the control of ECUs through OBD connexions. Authors in study [98], were able to access a vehicle's ECUs through Bluetooth and long-range connections allowing them to analyse the firmware and execute their codes. The authors reported that an attacker can use the same process to remotely inject malicious codes in a targeted ECU and compromise its functions. In Black Hat 2015, some researchers demonstrated a successful attack on a Jeep Cherokee ECUs using remote interfaces [99]. The authors were able to control the vehicle's braking, steering, and acceleration systems. Authors in study [100], focused a study on discovering weaknesses in the deployed access control and communication mechanisms on Tesla vehicles, the "P85 and P75 models", and demonstrated how ECUs can be remotely controlled by sending malicious packets to the CAN via wireless technologies. Authors experimented with their attack, to remotely control the steering ECU of the Tesla Model S 75 [101]. Authors in study [102], demonstrated CAN vulnerabilities using experimental fuzzy-testing and reported that an attacker can easily access the CAN network and control a targeted ECU of the vehicle with necessary protocol analysis tools.

2) ECU Defences: Many mitigation solutions have been proposed in the literature to prevent ECU attacks. Authors in [103], proposed an attack detection technique which calculates entropy during normal and abnormal CAN communications to detect suspicious activities. The authors in study [104], proposed a technique to monitor all messages in the CAN network where each ECU will use a flag to indicate a message transmission time, and therefore, detect unauthorized messages based on the time threshold. This method was criticized in study [105], because it requires modifications in every ECU in the vehicle, then proposed to use identity checking of ECUs and observe the frequency of their message transmissions. If a significant change in frequency is detected from an ECU, then it can be considered compromised. A similar technique was proposed in stuy [106], to detect abnormal massages based on interval measurements of periodic CAN messages. Authors in study [107], proposed to use a machine learning-based device that can be connected to OBD ports to detect malicious patterns from the CAN traffic data and disable the messages when an attack is detected to prevent ECUs from being compromised. Authors in study [108], proposed to implement a hardware-based protocol that can achieve both CAN access authentication and message encryptions. Authors in [109], proposed a technique to monitor the correlations between ECU messages and estimate the behaviour of the vehicle. In this method, a specific ECU is detected as compromised when there is a sudden change in its messages but a sudden change in the vehicle's behaviour would mean multiple ECU attacks. Authors in study [110], proposed an Intrusion Detection System (IDS) to detect CAN network attacks based on ML algorithms. They experimented with their model using a CAN dataset and claimed to successfully classify DoS and Fuzzing attacks with high accuracy. Authors in study [111], proposed a secure boot scheme based on cryptographic algorithms that can protect the CAN network from malicious software being executed by the

vehicle's ECUs. After experiments, the authors claimed to achieve good performances with the Cipher-based MAC (CMAC) and the elliptic curve digital signature (ECDS) algorithms in terms of authentication and execution speed. Authors in study [112], also proposed an ML-based anomaly detection for CAN networks using the deep autoencoder method and claim to achieve high detection accuracy of up to 99.98%.

C. Vehicular Communications: Attacks and Defences

Vehicles are mobile and their interactions with various external entities make them vulnerable to several cyberattacks.

Attacks: Authors in study [113] conducted a simulation on a group of cooperative driving AVs where they experimented with an attack to compromise one of the vehicles and then used it to transmit false information in the vehicular network, which resulted in sudden disturbances in vehicles' speeds. A DoS attack was also experimented in study [114], by saturating a V2I network channels with excessive noise messages through simulation, where authors showed that this kind of attack in practice, can block all vehicles from sending messages in the network and therefore interrupt the vehicles' cooperation. In study [40], a group of researchers conducted a study to explore the security of automotive APIs, telematic systems, and the infrastructures that support them. The authors discovered multiple vulnerabilities across 19 major global suppliers and original equipment manufacturers (OEM) and exploited them to remotely control vehicles and access sensitive data.

1) Authentication defence mechanisms: Authors in study [115], proposed an authentication method for V2V communications in VANET, where vehicles periodically broadcast their presence information to others and record the received announcements to determine a neighbouring group, and then identify malicious nodes by sharing the composition of groups. Authors in study [116] proposed a V2I authentication method called "Security Credential Management System". The method was based on a public-key infrastructure and claimed to provide good privacy protection, but it suffers from high computation and communication delays.

Authors in study [117] proposed an authentication method to achieve group signatures for short-term communications in VANET based on the Boneh-Shacham algorithm. Authors in study [118] also proposed an authentication system for VANET which generates pseudonyms based on vehicles' IDs through public key cryptography and then uses these pseudonyms in the authentication processes for privacy-preserving purposes. They used an ID-based signature for V2I authentication and an ID-based online/offline signature for V2V authentication and defended the feasibility and efficiency of their method in vehicular networks based on performance evaluations.

Authors in study [119] proposed a lightweight authentication method for handover in V2X communications where each vehicle can be allocated a temporary identity from its home network and then use that identity when moved to a new network. The authors claimed to achieve better performance with low computation overhead through simulations. Authors in [120] proposed a security technique for vehicular LTE networks which can mutually authenticate vehicle nodes and preserve their privacy. They evaluated their method to have better performances in terms of communication cost, security level, and less computation. A privacy management algorithm based on hybrid cryptography was proposed in study [121], to ensure trusted communication between vehicles. The authors used an asymmetric identity-based digital signature and claimed to achieve better performances in terms of communication latency, computation and storage overheads.

Authors in study [122] proposed a self-checking authentication method for VANET where vehicles and RSUs can verify each other without including a Trusted Authority (TA). Initially, the TA is responsible for the registration of all vehicles and RSUs before they join the vehicular network environment and therefore TA will intervene in the vehicle's authentication process through RSUs. This method proposed to allocate a group signature to vehicles at their first authentication from one RSU domain and then use the same signature for authentication in other domains without going through the whole process. Authors claim that this method meets security requirements and benefits from faster authentication.

Authors in study [123] proposed a multifactor authentication process for AVs and claimed to achieve good security checks without revealing sensitive information of users. Authors in study [124] also proposed a multifactor authentication for remote vehicle diagnosis and maintenance which requires both biometric and password verifications from the vehicle's owner or the Service Centre to ensure legitimate access to the system. Through performance analysis of the technique, the authors claimed that it achieves a robust security level. An edge-based vehicular authentication architecture was proposed in study [125], where different vehicles can be grouped to form a vehicular cloud. The authors claim easier attack detections using deep learning algorithms in this technique that offer a lightweight authentication of vehicles for secure V2V communications.

Authors in study [126] proposed an identity-based cryptographic method for V2V authentications and security key agreement, where the ID of each vehicle is used as its public key, which can expose this method to privacy leakage. A Blockchain-based One-Time authentication method was proposed in study [127], for V2X communications. In this method, the identities of nodes are encrypted before sharing instead of revealing the real identities, and different proofs are generated to authenticate nodes which are verified through a noninteractive blockchain. Based on security analysis, the authors claim to achieve secure V2X authentications with reduced delay. Authors in study [128], proposed an aggregate and continuous authentication technique using federated learning for VANET applications. Based on the edge devices as learning centre between vehicles and RSUs, the authors claimed to achieve a secure and privacy-preserving authentication with reduced communication overheads.

2) Confidentiality defence mechanisms: In study [129], a "cryptographic mix-zone (CMIX)" algorithm was proposed to secure exchanged data in vehicular networks. In CMIX, the encryption process is based on a group secret key, where the same key is shared between all the vehicle nodes in the network to save time from individual key sharing. However, all the security is compromised when an attacker can intercept the encryption key during its broadcasting.

Authors in study [130] proposed a game theory technique known as the Markovian game to achieve secure communication, where each vehicle in the network is considered a player and players are either data holders (DH) or data requesters (DR). In this game, each vehicle earns income according to the provided services and uses that income to buy access to private data. If a DR node wants to access private data from a DH node, it will propose a motivation price then the DH will decide a privacy concession according to its satisfaction. The problem with this game is that the DH cannot verify if the DR is a malicious node or not before privacy concession. Therefore, the algorithm should consider other parameters to prevent network intrusion.

Authors in study [131] proposed a secure V2X communication method based on a hash chain of secret key cryptography and claimed to provide secure messaging between vehicles at low cost. The authors in [132] proposed a batch verification method using the "Paillier cryptographic algorithm" to solve privacy issues in VANETs, in which, vehicles can cooperate to identify malicious users without disclosing sensitive information. This method can achieve privacy-preserving communications but does not guarantee the confidentiality of exchanged data.

3) Network monitoring defence mechanisms: Authors in study [133], proposed a security algorithm to detect malicious vehicles based on their behaviours in the network and then isolate them from the rest of entities. This method can reduce the chances of successful sybil attacks but isolating a vehicle node from the network as a prevention technique can represent a danger in some situations, especially in complex traffic. Authors in study [134] proposed an intrusion detection system to detect attack scenarios against vehicular networks including packet duplication, selective forwarding, resource exhaustion, wormhole, black hole, and Sybil attacks. After simulation, the authors claim that the proposed algorithm can provide good attack detection accuracy with minimum detection time.

Authors in study [135] proposed an intrusion detection system for vehicular networks based on "deep neural network (DNN)" to detect attacks. Using an unsupervised training, the DNN algorithm could accurately classify normal packets and attacked packets and able to detect malicious events against the vehicle as a result. Therefore, this method can perform better in vehicular networks when many attacked packets from different attack scenarios are used in the training process of the DNN.

Authors in study [136] proposed a voting technique to identify rogue nodes in VANET. In this method, two vehicles vote for each other when they can communicate without any security issues. The trust level of a vehicle in the network is evaluated according to the number of gathered votes, where a vehicle with a small value of a vote is considered a rogue node and a potential source of attack. This method can achieve good performance in a fixed number of nodes since it is an experience-based system but does not perform in scalable network scenarios like vehicular networks, where vehicles can join a locale network and leave at any time due to their mobility. Authors in study [137] proposed a coalitional security game to detect malicious nodes in vehicular networks based on Dempster-Shafer's theory. The game consists of building trusted relationships between vehicles based on their reputation, experience, and knowledge. However, attackers can target a vehicle with experience and a good reputation and use it to perform attacks in the network. Also, vehicles can be in new environments at any time due to their mobility without previous experience gained from that environment.

Authors in study [138] proposed an intrusion detection system using ML models to detect "Distributed Denial of Service (DDoS)" attacks in V2I communications. The authors claimed to achieve good detection accuracy after various testing. The same approach was proposed in study [139] based on the Support Vector Machine algorithm where authors achieved high DDoS detection performances through simulations. Authors in study [140] proposed an attack detection mechanism for AVs that works both in online and offline modes. The offline phase is used to establish parameters based on which, the detection of attacks and responses are executed in the online phase.

IV. Discussion

Security is a very active research area for information technologies, and the introduction of AVs has increased the interest where each newly published work can offer fresh approaches to system security problems. However, most of the existing security standards are still facing challenges in addressing issues in this cutting-edge technology where additional critical parameters are being considered regarding real-time communication, resource constraint computation, user privacy, fault detection, network scalability, quality of service, etc. [141]. The previous security mechanisms presented in the literature are discussed in this section to point out the open security challenges for further investigations.

A. Sensors

Sensors represent the perception elements that collect data for AVs and are used to make decisions. Therefore, the security of sensors is crucial and the proposed attack mitigation methods should consider some requirements including:

- Detection of adversarial signals such as spoofing and jamming attack signals, and filter them to allow good perception of legitimate signals under attack situations;
- Availability: the solution should not disrupt other services during its execution and should have faster execution to meet the real-time functionality of AVs;

The defence strategies related to the security of sensors are discussed in Table I.

B. The In-Vehicle Network

In the internal network of the vehicle, the components interact to perform driving tasks together, and any successful attack or dysfunction can compromise the vehicle's normal operations. Therefore, the security measures should include the following requirements:

- Authentication: Every component should be identified and trusted before accessing the CAN network;
- Attack detection: suspicious activities in the CAN network should be identified, and compromised nodes should be excluded from sending data in the CAN.
- Availability: the solution should not disrupt other services during its execution and should have faster execution to meet the real-time functionality of AVs;

The defence strategies related to the security of CAN networks are discussed in Table II.

TABLE I. DISCUSSION OF SECURITY METHODS FOR SENSORS

Attack Types	Target components	Proposed Defense Strategies	Contributions	Limitations
Sensor Spoofing and Jamming	LiDAR, Radar, GPS	1) "Prevention of spoofing and jamming attacks" using multiple sensors [44], [63]. 2) "Detection of spoofing and jamming attacks" based on signals' directions [55], [56]. 3) "Detection of spoofing and jamming attacks" using the ML models [48], [49], [48], [49], [50], [57], [73], [74]. 4) "Detection of spoofing and jamming attacks" based on signals' authentication [45], [47], [64], [69].	1) The use of multiple sensors provides an overlapping coverage of the vehicle's surroundings, which can therefore reduce attack chances since it becomes difficult to compromise all sensors together. 2) The detection of attack directions can help to reject signals arriving from them and therefore prevent attacks. 3) The ML models increase the detection accuracy of spoofing and jamming signals. 4) The authentication of signals through modulation or signature methods, helps to identify attack signals from legitimate ones.	1) The main challenge with the use of multiple sensors to mitigate spoofing or jamming attacks is its implementation increases the cost. 2) The detection of attack signals based on their directions can be performed when the nodes are fixed, which makes it inefficient for vehicular applications due to the mobility of vehicles. 3) The ML-based attack detection methods lack experiments to determine their efficiency in realistic AV environments. 4) The authentication of signals requires computational modifications in sensor nodes, which represents a high implementation cost and also involves higher computational delays.
		Open challenges: The spoofing and jamming attacks against sensors remain a serious challenge in the context of AVs. Most of the existing solutions aim to detect spoofing and jamming signals, but there is a lack of efficient methods to filter them and allow sensors to correctly collect legitimate signals in attack situations. Therefore, further investigations are needed to guarantee the security of sensors for AV applications.		
Sensor Blinding and Adversarial images	Cameras	1) Prevention of blinding attacks using multiple cameras [43]. 2) Prevention of blinding attacks using light filters in cameras [43], [83]. 3) Detection of blinding and adversarial image attacks using ML models [84], [85], [86], [87], [88], [89], [90], [91], [92].	1) Multiple cameras provide overlapping views of the vehicle's surroundings to capture redundant images, which makes it difficult to blind all cameras together, and therefore, reduce attack chances. 2) The integration of light filters into cameras can help to cut near-infrared lights and therefore prevent blinding attacks. 3) The ML models increase the detection accuracy of adversarial image attacks.	1) The main challenge with the use of multiple cameras to mitigate blinding attacks is that it represents a high implementation cost. 2) The implementation of light filters needs to be experimented on real cameras to validate their effectiveness for AV applications. 3) Complex and adequate dataset of adversarial examples are still needed to train ML models and extensively experiment them on realistic cameras to determine their effectiveness.

TABLE II. DISCUSSION OF SECURITY METHODS FOR THE CAN NETWORK

Attack Types	Target components	Proposed Defense Strategies	Contributions	Limitations
Malware and Message Injection	CAN network, ECUs	1) "Detection of CAN network attacks" based on entropy calculation [103]. 2) "Detection of CAN network attacks" based on message transmission time [104]. 3) "Detection of CAN network attacks" based on message frequency [105], [106], [109]. 4) "Detection of CAN network attacks" based on authentication of ECUs [105]. 5) "Detection of CAN network attacks" based on ML models [107], [110], [112]. 6) "Prevention of	1) The changes in entropy can identify irregular activities, which can be useful in detecting CAN traffic anomalies. 2) The of message transmission times comparison is useful in identifying malicious data if the transmission time is higher than expected, which can particularly prevent message replay attacks without heavy computations. 3) The frequency of messages can help to determine the behaviour of different nodes in the CAN network, and therefore, detect abnormal actions. 4) The authentication of ECUs can prevent other ECUs from receiving malicious data from unidentified or illegitimate nodes. 5) The ML models can detect complex attacks with high accuracy. They can analyze large volumes of data and easily adapt to evolving attack patterns using updated datasets. This can monitor the CAN network in real-time. 6) The encryption of messages can prevent unauthorized access to data and guarantee	1) The main challenge with entropy calculation is its high sensitivity to data distribution, which must be well modelled to provide meaningful entropy values. Also, small changes in data distribution can lead to significant changes in entropy values making it practically inefficient for vehicular security. 2) The use of message transmission time can negatively impact the network in some unexpected situations such as transmission delays due to congestions or routing issues can falsely flag legitimate messages as malicious. Also, this can be vulnerable when the attacker manipulates the time. 3) The attack detection based on the frequency of messages may only be useful for the security of sensors, which collect data at a regular rate. However, this method is inefficient for ECUs that randomly transmit messages based on the needs. 4) The authentication of ECUs requires computational modifications in each ECU of the vehicle, which represents a high implementation cost and also involves higher delays. 5) The challenge with ML models is that their Training and deployment require significant computational resources, which may not be feasible in constrained environments like ECUs. Also, there is a lack of experiments to determine the effectiveness of the ML models on realistic CAN networks. 6) Many existing CAN networks lack built-in support for encryption, which requires significant hardware or software

		CAN network attacks" using encryption techniques [108], [111].	the integrity of exchanged information in the CAN network.	upgrades. Also, it would be challenging to implement and execute encryption algorithms in CAN networks because of their limited processing power and memory.
		Open challenges: The AVs remain vulnerable to malware and message injection attacks through OBD ports or telematics. Traditionally, the OBD ports are protected by a physical lock, which does not guarantee effective security. However, no security method was found in the literature that can distinguish legitimate OBD devices from malicious OBD devices when connected to the OBD port. Therefore, further investigations are needed to guarantee the security of ECUs for vehicular applications.		

C. Vehicular Communications

Each AV is an autonomous system susceptible to joining a network environment where it will interact with everything using wireless interfaces. The exchanged information between the vehicle with the outside world will determine its driving behaviour in traffic, making it vulnerable to various attacks. Therefore, the V2X communications protocols should include the following requirements:

- Authentication: Every entity including vehicles, smart devices, and RSUs, should be identified and verified as trusted before accessing the vehicular network;
- Data protection: Exchanged information between entities in the vehicular network should be authentic and confidential to avoid unauthorized access;
- Attack detection: The vehicular network should be controlled to detect suspicious activities, and exclude compromised entities from sending data in the network;
- Compatibility: The solution should not disrupt other services during its execution.
- Computational efficiency: The solution should have faster execution with low implementation cost to meet real-time and resource-constraint functionality of AVs;
- Scalability: The solution should accept the changes in the number of network entities.

The defence strategies related to the security of V2X communications are discussed in Table III.

TABLE III. DISCUSSION OF SECURITY METHODS FOR VEHICULAR COMMUNICATIONS

Attack Types	Target components	Proposed Defense Strategies	Contributions	Limitations
Network Intrusion attacks (identity theft, Sybil, replay, …) Eavesdropping (man in the middle, data manipulation, …),	Communication Protocols	1) Collaborative vehicular authentication [115], [125]. 2) Public key-based vehicular authentication [116], [118], [121], [126]. 3) Group signature-based vehicular authentication [117], [122]. 4) Identity-based vehicular authentication [119], [120]. 5) Multifactor-based vehicular authentication [123], [124]. 6) Blockchain-based vehicular authentication [127].	1) The collaborative authentication is decentralized and reduces the risk of single-point vulnerabilities. As multiple entities validate a vehicle's credentials, this technique can help balance the load of authentication tasks and identify malicious nodes more effectively. 2) The public key authentication uses strong encryption algorithms suitable for large-scale networks like vehicular networks, to ensure the integrity and authenticity of exchanged messages. 3) The group signature cancels the need for individual authentications, reducing communication delays. It also allows vehicles to authenticate themselves without revealing their specific identity, which enhances user privacy. 4) The identity-based authentication uses simple structures rather than complex and heavy cryptographic algorithms, which reduces computation and communication delays, making it suitable for time-sensitive applications. Also, it is easier to integrate identity-based methods across different vehicular networks to meet specific security requirements. 5) Combining multiple authentication factors (e.g., password/PIN, biometric data, cryptographic keys) makes it significantly harder for attackers to compromise the system. 6) The blockchain provides robust cryptographic security and immutability, making it difficult for attackers to alter authentication records. 7) The ML models gain from the high	1) The challenge with collaborative authentication is that it involves multiple messages exchanged among vehicles or nodes, leading to increased network traffic, and therefore introducing communication delays. Also, this method can lead to security and privacy breaches because of the exchange of vehicles' identity that can be intercepted and manipulated by attackers to have access to the network. 2) The public key operations (e.g., encryption, decryption, and signature verification) are computationally intensive, which can introduce delays and may affect the real-time requirements of vehicular networks. Also, this method can put the security of the entire network at risk, when the private keys or the certificate authority that it relies on, are compromised. 3) Generating and verifying group signatures can be computationally intensive, especially in a large number of group participants, which can impact real-time applications and reduce the network performance in real-world vehicular environments. 4) While promising, identity-based methods are less commonly deployed compared to certificate-based systems, limiting their effectiveness in verification and interoperability with existing infrastructures. 5) The authentication based on factors like biometrics can frequently fail due to mismeasurements or environmental conditions (e.g., dirt affecting fingerprint scanners). Also, authenticating multiple factors can take additional computation time, which may affect real-time applications like collision avoidance or emergency communications. 6) Blockchain transactions can require significant time to be validated and added to the ledger, which may not meet the real-time requirements of vehicular networks. Also, the increase in the number of vehicles and authentication transactions can lead to blockchain bloat, requiring more storage and computational resources.

Network saturation (DoS and DDoS)		7) ML-based intrusion detection [128], [134], [135], [138], [139].	accuracy of attack detection capable of analyzing large volumes of data to detect complex attacks with the ability to adapt to evolving attack patterns by retraining with updated datasets. This can monitor vehicular communications on a real-time basis.	7) The challenge with ML models is that their training and deployment require significant computational resources, which may become intensive for vehicles in case of the implementation of multiple ML algorithms. Also, there is a lack of experiments to determine the effectiveness of the ML models on realistic vehicular networks
		8) Game theory-based intrusion detection [130], [136], [137].	8) The game theory models allow the system to predict and counteract attacker strategies effectively by making the cost of an attack higher than its potential benefit. A well-designed game-theoretic approach can enhance the precision of attack detection when the attacker's behaviour patterns are incorporated.	8) The main challenge with game theory-based security methods is that they require detailed knowledge of attacker and defender behaviours to create a realistic game-theoretic model. Due to this dependency on accurate input data, such as network traffic patterns and known attack strategies, the game theory model can easily fail to detect an attack effectively if the attacker uses strategies outside the modelled game.
		9) Data protection based on cryptographic algorithms [129], [131], [132].	9) Cryptographic algorithms provide robust protection against unauthorized access and ensure data confidentiality throughout its lifecycle, even when transmitted over insecure channels. They can be implemented across various systems including vehicular networks.	9) Cryptographic algorithms can be resource-intensive, leading to delays in real-time systems like vehicular networks. Choosing a stronger encryption algorithm often involves a trade-off between security and performance, particularly in resource-constrained environments like IoT-based systems.
		Open challenges: Due to the high mobility of vehicles, they are permanently vulnerable to attacks through interactions with potentially compromised entities. Therefore, strong, efficient, and lightweight security protocols are still needed to defend vehicular networks from different intrusion, eavesdropping, and saturation attacks.		

V. Proposed Security Measures

To achieve good security and privacy requirements for vehicular applications while gaining from low computation and efficient implementation, we propose the use of powerful and innovative techniques. First, the cryptographic hashing algorithm is used for identity-based authentication, which achieves complex mathematical operations with faster computation. Secondly, homomorphic encryption is to be used to protect sensitive data communication between network entities for enhanced privacy and confidentiality. Finally, to build a Machine Learning based intrusion detection system using the transfer learning technique for multiple attack detection capability with efficient implementation.

A. Authentication Protocol

The proposed authentication protocol includes vehicles and their respective users, RSUs, and TA as illustrated in Fig. 10. First, each vehicle should be used by a legitimate user who is authenticated before the vehicular authentication in the network. The user authentication phase will protect user information to preserve privacy and avoid malicious traceability. Secondly, every vehicle and RSU is registered by the TA before being allowed in the vehicular network. In this registration phase, TA protects the privacy of vehicles and RSUs and provides secure authentication parameters for them. Third, vehicles are authenticated by RSUs to be admitted in their respective communication ranges, and vehicles authenticate each other to communicate among themselves. The authentication phase is based on mutual authentication where entities can identify each other and securely agree on a communication key. In this phase, each entity uses a pseudonym identity and other parameters received from TA during the registrations phase which avoid sharing the real identity and therefore preserve their privacy in the network. Finally, the authenticated or legitimate entities can securely participate in vehicular communications.

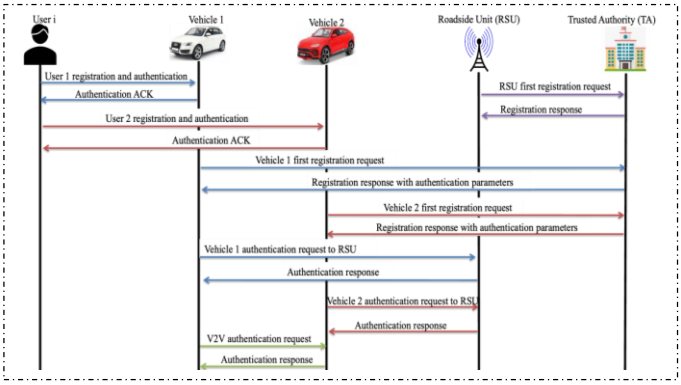

Fig. 10. Vehicular network authentication.

B. Privacy and Confidentiality

The proposed privacy and confidentiality mechanism for secure communication between vehicles, is based on homomorphic encryption as illustrated in Fig. 11. The homomorphic encryption offers the possibility to perform complex computations and data analysis on encrypted information without the need to decrypt them before [142], [143]. This represents a powerful solution for maintaining confidentiality and privacy during the transmission and processing of sensitive data. In the context of vehicular networks, each node can be a potential malicious node trying to collect private information. The homomorphic encryption can prevent unauthorized access to valuable information and therefore reduce the risk of data manipulation and breaches. Also, it enables traffic data analysis by the traffic authority and transportation companies without compromising the privacy of vehicular users and passengers.

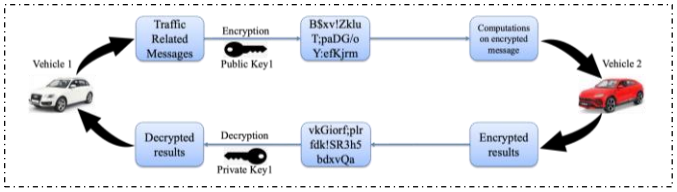

Fig. 11. Vehicular homomorphic encryption.

C. Intrusion Detection System

The proposed intrusion detection system for monitoring vehicular communications is based on transfer learning techniques as illustrated in Fig. 12. The transfer learning makes it possible to train a machine learning model using different datasets while gaining knowledge from all of them [144]. In this process, the model is trained with a starting dataset then the pre-trained model is trained again with a new dataset. Instead of implementing different models in the same device to detect individual types of attacks, transfer learning allows the accumulation of knowledge in a single model to save time and resources which is therefore suitable for vehicular applications.

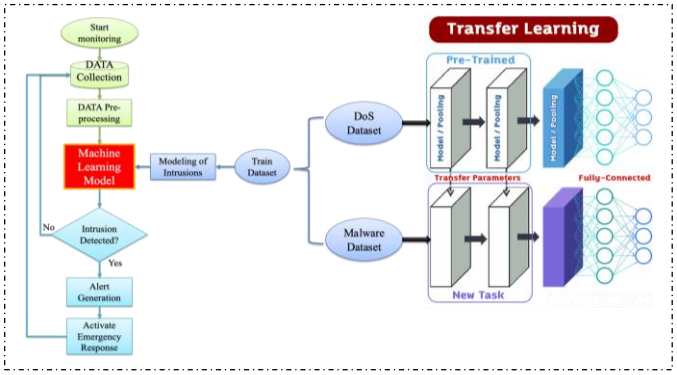

Fig. 12. Intrusion detection system based on transfer learning.

VI. Conclusion

Future transportation is expected to improve the quality of living by providing more safer and reliable mobility. While the introduction of autonomous vehicles has been presented to achieve this goal, it is also opening a new space for cyberattacks. Therefore, the cybersecurity concerns in the transportation area have raised interest from researchers and security experts to investigate and propose security measures for a trusted deployment. This paper reviewed the state of the art of cybersecurity issues defence strategies for AVs based on existing experiments and discussed methods in the literature. The review is organized by grouping attack methods and proposed defence techniques according to the target AV components. Based on this review, three major attack scenarios against AVs have been identified: 1) the attacker can target a component to interrupt its operations; 2) the attacker can target a component to have control over its operations without interrupting it; 3) the attacker can observe exchanged information without interrupting or controlling a component's operations. In response to the attacks, different defence approaches were proposed, which can also be categorised into three aspects including authentication, data protection, and intrusion detection. The authentication consists of identity verification and communication establishment to ensure that only trusted and legitimate entities are interacting. Data protection ensures that data transmitted between legitimate entities are trusted and secured from third parties. And, intrusion detection focuses on monitoring the interaction environment of legitimate entities to detect suspicious activities. The existing defence strategies were discussed to highlight their benefits in securing autonomous vehicles and also to show their limitations in satisfying critical requirements of vehicular networks, such as real-time and resource constraint applications, which can motivate further investigations. Furthermore, this paper presents some research directions that can be used to develop robust, efficient, and lightweight security measures, and therefore, contribute to building a trustworthy autonomous transportation ecosystem.

***Abstract*—Medical records are essential for disease detection to help establish a diagnosis. Many issues with imbalanced classification are discovered in many cases of early disease detection and diagnosis using machine learning methods, resulting in decreased accuracy values due to imbalanced data distribution caused by the number of positive patients with less disease than normal individuals. To improve the accuracy of the results, a classification architectural model is proposed through a modified oversampling method (SMOTE) using Minkowski distance and adding entropy as a weight value estimation to figure out the number of samples to be made. The feature selection procedure will adopt the hybrid Particle Swarm Optimisation Grey-Wolf Optimisation approach (PSO GWO). Dataset selection evaluated high, medium, and low data dimensions based on the number of features and the total number of dataset samples. The six classification algorithms were compared using datasets involving diabetes, heart, and breast cancer. The final classification results indicated an average accuracy of 74% for diabetes, 83% for heart, and 96% for breast cancer. The proposed approach successfully solves imbalances in medical record data, outperforming Naïve Bayes, Logistic Regression, Support Vector Machine (SVM), and Random Forest classification approaches.**

***Keywords*—Medical record; imbalanced data; classification; distance; entropy**

I. INTRODUCTION

Developing professional and quality health services requires a knowledge base to provide health services for patients based on evidence of the latest medical actions obtained from medical records of every action performed on patients [1]. Medical records are considered a key factor for improving the quality and safety of health services [2]. The use of medical records as documentation of patient care is increasingly being used to understand the clinical manifestations of various diseases, as well as the relationship between multiple diseases [3] [4]. Different knowledge bases have been engineered to extract useful information from medical records to assist the learning process for health professionals in making diagnoses [5] [6].

Medical record data stores many critical patient attributes from several medical action records and patient health records that describe a health condition [7] [8]. In many cases of early disease detection and diagnosis using machine learning methods, the problem of unbalanced classification is a case that is often encountered where the distribution of negative patients is greater than that of positive patients with the disease, causing an imbalance [9]. Several previous studies have shown that imbalanced data causes a decrease in accuracy values due to unequal class distribution, causing minority classes to be grouped into the majority class [10].

Several improvement methods are proposed to balance the amount of data in different classes through integration methods or improving learning methods by adding samples to the minority class (oversampling) or by removing samples from the majority class (undersampling) [11]. Unbalanced algorithms have three learning approach methods: data level, algorithm level, and hybrid methods [12]. The data level method improves classification performance by changing the distribution of data sets based on classes to balance the data. In contrast, the algorithm level method modifies the classification algorithm to adapt to unbalanced data structures, while the hybrid method combines the data level method and the algorithm level method in an integrated manner. Simultaneously, it is necessary to achieve the best performance [5] [13].

Oversampling techniques have been proven effective in resolving data imbalance problems. The Synthetic Minority Oversampling Technique (SMOTE) is the most popular technique for overcoming data imbalance [14]. The SMOTE method interpolates several data points from the minority class by considering neighbouring point data to produce new samples, but the interpolation process is ineffective for high-dimensional data [15] [16]. SMOTE uses Euclidean distance to calculate the neighbour distance for each minority class instance. They often increase overlap because the distance between each other is almost uniform and converges to the same value for all the cases, thereby reducing the accuracy value during the classification process [17]. Several previous studies have made improvements to the SMOTE method, including adding weights [18], learning rate [19], or combining two algorithms to improve performance and accuracy [20]. This research proposes modifications to SMOTE by using Minkowski distance and adding entropy as a weight value calculation to calculate the number of samples to be made. Minkowski distance is a measurement metric in normed vector spaces built on the distance spectrum and is considered a generalization of Euclidean and Manhattan distance. Minkowski distance can also describe the geometric structure of majority and minority class data [21]. The plan being developed for ensemble models will integrate the balanced data and then select the best features to be utilized by the classification method to achieve the highest level of accuracy. All stages will be carried out in a structured manner following the proposed design, and the research contribution will be determined so that the direction is clear and measurable.

The following are the contributions to this research:

1) This research presents improvements to the SMOTE method to overcome data imbalance by adding entropy as a weight to generate the number of data instances and changing the distance learning method to overcome overfitting.

2) The feature selection process in this research presents a hybrid architecture that combines Particle Swarm Optimization (PSO) with Grey Wolf Optimization (GWO). Combining two algorithms for feature selection can reduce the number of attributes to increase accuracy and computing time.

3) This research compares several classification methods, such as Decision Tree, K-NN, Logistic Regression, Naïve Bayes, Random Forest, and SVM, to see the best performance of the six methods used in disease classification research experiments.

4) Ensemble learning techniques improve medical record data classification results in this research. This research aims to optimize the accuracy of classification results by using the advantages of various model comparisons to overcome the complexity of data imbalance and reduce data dimensions. That offers a perspective for improving the accuracy of pattern recognition results in medical record data.

II. Literature Review

A. Imbalance Data

Class imbalance is a condition where the number of *instances of* the majority class is greater than the number *of cases of the* minority class. The difference in the number of samples in each class in the classification is known as an unbalanced data set [22]. Extension *ensemble* for unbalanced learning considers changes in the pattern probability function during the training phase, where training on unbalanced data tends to overtrain the majority class, while training for the minority class becomes difficult to predict due to undertraining [23][24]. Data imbalance can be divided into two types, namely relative imbalance and absolute imbalance, while based on the cause of the problem, the imbalance can be divided into two: intrinsic and extrinsic. Intrinsic indicates an inherent property of the data. For example, the probability of equipment failing is much lower than standard running equipment, or the number of people with cancer is less than that of healthy people. Extrinsic means other or external factors that cause data imbalance. For example, sporadic interruptions occur when balanced data is transmitted to the database [25].

B. Feature Selection

Dimensionality reduction is done by selecting features to increase accuracy by eliminating irrelevant features and assigning selected features to make the data easier to understand [26]. In the feature determination process, there are three approaches used to select features:

1) Filter method, selecting features based on feature relevance using ranking criteria, where the lowest calculated value will be removed. The filter method does not depend on the classification algorithm used in modelling so that it can be generalized and impacts accelerating computing time.

2) The wrapper method is part of a supervised algorithm where features are selected based on the relationship between features by comparing the resulting subset of features. The training and testing process is based on predicting the representativeness of each feature, which causes the computing time to become more complex.

3) The embedded method performs feature selection by looking for an optimal subset of features and including them in the training process of the classifier, thereby reducing computing time.

C. Classification

Utilization of machine learning helping to enforce fast, accurate diagnosis and detection is one of the efforts made in the health sector. Algorithm development machine learning, used to predict and diagnose disease based on medical record data, can help reduce diagnosis errors and independent pre-diagnosis learning materials. Several studies are related to solving or detecting diseases through classification methods, including the K-NN method, which is used to classify medical health data related to diseases and drugs [27] [28]. Method Naïve Bayes and Random Forest, which is used to diagnose and detect various diseases [29] [30], the SVM method is used to classify medical record data in the form of images [31] [32]. The utilization of machine learning also touches on digital data-based disease classification data processing, such as the utilization of telehealth and IoT using the decision tree method [33]. Combining two machine learning methods or modifying a technique has been developed to improve medical record data classification results and diagnose diseases [34]. The classification results of medical record data in previous research show variations in accuracy. Several factors influence the level of accuracy, including high-dimensional data and data imbalance.

The model proposed in this research is to overcome data imbalance in medical record data, where in several previous studies, many modifications or additional functions have been made to overcome the imbalance problem by adding entropy and changing the distance calculation to make it more flexible for data with different dimensions. Meanwhile, the feature selection process uses a metaheuristic method that focuses on finding optimal solutions flexibly. PSOGWO is used to optimize subsets to get features that provide the best performance on the model. This model was tested using six algorithms: decision tree, logistic regression, naïve Bayes, KNN, random forest, and SVM to test the ensemble combination that produces the most optimal level of accuracy.

III. Methodology

The methodology used in the research contains comprehensive stages of each built model process. The stages for overcoming the data imbalance problem begin with preparing a medical record dataset, data preprocessing, feature selection, classification, and evaluation methods. The research stages are shown in Fig. 1.

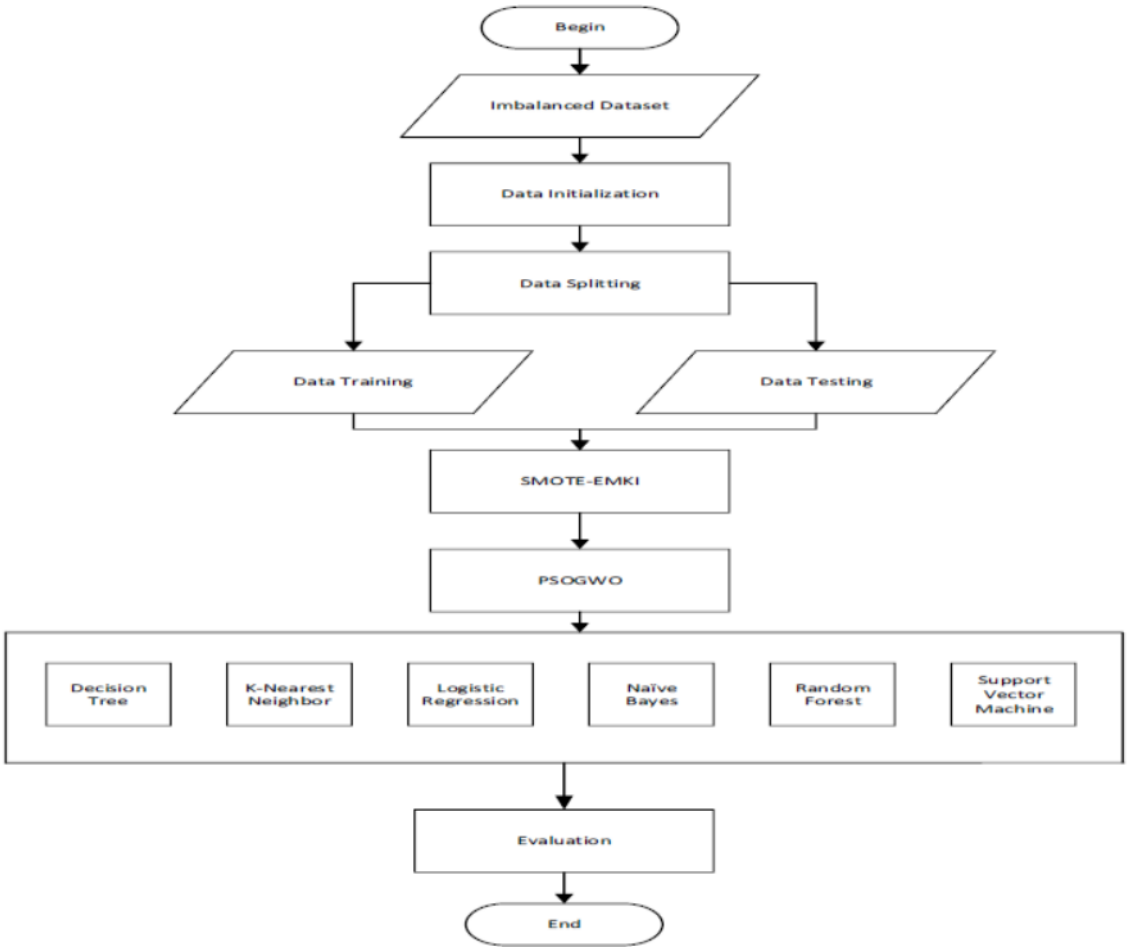

Fig. 1. The proposed architecture.

A. Dataset

The dataset used in this research is medical record data for diabetes, heart disease, and breast cancer, accessed in the UC repository *machine learning* and Kaggle. The selection of medical record data is based on the prevalence rate of sufferers, which increases yearly. Detailed data consists of the number of features, number of example data, number of minor data, number of classes, and Imbalanced Ratio (IR), described in Table I.

TABLE I. DESCRIPTION OF MEDICAL RECORDS DATASET

Dataset	Feature	Instance	Minority	Class	IR
Diabetes	8	768	268	2	1.86
Heart	14	1025	499	2	1.054
Breast Cancer	32	569	212	2	1.68

B. Data Imbalance Method

The approach used in this research is to modify the SMOTE algorithm by adding an entropy value at the beginning of the data balancing process and changing the distance calculation method from Euclidean Distance to Minkowski with the advantage of distance adjustment capabilities. The development stages of this model start from:

Step 1: Calculate the entropy weight for each majority and minority class. Entropy is used to measure how balanced the class distribution is in the dataset, where the entropy calculation for each class is carried out before the distance calculation. The entropy equation used is:

$$Entropy\ (S) = \ \sum_{i=1}^{C} p_{i\ log_2}(p_i) \qquad (1)$$

High entropy values indicate a more significant imbalance, while low entropy values indicate a more balanced class distribution.

Step 2: Determine the number of synthetic samples. The number of synthetic samples that need to be added is calculated based on the entropy proportion of the majority and minority

classes. If the entropy of the minority class is higher, the class imbalance is more significant, so many synthetic samples need to be added.

Step 3: Calculate the distance according to the given weight. After calculating the entropy value, normalization is carried out before proceeding to the distance calculation. Where the previous distance calculation using Euclidean distance was changed using Minkowski to calculate the closest K value from the minority class with the equation:

$$D_{(p,q)} = \left(\sum_{i=1}^{n} |p_i - q_i|^r\right)^{1/r} \quad (2)$$

Step 4: Synthetic interpolation creates synthetic samples based on linear interpolation between minority data points and their nearest neighbours.

One of the problems in SMOTE is that the synthetic samples produced have a high level of similarity to existing samples, so they do not adequately represent the diversity of minority classes. Adding entropy in the SMOTE technique is intended to improve the quality of synthetic samples and reduce the possibility of bias. Entropy is used to help select sample points and interpolation, where the results can increase the representativeness and variation of synthetic samples. Entropy positioning is also a consideration in this research; entropy is placed before applying the SMOTE method with consideration of the entropy value used to determine the number of synthetic samples needed. The entropy value also helps assess relevant features and eliminates the possibility of redundant minority classes. Placing entropy before the SMOTE process helps increase data diversity, accelerates convergence, and reduces the potential for overfitting.

A part from adding entropy, the proposed model also changes the distance calculation technique from Euclidean Distance to Minkowski Distance. This change aims to provide flexibility in measuring the distance between data points for data with different dimensions, thereby increasing the quality of synthetic samples. Changing the distance calculation method to Minkowski distance also helps determine the nearest neighbour selection of parameters to produce synthetic samples. In addition, the parameters can be adjusted to obtain distance measurements that better suit the characteristics of the data or specific features so that when the parameters are chosen appropriately, the diversity of the resulting synthetic samples can be increased. The SMOTE algorithm has been modified by adding entropy and replacing the distance approach with Minkowski, now called EMKI SMOTE. Furthermore, the results of improving this method will be used in the classification process, which was previously preceded by a feature selection process.

C. Algorithm PSO GWO

One of the population-based metaheuristic optimization techniques is Particle Swarm Optimization (PSO), where the initial inspiration for this method was the social behavior of flocks of birds or schools of fish when foraging for food [35] [36]. In this technique, a number of particles are allowed to move in a multidimensional search space, where an initial population is generated randomly in the search domain [37] [38]. All particles in the moving swarm update their positions using Eq. (3) and Eq. (4) at each iteration. The entire change history of the best position information of each particle in the cluster is also updated and saved.

$$X^{-i}{}_{n+1} = X_n^{-1} + V_{n+1}^{-1}, \quad (3)$$

$$V^{-i}{}_{n+1} = \omega V^{-1}{}_n + c_1 r_1 \left(\overline{p}^i{}_n - \overline{x}^i{}_n\right) \quad (4)$$

The particle symbols used in swarm for optimization are as follows:

N: The iteration steps carried out

r1 dan r2: Value representing a random number in the range [0, 1]

ω : Parameter weight inertia

c1 dan c2 : Coefficients representing optimization parameters

x : Position vector

v : Velocity vector

$\overline{x}^i$: The best position that the i particle has achieved

$\overline{p}^g$: The best position representation available on the *swarm*.

In the PSO algorithm, the position and velocity of the particles are determined randomly in the search space to find the best value. The goal of this operation is to avoid local minima. The search is continued until optimal results are achieved or based on achieving a predetermined maximum number of iterations. The iteration process is carried out to obtain the best solution through the following equation:

$$x_i^{k+1} = \begin{Bmatrix} x_i new^{i \iint (x_i new) \leq \int (x_i)} \\ x_i otherwise \end{Bmatrix} \quad (5)$$

The grey wolf leadership hierarchy at the top of the food chain is the rationale for the GWO algorithm. The grey wolf group is divided into four categories, alpha, beta, delta and omega. The alpha wolf represents the highest hierarchy, which provides the best solution for the group, while the second and third hierarchies are occupied by the beta and delta wolves, respectively. The omega wolf's role in the pack as the best solution candidate in the pack if needed. The stages in hunting prey by groups of grey wolves are divided into three parts, namely: the first stage is carrying out reconnaissance on the prey to be hunted, the second stage is stopping the movement of the prey by circling and confining it so that it makes it easier to attack and prey on the victim as the final stage. Eq. (6) and Eq. (7) provide a mathematical model for surrounding the victim.

$$D = \left|C \times X_p(t) - X(t)\right| \quad (6)$$

$$X(t+1) = X_p(t) - A \times D \quad (7)$$

Here, t denotes the number of instantaneous iterations, X_p is the prey position, X is the grey wolf's location, and A and C

are the vector coefficients. The coefficients A and C are calculated as shown in Eq. (8) and Eq. (9).

$$A = a \times (2 \times r_1 - 1) \quad (8)$$

$$C = 2 \times r_2 \quad (9)$$

The number of drops linearly from two to zero as the number of iterations decreases. r_1 and r_2 are random numbers picked uniformly from [0,1].

Alpha wolves direct grey wolves to the location of their prey. Alpha wolves occasionally receive assistance from beta and delta wolves. The GWO method assumes that the alpha wolf is the best option, with beta and delta wolves coming in second and third. As a result, the other wolves in the population migrated following the positions of these three wolves. The formulated mathematically in Eq. (10), (11), and (12):

$$D_\alpha = |C_1 \times X_\alpha - X(t)| \quad (10)$$

$$D_\beta = |C_2 \times X_\beta - X(t)| \quad (11)$$

$$D_\delta = |C_3 \times X_\delta - X(t)| \quad (12)$$

Values X_α, X_β, and X_δ each represent the three best wolves in each iteration.

$$X_1 = |X_\alpha - a_1 D_\alpha| \quad (13)$$

$$X_2 = |X_\beta - a_2 D_\beta| \quad (14)$$

$$X_3 = |X_\delta - a_3 D_\delta| \quad (15)$$

$$X_P(t+1) = \frac{X_1 + X_2 + X_3}{3} \quad (16)$$

Here, the new prey position is expressed as Xp(t + 1) as the mean of the positions of the three best wolves in the population. The grey wolf completes the hunt by attacking its prey. To attack, they must be close enough to their prey. When Eq. (5) is checked, A takes varying values from [− 2a, 2a] while A takes decreasing values from 2 to 0. When the |A| value exceeds or equals 1, the existing hunt is abandoned to find a better solution. The grey wolf is forced to attack the prey if the prey is close enough to a value less than 1. This approach prevents wolves from getting stuck at local minima. The search is complete when the GWO algorithm reaches the desired number of iterations.

D. Evaluation Metric

An evaluation of model performance is needed to see the effectiveness of the proposed ensemble model. Model performance is measured using accuracy, precision, recall, and F1 score metrics based on actual and predicted results from the classification process, where the basis for calculating metrics can be defined as follows: True Positive (TP) notation: the amount of data labelled positive and classified by the model labelled positive; True Negative (TN) is the amount of data labelled negative and classified as negative; False Positive (FP) is the amount of actual data labelled negative and predicted positive; False Negative (FN) is the amount of actual data labelled positive and predicted negative.

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \quad (17)$$

$$Precision = \frac{TP}{TP+FP} \quad (18)$$

$$Recall = \frac{TP}{TP+FN} \quad (19)$$

$$F1\ score = 2\,x\,\frac{Precision\ x\ Recall}{Precision+Recall} \quad (20)$$

IV. Result and Discussion

The designed EMKI SMOTE model causes the process of creating synthetic samples in the minority class to become more dynamic and diverse. The modification results in Table II show a significant improvement in overcoming data imbalance. The imbalance ratio (IR) in the Table compares the ratios before and after the modification was applied.

TABLE II. Imbalance Ratio

Dataset	Imbalance Ratio	
	SMOTE	EMKI SMOTE
Diabetes	1: 1.86	1: 1.47
Heart	1: 1.05	1: 1.02
Breast Cancer	1: 1.68	1: 1.43

Applying the EMKI SMOTE method to the model allows for the balance of data and the production of diverse synthetic samples so that the minority class data is more representative. Adding entropy and the Minkowski method for calculating distance can also eliminate redundant sample selection, reducing the risk of overfitting. After completing the data imbalance stage, the model will continue with the feature selection stage.

Particle Swarm Optimization - Grey Wolf Optimization (PSO-GWO) feature selection is a hybrid method that takes advantage of the benefits of both optimization algorithms to pick the most relevant subset of features in a dataset. PSO (Particle Swarm Optimization) is an algorithm inspired by the behaviour of flocks of birds or fish, in which each particle represents a solution and interacts with the others to discover the optimal position. Meanwhile, GWO (Grey Wolf Optimization) is an algorithm inspired by grey wolf hunting behaviours that uses a highly efficient search mechanism that divides roles among alpha, beta, and delta wolves. In feature selection, PSO identifies an initial solution, and GWO enhances the search for the solution by steering it in a more efficient path. The combination of these two algorithms aids in overcoming the dataset's complexity and feature redundancy, resulting in a more efficient model with improved performance. The PSO-GWO method can avoid traps in local search and speed up feature selection while maintaining model fidelity.

Feature selection in this study uses a combined algorithm between Particle Swarm Optimization and Grey Wolf Optimization (PSO-GWO) to produce the best feature selection process from the tested medical record datasets. The selection of features using this method will select attributes as representatives for each dataset. Fig. 2 shows the results of feature selection before using the feature selection method, after using the PSO GWO method, and the results of feature selection after the dataset is balanced, showing the results of feature selection with the optimal number of features without losing information for the classification process.

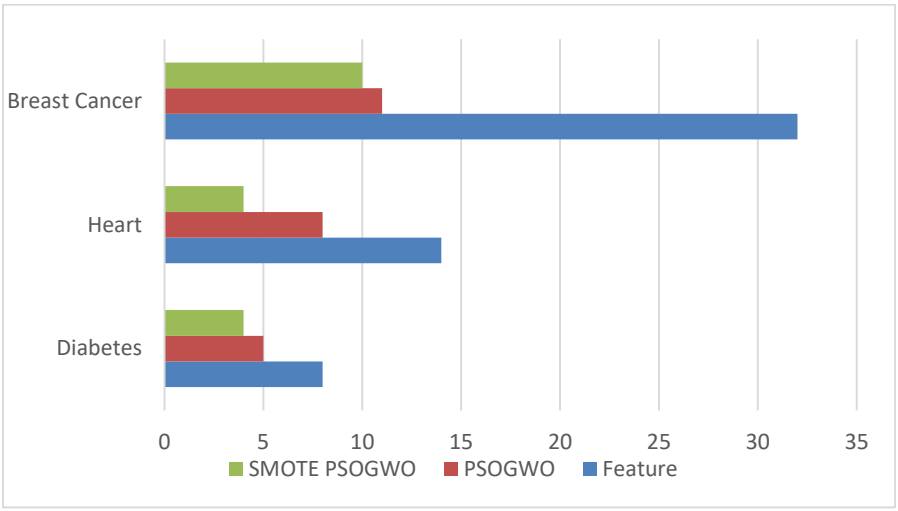

Fig. 2. Feature selection results using the PSO GWO.

The classification process divides the dataset into two parts: training data and testing data. The data is divided proportionally using the holdout method. Training data helps the model recognize patterns or relationships between features and labels while testing data measures the accuracy or significance of the model in classifying data that has not been introduced previously.

The experiment used medical record data for diabetes, heart disease, and breast cancer accessed from the UCI Machine Learning Repository. The results of feature selection with balanced data then go through the classification stage. The classification process uses a Decision Tree, KNN, Logistic Regression, Naïve Bayes, Random Forest, and SVM methods. The classification method comparison process is intended to strengthen evidence regarding the performance of the proposed model. Fig. 3 shows a confusion matrix graph for testing data on diabetes.

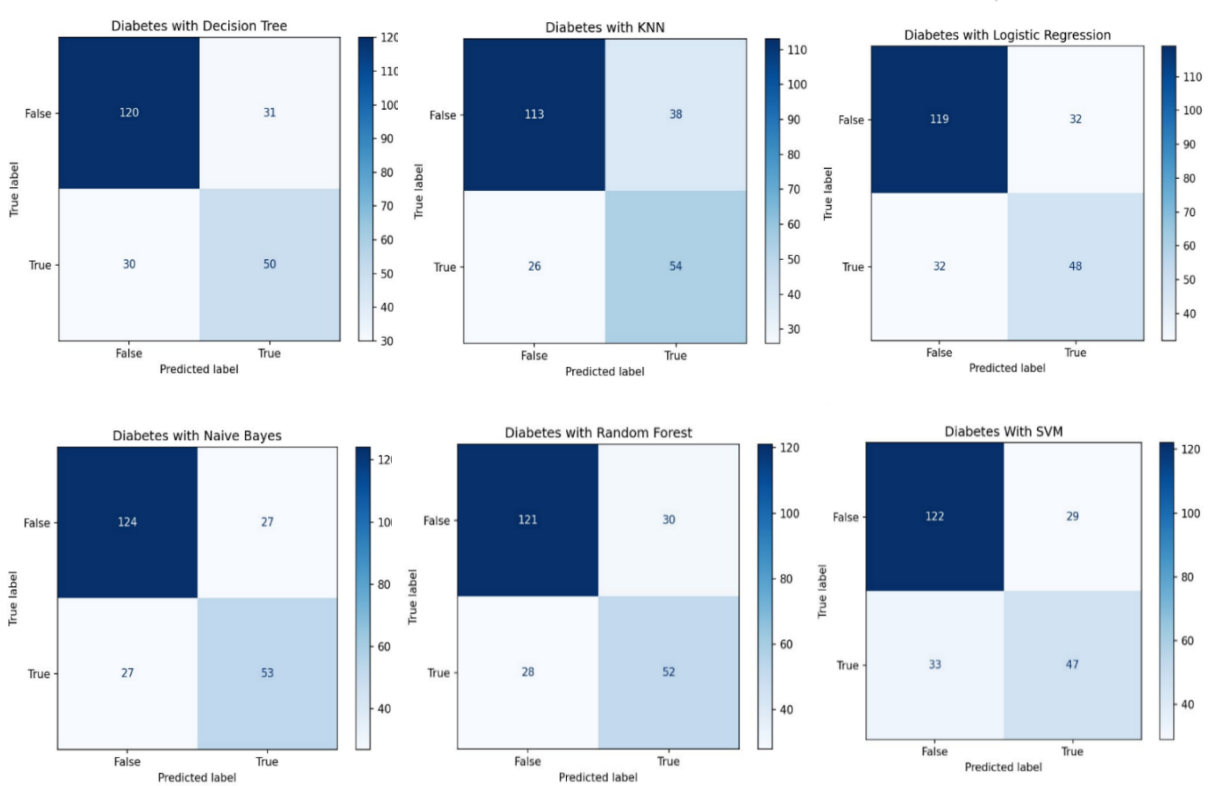

Fig. 3. Confusion matrix for the diabetes dataset.

The test results show that the diabetes dataset, when tested using six classification methods, shows an average Accuracy value of 0.7411, with an average value for precision of 0.79355, while an average value for recall is 0.8026 and an average F1 score of 0.7984. The methods that provide the best performance results are the Naïve Bayes and Random Forest methods, while the lowest performance results in experiments using the Decision Tree method. Details of the experimental results using each classification method are shown in Table III.

TABLE III. EVALUATION MATRIX DIABETES

Dataset	Classifier	Accuracy	Precision	Recall	F1 Score
Diabetes	Decision Tree	0.7359	0.7947	0.7947	0.7946
	K Nearest Neighbor	0.7229	0.7483	0.8129	0.7792
	Logistic Regression	0.7229	0.7880	0.7880	0.7887
	Naïve Bayes	0.7662	0.8211	0.8211	0.8210
	Random Forest	0.7489	0.8013	0.8120	0.8066
	Support Vector Machine	0.7316	0.8079	0.7870	0.8008

The second test was carried out on the heart disease dataset, where the classification process was given the same treatment for each stage as in the diabetes dataset. The confusion matrix of the results of heart disease data testing is shown in Fig. 4. The experimental results show increased accuracy, precision, recall, and F1 score after the medical data was balanced using EMKI SMOTE. Analysis of the experimental results also shows that the PSO GWO method used in the feature selection process combined with EMKI SMOTE produces several relevant features to use during the classification process.

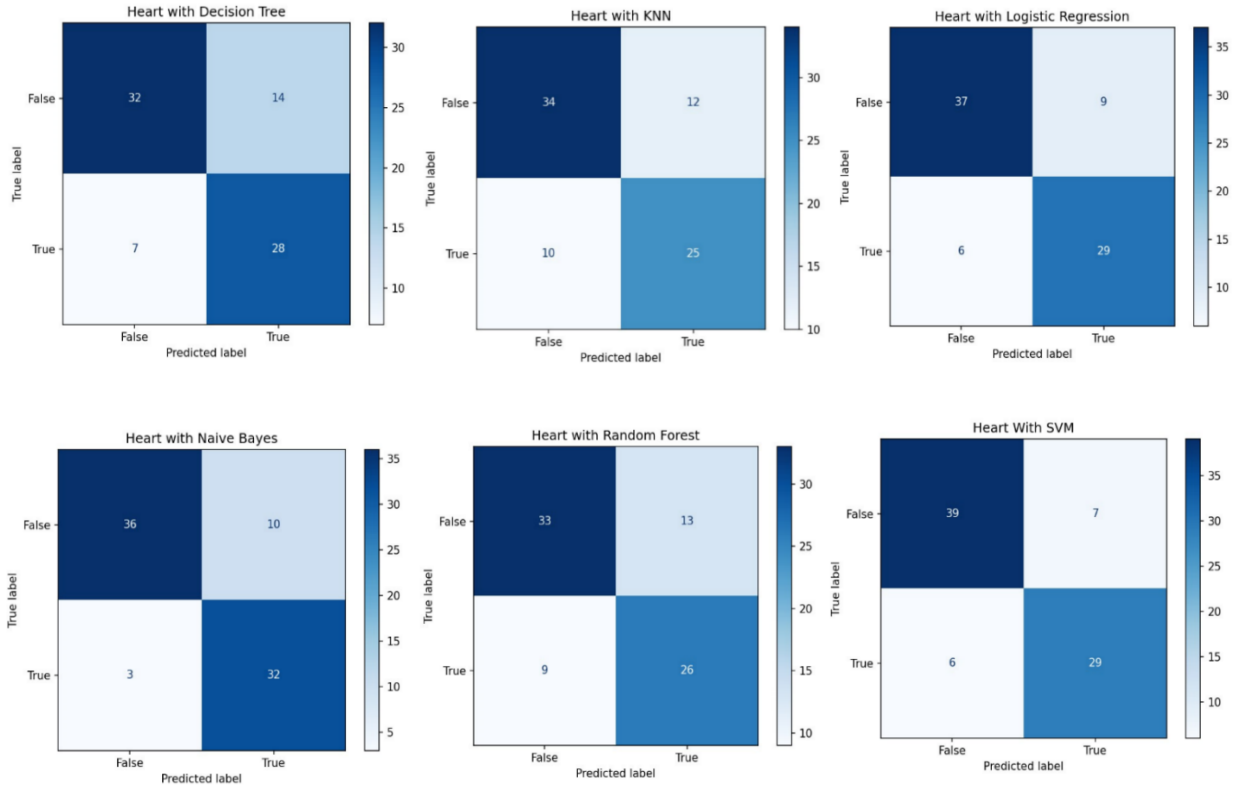

Fig. 4. Confusion matrix for heart disease data.

Experiments using the heart disease dataset showed an average accuracy of 0.7818, precision of 0.7644, recall of 0.8381, and F1 Score of 0.7989. Meanwhile, the best-combined method is EMKI SMOTE, PSO GWO combined with SVM, Naïve Bayes, and Logistic Regression, which is shown as a whole in Table IV.

The third experiment was carried out on the breast cancer dataset, with 32 features. The experimental results of the model also show that the feature selection results are significant and relevant, thus influencing the improvement of experimental results. The Minority class value is lower than the majority, with an imbalance ratio of 1.68, after being corrected with the proposed model, indicating good and even experimental results for the six classification methods.

TABLE IV. EVALUATION MATRIX HEART

Dataset	Classifier	Accuracy	Precision	Recall	F1 Score
Heart	Decision Tree	0.7407	0.6956	0.8205	0.7527
	K Nearest Neighbor	0.7283	0.7391	0.7727	0.7555
	Logistic Regression	0.8148	0.8043	0.8604	0.8313
	Naïve Bayes	0.8395	0.7826	0.9230	0.8469
	Random Forest	0.7283	0.7173	0.7857	0.7499
	Support Vector Machine	0.8395	0.8478	0.8667	0.8571

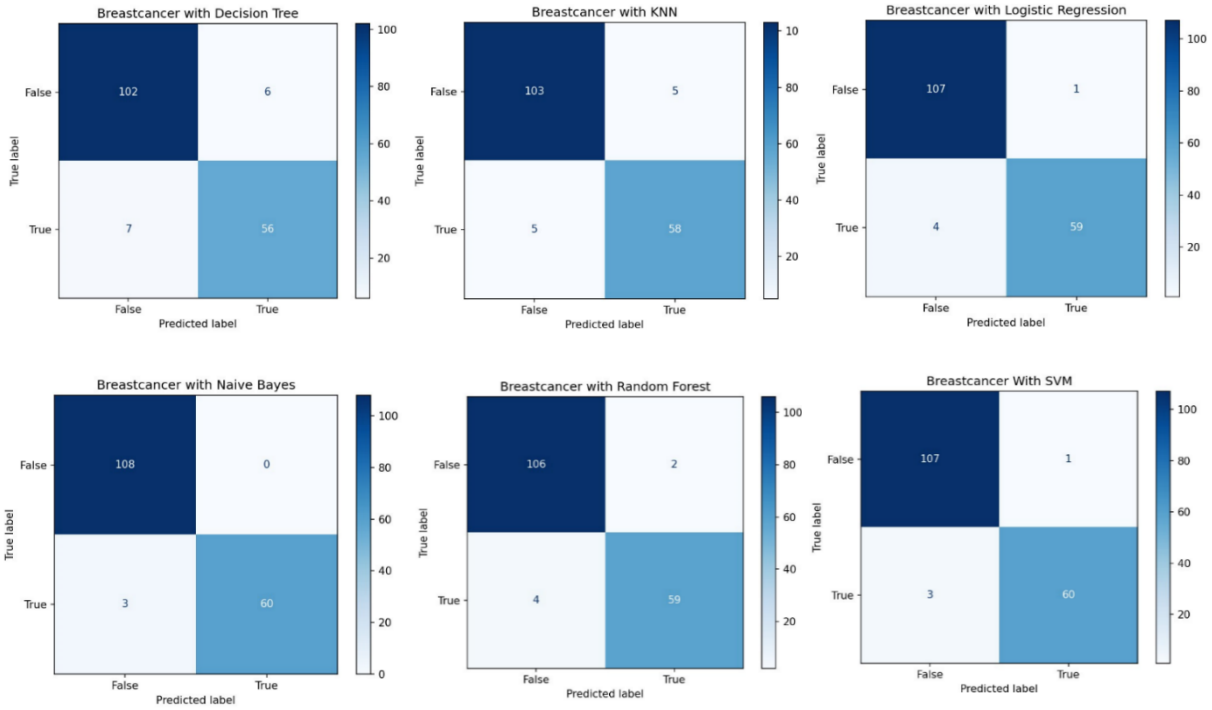

Fig. 5. Confusion matrix for breast cancer.

The application of the EMKI SMOTE model combined with PSO GWO produces averages for accuracy, precision, recall, and F1 Score in the range of 0.9684 with the best results in the Naïve Bayes, SVM, and Logistic Regression classification methods as shown in Table V.

The application of the EMKI SMOTE model combined with the PSO GWO method on medical record data was due to the discovery of a lot of unbalanced data, with the prevalence of patients in normal conditions being higher than patients suffering from disease. The experiment also selected datasets by considering high, medium, and low data dimensions based on the number of features and the total number of dataset samples. Analysis of experimental results from various aspects shows a significant increase in results, and computing time calculations also indicate that the training and testing process is faster.

TABLE V. EVALUATION MATRIX BREAST CANCER

Dataset	Classifier	Accuracy	Precision	Recall	F1 Score
Breast Cancer	Decision Tree	0.9239	0.9444	0.9357	0.9399
	K Nearest Neighbor	0.9415	0.9537	0.9537	0.9536
	Logistic Regression	0.9707	0.9907	0.9639	0.9770
	Naïve Bayes	0.9824	1.00	0.9729	0.9863
	Random Forest	0.9649	0.9814	0.9636	0.9723
	Support Vector Machine	0.9766	0.9907	0.9727	0.9816

V. CONCLUSION

Imbalanced class data has become an essential problem in medical diagnosis, but using classification algorithms alone cannot meet the classification needs effectively. This research proposes a combined method by modifying the distance calculation using Minkowski and adding entropy to determine the value of the number of samples created. The proposed calculation model is hereafter called EMKI SMOTE. The EMKI SMOTE oversampling approach is designed to handle imbalances between majority and minority classes in data so that it can produce relevant features in high-dimensional data. Next, the balanced data will be ensembled using the PSO GWO method in the feature selection process. The combined results of the data balance method and feature selection will then be used in the training and testing process using the classification method. The research results show increased accuracy, especially in the Naïve Bayes method, Logistic Regression, and SVM using diabetes, heart, and breast cancer datasets. The further development of this research model is to obtain constant balanced data, namely, by determining the interval between the majority and minority sample numbers. In addition to adding parameters to the dataset model configuration, it is possible to balance the data, which causes an increase in accuracy. Meanwhile, testing large amounts of data and high dimensions by making several substitutions in the feature selection method is also considered to increase the accuracy of classification results and help in the problem of early disease detection.

ACKNOWLEDGMENT

We are grateful to everyone who helped with this study, especially the promoter and co-promoter who advised completing it. In addition, I want to convey my heartfelt gratitude to the Indo Global Mandiri University for allowing me to improve personally.

***Abstract*—Noninvasive and accurate methods for diagnosing respiratory diseases are essential to improving healthcare consequences. The Internet of Medical Things (IoMT) is critical in driving developments in this field. This work presents an IoMT-enabled approach for lung disease detection and classification, using deep learning techniques to analyze lung sounds. The proposed approach uses three datasets: the Respiratory Sound, the Coronahack Respiratory Sound, and the Coswara Sound. Traditional machine learning models, including the Extra Tree Classifier and AdaBoost Classifier, are used to benchmark performance. The Extra Tree Classifier achieved 94.12%, 95.23%, and 94.21% across the datasets, while the AdaBoost Classifier showed improvements with 95.42%, 96.33%, and 94.76%. The proposed deep neural network (DNN) achieves accuracies of 98.92%, 99.33%, and 99.36% for the same datasets. This study explores the transformative potential of the Internet of Medical Things (IoMT) in augmenting diagnostic precision and advancing the field of respiratory healthcare.**

***Keywords*—Deep learning; respiratory sound; coronahack respiratory sound and coswara sound; IoMT**

I. Introduction

According to epidemiological statistics on respiratory disorders published by the World Health Organization (WHO), 210 million people worldwide suffer from chronic obstructive pulmonary disease (COPD), and 30 million people have asthma. Studies show that between 15 and 25 million people in India have asthma [1]. Physicians often use the noninvasive, low-cost lung auscultatory technique to assess the state of the lungs [2]. The noises the lungs make while air passes through them during breathing are known as lung sounds [3].

It is critical for recognizing lung diseases because it provides precise lung function data. Aberrant and accidental lung sounds are the two general classifications for lung sounds [4]. The Vesicular, Bronchial, Broncho-Vesicular, and Tracheal lung sounds are common [5]. Accidental lung sounds can be classified as constant or intermittent, depending on their duration and persistence [6]. Early identification and close observation of pneumonia are essential for adequate medical care [7]. Lung inspection is a standard clinical procedure for diagnosing respiratory disorders [8]. It involves hearing the sounds of an individual's lungs with a stethoscope. Usually, these noises are classified as either abnormal or normal [9]. The frequent unusual noises audible over characteristic lung sounds are crackles, wheezes, and squawks; they commonly exist in a lung condition [10].

Common lung sounds and cyclical patterns represent air passage during breathing. Pulmonary illnesses characterized by persistent, incomplete reversible airflow obstruction and normal breathing [11]. Auscultation using a listening instrument is only a qualitative diagnostic tool, even though it provides direct information [12]. However, the results of auscultation evaluation are inadequate due to several factors, such as inter and intra-observer inconsistency, bias errors in distinguishing fine sound structures, and frequency reduction [13]. Lung sound-based diagnosis is accurate and free of subjectivity errors due to the application of computer-based automated approaches and developments in lung sound recording techniques [14]. Computer-based lung sound assessment allows for a comprehensive assessment of lung sound features through visual representations, recording evaluations, suppression of noise contaminants, and evaluation of changes in lung sound action [15]. The sounds generated by air passing through the tracheobronchial tree are sounds produced by the respiratory system [16].

A. Common Lungs Disease

Asthma is a chronic respiratory condition characterized by inflammation and narrowing of the airways, leading to recurring episodes of wheezing, shortness of breath, chest tightness, and coughing [17]. It affects people of all ages but often starts in childhood and can persist into adulthood[18]. New opportunities for the early identification and categorization of lung diseases related to asthma are created by the combination of deep learning algorithms and heart sound analysis [19]. These algorithms can identify intricate patterns in cardiac sound data, which makes it possible to create precise and effective diagnostic models [20].

The respiratory ailment known as bronchitis is typified by discomfort in the bronchial tubes, the airways that supply oxygen to the lungs [21]. Two primary types of bronchitis can be distinguished: acute and chronic. Pneumonia is a dangerous respiratory system infection that affects the lungs [22]. Numerous pathogens, such as bacteria, viruses, fungi, or parasites, cause it. All ages are susceptible to pneumonia, but

young children, aged people, and those with compromised immune systems are most at risk.

The symptoms of Chronic Obstructive Pulmonary Disease (COPD) frequently include wheezes and reduced breath sounds, which indicate airway narrowing and blockage. These auditory characteristics are analyzed by deep learning models to consistently identify COPD trends in IoMT-enabled, noninvasive detection. These devices capture precise auditory cues, allowing for early and accurate COPD monitoring and classification, facilitating proactive treatment and intervention.

Crackles in lung sounds, a sign of respiratory disorders like pneumonia or bronchitis, are detected using IoMT-enabled, noninvasive lung disease detection. Deep learning models analyze these acoustic patterns, providing accurate classification and automated assessment of potential lung abnormalities. Wheezes, high-pitched sounds during exhalation, indicate airway obstructions in conditions like asthma or COPD. IoMT-enabled lung disease detection uses deep learning algorithms to improve diagnostic accuracy, distinguishing between obstructive and restrictive respiratory disorders and facilitating timely medical interventions.

B. Research Objectives and Motivation

1) Develop a noninvasive system for detecting and classifying lung diseases using lung sound data collected via IoMT (Internet of Medical Things) devices.

2) Implement deep learning techniques, including an Extra Tree Classifier, an AdaBoost Classifier, and a Deep Neural Network, to classify lung disease from sound data.

3) Analyze the effectiveness of enabling monitoring, correct diagnosis, and efficient data processing for remote healthcare applications.

Motivation: Respiratory health is safety-critical for human life, as effective diagnosis and treatment are essential to prevent severe consequences. Traditional methods are invasive and inaccessible, so there is a need for advancements in this domain. This work includes developing a noninvasive IoMT-enabled using deep learning for accurate and accessible lung disease detection, ensuring diagnosis, and supporting remote healthcare solutions.

II. Literature Review

Neural network model, lowering data leakage and memory utilization. CNN-LSTM layers, self-attention layers, dropout, Fully Linked (FC), and softmax layers comprise the model using the ICBHI 2017 dataset. The purpose of hyperparameter tuning is to reduce training failure. Self-attention is an independent layer that works with LSTM and CNN models [23]. According to experimental data, the suggested CNN+LSTM+Selfattention model performs better overall in terms of accuracy score than the CNN+LSTM+Hybrid CNN+LSTM, CNN+LSTM+Simple Attention, and CNN+GRU+Selfattention models. With a score of 57.02% for the initial train-test split, the model produces more dependable results.

A DNN is developed to diagnose interstitial lung diseases (ILD) in patients with connective tissue diseases (CTD), and preprocessing methods are evaluated on various lung sound data sets. The DNN offers remarkable accuracy on high-resolution CT scans, with an F1-score and an F2-score of 97% [24]. Since screening for ILD in patients with chronic autoimmune disorders is still a work in progress, this technique serves as an enabler for the early, safe, accurate, and affordable identification of CTD-ILD.

Augmentation techniques to resolve the imbalanced dataset problem. The model, which has two LSTM layers, five convolutional blocks, and no augmentation, achieves a remarkable F1 score of 0.9887 in 91 s per training epoch. Misclassifications accounted for just 3.05% of COVID-19 data and mostly happened in typical instances [25]. While the standard class showed recall and an F1 score, the pneumonia class showed exceptional precision. Deep Residual Network (DRN) uses a fractional water cycle swarm optimizer (Fr-WCSO-based DRN) to identify lung disorders from respiratory sound waves. The Fr-WCSO is a novel design that combines the Water Cycle Algorithm and Competitive Swarm Optimizer with Fractional Calculus and Water Cycle Swarm Optimizer (WCSO). To reduce overfitting problems, the system preprocesses respiratory input sound signals, identifies relevant features, and augments data [26]. DRN training and feature selection are then carried out using the Fr-WCSO algorithm.

Hybrid Interpretable Strategies with Ensemble Techniques (HISET) for respiratory sound classification. The first approach uses a GSSR technique, and the second uses a novel Realm Revamping Sparse Representation Classification (RR-SRC) technique, the third uses Distance Metric dependent Variational Mode Decomposition (DM-VMD) with Extreme Learning Machine (ELM) classification process, the fourth uses Harris Hawks Optimization with Scaling Factor based Pliable Differential Evolution (SFPDE), and the fifth uses Gray Wolf Optimization based Support Vector Classification (GWO-SVC) and Grasshopper Optimization Algorithm (GOA) based Sparse Autoencoder for dimensionality reduction techniques [27]. The ICBHI dataset is used to analyze the results, and the best results are obtained for the 2-class classification when Manhattan distance-based VMD-ELM is used. This method reported an accuracy of 95.39% for the 3-class classification, 90.61% for the 3-class classification, and 89.27% for the 4-class classification. The classification of pulmonary sounds obtained from patients with connective tissue illnesses using deep learning techniques [28].

Features such as Wavelet Entropy (WE) and wavelet packet energy (WPE) are extracted from the LS. Various classifiers, including Support Vector Machine (SVM), Decision Tree (DT), k-nearest Neighbor (KNN), and Discriminant Analysis (DA), are employed to classify healthy, COPD, and asthma cases using WE and WPE features. The proposed algorithm achieves a notable classification accuracy of 99.3% with the Decision Tree (DT) classifier, effectively distinguishing between healthy individuals and those with asthma or COPD based on LS[29]. Future work will validate this algorithm with real-time LS data from asthmatic and COPD patients.

Section I introduces the research work, focusing on using IoMT and deep learning for noninvasive lung disease diagnosis. Section II reviews the existing literature,

highlighting the limitations of conventional methods and the potential of IoMT technologies. Section III discusses the background studies, describing foundational principles and relevant advancements in IoMT and lung sound analysis. Section IV outlines the materials and methods, including data acquisition and deep learning techniques. Section V presents the results and discussions, analyzing findings. Section VI concludes the study, summarizing contributions, implications, and recommendations for future work.

III. Background Studies

A. Internet of Medical Things

The Internet of Medical Things (IoMT) refers to a network of interconnected medical devices, software applications, and healthcare systems designed to collect, transmit, and analyze patient data in real time. IoMT advanced technologies, i.e., sensors, wearable devices, remote monitoring tools, and cloud computing, to provide continuous healthcare solutions. These systems enable personalized patient care, early disease detection, and effective chronic disease management by continuously tracking vital signs and other health parameters.

IoMT enhances patient outcomes by enabling remote consultations, reducing hospital visits, and facilitating proactive treatment through real-time alerts. It also streamlines healthcare workflows by integrating data from diverse sources, improving clinical decision-making. However, IoMT faces challenges, including data security, interoperability, and compliance with regulatory standards. Despite these hurdles, IoMT represents a transformative advancement in modern healthcare, driving a shift toward precision medicine and empowering patients to actively engage in health management.

B. Extra Tree Classifier

One method of group decision-tree education is called the Extra Trees Classifier. When splitting a tree node, the Extra Trees classifier strongly randomizes the choice of features and reduces points, producing an unpruned collection of decision trees and trees. Extra trees function by combining the output of several de-correlated decision trees into a forest, from which they derive the classification result determined by the bulk of the voting technique. Compared to conventional decision trees or even random forests, this model adds more randomness by constructing multiple decision trees using arbitrary portions of characteristics and splitting at random points. This volatility reduces overfitting and improves the model's ability to generalize. Features taken from the audio recordings, such as time-domain, frequency-domain, and time-frequency domain characteristics, are fed into the Extra Tree classifier in the context of lung sound analysis. The model uses the rich and varied feature set to differentiate between various lung sounds, including wheezes, crackles, and other pathological sounds connected to illnesses like pneumonia, COPD, or asthma, as well as typical breathing.

C. AdaBoost Classifier

The AdaBoost methodology is a method for improving the performance of a model by combining weak classifiers. It involves extracting relevant features from audio recordings, such as time-domain and frequency-domain features, and training a weak classifier, typically a decision tree with a single split. Classifier kj can express an opinion, denoted by kj(xi) when their proposal is considered a training example for classifier acquisition for a given input model xi. Taking into account the issue of splitting the learning vector gathering into two classes, kj(xi) only accepts two values, such as 0 or 1, respectively, as shown in equation Sign C(xi), the sign of the linear mixture of the weighted total of the sub-classifiers' opinions, determines the classifier K's ultimate decision.

$$C(x_i) = a_1 k_1(x_i) + a_2 k_2(x_i) + a_l k_l(x_i)$$

Where weights are denoted bya_1, a_2,..., a_l And sub-classifiers by k_1, k_2,..., k_l. To generate a set of subpar learners, the adaboost technique keeps track of weights across instruction data and continually adjusts them after each weak learning cycle. The weights of training instances that the current weak learner incorrectly classifies will be increased, while the weights of training instances that are correctly classified will be decreased.

D. Deep Neural Network

The components of deep learning networks developed in the two-stage model will be clarified in the following part on artificial neural networks. Artificial Neural Networks (ANNs) are dynamic models that can adapt their internal architectures to meet specific functional requirements, making them ideal for managing nonlinear type issues. The essential parts of an ANN are the links and nodes that make up it, each with an output and input for interaction with other nodes or the surroundings. Each neuron in the network applies an activation function to introduce non-linearity through weighted connections. A labeled dataset is used to train the network, which uses a loss function to minimize the error between predicted and actual class labels during training by adjusting the weights of the connections through backpropagation. The learning process is one of the core characteristics of ANN, as they can understand the connections that define the data by adapting its connection to the information structure that makes up its surroundings. Neurons can be arranged in any topological configuration based on the kind and volume of input data. The feed towards construction is used in designing the most widely used ANN, with an input layer typically consisting of a particular amount of neurons paired. The data is sent to the secret layer or layers operating within the ANN and the output layer are created specifically to address the issue and provide the solution. Each neuron in the layer below is linked to every other neuron, with a fixed number of inputs and weights. Measurements are crucial for operating the deep neural network as they can be learned parameters.

$$C(x_i) = a_1 k_1(x_i) + a_2 k_2(x_i) + \cdots + a_l k_l(x_i)$$

Weight values are randomly initialized to be near zero but not zero before acquiring starts. The values of the data are modified to new information during learning, and this modification will aid in determining the significance of inputs. The activation function translates the weighted average from one neuron into the afterwards neuron's stimulation. Numerous mechanisms for activation are described in this research. Two factors influence the selection of rectified linear activation units in hidden layers in this work: (1) their ease of computation; and (2) the possibility of deep neural network

optimization because of their linear behaviour. After receiving input from hidden layer #2, the network's output layer transforms it into a binary (zero = unhealthy or one = healthy). The following equation is a representation of the sigmoid activation function:

$$\check{y} = \frac{1}{1 + e^{-z\prime}}$$

Where ў the neuron's results and z is the hidden layer #2 outputs.The average error was determined for each sample using the loss function with cross entropy. Here is a representation of the cross-entropy loss function in equation.

$$H\ (y, \check{y}) = -\sum_{i=1}^{n} y_i - \mathrm{Log}(\check{y}_i)$$

Where ў the network's output and y is is the real value. After every single propagation forward, the neural network searches for a set of heavy objects that minimizes the variance among the expected and actual values.

IV. Material and Methods

A. Dataset Descriptions

The audio files used in the thesis came from three distinct data sets. A variety of numbers of audio files from different datasets are included to create a balanced dataset. Table I Describes three Datasets used in this work.

1) Respiratory sound: The Respiratory Sound is a collection of 920 audio recordings from two research teams in different countries. Samples gathered at the Hospital Infante D. Pedro in Aveiro, Portugal, and the ESSUA Respiratory Research and Rehabilitation Laboratory by the School of Health Sciences, University of Aveiro research team. The second research team, from the Universities of Coimbra and Aristotle University of Thessaloniki, gathered respiratory sounds at the Papanikolaou General Hospital in Thessaloniki and the General Hospital of Imathia in Greece. Most of the database consists of audio, with samples from two hospitals in Portugal and Greece. The researchers analyzed the recordings using various instruments, including stethoscopes and microphones. They found 761 recordings suitable for evaluation, and 761 audio files were added to the model dataset without additional requirements [30]. The database includes 6898 breathing cycles from 126 patients, with 1864 having crackles, 886 having wheezes, and 506 having both.

2) Coronahack respiratory sound: The Coronahack Respiratory Sound includes respiration sound files from both COVID-19-affected and non-affected users. The file Corona-Hack-Respiratory-Sound-Metadata.csv includes additional disturbances and demographic data about the user. Audio recordings of patients with asthma or pneumonia were included in the dataset. Respiratory sound recordings from people with asthma or pneumonia were carefully selected from records that did not indicate probable COVID-19. The dataset contained these recordings [31].

3) Coswara sound: Coswara aims to develop a cost-effective method for diagnosing COVID-19 using speech, cough, and breath sounds. The study focuses on respiratory distress, a common symptom of the illness, and measures disease biomarkers in the acoustics of these noises. The project collects voice samples from healthy and sick individuals, examining nine categories of breathing, coughing, vowel phonation, and counting. Age, gender, location, current health status, and co-morbidities are collected. The dataset includes audio recordings from patients who have not contracted COVID-19 or recovered, tagged as "Asthma" or "Pneumonia." Thirty-eight healthy voice files with respiratory sound for at least 10 seconds were included in the dataset. The study includes 38 healthy, 58 asthmatic, and nine pneumonia voice recordings under specific conditions. The Coswara dataset is valuable for understanding and diagnosing COVID-19[32].

B. Preprocessing

Preprocessing is essential for IoMT-enabled noninvasive lung disease classification and detection. Fig. 1 displays the proposed methodology for this work Preprocessing procedures are necessary to prepare the data for successful categorization since lung sound recordings frequently contain noise and unpredictability due to patient movements and natural influences. Special values in proportional variables are crucial for maintaining data integrity and optimizing model performance in lung disease detection and classification from lung sound analysis. 'Nan' values, which occur when numerator and denominator are zero, are removed in the first preprocessing step. Normalization or scaling techniques can be used to handle these special cases. When the denominator is zero, special values arise, such as positive infinity (+∞) or negative infinity (-∞), as shown in Eq. (1). These extreme values can significantly impact deep learning model performance during training.

$$X = \begin{cases} \frac{N}{D} & if\ D \neq 0 \\ +\infty & \text{if } N > 0 \text{ and } D = 0 \\ -\infty & \text{if } N < 0 \text{ and } D = 0 \end{cases} \quad (1)$$

TABLE I. Three Datasets used in this Work

Dataset Name	Audio Samples	Patients	Key Features	Source
Respiratory Sound	920 recordings, 761 used	126 patients, 6898 breathing cycles (1864 crackles, 886 wheezes, 506 both)	Breathing sounds recorded using stethoscopes and microphones	[30]
Coronahack Respiratory Sound	Varied, includes both COVID-19 and non-COVID-19 patients	Includes asthmatic, pneumonia, and COVID-19-negative patients	Demographic data, respiratory conditions, and sound disturbances included	[31]
Coswara Sound	38 healthy, 58 asthmatic, 9 pneumonia	Data collected includes age, gender, health status, and co-morbidities	Focus on speech, cough, and breath sounds for diagnosing respiratory distress	[32]

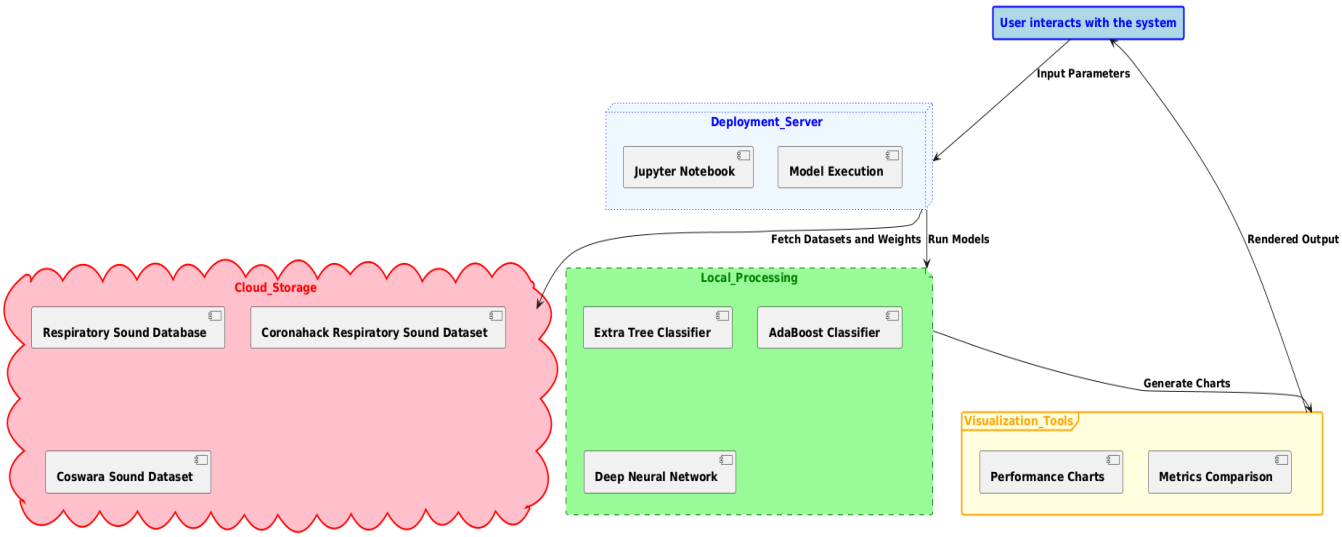

Fig. 1. Proposed methodology for this work.

The Weight of Evidence (woe) measures how well an organizing technique can discriminate between positive and negative results, or between 1 and 0. This method works for any issue where the binary variable is the target, even though it was initially created to create a predictive model for assessing credit default risk in the finance and credit sectors. The amount of evidence that either confirms or disproves a hypothesis is measured by its weight. The Weight of Evidence is determined as follows in Eq. (2):

$$WoE = \ln\left(\frac{Distribution\ of\ 1's}{Distribution\ of\ 0's}\right) * 100 \qquad (2)$$

Feature elimination is crucial for optimizing model performance by removing unnecessary, redundant, or noisy features from the dataset using statistical testing, correlation analysis, and machine learning algorithms. Feature elimination techniques such as Recursive Feature Elimination (RFE) remove irrelevant or redundant features, reducing overfitting and computational load. The model's performance metric is calculated without feature removal, and the impact of eliminating features is assessed. The model's performance metric J is calculated without feature x_j, and the impact of elimination x_j is shown in Eq. (3).

$$J_{-x_j} = J\left(X\left\{x_j\right\}\right) \qquad (3)$$

C. Feature Extraction

An individual measurable functionality or characteristic that defines a phenomenon is called a feature in machine learning. Useful algorithmic methods for classification rely on selecting independent, making distinctions, and useful characteristics. In this work, 1522 features from different categories were created for each sound recording as follows:

1) Time domain features: Three distinct groups are created from the signal's time series features: the audio recording's 0–1 s, 0–6 s, and 0–10 s segments. The relevant signal's increasing average series and accumulative series were calculated. The number of data points in the initial collection always equals the total moving average's term count, as shown in Eq. (4). C_k Is defined recursively as follows, where x1, x2,..., xn are the related respiration sound time series and C1, C2,..., Cn are the accumulated average with weights a series.

$$C_k = \frac{(x_k + (k-1) * x_{k-1})}{k} \qquad (4)$$

2) Spectral feature: It is essential to differentiate between typical and abnormal respiratory conditions by capturing the frequency domain characteristics of lung sounds through features.

a) Time-frequency spectrogram statistical features: Mel-spectrogram, MFCC, Short-Term Fourier Transform, and Chroma In the earlier part, each respiration sound was subjected to a Short Term Fourier Transform to transform it into a time-frequency spectroscopy and extract features akin to those found in a spirometer. After computations, a long list of factors is created, which includes the statistical properties of the time-frequency spectra obtained for the 0–1, 0–6, and 0–10 s periods of each audio recording.

b) Power spectrogram statistical features: Power spectrogram statistical features provide insights into power distribution across different frequencies over time, which is essential for identifying and distinguishing various respiratory conditions, is described in Eq. (5).

$$f(x) = c_o + c_1 * x \qquad (5)$$

Where c_1 Is the coefficient of the corresponding column and c_o is the constant term.

D. Feature Elimination Process

Feature elimination is crucial for optimizing model performance by removing unnecessary, redundant, or noisy features from the dataset using statistical testing, correlation analysis, and machine learning algorithms.

1) GINI Elimination: The Receiver Operating Characteristic (ROC) curve is a crucial tool in signal detection

theory, used alongside the Neyman-Pearson method to visualize a classifier's efficacy. It is used for assessing and comparing the overall efficacy of testing or diagnostic procedures. The AUC index, a summary of the ROC curve, is often used in this assessment. The process is summarized as follows:

a) The training and test sets of the data set are split 80/20.

b) The single-variate regression procedure was applied to each variable's training set to determine the AUC of each variable.

c) Using the AUC values as a guide, the Gini coefficient for each variable was determined using the formula below Eq. (6):

$$GINI = (2 * AUC - 1) * 100 \quad (6)$$

E. Machine Learning Models

This section includes the details of two-stage machine/deep learning models and the working principles of applied algorithms. The Extra Tree Classifier and Ada Boost Classifier techniques with the most effective binary categorization were chosen as modeling algorithms using Python's open-source "pycaret" library.

Weight values are randomly initialized to be near zero but not zero before acquiring starts. The values of the data are modified to new information during learning, and this modification will aid in determining the significance of inputs. The activation function translates the weighted average from one neuron into the afterwards neuron's stimulation. Numerous mechanisms for activation are described in this research. Two factors influence the selection of rectified linear activation units in hidden layers in this work: (1) their ease of computation; and (2) the possibility of deep neural network optimization because of their linear behaviour. After receiving input from hidden layer #2, the network's output layer transforms it into a binary (zero = unhealthy or one = healthy). The following Eq. (7) is a representation of the sigmoid activation function:

$$\check{y} = \frac{1}{1+ e^{-z\prime}} \quad (7)$$

Where ŷ the neuron's results and z is the hidden layer #2 outputs. The average error was determined for each sample using the loss function with cross entropy. Here is a representation of the cross-entropy loss function in Eq. (8):

$$H\ (y, \check{y}) = -\sum_{i=1}^{n} y_i - \mathrm{Log}(\check{y}_i) \quad (8)$$

Where ŷ the network's output and y is the real value. After every single propagation forward, the neural network searches for a set of heavy objects that minimizes the variance between the expected and actual values.

Dropout is a regularization technique for deep neural networks that helps lessen learning when nerve cells are interconnected. It suggests that a subset of randomly chosen neurons from a particular layer may be removed during learning. As a result, during a specific forward or backward pass, the results of the eliminated nerve cells disappear. In the present study, every iteration saw the removal of 0.1% of the neurons in the relevant layer from the input and hidden layers.

F. Evaluation Measures

We utilize various assessment measures to evaluate the effectiveness of the proposed models. These measures provide insight into the models' accuracy, predictive power, and generalization capability. The percentage of accurately categorized cases out of all instances is known as accuracy, as shown in Eq. (9).

$$\text{Accuracy} = \frac{Number\ of\ correct\ prediction}{Total\ numer\ of\ prediction} * 100 \quad (9)$$

Other evaluation measures adopted for assessing the proposed models are specificity, sensitivity, and F1 score, shown in Eq. (10) and Eq. (11). The specificity and sensitivity formula are as follows:

$$Specificity = \frac{True\ positive}{True\ positive+False\ negative} \quad (10)$$

$$Sensitivity = \frac{True\ negative}{True\ negative+False\ positive} \quad (11)$$

True positives (TP) are positive in the test set and correctly labeled as positive by the classifier. True negatives (TN) are negative in the test set and correctly labeled as negative by the classifier. False positives (FP) are negative in the test set but incorrectly labeled as positive by the classifier. False negatives (FN) are positive in the test set but incorrectly labeled as negative by the classifier. Eq. (12) shows that the F1 score is the harmonic mean of precision and recall, providing a combined measure of precision and recall.

$$F1\ score = 2 * \frac{Precision*Recall}{Precision\ +Recall} \quad (12)$$

Where precision and recall are calculated Eq. (13) and Eq. (14), respectively.

$$Precision = \frac{True\ positive}{True\ positive+False\ positive} \quad (13)$$

$$Recall = \frac{True\ positive}{True\ positive+False\ negative} \quad (14)$$

V. Discussion and Results

Spectrogram (top) and onset strength analysis (bottom) of lung sound data, critical for IoMT-enabled noninvasive lung disease detection. The spectrogram visualizes frequency (Hz) over time, with color intensity indicating sound energy. It highlights distinct acoustic patterns associated with respiratory cycles, facilitating feature extraction for disease classification. The onset strength graph below shows temporal variations in sound intensity, with detected onsets marked by red dashed lines, capturing significant events like wheezes or crackles. These features, analyzed using deep learning, improve the precision of lung sound classification, aiding in early and accurate detection of pulmonary diseases. Fig. 2 represents Spectro-Temporal Analysis for IoMT-Based Lung Disease Detection.

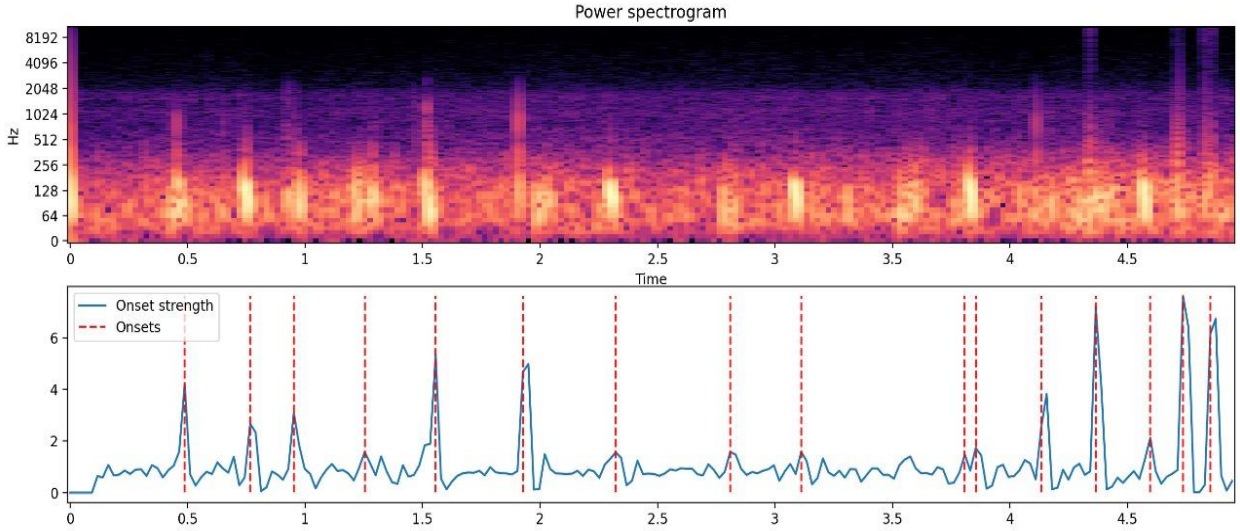

Fig. 2. Spectro-Temporal analysis for IoMT-Based lung disease detection.

Onset detection and energy analysis for lung sounds, crucial for IoMT-based noninvasive respiratory disease classification. The top graph visualizes onset strength with raw onsets (blue peaks) and backtracked onsets (red vertical lines). These onsets correspond to significant acoustic events, such as wheezes or crackles, indicative of lung abnormalities. By combining onset detection and energy analysis, these features enhance the ability of deep learning algorithms to accurately classify lung diseases, enabling early diagnosis through efficient feature extraction and temporal event mapping. This dual-layer analysis improves robustness in detecting subtle patterns in lung sounds, aiding real-time and remote healthcare applications. Fig. 3 shows Onset and Energy Analysis for Lung Sound Classification.

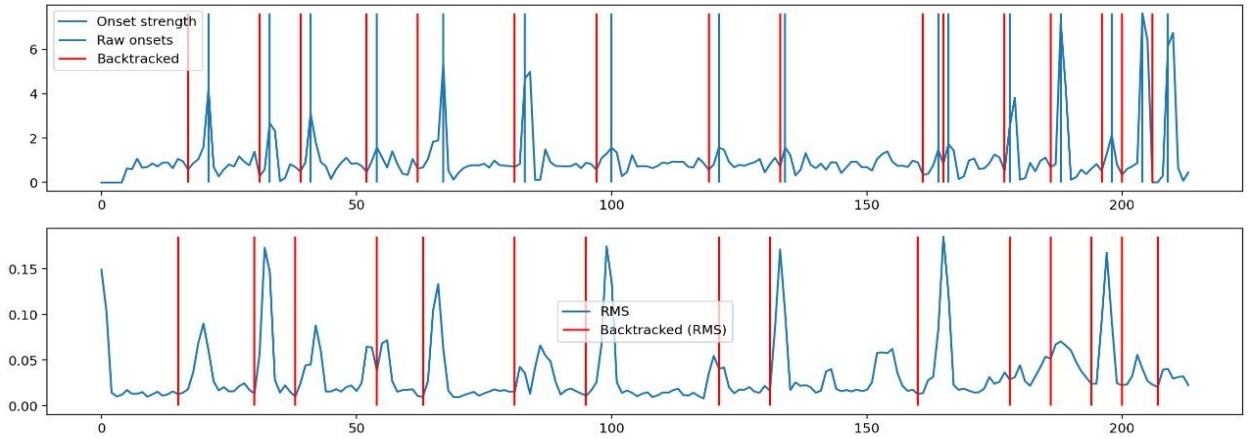

Fig. 3. Onset and energy analysis for lung sound classification.

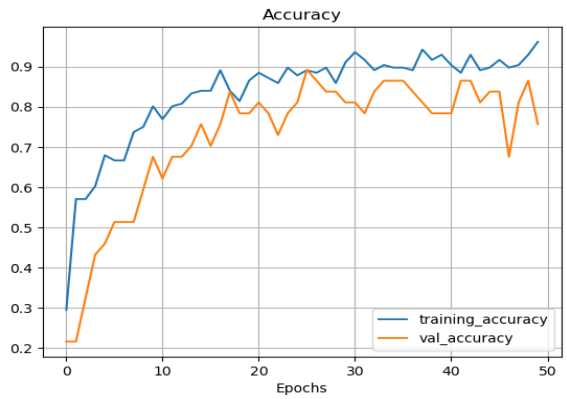

Fig. 4. Training history.

The Fig. 4 shows the training and validation accuracy trends over 50 epochs in a machine learning model. The x-axis represents epochs, and the y-axis represents accuracy values ranging from 0 to 1. The training accuracy (blue line) steadily improves, indicating the model's ability to fit the training data, with slight fluctuations towards the later epochs. The validation accuracy (orange line) increases initially, stabilizes, and exhibits minor oscillations, reflecting the model's generalization performance. The gap between training and validation accuracy suggests potential overfitting, as training accuracy surpasses validation accuracy in later epochs. This trend presents the need for optimization or regularization techniques.

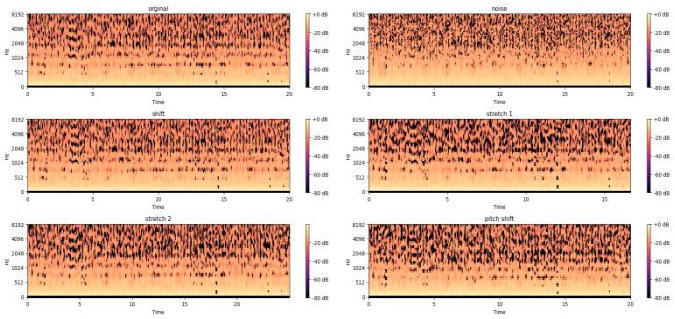

Fig. 5. Unaltered audio spectrogram.

The Fig. 5 show spectrograms visualizing feature extraction from an audio signal under different augmentations. The first plot (original) shows the unaltered spectrogram. Subsequent plots depict the effects of augmentations: noise addition, time shift, time stretching (two variations), and pitch shifting. These transformations simulate variability in audio datasets to improve machine learning model generalizability. The model can robustly learn features under varying conditions by augmenting the original signal, critical in tasks like speech recognition or environmental sound classification.

The results presents analysis of three machine learning models—AdaBoost Classifier, Extra Tree Classifier, and Deep Neural Network—evaluated on three datasets: the Respiratory Sound, Coronahack Respiratory Sound, and Coswara Sound. Each model's performance is measured using precision, recall, F1-score, and overall accuracy across diseases like crackles, wheezes, COVID-19, asthma, pneumonia, and healthy cases.

Table II, III and IV shows the performance of the models. Accuracy ranged from 94.12% to 95.23%, with consistent precision, recall, and F1-scores for all diseases, indicating robust yet moderate effectiveness. Table II displays the AdaBoost Classifier's assessment, which improved accuracy (95.42%–96.33%) and balanced precision-recall for detecting COVID-19 and other diseases, suggesting its superior predictive reliability compared to the ensemble approach. Table III evaluates a Deep Neural Network, showcasing the highest performance metrics, with accuracy surpassing 98% across all datasets. The network's precision, recall, and F1 scores consistently reached 0.99 for most diseases, demonstrating its efficacy in detecting subtle respiratory anomalies.

TABLE II. PERFORMANCE MEASURES OF EXTRA TREE CLASSIFIER

Dataset used for experiments	Diseases	Precision	Recall	F1-score	Overall Accuracy
Respiratory Sound	Crackles	0.95	0.96	0.95	**94.12%**
	Wheezes	0.93	0.94	0.96	
Coronahack respiratory sound	COVID-19	0.94	0.95	0.93	**95.23%**
	Healthy	0.96	0.93	0.92	
Coswara sound	Asthma	0.92	0.94	0.94	**94.21%**
	Pneumonia	0.94	0.93	0.94	
	Healthy	0.92	0.94	0.94	

TABLE III. PERFORMANCE MEASURES OF ADA BOOST CLASSIFIER

Dataset used for experiments	Diseases	Precision	Recall	F1-score	Accuracy
Respiratory Sound	Crackles	0.96	0.94	0.95	95.42%
	Wheezes	0.94	0.96	0.95	
Coronahack respiratory sound	COVID-19	0.97	0.96	0.97	96.33%
	Healthy	0.95	0.96	0.96	
Coswara sound	Asthma	0.96	0.95	0.94	94.76%
	Pneumonia	0.97	0.96	0.95	
	Healthy	0.95	0.95	0.96	

TABLE IV. PERFORMANCE MEASURES OF DEEP NEURAL NETWORK

Dataset used for experiments	Diseases	Precision	Recall	F1-score	Accuracy
Respiratory Sound	Crackles	0.99	0.98	0.98	98.92%
	Wheezes	0.99	0.99	0.99	
Coronahack respiratory sound	COVID-19	0.98	0.99	0.99	99.33%
	Healthy	0.99	0.99	0.99	
Coswara sound	Asthma	0.99	0.99	0.99	99.36%
	Pneumonia	0.98	0.99	0.99	
	Healthy	0.97	0.98	0.99	

VI. Conclusion and Future Work

This work presents an IoMT-based noninvasive approach to lungs disease detection and classification. The work uses an IoMT-enabled, noninvasive approach for lung disease detection and classification using Respiratory Sound, Coronahack Respiratory Sound, and Coswara Sound. Using machine learning models such as the Extra Trees classifier and AdaBoost classifier alongside a proposed deep learning model, this approach achieved impressive accuracy levels across various respiratory conditions. . The DNN achieves accuracy across all datasets, with 98.92% for the Respiratory Sound, 99.33% for the Coronahack Respiratory Sound, and 99.36% for the Coswara Sound. These results highlight the potential of deep learning models to support reliable and accurate respiratory health assessment in IoMT applications. Future work will enhance model robustness to handle diverse datasets and real-world variations and optimize the model for low-power IoMT devices to facilitate clinical deployment. Future work will optimize the proposed model for real-world applications, explore additional features such as multi-modal data for improved accuracy, and conduct large-scale evaluations across diverse network environments to assess generalizability.

***Abstract*—Machine learning techniques are increasingly used in orthopaedic surgery to assess risks such as length of stay, complications, infections, and mortality, offering an alternative to traditional methods. However, model performance varies depending on private institutional data, and optimizing hyperparameters for better predictions remains a challenge. This study incorporates automatic hyperparameter tuning to improve readmission prediction in orthopaedics using a public medical dataset. Bayesian Optimization was applied to optimize hyperparameters for seven machine learning algorithms—Extreme Gradient Boosting, Stochastic Gradient Boosting, Random Forest, Support Vector Machine, Decision Tree, Neural Network, and Elastic-net Penalized Logistic Regression—predicting readmission risk after Total Hip Arthroplasty (THA). Data from the MIMIC-IV database, including 1,153 THA patients, was used. Model performance was evaluated using Precision, Recall, and AUC-ROC, comparing optimized algorithms to those without hyperparameter tuning from previous studies. The optimized Extreme Gradient Boosting algorithm achieved the highest AUC-ROC of 0.996, while other models also showed improved accuracy, precision, and recall. This research successfully developed and validated optimized machine learning models using Bayesian Optimization, enhancing readmission prediction following THA based on patient demographics and preoperative diagnosis. The results demonstrate superior performance compared to prior studies that either lacked hyperparameter optimization or relied on exhaustive search methods.**

***Keywords*—Total hip arthroplasty; orthopaedic surgery; Bayesian Optimization; machine learning algorithm; hyperparameter optimization**

I. Introduction

Total Hip Arthroplasty (THA) is a surgery to replace the entire hip joint with an artificial joint, called an implant, and is typically performed on patients with severe osteoarthritis and having a prevalent rate of 1.2% [1], [2], [3]. THA is an effective option for reducing pain and improving hip joint function in patients with severe symptomatic osteoarthritis, with a success rate of more than 85% and clinical outcomes lasting for 15 to 25 years [4], [5], [6], [7]. The demand for THA procedures has significantly increased and is expected to continue to rise until 2040 [8], [9], [10]. However, like all surgery procedures, THA comes with risks concerning a patient's condition for infection, dislocation, and mortality and may require unplanned hospital readmission for a corrective procedure or even a revision surgery. Dislocation, complication (both implant and non-implant-associated complication), including infection and mental status, are identified as the reasons for readmission after THA [11], [12]. Meanwhile, 30-day readmission rate of 5% to 9.5% and 5% to 10% for 90-day readmission have also been reported [13], [14], [15], [16], [17], [18].

Bundled payments in healthcare have been established in several countries, such as United States, The Netherlands, Sweden, United Kingdom, and Indonesia, as part of a transition toward value-based treatment. This payment structure makes healthcare providers receive incentives for coordinating treatments, preventing complications and failures, and reducing unnecessary or duplicate tests and treatments, including unplanned hospital readmission [19], [20], [21], [22]. Therefore, a readmission risk prediction system for THA surgery is valuable in not only improving cost management, but also in improving patient care quality. It serves as a tool in the cooperative decision-making process between patients and doctors regarding the final decision to undertake the elective THA surgery, as well as in providing pre- and post-operative treatment tailored to the patient's condition [23], [24], [25]. Based on the predicted risks, in which is very individuals for each patient, doctors may design a customized treatment procedure such as medication prescription, diets, and/or supervised exercise before and after the surgery. The readmission risk prediction system is also a source of information for the hospital to manage the distribution of its resources, such as specialty doctors, operating rooms, inpatient

rooms, and medical equipment [26], [27]. With the rise of medical expenses, implementing effective and efficient procedures across all channels puts hospital management to the test while maintaining the quality of care, as often mirrored by the concept of patient-centered care [28].

Both classical and machine learning-based methods have already applied to predict the risk, including readmission risk, of THA surgery. Classical methods to predict the risk of THA surgery, as well as general surgery, are currently used, such as the Risk Assessment and Predictor Tool (RAPT) [29], Charlson Comorbidity Index (CCI) [30], and Elixhauser Comorbidity Index (ECI) [31], [32]. CCI and ECI measure risks associated with mortality, hospital length of stay, and hospital charges based on the overall severity of comorbidities. Instead, RAPT predicts discharge destination and length of stay for patients after hip or knee arthroplasty. With the rising complexity of patient electronic medical history data, a solution based on artificial intelligence (AI) and machine learning (ML) is critical to understanding each unique health profile of a patient and providing more accurate information related to risks to doctors and patients.

Machine learning (ML) algorithms have been effectively introduced and used in a variety of medical sectors such as predicting length of stay of lung cancer patients [33], elderly patients readmission risk prediction [34], and heart disease classification [35]; nonetheless, its technology is relatively new in the field of orthopaedic surgery [36]. Although classical approaches to calculate complication and mortality risks using patient demographic characteristics and comorbidities do exist, they are considered having weak discrimination, are not verified, and not general enough to accurately predict risk preoperatively and mostly are developed using multivariable regressions techniques [37]. According to the authors' preliminary literature review [38], various ML algorithms have been utilized to predict THA outcomes using AI/ML technology. Among them are Logistic Regression [39], [40], [41], Linear Support Vector Machine [39], [42], Linear Discriminant Analysis [39], Elastic Net Penalized Linear Regression [40], [43], Random Forest [40], [42], [43], Neural Networks [42], [43], Stochastic Gradient Boosting [42], [43], [44], and an automated machine learning tool developed for prognosis (dubbed AutoPrognosis) [45]. Specifically for predicting readmission risk, some machine learning tools used were a Random Forest approach with Natural Language Processing (NLP) feature [46], Linear Regression, Support Vector Machine, Random Forest to predict 90-day readmission [47], Logistic Regression [48], and Light Gradient Boosting Machine [49].

Research by Kuo et al. [50] aimed to predict periprosthetic joint infection by implementing two levels of ML architecture. Naïve-Bayes, eXtreme Gradient Boosting, Linear Regression, and Random Forest were put in the first level as base classifiers, while Support Vector Machine as the meta-classifier acted in the second level as the final decision maker based on the prediction result of the first level. Some patient-related variables used were demographic, biomedical, comorbidity, surgery-related variables and had a very good Area under Curve (AUC) score of 0.988. There was no additional information on hyperparameters fixed for the final classification algorithms in each level.

Research by Klemt [36] investigated the risk of failure of a revision THA involving similar variables to [50] using Neural Network, Elastic-net penalized logistic regression, and Random Forest and achieved the highest AUC score of 0.85 for Neural Network.

The investigation to predict complication and irregular surgery duration was performed in study [44] using eXtreme Gradient Boosting algorithm which incorporated 12 (twelve) variables related to patient demographic, implant type, and surgeon experience. The AUC scores were 0.64 for complication prediction and 0.89 for surgery duration. Based on the supplied codes in GitHub, hyperparameters search was performed using GridSearch method.

Nham et al. [39] conducted a study exploring various tree-based algorithms, neural networks, statistical and probabilistic approaches, and Support Vector Machine (SVM) to predict in-patient mortality, discharge disposition, and length of stay. The study incorporated patient-specific variables, such as demographic, diagnosis, and mortality risk, and also situational variables, such as operation location, hospital type, and number of hospital beds. The best three algorithms were different for each predicted outcome, but Linear Support Vector Machine (LSVM) and Decision List (DL) were the most frequent to appear in the best three. Again, there was no discussion on how to select the best hyperparameters for each algorithm.

A machine learning prediction of all-cause complications within two years of primary THA was introduced by Kunze [42] using preoperative variables, such as demographics, comorbidities, known allergies, and Modified Harris Hip Score. The study investigated several machine learning algorithms such as stochastic gradient boosting, random forest, support vector machine, neural network, and Elastic-net penalized logistic regression, including their hyperparameter settings which were tuned through a grid search approach. The best performing algorithm was Elastic-net penalized logistic regression with an AUC value of 0.93 on test set.

Research by Shah et al. [37] is one of the studies that applied Bayesian Optimization to optimize hyperparameters in an Automated Machine Learning (AutoML) environment. It consists of an ensemble of several machine learning pipelines, each fitted with its own hyperparameters, to make prediction on complications after THA procedure. It achieved AUC value of 0.732 and claimed to exceed the performance of other single-type machine learning algorithms such as Logistic Regression, XGBoost, Gradient Boosting, AdaBoost, and Random Forest.

Specifically for predicting readmission risk, research by Slezak et al. used and compared multiple machine learning techniques such as Light Gradient Boosting Machine (LGBM), Logistic Regression (LR), eXtreme Gradient Boosting (XGB), and Random Forests (RF) to predict risk for readmission after Total Joint Replacement surgery [49]. They included American Society of Anaesthesiologists Physical Status Classification (ASA) and modified Frailty Index (mFI-5) as the contributing

factors and achieved an AUC value of 0.672 with LGBM being the best algorithm for readmission prediction.

Unplanned 90-day readmission after THA was also predicted with LR [48] and the predictive performance of the model was evaluated using the validation dataset, resulting in an AUC value of 0.715. All variables were grouped into five categories, including demographics, perioperative factors, past surgical histories, comorbidities, and medication usages, where contributing factors for each category were identified.

Another prediction of 90-day readmission after TJA (Total Joint Arthroplasty) using comprehensive data from electronic medical records and patient-reported outcome measures was investigated in study [47] by utilizing a variety of machine learning algorithms including LR, LR with LASSO (Least Absolute Shrinkage and Selection Operator) penalty, SVM, and RF. They achieved quite an impressive AUC score of 0.862 with LR-LASSO being the best performing algorithm and selected nine significant variables including diabetes, prior use of corticosteroid medication, and number of follow-up visits to orthopaedic clinics as the significant risk factors.

Most of the machine learning algorithms applied require fine-tuning on a number of the hyperparameters (i.e., the pre-set algorithm parameters to control the learning process and determine the values of model parameters) to achieve the best result (i.e., highest accuracy and precision, lowest error, or highest discriminant value). Finding the best hyperparameters are a manual trial-and-error process, though there has been an increase in using automatic search algorithms (i.e., Hyperparameter Optimization) such as Grid Search, Random Search, Evolutionary-based Search, and Bayesian Optimization. Only a few earlier studies on predicting THA outcomes using machine learning have included automatic hyperparameter tuning with Grid Search [42] and the Bayesian Optimization methodology [37].

In addition, risk prediction of THA patients in earlier studies were based on data from respective authors' affiliations, thus might not be suitable for benchmarking the algorithms' performance and is difficult in terms of reproducibility to verify the results [51]. To the author's knowledge, no previous research related to predicting outcomes following Total Hip Arthroplasty surgery has used public datasets.

Machine learning techniques have proven to be effective in creating models to predict post-operative risks in THA patients, albeit there is no definitive technique best suited for all outcomes. Several previously cited articles briefly discussed how to determine the appropriate hyperparameters for each machine learning algorithm utilized using Grid Search approach, such as [42] and [44], which include systematically testing all possible hyperparameter combinations in the search space, but it is a time consuming and repetitive activity. With the rapidly increasing number and complexity of electronic medical records generated in this big data era, sweeping hyperparameters in the hyperparameter search space thoroughly as Grid Search does would take hours or days as the number of hyperparameters increases and finding the best ones remains a challenge. While Random Search provides better solution by randomly sampling points in the search domain, it is also less efficient for expensive evaluation functions [52]. Another more advanced method such as Bayesian Optimization capable of finding global optimization in a complex problem is gaining more recognition [37], [45]. Consequently, this study aims to provide a Bayesian Optimization approach to MLA in readmission risk predicting after THA operation. This research performed experiments on various machine learning algorithms commonly utilized in existing research with the optimization enhancement on a publicly available medical dataset MIMIC and evaluate the generalizability of the algorithms' claimed performance.

Hyperparameter optimization is particularly advantageous in improving the performance of machine learning algorithms and reducing tedious human effort to find the best setting [53]. It is also widely known that different hyperparameter settings work best for different datasets [54]. In the prediction of THA outcome context, one can expect a more accurate readmission risk prediction while delivering broader and easy-to-use machine learning tools to benefit non-technical expert users (i.e., doctors), incorporating hyperparameter optimization in the machine learning algorithms used. An automated hyperparameter optimization provides the search for the best hyperparameter configuration for each machine learning algorithm used automatically, thus improving accuracy and efficiency, as well as lowering error [55]. Meanwhile, automation makes it easier and simpler for non-technical experts to use various machine-learning technologies and gain more from the outcomes [53], [56]. The suggested system's contributions include the following:

1) Development of readmission risk prediction method: The study proposes to incorporate automatic hyperparameters tuning to the machine learning algorithm selected by users, providing a more accurate and precise prediction result while offering ease and simplicity in applying and customizing machine learning algorithms to non-technical expert users.

2) Exploration of hyperparameters optimization algorithm based on statistical approach: The study introduces a Bayesian Optimization method which is based on statistical calculation to find the best hyperparameters setting of the machine learning algorithm selected by users.

3) Performance evaluation on known public tabular dataset (Medical Information Mart for Intensive Care-IV) MIMIC-IV: To evaluate the generalizability of high performing machine learning algorithms acclaimed in previous studies, this study uses a known public medical dataset MIMIC-IV [57], which is based on real medical dataset.

4) Performance evaluation with robust metrics: to assess the effectiveness of the proposed system, the study introduces four evaluation metrics: Accuracy, Precision, Recall, and Area under the Curve Receiver Operating Characteristic (AUC-ROC) values. These metrics measure the algorithm's performance quality quantitatively.

This journal article is organized as follows: Section I introduces the background, objectives, and significance of the study; Section II details the methods, including data sources,

preprocessing, and machine learning techniques; Section III presents the results of the experiments; Section IV discusses the findings in comparison to existing research; and Section V concludes with key takeaways and future research directions.

II. METHODS

A. System Overview

The proposed readmission risk prediction system after THA operation furnishes decision support feature to both patients and healthcare professionals in the domain of peril prognosis. The system processes medical data from the electronic medical record dataset which integrates various relevant attributes from a number of tables. All related data from patients underwent THA procedure are extracted, including demographics, diagnosis, and postoperative procedures of medical rehabilitation, if any. Additionally, some data imputations of missing values from the attributes were performed and the readmission status of patients within a year after the THA procedure is set to be the target value of prediction. The system includes a varied array of classification algorithms in previous studies, including eXtreme Gradient Boosting (XGB), Stochastic Gradient Boosting (SGB), Random Forest (RF), Support Vector Machine (SVM), Decision Tree (DT), Neural Network (NN), and Elastic-net Penalized Logistic Regression (EnPLR). The best hyperparameters of those algorithms are then selected using Bayesian Optimization (BO) technique to ensure maximum results of the classification algorithms in predicting the readmission risk. Evaluation metrics such as Precision, Recall, and Area under the Receiver Operating Characteristic (AUROC) curve are employed to measure the algorithms' performance quality. Fig. 1 explicates the system overview of the proposed readmission risk prediction system.

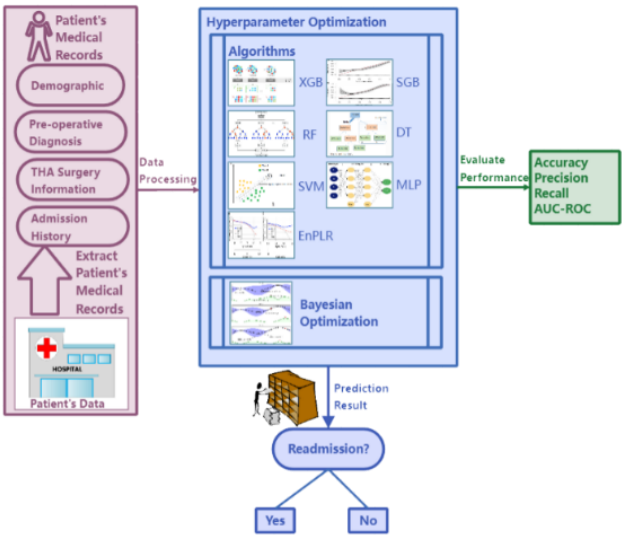

Fig. 1. System overview of optimized readmission risk prediction model.

The proposed method predicts the readmission risk of a THA patient based on one's demographics and preoperative diagnosis to help doctors plan preoperative treatments, aid patients in making informed decision on the surgery, and to assist hospitals managing their resources efficiently and properly with data-driven decision making. The system involved steps as follows:

1) Preprocess the patient dataset from MIMIC-IV (Medical Information Mart for Intensive Care version IV, which is a large de-identified public dataset of patients admitted to the emergency unit at the Beth Israel Deaconess Medical Center in Boston, MA). Duplicate data is identified and removed.

2) Identify the hyperparameters of previously utilized machine learning algorithms, including XGB, SGB, RF, SVM, DL, NN, and EnPLR, and perform the Bayesian Optimization technique to find the best hyperparameters for each algorithm.

3) Divide the dataset into 70% training and 30% testing set with stratified sampling.

4) Compare the model performance using evaluation metrics such as Precision, Recall, and AUROC.

B. Algorithm Introduction

1) eXtreme Gradient Boosting (XGB): XGB is a tree boosting machine learning algorithm whose capability of handling sparse data becomes one of its highlight features. The algorithm was introduced by Chen and Guestrin [58] and has won various machine learning competitions. It implements gradient boosting technique to perform additive optimization and incorporates a regularized model to prevent overfitting using L1 and L2 regularization methods. The algorithm is available in various popular languages such as Python, R, C, C++, and Java.

2) Stochastic Gradient Boosting (SGB): Introduced long before XGB, SGB has different approach to prevent overfitting in a general gradient boosting technique. It proposed a randomness into the algorithm by drawing a subsample, which is a fraction f of the size of the training set, to replace the full training data set at each iteration [59]. In scikit-learn, SGB is implemented with GradientBoostingClassifier by defining subsample hyperparameter < 1.

3) Random Forest (RF): RF works by building multiple decision trees and combines the output to give a single result. RF technique extends the bagging approach by combining bagging and feature randomness to generate an uncorrelated forest of decision trees [60]. Some of key benefits of RF are its capability to handle classification and regression tasks, and it is also easy to determine feature importance from the prediction result. This advantage can help to identify which features contribute the most to the prediction made.

4) Support Vector Machine (SVM): SVM has the ability to perform both linear and non-linear classification using a kernel trick. It works by constructing a hyperplane in a high dimension space and determine functional margin of data points (called support vectors) which define a separation boundary between classes [61].

5) Decision Tree (DT): In this study, DT is used as a replacement of Decision List (DL), since a Python's scikit-learn implementation of DL is not available. DT is a simpler

version of RF which consists of decision nodes, chance nodes, and end nodes. Following the path from root and making decisions at every branch according to the attribute value leading to an end node will create a rule that defines the temporal or causal relations among attributes.

6) Neural network: The Neural Network implemented in this study is Multi-Layer Perceptron (MLP), which is a supervised learning algorithm that maps a number of inputs to a number of outputs with a number of nodes in between (called hidden layers). The nodes in the hidden layers transform the values from the previous layer by adjusting the nodes' weights and propagate the result to the next layer. MLP implements a regularization technique (called L2) to avoid overfitting by punishing weights of large magnitudes.

7) Elastic-net Penalized Logistic Regression (EnPLR): EnPLR is a modified version of the classic Logistic Regression with a regularization method to overcome overfitting that linearly combines L1 (LASSO-Least Absolute Shrinkage and Selection Operator) and L2 (Ridge Regression). In scikit-learn, EnPLR is implemented with LogisticRegression model by setting hyperparameters solver=saga, penalty=elasticnet, and l1_ratio=0.5.

8) Hyperparameter optimization with Bayesian Optimization (BO): Hyperparameter optimization is a process to fine tuning the hyperparameter values of machine learning algorithms to obtain the best setting which yield the best result, in a classification or regression problem. The domains of hyperparameter may range from real values (i.e. learning rate), integer (i.e. number of layers), binary (i.e. with or without early stopping), to category (i.e. a selection of optimizer functions). Let $\mathcal{A}$ be a machine learning algorithm with N hyperparameters. The domain of n-th hyperparameter is denoted as Λ_n and the overall configuration hyperparameter space is denoted as $\Lambda = \Lambda_1 \, x \, \Lambda_2 \, x \, ... \, \Lambda_N$. A hyperparameter vector is denoted as $\lambda \in \Lambda$ and a machine learning algorithm with its instantiated hyperparameter λ is denoted as $\mathcal{A}_\lambda$. Given a dataset $\mathcal{D}$, the goal of hyperparameter optimization is to find Eq. (1) as in [53]:

$$\lambda^* = \underset{\lambda \in \mathcal{A}}{argmin} \, \mathbb{E}_{(D_{train}, D_{valid}) \sim \mathcal{D}} \boldsymbol{V}(\mathcal{L}, \mathcal{A}_\lambda, D_{train}, D_{valid}) \quad (1)$$

with $\boldsymbol{V}(\mathcal{L}, \mathcal{A}_\lambda, D_{train}, D_{valid})$ measures the loss value of the model generated by algorithm A with hyperparameter λ on the training data D_{train} and evaluated on validation data D_{valid}. $D \sim \mathcal{D}$ denoted the finite data which its expectation needs to be approximated.

Grid Search and Random Search are the two most basic and simple hyperparameter optimization methods. While Grid Search performs exhaustive search on the hyperparameter search space, Random Search [56] samples a hyperparameter configuration randomly until it satisfies a defined threshold value. On the other hand, Bayesian Optimization (BO) is a global optimization framework approach of a black box objective function with high complexity and undefined shape and offers better efficiency given limited evaluation budget [62], [63].

BO is used in hyperparameter optimization (HO) that constructs a probability model of an objective function and use it to select the most promising hyperparameters to be evaluated in the real objective function [64]. Utilizing a Bayesian approach, BO takes note of the result of the previous evaluation to build a probability model which maps hyperparameters onto a probability score of an objective function, *P(score|hyperparameters)*, called a surrogate function. Compared to the original function, the new function is easier to be evaluated and the Bayesian method works by finding the next hyperparameter having the best performance on the surrogate function to be evaluated on the real objective function. In a BO, a Gaussian Process (GP) is used as a surrogate function to produce a posterior distribution over the function values based on observed data.

Meanwhile, an acquisition function selects the next point for the surrogate function, with common options including probability of improvement, expected improvement, and upper confidence bounds. This study uses the Bayesian Optimization library *bayes-opt*, which defaults to upper confidence bounds to balance exploitation of high surrogate values and exploration of uncertain regions.

C. Datasets

The proposed study utilized public medical dataset from MIMIC-IV (Medical Information Mart for Intensive Care version IV) [62] from Beth Israel Deaconess Medical Centre in Boston, MA, United States. The dataset consists of 223,452 patients in its hospitalization hosp module and after a careful selection resulted in 1,153 unique THA patients' data. The target variable is readmission within one year of first THA procedure which is a Boolean value TRUE or FALSE.

A comprehensive description of characteristics of the patient data is provided in Table I. Most of the demographic-related variables are summarized as mean values, while the rest are written based on their respective numbers and percentage. The numbers in preoperative diagnosis variable do not sum up to the total number of patients as a patient may have more than one diagnosis.

D. Preprocessing

Data preprocessing involves identifying and removing duplicates, missing values, and erroneous information from the data. Proper techniques such as Label Encoding and One-Hot Encoding are applied to transform categorical data into a numerical format [63]. Additionally, a standard scaler is applied to ensure all attribute values are standardized. The overall preprocessing step is summarized in Fig. 2.

Data preprocessing involved extracting relevant data from the general dataset, identifying 1,153 unique THA patients with 55 variables (54 inputs and 1 output), as summarized in Table I. Patients had up to 39 preoperative diagnoses, totalling 1,881 distinct diagnoses coded in International Classification of Diseases ICD-9 and ICD-10.

In addition, a feature processing was applied. Missing values in weight, height, and Body Mass Index (BMI) were handled by filling with the mean value of the attribute column. All 1,881 diagnosis ICDs were assigned integer values from 1 to 1881 (a value of 9999 was given to empty cells), implant

materials variable in categorical type were assigned 1 to 7 (99 for empty cells), implant type in categorical were assigned values of 1 to 4 (9 for empty cells), and insurance type in categorical were assigned values of 1 to 3.

TABLE I. CHARACTERISTICS OF THA PATIENTS

Variables	All Patients (n=1,153)	
	Mean	(IQR)
Demographics		
Age (years)	65.66	16 (58-74)
Weight (pounds)	180.91	65.75 (146.25-212)
Height (feet)	43.67	67 (0-67)
Body Mass Index (kg/m^2)	28.98	8.05 (24.6-32.65)
Preoperative Blood pressure		
Systole	131.62	20 (120-140)
Diastole	74.88	15 (67-82)
	Number	**(%)**
Male Sex	506	43.88
Insurance type		
Medicare	505	43.80
Medicaid	35	3.03
Other	613	53.16
Preoperative diagnosis		
Osteoarthritis	1,023	8.9
Hypertension	579	5.04
Hyperlipidemia	440	3.83
Esophageal reflux	336	3.83
Nicotine/tobacco dependence	207	2.93
Anemia	338	2.94
Depressive disorder	111	0.97
Anxiety disorder	154	1.34

Readmission within one-year post-THA	237	20.55

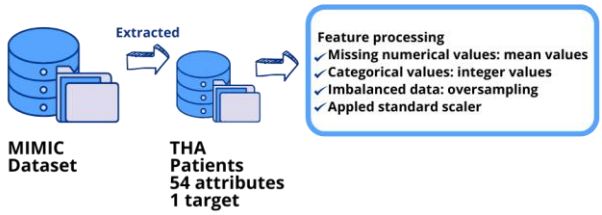

Fig. 2. Preprocessing steps.

Since the dataset is imbalanced, with 237 TRUE and 916 FALSE, a simple random oversampling method to duplicate examples in the minority class was applied using *imbalanced-learn* library [64]. The oversampling method produced equal size of data for each target class, which were 916 TRUE and 916 FALSE.

III. RESULTS

A. Algorithm Selection and Hyperparameter Optimization (HO)

The experiment was conducted in two modes for each algorithm: without and with hyperparameter optimization (HO). A limitation of the bayes-opt library is its restriction to numeric attributes, preventing the optimization of categorical and Boolean hyperparameters. Five numerical hyperparameters were optimized for each algorithm, except for Support Vector Machine and Elastic-net Penalized Logistic Regression, which had only three due to categorical constraints. Table II presents the optimized hyperparameters, their values, and a comparison of accuracy and AUROC between Bayesian Optimization (BO) and default hyperparameters.

The convergence plot in Fig. 3 shows that six of seven algorithms (except SVM) reached a steady value within six iterations, indicating BO has effectively estimated the optimization target. Even SVM's sharp increase in the 14th iteration [Fig. 3(d)] remained within the 95% Confidence Interval (CI).

The objective plot in Fig. 4 visualizes the distribution of hyperparameter values when the BO searched for the optimized ones. The diagonal subplots represent histograms of the sampled values for each parameter and aid in visualizing the distribution of parameter values used during optimization. This illustrates how BO investigated the parameter space. The red dashed line represents the optimized hyperparameter value while the blue line plots the AUC-ROC value as the objective target around the optimized hyperparameter value. If the majority of a parameter's samples are concentrated in a specific range, it may indicate that this range has values that are near ideal. For example, four straight lines in the diagonal subplots of XGB [Fig. 4(a)] indicates that all the sampled values of expGamma (an exponential transformation of Gamma), learning_rate, max_depth, and min_child_weight between their respective ranges yield a near optimal AUC-ROC value, i.e. 0.9955. Meanwhile, the off-diagonal contour subplots show pairwise interactions between two hyperparameters, where darker colors indicate better values. The contour identifies regions where the parameter combinations yield optimal results. For example, the off-diagonal subplot between expGamma and expC (the exponential transformation of C) in Fig. 4(c) indicates that the red star value ($expGamma = 0.584$, thus $Gamma = 10^{0.584} = 3.837$) in the dark region represents the optimal value of expGamma when combined with the value of expC. In Fig. 4(a), the red star in n_estimators plot (n_estimators=1818.9744) resides within the narrow darker area, indicating that the value is optimal or near optimal.

TABLE II. THE HYPERPARAMETERS OF EACH ALGORITHM AND THEIR OPTIMIZED VALUES

Algorithm	Hyperparameters	Bounds		optimized value	without HO		with HO	
		min	max		auc-roc	fit time (s)	auc-roc	elapsed time (s)
XGB	learning_rate	0.01	0.8	0.0352	0.9955	0.18	0.9958	582.11

Fig. 4. The objective plot of (a) XGB, (b) EnPLR, and (c) SVM. The red stars represent the best values of each hyperparameter.

B. *Performance Evaluation*

Table II shows the time required for each approach to complete optimization. All seven algorithms took longer with Bayesian Optimization (BO) than with default hyperparameters, with execution times increasing from 155 times longer (MLP) to 24,605 times longer (SVM). This added duration is expected in hyperparameter tuning, balancing computational cost with improved AUC-ROC performance.

Table III presents performance metrics: Accuracy, Precision, Recall, and AUC-ROC. SGB, SVM, and MLP showed improvements in all four metrics after optimization, while RF and DT performed worse. Optimization had minimal impact on XGB and EnPLR.

Additionally, MLP's default setting (max_iter = 200) failed to converge, requiring an increase to max_iter = 1000 in the optimized version. Similarly, EnPLR failed to converge in both cases, even after raising max_iter to 10,000 in the optimized version.

TABLE III. PERFORMANCE EVALUATION COMPARISON OF ALGORITHM

Alg.	Accuracy		Precision		Recall		AUROC	
	w/o HO	with HO	w/o HO	with HO	w/o HO	with HO	w/o HO	with HO
XGB	0.945	0.950	0.908	0.916	0.991	**0.991**	0.995	**0.996**
SGB↑	0.801	0.976	0.767	**0.971**	0.866	0.982	0.879	0.994
RF↓	0.978	0.967	0.965	0.947	0.991	0.989	0.994	0.994
SVM↑	0.693	**0.991**	0674	0.947	0.750	0.989	0.764	0.994
DT↓	0.878	0.820	0.814	0.780	0.985	0.894	0.878	0.878
MLP↑	0.862	0.900	0.813	0.843	0.942	0.986	0.914	0.950

↑: an increased value when using BO; ↓: a decreased value when using BO

IV. Discussion

Previous THA-related studies have employed machine learning techniques using institution-specific datasets, contributing to research advancements. However, many relied on Grid Search for hyperparameter tuning or default algorithm settings, limiting optimization efficiency. Only a few studies explored advanced methods such as Bayesian Optimization (BO) to enhance predictive performance, despite its potential for complex optimization problems.

This study applies BO across multiple machine learning algorithms commonly used in previous research to improve readmission prediction. Our results demonstrate that optimized hyperparameters significantly enhance AUC-ROC scores compared to default settings. While prior studies addressed different adverse event predictions, they shared a common challenge: imbalanced datasets, as adverse events are rare.

Comparing model performance, this study outperformed previous research across several algorithms. The Extreme Gradient Boosting (XGB) algorithm achieved the highest AUC-ROC score (0.996), surpassing [44], other cited works [36], [37], [39], [42], [50], and specifically [49] for predicting readmission risk. Similarly, the Multilayer Perceptron (MLP) achieved an AUC-ROC of 0.914, higher than the Neural Network in [36] (0.85). The Support Vector Machine (SVM) in this study achieved 0.994, far outperforming previous studies [39], which reported 0.74 (Length of Stay), 0.8 (Discharge), and 0.97 (Mortality). The Stochastic Gradient Boosting (SGB) algorithm improved to 0.994, higher than 0.88 in [42]. Random Forest (RF) achieved 0.994, surpassing 0.80 in [36], 0.91 in [42], and 0.83 in [47] for readmission prediction. However, Elastic-Net Penalized Logistic Regression (EnPLR) underperformed (0.662), falling below 0.732 in [37], 0.93 in [42], and 0.86 in [47]. These findings highlight the effectiveness of Bayesian Optimization in tuning machine learning models, addressing limitations in previous studies that relied on basic or exhaustive hyperparameter searches.

Additionally, the MIMIC-IV dataset used in this study provides a publicly available benchmark to validate models trained on private institutional datasets, which often restrict benchmarking and generalizability. SVM, which performed best in some studies [39], [50], showed weaker performance before optimization, while XGB, previously considered suboptimal [39], [44], demonstrated superior results. This suggests that models trained on private datasets may not always generalize well to broader patient populations.

Furthermore, Table III indicates that Recall scores are consistently higher than Accuracy and Precision, suggesting that models prioritize identifying positive cases, reducing false negatives. This is critical in medical applications, where minimizing false negatives (missed readmission cases) is more important than false positives, which can be addressed with further evaluation [65], [66], [67].

The discrepancy in comparative results between datasets may stem from differences in patient populations, clinical settings, and data preprocessing. The MIMIC-IV dataset includes a more diverse patient cohort from multiple institutions, whereas private datasets from previous studies may be more homogeneous. Additionally, the inclusion/exclusion criteria and feature selection may introduce variability in model performance.

The varying performance of models across datasets suggests that some algorithms are more sensitive to dataset structure. For instance, tree-based models (XGB, RF, SGB) performed consistently well, likely due to their robustness in handling structured tabular data. SVM, which performed best in some previous studies, showed inferior performance before optimization in our dataset, suggesting that hyperparameter tuning plays a crucial role in improving its adaptability to different data distributions. Our results show that Bayesian Optimization significantly improves performance consistency across datasets. Without proper hyperparameter tuning, models such as SVM and MLP may underperform in certain datasets due to suboptimal parameter selection. This highlights the importance of adaptive optimization techniques in ensuring machine learning models generalize well across different clinical datasets.

Despite its contributions, this study has several limitations. First, as a retrospective analysis relying on past medical records and billed ICD codes, it is susceptible to errors such as miscoding or missing values, which could impact machine learning predictions. Second, the bayes-opt library used for hyperparameter tuning is still under active development, and its latest version (1.5.1 as of July 10, 2024) does not yet support categorical and Boolean hyperparameters. As a result, key parameters such as SVM kernels, MLP activation functions, and RF criteria could not be optimized, potentially limiting model performance. Lastly, the dataset exhibited class imbalance, with significantly fewer TRUE cases than FALSE cases. While this study employed oversampling to address the issue, more advanced techniques could further enhance predictive accuracy. Future research should explore alternative resampling strategies and hyperparameter tuning methods to refine model performance.

V. Conclusion

This study successfully developed, trained, tested, and validated Bayesian Optimization for hyperparameter tuning across seven machine learning algorithms to predict readmission risk following Total Hip Arthroplasty (THA). By comparing these optimized models to previous studies that either lacked hyperparameter tuning or employed different optimization methods, the results demonstrated that Bayesian Optimization significantly enhances predictive performance. This underscores the critical role of hyperparameter tuning in maximizing model accuracy, improving decision-making, and increasing confidence in integrating machine learning into THA patient management.

Additionally, this study highlights the importance of external evaluation using a publicly available dataset, ensuring that machine learning models trained on institution-specific data can generalize effectively across different patient populations. The findings suggest that standardized evaluation is essential for ensuring model robustness and reliability in clinical applications.

While this study addressed key challenges in predictive modeling for THA readmission, limitations remain, particularly regarding class imbalance and the scope of readmission prediction. Future research may explore advanced resampling techniques to further improve model performance and investigate more specific predictive outcomes, such as infection-related readmission, revision THA, or Length of Stay.

ACKNOWLEDGMENT

This research is supported by School of Postgraduate Studies-Diponegoro University and University of Pembangunan Nasional Veteran Jawa Timur.

ETHICAL APPROVAL

This study used the MIMIC-IV database (Medical Information Mart for Intensive Care, version 2.0), a publicly available and de-identified dataset, which complies with the Health Insurance Portability and Accountability Act (HIPAA) standards. Access to the dataset was granted after completing the Collaborative Institutional Training Initiative (CITI) Program training and acceptance of the Data Use Agreement (DUA). Ethical approval for the original data collection was obtained by the Institutional Review Board (IRB) of Beth Israel Deaconess Medical Center (BIDMC), and the requirement for individual patient consent was waived. Therefore, no additional ethical approval was required for this study.

Forecasting Models for Predicting Global Supply Chain Disruptions in Trade Economics

Limei Fu
Tourism Management, Hainan Vocational University of Science and Technology, Haikou, Hainan Province, 571126, China

***Abstract*—Global supply chain disruptions have evolved into a critical challenge for trade economics, and have caused them to reach across industries and economies around the globe. The ability to foresee these disruptions is crucial for policymakers, businesses, and supply chain managers who want to develop actionable strategies for stability. The current document focuses on analyzing the potential application of forecasting models to predict global supply chain disruptions and their efficacy and limitations. A comparison of statistical, machine learning, and hybrid models is performed, and the best methods for predicting disruptions arising from geopolitical events, pandemics, natural disasters, and other external factors are identified. The study considers real-world datasets and various scenario analyses to provide actionable insights. The key findings were obtained by integrating various sources of information, including trade volume fluctuations, transportation bottlenecks, and economic indicators, into predictive frameworks. It is thus a novel contribution to the field of study done by this research to build up an advanced forecasting model that can boost the resilience level and elasticity level of global supply chains, finally playing a key role in the sustainability of trade economics.**

***Keywords*—Supply chain disruptions; forecasting models; trade economics; predictive analytics; global resilience**

I. Introduction

Rightly termed the backbone of contemporary trade economics, global supply chains allow for the smooth transfer of goods, services, and capital across borders. They are integral to global commerce as they bring together in a complex yet interrelated network of economic activities manufacturers, suppliers, distributors, and consumers. However, these elaborate systems are also very sensitive to disruptions, such as geopolitical tensions and economic sanctions, as well as the ever-present threat of natural disasters and pandemics [1]. The disruption of such services has serious consequences, often leading to breaks in the flow of goods and services, affecting global economic stability, business profitability, and consumer welfare. In this context, the eventual forecasting of global supply chain [2-3] disruptions has emerged as a very important and strategic research area the main goal of which is to help the stakeholders effectively anticipate and deal with risks.

The most recent changes regarding how countries interact with one another have acted as the accelerator for the increased susceptibility of supply chains to external shocks[4]. The COVID-19 pandemic, for example, illustrated how easily these supply chains can be disrupted with halting production, shipping delays, and having inadequate materials all becoming standard. Geopolitical events such as trade wars, as well as regional conflicts, have moreover reinforced the need for strong predictive machinery. The traditional methods of managing risks such as reactivity to a problem are today not enough. Instead, proactive strategies that rely on sophisticated forecasting models are now critical [5-6].

Forecasting models refer to techniques that use historical records, statistical methods, and computational tools to predict future events and trends. Models of this kind have been useful in such global phenomena as the supply chain problems occurring in the world through the follow-up of various sets of data and sensitivity analyses of the contributing factors, like weather, trade volumes, and even political events, to the point of realizing the critical points [7-8]. Forecasting models serve to indicate risks early on, thus providing the companies and governments the power to manage necessary assets and the business continuity resourcing to minimize any interruptions. On the other hand, the use of trustworthy forecasting methods based on such models in global supply chains is challenging because of the diverse nature of disturbances and the intricate structure of the complex networks of supply and demand that are interconnected [9-10].

Our studies on the forecasting models have unearthed several forecasting models, all of which come with unique benefits and downsides. The most straightforward models are based on historical statistical data, which is why they are widely applied. It is easy to understand the long-term and seasonal changes presented through this model, but it might be hard for them to capture the unpredicted and on-the-spot ones [11]. The use of such models like the neural network or decision tree machine learning has been on the increase, as those models have a clearer picture of reality and thus provide better forecasts by capturing the non-linear relationships and picking up the data regardless of the data collection procedure. As a kind of progressive matter among researchers [12-13], Hybrid models have also emerged, which are based on a combination of statistical algorithms and machine learning techniques and thus can become a good balance between clarity and accuracy of prediction.

Although methodologies for prediction have grown by leaps and bounds, in the realm of global supply chain forecasting capabilities, there are still noticeable gaps in precision. A major hindrance is the lack of high-quality, timely data, often due to poor infrastructure in some areas. Furthermore, the complexity and mutual reliance of global supply chains [14-15] make it difficult to model interactions and cascading effects. For example, an incident in one location or industry can affect the entire supply chain, hence a holistic and systemic approach to forecasting is needed.

To address these challenges, both researchers and practitioners have noted the diversity of data sources and the integration of different fields as crucial. Concurrently, the technological advances in data analytics, artificial intelligence, and cloud computing can create new ways for us to develop complex forecasting models [16]. For example, the availability of satellite imagery along with IoT devices enables us to learn about bottlenecks and inventories in real-time while using news sentiment analysis, and social media can tell the early indications of geopolitical risks [17-18]. Therefore, the incorporation of such technologies in forecasting models could lead to greater precision and reliability, which in turn, could be helpful for decision-makers.

The urgency of the consequences of global supply chain disruptions emphasizes the need for forecasting accuracy in the economic sector. Supply chain disruptions can lead to increasing costs, a decline of productivity, and a reduction of order at the company level. Consequently, firms may suffer the resulting consequences of inflation, unemployment, and increasing economic disparities that have broader implications [19]. Furthermore, such disruptions could bring the international trade system to its knees, reduce the confidence of consumers, and bring growth economic grind to a halt. The power of forecasting models to facilitate timely and informed decision-making, to minimize these negative effects, and to contribute to the overall sustainability of global supply chains is huge [20-21].

The advantages of forecasting models impact the immediate dangers created by making such models an essential part of sustainable and ethical trade practices. Additionally, it can be said that variations in the supply chain can strongly influence weak populations such as the laborers in developing nations who rely on a constant flow of external trade to survive [22]. The predictions and prevention of disruptions in the initial stages could be achieved through modeling forecasts which are also associated with the survival of these communities and their sustainable economic development. In addition, accurate predictions can make the process environmentally sustainable by minimizing waste, optimizing the logistics, and reducing the supply chain's carbon footprint during the operations [23-24].

A. Objectives

1) To carry out the evaluation and comparison of the efficiency, precision, extensibility, and flexibility of the mobile hybrid of statistical machine learning models in forecasting global supply chain disturbances.

2) To explore the significance of applying an assorted array of data that encompasses economic variables, political alterations, and technical considerations in the modeling processes to enhance the efficiency of their prognosis.

3) To establish a specific and reliable forecasting model that can address the limitations of the previous ones and offer sound advice for minimizing supply chain risks.

This research proposes to attain set objectives that will connect the development of theories with the practical aspects of global supply chain disruption forecasting now and in the future. The findings will not only provide valuable guidance for researchers and practitioners but also contribute to the broader discourse on building resilient and sustainable supply chains.

To sum up, the escalated regularity and intensity of global supply chain interruptions require a fundamental change in modus operandi, going from a reactive to a proactive risk management framework [25-26]. By employing forecasting models' stakeholders, the ones involved in the supply chain, can point out the unforeseen problems. Hence, the potential of these models can be exploited after deeply analyzing the technical, data-related as well as conceptual problems. The research brings forward a fruitful look into the unsolved questions of this field, ultimately leading to the mobile solution, green and pro-active supply chain economy globally.

This paper consists of the following sections: In Section 2, a comprehensive literature review is presented with an emphasis on major research contributions and also the gaps addressed by the proposed model. The details of the data preprocessing, model development, and evaluation metrics are given in Section 3. The results of the forecasting model's performance are presented both quantitatively and graphically in Section 4. The important findings, practicality, and recommendations for further improvements of the findings are articulated in Section 5. Lastly, in Section 6, the paper's conclusion is drawn, and a summary of the research work's principal points, the deficiencies of the study, and the potential avenues for future research are given.

II. Literature Review

The area of global supply chain forecasting has become heavily discussed over the past few years because the occurrences and results of disruptions in trade economics are increasing. Researchers have investigated multiple models and methodologies in their search to accurately anticipate and act on these disruptions using techniques such as statistical analysis, machine learning, and data integration [27]. The current section is a summary of important investigations in this field, pointing out the progress made, the techniques used, and the drawbacks of each one to help give a complete view of the prevailing situation in research. The results from these investigations create the basis for the identification of the gaps and the suggestion of a better forecasting system.

The study conducted by Bhadra et al [28]. targets the disruptive factors brought by the Russian-Ukrainian conflict to the world food supply chain with special emphasis on South Korea's Food, Beverage, and Tobacco (F&B) sector. The research uses Autoregressive Integrated Moving Average (ARIMA) modeling to show that the escalation of the conflict leads to a negative trend in the KOSDAQ F&B sector returns. The study highlights that South Korea has to normalize the use of healthy, safe food as well as develop its domestic agri-economy for an overall self-sufficiency.

Shafipour et al. [29] proposed a new approach that is real time, yet comprehensive, in trying scenarios of the Supply Chain Network in the medical field. The authors highlighted a need for a change in perspectives towards the medical and engineering fields, a two-way approach that includes both issues, and thus they suggested an integration of the software aspects of communication with the problem-solving ones to

involve all the stakeholders in the enhancement of communication and problem-solving in the medical field. The authors came to the conclusion that by integrating all the important factors in the actual implementation process, it is possible to cover all the aspects of the project and thus ensure its success.

Zheng et al. [30] studied the impact of the COVID-19 epidemic on the medical mask supply chain through a simulation model utilizing AnyLogistix. Their findings stress the importance of having a backup facility and correctly optimizing the inventory level so that the supply chain can recover in the face of adversity. According to the same research work, the duration of the disruption period for the supply chain's downstream facilities is the main factor that affected the performance of the supply chain, which during future disturbances offers methods to better the flexibility and the resilience of medical mask supply chains through. In a medical mask supply chain, it was found that well-managed inventory levels and the provision of backup capacity both can reduce the effect of the agri-food chain crises on the selection.

Queiroz et al. [31] explored how blockchain technology (BCT) can be integrated into operations and supply chain management (OSCM) processes and practices in Brazil. The study adopted the Unified Theory of Acceptance and Use of Technology (UTAUT) model and identified trust, facilitating conditions, social influence, and effort expectancy as the most influential factors of BCT adoption. The research shed light on the challenges and barriers that blockchain technology faces in the transformation of societies, especially in developing economies such as Brazil.

Manupati et al. [32] propose a disruption prediction model in a supply chain network that involves smart contracts via blockchain technology. The authors advocate using a genetic algorithm-based methodology that intelligently addresses both pre- and post-disruption situations, thereby ensuring a holistic decision-making environment for disruption management. The research findings provide key insights for organizations in adapting and overcoming supply chain disruption caused by various, complex multi-tier supply chains.

Paul et al. [33] strive to understand how to gauge transportation disruption risks in supply chains using the tool called Bayesian Belief Network (BBN). The study highlights the most vulnerable sources of disruption and the parameters relating to those by developing a BBN-based model. The research, illustrated with a case study from the pharmaceuticals sector in Bangladesh, illustrated the power of BBN as a tool for predicting calamities in transportation and as a facilitator for supply chains development strategies that secured the transport of sensitive materials across delivery networks.

Camur et al. [34] have conducted research on the COVID-19 pandemic and geopolitical conflicts to determine their impact on global supply chains by analyzing the unpredictability of product delivery dates in logistics services. Through various regression models, including Random Forest (RF) and Gradient Boosting Machine (GBM), the study obtained the fact that tree-based models yield the best results for predicting availability dates. Results indicated that these models could be implemented to manage supply chain interruptions and thus lessen the risks involved.

TABLE I. LITERATURE COMPARISON

Authors	Focus	Key Methodology	Findings
Bhadra et al.	Supply chain disruptions in the F&B sector due to geopolitical events	ARIMA model for stock return prediction	Negative trend in F&B stock returns observed due to the Russia-Ukraine conflict; need for domestic self-sufficiency in food production
Shafipour et al.	Predicting time-to-disruptive events in supply chains using survival analysis techniques	Statistical flowgraph models (SFGMs) for time-to-event data analysis	SFGMs offer insights into system reliability, hazard functions, and identify supply chain weaknesses for better disruption management
Zheng et al.	Impact of the pandemic on the medical mask supply chain and strategies for resilience	Simulation models with AnyLogistix, Green Field Analysis, and risk analysis	Adding backup facilities and optimizing inventory levels helps improve supply chain resilience during disruptions
Queiroz et al.	Adoption of blockchain technology (BCT) in supply chain management and related barriers	UTAUT model, PLS-SEM for empirical validation of blockchain adoption factors	Key factors such as trust, facilitating conditions, and social influence significantly impact BCT adoption in supply chains in Brazil
Manupati et al.	Recovery strategies in supply chains using blockchain technology and smart contracts	Genetic algorithm-based approach for disruption prediction and recovery strategies	Integration of pre- and post-disruption strategies offers holistic decision support for managing supply chain disruptions and minimizing performance loss
Paul et al.	Assessing transportation disruptions in supply chains and their risk factors	Bayesian Belief Network (BBN) model for disruption risk analysis	BBN captures interdependencies between disruption risk factors and helps build resilient strategies for managing transportation disruptions
Camur et al.	Impact of geopolitical and pandemic disruptions on predicting product availability dates in supply chains	Regression models (RF, GBM, Random Forest, and Neural Networks) for prediction	Tree-based models (RF, GBM) perform best in predicting product availability dates, aiding in better supply chain management during disruptions
Mittal et al.	Predicting and mitigating risks in supply chains using AI-driven machine learning and deep learning models	Machine learning (ML) and deep learning (DL) models, including CNN networks	Deep CNN regression model outperforms others in predicting supply chain risks, offering insights for better resilience and stability in operations
Proposed Model	AI-Driven Global Supply Chain Forecasting	RNN-LSTM with Attention Mechanism and Ensemble Learning	Enhances accuracy, captures long-term dependencies, and adapts dynamically to emerging risks.

On the other hand, Mittal et al. [35], backed by Artificial Intelligence, have put forward a suggestion to counteract the vulnerabilities in the supply chain that arise due to the external forces like pandemics and inflation, etc. In order to explain it, the study made the best use of machine learning and deep learning that are including linear regression and convolutional neural networks (CNN), while also a different way of augmenting the data has been proposed by use of the Fuzzy C-means method. The Deep CNN regression model reaches a higher forecasting capacity than other models regarding potential risks in the supply chain and at the same time it provides information for strategists and planners on how to improve the stability and resilience of the supply chain.

III. METHODOLOGY

The methodology that has been adopted in this research has been framed in such a way that it handles the challenges of effectively forecasting the occasions of global supply chain disruptions. The integration of advanced computational techniques, data preprocessing methods, and performance evaluation frameworks makes the study a robust one that can predict disruptions and provide action-oriented insights. The methodology proposed in this paper has a systematic approach as the central idea, covering the topics of data acquisition, preprocessing, and the development, evaluation, and iterative refinement of models.

The key to the success of the proposed methodology is the careful integration of different data sources that signify the major factors of global supply chain disruptions. In particular, external factors such as geopolitical events, natural disasters, and pandemics as well as trade and economic data such as import-export volumes, exchange rates, and commodity prices are the sources of information; logistics data including shipping schedules, container availability, and transportation bottlenecks; and historical disruption records are the focus of the coverage. The advantages of using multiple data sources provide the forecasting models with a thorough understanding of the global supply chain landscape. Being in a position to use real-time data, the model can dynamically adjust itself to new situations and rising risks.

To ensure the quality and the proper use of forecasting data, the acquired data should be cleaned beforehand. The cleaning stage consists of data gathering for fixing issues like missing values, outliers, and inconsistencies; selection of the most relevant disposition of the information geared towards predicting disruptions; and conversion techniques, like normalization and scaling, for the standardization of the input data. These steps in the preprocessing process of the data will enhance the performance and reliability of the forecasting model as they will trim the noise and hence will increase the interpretability of the data.

The methodology is centered on the refining of a superior forecasting model architectural design. This study has utilized deep learning techniques like recurrent neural networks (RNNs), and in particular, long short-term memory (LSTM) networks, for this type of forecasting, which are well adapted to time series forecasting since they have a unique ability to capture temporal relationships between time steps due to their memory capacity. Moreover, the attention mechanism has been blended into the model's structure to enhance its prediction capabilities by directing the model on the most important features and the most crucial time steps. Simultaneously, ensemble methods leveraging the strengths of multiple models were employed to enhance robustness and reduce the possibility of overfitting.

The forecasting pipeline integrates scenario analysis and impact forecasting, providing a comprehensive view of different disruptions. Scenario analysis is a technique that uses the generation of both, positive, and negative what-if scenarios to help in making up-to-date predictions. The quantification of the potential consequences of disruptions on the important metrics of the supply chain, such as lead times, costs, and service levels, is being performed by the impact forecasting. Data visualization methods are then used to display the forecasting results simply and practically to make the decision-making process easier for stakeholders.

The forecasting model's performance is submitted to the evaluation using a previously determined group of metrics including accuracy, lead time, and scenario coverage. The model's accuracy to predict the disruptions accurately is the measure of its success, while the lead time is a measure of its speed of warning. Scenario coverage is the measure of how well the model will respond to any disruptions by its realization of a wide variety of alternative scenarios which ensures its generalizability in the various contexts. All the thus evaluated metrics will assist the methodology so that the suggested model would live up to the real-world applications requirement.

The proposed methodology's significant feature is its continuous improvement emphasis. The unpredictable nature of global supply chains requires that the forecasting model be constantly updated with the latest data and external factors. Through the methodology, the process of data updates, model refinements, and mechanisms for adaptability are incorporated to ensure that forecasting remains relevant and effective over time. The model method is based on the principle of iterative enhancement, which conforms to the principles of continuous learning and improvement.

The working of the proposed forecasting model within a conceptual framework such as the one presented in “Fig 1” is illustrated. The framework begins with the collection of input data from various sources such as external factors, trade and economic data, logistics, and historical disruption records. The preprocessing of the data involves data cleaning, feature selection, and data transformation to make the data suitable for analysis. The figure highlights the architecture of the core forecasting model which consists of RNNs, LSTMs, attention mechanisms, and ensemble techniques forming the model's input and output layers. The pipeline of forecasting integrates scenario analysis, impact forecasting, and data presentation to produce actionable insights. Risk management, policy advisement, and continuous monitoring are the applications of the forecasting model that are critical for the solution of supply chain disruptions. The model's accuracy metric module measures how successful the model was, how fast it was, and how deeply the scenarios were analyzed while the continuous improvement component guarantees the ability to change the

data and the model when necessary. This integrated approach is the theoretical framework of the proposed methodology and it is a detailed solution for predicting global supply chain disruptions.

Thus, adopting this structured methodology ensures that the suggested forecasting model overcomes the limitations of present methods and gives a scalable, adjustable, and practical framework for predicting worldwide supply chain disruptions. The approach of the software development variable is capable of sustaining the extremely important data of diversity, new sources of training, and procedures of incremental improvement which constitute the improvement guarantee for the model such that it can stand up against the highly complex and linking global trade environment.

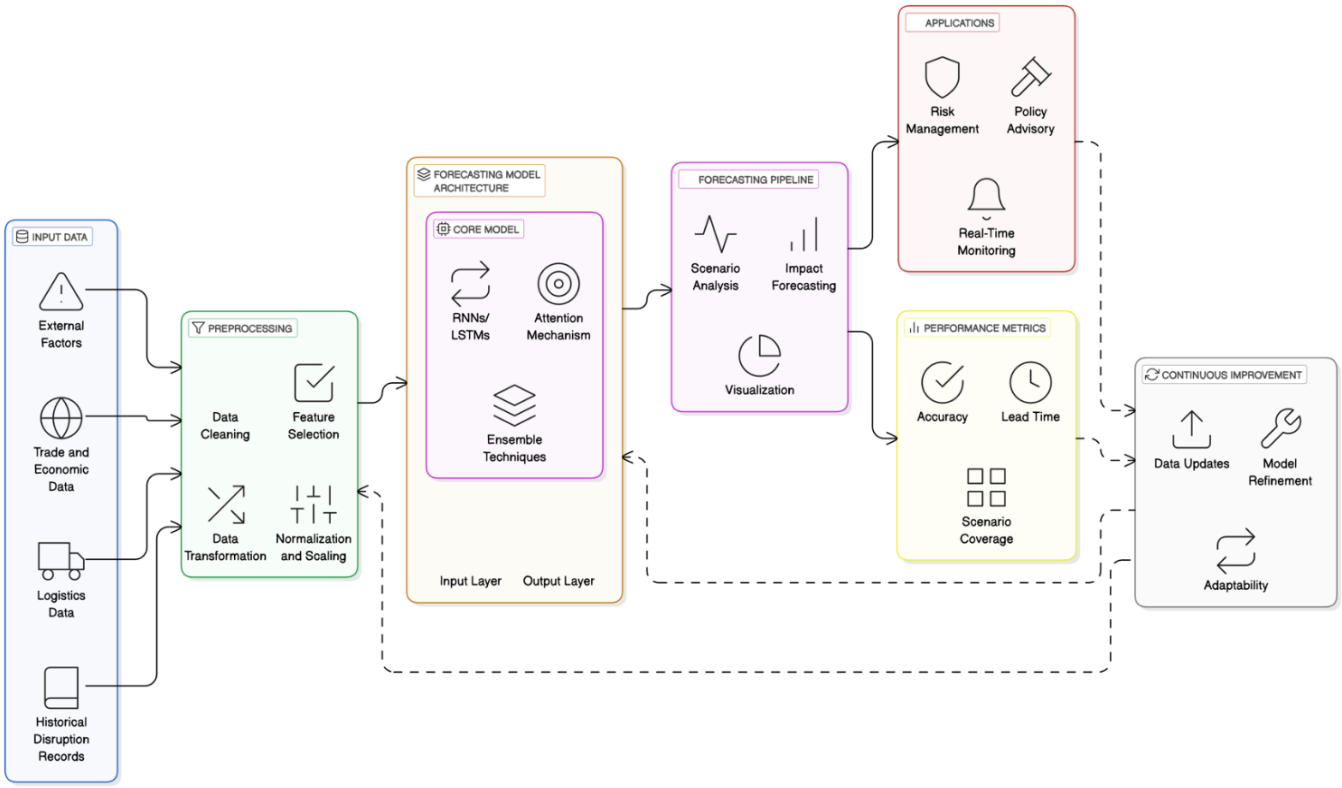

Fig. 1. Proposed model diagram.

IV. Simulation and Results

The findings of this study shed light on how good the proposed forecasting model is in predicting disruptions in the global supply chain. In the training and evaluation phase, the model was implemented using the Supply Chain Data dataset sourced from Kaggle (Dataset Reference), which encompasses the historical records of disruptions, the trends in trade volume, and logistic information. The key findings are the main focus of the discussion below in "Table II".

The appropriateness of the model's predictions was checked as both the predicted numbers and the real ones were compared for the 12 months of 2024. The results, which are shown in "Fig. 2", indicate a tight coupling between the predicted disruptions and those that happened. A case that can be cited in this case is the disruption forecasted by the model for January where it was observed that there were only two disruptions, while the number the model predicted was three. In another instance, April and July were forecasts 7 and 9 which coincided perfectly with the real figures for instance. Despite this, the former diverged from the latter slightly in some months; it is nevertheless the case that generally, the right-wrong count as well as the sum were of a considerable size thus demonstrating that the model does a remarkable job detecting violations regardless of the diversity of cases presented.

TABLE II. Supply Chain Forecasting Data

Month	Predicted Disruptions	Actual Disruptions	Lead Times (Weeks)
Jan	3	2	2.5
Feb	4	5	2.7
Mar	5	4	2.6
Apr	7	8	2.8
May	6	7	2.9
Jun	8	9	3.0
Jul	9	10	3.1
Aug	10	11	3.2
Sep	8	9	3.1
Oct	7	8	3.0
Nov	6	7	2.9
Dec	5	6	2.8

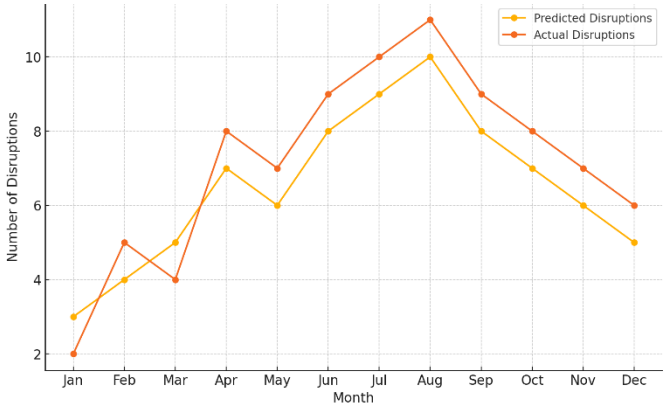

Fig. 2. Predicted vs actual supply chain dsisruptions (2024).

Also, a prime performance indicator that was evaluated was the lead time of disruption alerts which essentially shows the capability of the model to give timely warnings. At the beginning of "Fig. 3", it can be seen that the average time lead times were 2.5 weeks in January and 3.2 weeks in August. With such timings, respective stakeholders can engage in proper planning and risk mitigation measures. The fact that led times were constant in different months until the recent one suggests that the model is not only sturdy but also can change its features quite well as per the changes in the supply chain environment

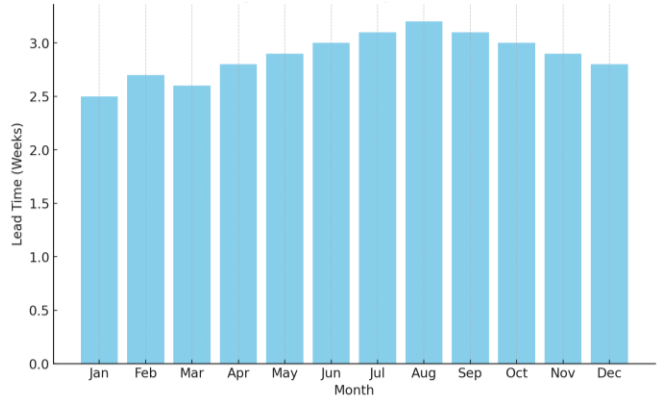

Fig. 3. Average lead times by month (2024).

The results further indicate the seasonal variability of disruption patterns. For example, it was the summer months (June to August) that saw the peak of disruptions, which could be a result of the increase in trade volume, geographical conditions, and political issues. In contrast, disruption levels were relatively low during the winter months, which points to times of low volatility in the global supply chain. These signals are crucial for policymakers and businesses to distribute resources meaningfully and control risks during the most dangerous times.

Different data sources were combined, and the model was developed ensuring each one of them did their part successfully. The researchers made use of selective outside data, for example, economic and trade data, logistics records, historical disruption trends, and sequestration were all used to identify different aspects of the model of the global supply chains ecosystem. The dynamic combination of external factors such as geopolitical events and natural disasters has contributed to the model's improved ability to precisely predict disruption. The innovative function of the model is indicative of the fact which manifold is the application of data in the construction of reliable forecasting models.

The proposed model was compared with baseline approaches including simple statistical models, which demonstrated significant improvements in accuracy and leading time. The latest technologies introduced in our model include recurrent neural networks (RNNs), long short-term memory (LSTM) networks, and attention mechanisms enabled it to capture the subtle temporal patterns and detect the complicated data signals. Additionally, the application of ensemble methods offered some duplication to the given model through the reduction of the influence of the outliers and noise on the outcomes of the methods resulting in an improved performance of the model.

The insights provided through visualizations and the forecasting pipeline were instrumental in decision-making. Scenario analysis, along with impact forecasting, integrated into the model allows stakeholders to explore various what-if scenarios and assess the potential consequences of disruptions. The graphical representations, such as those in Figures 2 and 3, helped readers intuitively understand the results, enabling informed and timely decision-making.

While the results seem promising, certain limitations were found during the evaluation process. Minor discrepancies between predicted and actual values in some months underscore the need for continuous model refinement and updates. Moreover, the reliance on high-quality and real-time data poses obstacles, especially in regions with limited data infrastructure. The ongoing data updates and the model should be developed in such a way as to fully address the weighty concerns and test the effectiveness of the model in changing supply chain contexts.

V. Discussion

In conclusion, the results show that the proposed forecasting model has a high ability to achieve not only accurate predictions of global supply chain disruptions but also the generation of useful information that decision-makers can act on. The graphical and tabular representations of the findings showcase the model's capability to recognize trends, quantify risks, and assist in the decision-making process. The diverse data sources integrated with the leading-edge computational techniques and a commitment to continuous improvement ensure that the model is well adapted to the challenges of contemporary supply chains. It is essential that we address the issue of resilience and sustainability in the global trade economic system, and this study is part of the ongoing discussions on this subject.

VI. Conclusion

The research findings highlight the significant role of data-driven forecasting models in understanding global supply chain disruptions and their impact on trade economics. The accuracy of the proposed model was shown to be high through closely predicted and actual situations as a result the deviation for the

majority of the months is very small. Also, in supplying an average lead time of 2.5 to 3.2 weeks, the model can bring crucial warnings early enough to allow for the application of risk mitigation strategies by stakeholders. Additionally, the integration of heterogeneous data sources like trade information, logistical data, and others played a key role in obtaining these outcomes while sophisticated computational methods such as RNNs and LSTMs with attention mechanisms were the foundational elements enabling the model to understand complicated patterns of time. Furthermore, the seasonal trends unveiled in the analysis highlight the importance of the model in providing actionable insights through it, especially in high-risk seasons, thus helping to achieve the goals of risk resilience and sustainability in the global supply chains.

However, the model has certain constraints that must be resolved. While the model performs well in most months, occasional deviations in forecasts highlight the need for continuous refinement. Furthermore, the data must be of high quality, timely, and recent, which is a hard task in those regions, where the technology is not well implemented for what is required such as the data infrastructure is insufficient. Consequently, in the upcoming work the primary emphasis will be on the model's flexibility to handle cases with missing data and the model's capacity to deal with exceptional handling situations among others. The areas of research that need improvement as indicated by these gripes are also anticipated to be the ones where similar systems can be studied and modified for a lot of other comparable industry settings in the future and even the other variables can have a global effect and therefore necessitate the interference of global tools in the supply chain management.

Developing an IoT Testing Framework for Autonomous Ground Vehicles

Murat Tashkyn, Amanzhol Temirbolat, Nurlybek Kenes, Amandyk Kartbayev
School of Information Technology and Engineering, Kazakh-British Technical University, Almaty, Kazakhstan

***Abstract*—Autonomous ground vehicles play a crucial role in the Internet of Things, offering transformative potential for applications such as urban transportation and delivery services. These vehicles can operate autonomously in uncertain environments, making reliable testing essential. This study develops and analyzes a testing framework for autonomous ground vehicles, focusing on their motion control systems and electronic modules. The research reviews testing methods for printed circuit boards (PCBs), highlighting the need for JTAG testing implementation for vehicle modules. Functional testing was conducted on key components such as cameras, LiDARs, and wireless interfaces under various conditions. Results show that JTAG testing successfully detects faults with precise localization, while functional tests confirm stable component performance. Environmental tests revealed that most components perform reliably within optimal conditions, with failures occurring at temperatures beyond ±70°C and humidity levels exceeding 90% RH. The developed testing system enhances the reliability of autonomous delivery vehicles.**

***Keywords*—Autonomous vehicle; testing system; IoT; functional testing; electronic modules; delivery automation**

I. Introduction

Intelligent autonomous vehicles are particularly relevant today. They can operate in uncertain environments and are of significant interest for a wide range of practical applications, including food delivery. This study focuses on the development and analysis of a testing system for unmanned delivery vehicles. Before such vehicles can be deployed in real-world operations, extensive testing is required to ensure their stability, reliability, and performance, as well as prior research on testing systems for unmanned delivery vehicles.

However, several challenges complicate the testing process for these vehicles.

- Testing in real-world conditions: It is essential to test delivery vehicle modules under conditions that closely mimic real environments. This includes verifying components under the influence of multiple adverse factors, such as humidity.
- Testing of PCB modules: Testing individual modules separately cannot guarantee the proper functioning of the entire delivery vehicle after assembly. Testing of all printed circuit boards (PCBs) as a unified system is necessary, since the vehicles are cyber-physical systems that perceive, process, and physically respond to information from the real world.
- Automation of testing: Manual testing introduces the risk of human error, which, even in a single component, can render the entire vehicle non-operational.
- Regulatory gaps: Unmanned delivery vehicles lack specific regulations and testing requirements, making their verification process unclear and inconsistent.

A plan of the testing system is developed, representing a set of methodologies for assessing the operational functionality and reliability of an autonomous delivery vehicle. They consist of several key subsystems, including a power supply, lighting system, motor, control system, communication, and sensing system. Thus, the delivery vehicles under investigation are complex systems comprising numerous modules. Each module requires thorough testing, as its functionality directly impacts the performance of the entire system. This would require complete disassembly and retesting of the vehicle.

The control system manages the operation of all components and coordinates their interactions. Drives are used to control movement and can be electric, hydraulic, or pneumatic, allowing the vehicle to maneuver in space, including on-the-spot rotations and 360-degree turns, which are particularly crucial in confined places. The control system also processes data from the perception system and makes decisions based on that information, without which its operation would be impossible.

At the core of the structural diagram is a computational device that governs the robot's actions through control algorithms, as shown in Fig. 1. This device processes video streams received from onboard cameras. Wheel controllers receive speed requirements for each wheel from the platform controller and manage the motor to maintain the specified speed under varying driving conditions. The peripheral controller regulates the operation of the lid motor, the locking mechanism, and the onboard lighting system.

The platform controller ensures power delivery to the platform, regulates current in each power branch, and switches to a backup power source when necessary. The power supply provides electricity to all the vehicle's systems. It can include various energy sources such as batteries, generators, or other power sources, which gives the potential for scaling the system to other types of autonomous transport or applications. Also EMC testing is a critical stage, ensuring that the system can operate with influence from external radiation sources.

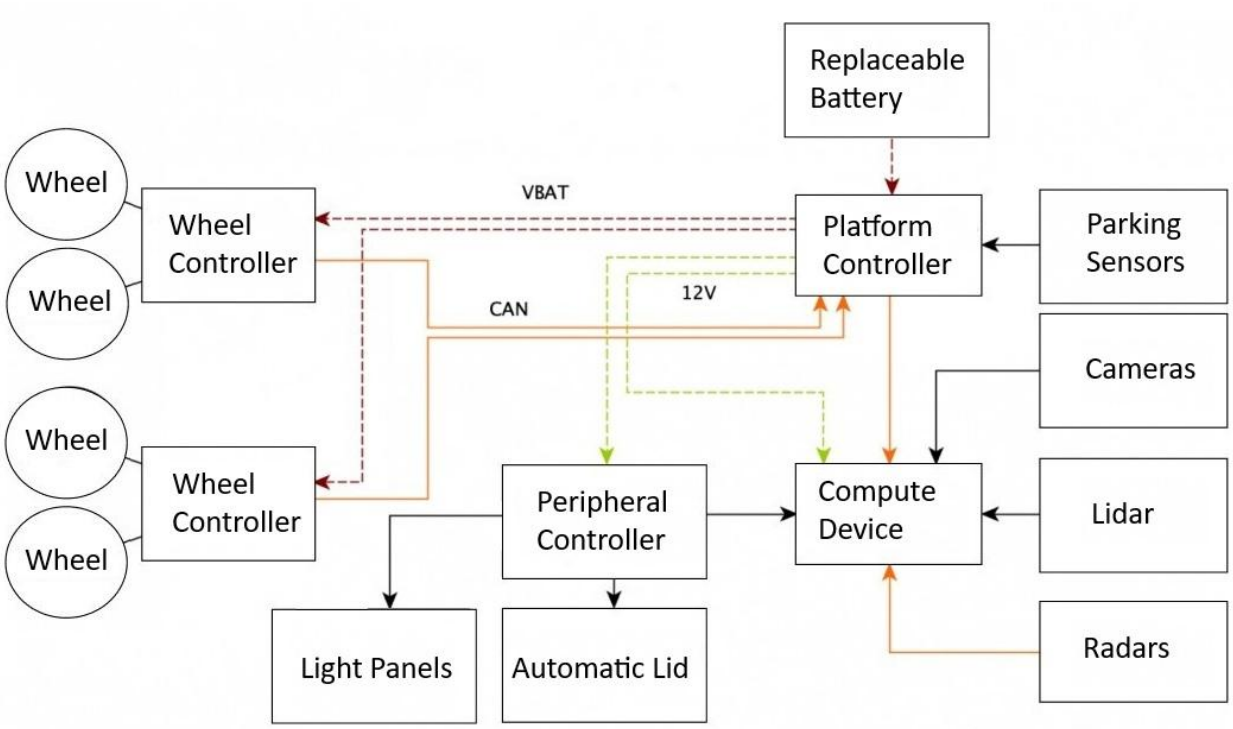

Fig. 1. The structural diagram of the vehicle under test.

Automation of the testing process can eliminate human error, enhance transparency, ensure consistent and controlled testing conditions, and allow for efficient data collection and analysis. To address these challenges, new testing methods applicable to unmanned delivery vehicles were developed. These methods ensure reliable performance in real-world conditions while meeting the demands for evaluation.

The paper is organized as follows: the related works in Section II reviews existing literature on testing systems and highlights the challenges. The methodologies in Section III details the proposed testing framework. The results in Section IV presents findings from implementing the system, focusing on performance metrics. The discussion in Section V analyzes the implications of the results, addressing limitations, and future opportunities. Finally, the conclusion summarizes the study's contributions which is given in Section VI.

II. Related Work

The research in the field of Internet of Things (IoT) and autonomous ground vehicles (AGVs) is rapidly evolving due to their significance in automation and smart transportation. IoT has been widely explored as a foundational technology for the communication and coordination of autonomous systems. Studies like Biswas and Wang emphasize the integration of IoT for data exchange between sensors, vehicles, and control systems, ensuring real-time decision-making and monitoring [1]. Similarly, Baliyan et al. have discussed the role of IoT in enhancing the efficiency and scalability of autonomous delivery vehicles [2]. The approach presented by Abdul Razak et al. [3] demonstrates how IoT-based monitoring can improve vehicle safety, which could be extended to autonomous ground vehicles for monitoring operator impairment in semi-autonomous modes due to alcohol consumption.

Testing methodologies for AGVs have been a significant focus in the literature. Son et al. presented a simulation-based testing framework to validate motion control systems in uncertain environments [4]. Their work highlighted the importance of virtual testing environments to mitigate risks during physical tests. Additionally, Brogle et al. proposed a hardware-in-the-loop (HIL) testing system for autonomous vehicles to evaluate hardware and software interactions under various operational conditions [5].

The implementation of JTAG (Joint Test Action Group) testing for PCB diagnostics has been widely adopted for automated electronic testing, as PCBs are integral to the operation of IoT-enabled systems. Techniques like boundary-scan testing (JTAG) have been explored in works such as Ling et al., which outlined the advantages of automating PCB testing processes [6]. Similarly, Yang et al. emphasized the need for adaptive testing systems to handle the growing complexity of electronic modules in autonomous systems [7].

Functional testing has been explored extensively in autonomous systems to validate their real-world applicability. Autonomous systems rely on accurate and robust sensors, including cameras, LiDARs, and wireless modules. Works by Jernigan et al. have focused on developing rigorous testing methodologies to ensure sensor reliability under varying environmental conditions [8]. Ma et al. further explored the resilience of wireless interfaces in harsh environments, which is critical for maintaining communication in delivery automation [9].

Resilience testing of AGVs and their components under extreme environmental conditions has been a critical focus area. Djoudi et al. proposed a comprehensive testing framework for unmanned delivery vehicles, emphasizing vibration and climate resistance testing [10]. Studies such as Zhang et al. have demonstrated methodologies to assess the durability of electronic modules in harsh climates, including extreme temperatures and vibrations [11]. Using microscopic traffic simulation in VISSIM and the Surrogate Safety Assessment Model (SSAM), Abuzwidah et al. [12] assessed CAV performance across 21 scenarios, highlighting substantial improvements in speed and reductions in accidents under different weather conditions. Their findings emphasize the necessity for CAVs to adapt dynamically to adverse weather for optimal safety. These analyses are crucial in identifying the limitations of functional testing, guiding the development of more effective testing protocols.

Automation in testing processes has become a cornerstone of quality assurance in AGVs. Research by Ostendorff et al. showcased improvements in boundary-scan testing techniques, enabling efficient fault detection in increasingly complex PCBs [13]. Research by Garikapati et al. demonstrated the application of automated AI testing frameworks for vehicle modules, significantly reducing manual effort and errors [14]. Similarly, Jeong et al. highlighted advancements in automated diagnostics for electronic modules, offering faster and more accurate fault detection [15].

Recent works, such as Sánchez-Martinez et al., have moved toward developing integrated testing systems combining hardware, software, and environmental validation [16]. Rahman and Thill reviewed the integration of autonomous vehicles within urban networks, focusing on the performance and the challenges of ensuring consistency [17]. Comparative studies, such as Kim and Kang, have evaluated testing methodologies for EVs, providing a framework to assess their applicability for specific use cases [18].

Advanced sensor systems such as LiDAR and cameras are pivotal in AGVs. Tang et al. examined the testing frameworks required for these sensors, focusing on accuracy, calibration, and environmental adaptability [19]. Studies like Giannaros et al. investigated the performance of wireless modules in urban and rural settings, ensuring seamless data exchange with control systems [20]. These studies emphasize the importance of testing frameworks in mitigating sensor-related failures in autonomous operations, and aligning testing protocols with specific application scenarios.

III. Methodology

The system is a comprehensive methodology for assessing the functional stability of autonomous delivery systems. Fig. 2 illustrates the testing system, which includes a series of specialized procedures aimed at identifying potential vulnerabilities and failures in the system's operation.

The testing process begins with JTAG testing of printed circuit boards, enabling the detection of possible defects in electrical circuits. Functional testing focuses on verifying the proper operation of critical components such as cameras, lidars, and wired and wireless connections.

This is followed by a series of tests for vibration and environmental resistance, designed to evaluate the system's ability to function under varying environmental conditions. Electromagnetic compatibility testing is a critical stage, ensuring that the system can operate without interference from external radiation sources. The delivery system testing framework represents a basic approach to evaluating the quality and reliability of autonomous delivery systems, ensuring their stable performance under diverse operational conditions.

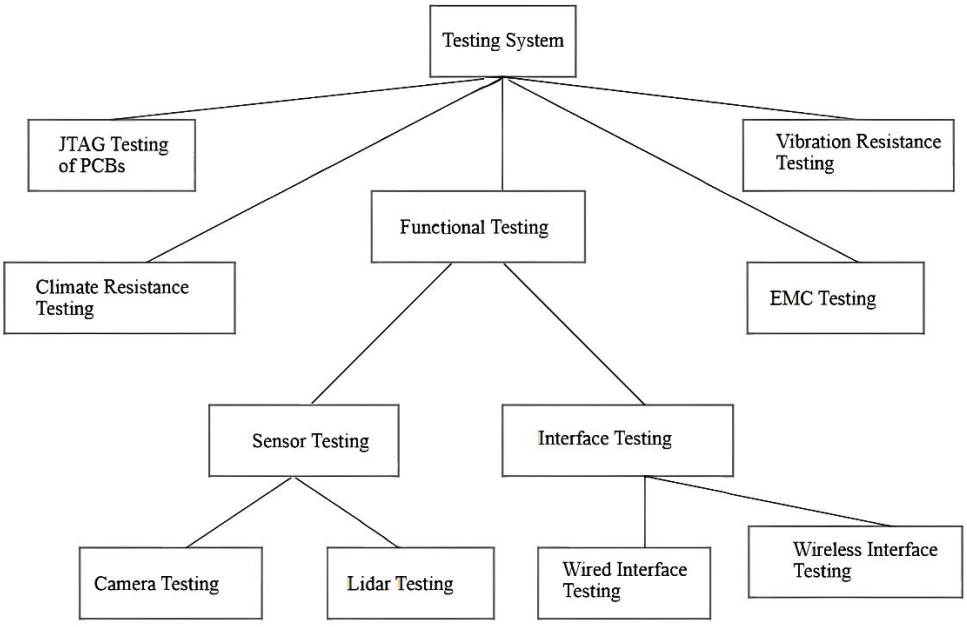

Fig. 2. The plan of the testing system.

A. PCB Testing

The testing of PCBs aims to select the most efficient method for further implementation, emphasizing the necessity of automating the testing process. Connection testing can detect missing pull-up resistors and signal "sticking" issues. This is achieved by setting specific values on the pins and comparing the read values against a predefined truth table.

Visual inspection and manual testing involve checking the quality of assembly, the presence and integrity of all components, and performing measurements using a multimeter. However, the increasing complexity of PCBs and the risk of human error reduce the efficiency of this method. An in-circuit tester (matrix testing) uses fixed sensor probes to check the integrity of soldered connections (Fig. 3 and Fig. 4). The disadvantages of this method include the high cost of the testing equipment, its large size, and the need to create a customized matrix contact field according to the PCB design.

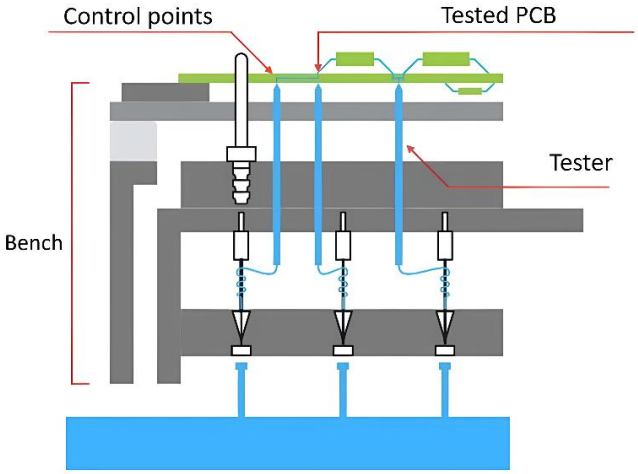

Fig. 3. Example of an in-circuit tester.

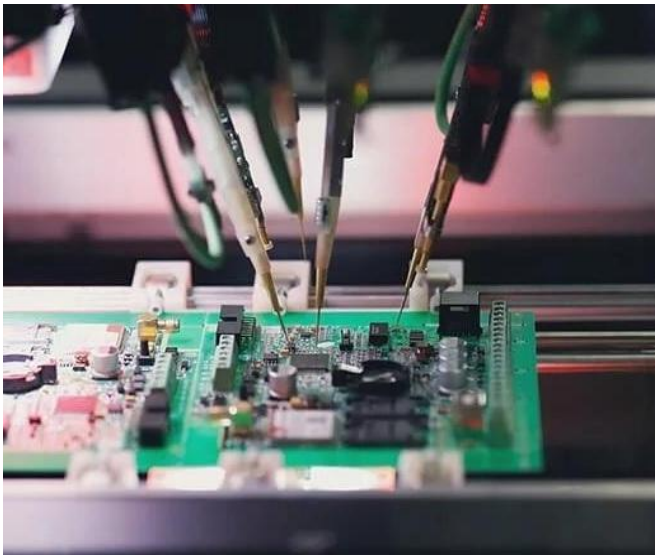

Fig. 4. Example of a flying grid tester.

JTAG testing, or connection testing, verifies whether the manufactured PCB matches the original design and identifies unintended circuit breaks or shorts [21]. For example, if the design specifies that certain chip pins must be connected somewhere on the board, the presence of the connection can be checked by applying values to one pin and reading them from others. Similarly, if the design specifies that certain pins should not be connected, JTAG testing can verify the absence of unexpected shorts by applying values to one pin and ensuring they do not influence others. The hardware of an autonomous delivery system can be tested in various ways, Table I provides more details of a comparison of PCB testing methods.

TABLE I. COMPARISON OF PCB TESTING METHODS

Method	*Error Probability*	*Performance*	*Retooling*	*Fixture Development*
Manual Testing	High	Low	Simple	Not Required
Matrix Tester	Low	High	Complex	Required
Flying grids	Low	High	Complex	Not Required
JTAG Testing	Low	High	Simple	Not Required

Thus, in the case of development and production involving numerous PCB designs manufactured in small batches, suitable testing options include purchasing a flying grids or utilizing JTAG testing. Both methods offer low error probability, high performance, and do not require the development of specialized fixtures. However, considering the cost and time required for reconfiguring the flying grids for each board, this work prioritizes JTAG testing.

B. JTAG Testing

To test a PCB using boundary scan, a BSDL (Boundary Scan Description Language) file must be downloaded from the chip manufacturer's website for each JTAG-supported chip. The supplementary text file describes the functions of the chip's pins.

The main advantage of boundary scan technology is the ability to set and read values at the pins without direct physical access. All signals between the device's core logic and its pins are intercepted by a serial scan path known as the Boundary Scan Register (BSR), which consists of a series of boundary scan cells. These cells are invisible during normal operation but can be used in test mode to set and/or read values from the device's pins or, in some cases, from the internal core logic. There are ten standard types of boundary scan cells, although manufacturers can define custom cell types to suit their hardware's functionality. The JTAG interface uses the following signal lines:

- TCK (Test Clock): To synchronize the internal operations of the state machine.
- TMS (Test Mode Select): Determines the next state of the state machine based on the rising edge of TCK.
- TDI (Test Data In): Represents data sent to the device's testing or programming logic. It is sampled on the rising edge of TCK when the state machine is in the correct state.

- TDO (Test Data Out): Represents data output from the device's testing or programming logic. It is valid on the falling edge of TCK when the state machine is in the correct state.
- TRST (Test Reset): An optional line that, if available, resets the TAP controller state machine.

JTAG is a synchronous interface, where signals are sampled on the rising edge of the clock (TCK) with the least significant bits first, and data output occurs on the falling edge. Boundary scan testing accelerates the preparation of tests for each project and eliminates the need for expensive test equipment. Furthermore, JTAG boundary scan can identify the precise location of faults, significantly simplifying diagnostics and repair.

With the increasing use of BGA (Ball Grid Array) packages, traditional PCB testing systems face limitations due to the inaccessibility of "internal" contacts. Boundary scan reduces test development costs by simplifying the management of chip pins for interaction with other board components. The standardized JTAG interface also allows individual tests to be created as library elements and reused across different projects, regardless of the JTAG-supported chips used. It is frequently used for programming chips on the board during production. When combined with boundary scan testing, this approach can save significant time and streamline the manufacturing process.

C. Functional Testing

To automate the testing process, it was necessary to choose a programming language and framework that would enable the development of a testing system with maximum simplicity and minimal programming expertise required for writing tests. Python was selected as the programming language due to its simplicity, flexibility, and widespread adoption.

In modern automated testing with Python, various testing frameworks are used. The most popular ones include:

- PyTest and PageObject;
- OpenHTF;
- Robot Framework.

The PyTest framework and the PageObject pattern allow separation of test logic from implementation, simplifying test management. However, they require significant effort during the initial development stage due to the need for low-level descriptions of testing processes and conditions for passing tests. While PyTest is excellent for integration and system testing, it may be excessive and less convenient for specific hardware board testing compared to Robot Framework. The OpenHTF library, developed by Google, was also considered. It includes a built-in graphical interface but has significant drawbacks, such as a lack of documentation, necessitating source code study, and the absence of academic work utilizing the framework.

Robot Framework offers several key advantages over other testing frameworks [22]. Its syntax is highly human-readable, making it easier to write and maintain tests, which is particularly beneficial in robotic development involving multi-disciplinary teams of hardware and software engineers. It includes built-in mechanisms for parallel test execution, detailed reporting, and logging, facilitating test analysis and statistical data collection. The framework also provides flexible mechanisms for Python integration, enabling the use of Python libraries during testing. Additionally, it allows the addition of new libraries and plugins for managing specific hardware and protocols. Thus, it is the most suitable choice for this task, offering a balance between test readability and maintainability.

To implement the delivery module testing system, readily available components were chosen, as they allow for quick hypothesis testing and reduce the development cost of the testing system. The Raspberry Pi Model 3 B+ was selected as the testing board due to its features, including an expanded 40-pin GPIO (General Purpose Input/Output) connector ideal for device testing (see Fig. 5). Additionally, the Raspberry Pi includes a CSI camera port, USB 2.0 ports, and a Micro SD slot for operating system booting and data storage. All tests conducted with the system's hardware are performed by the test bench operator.

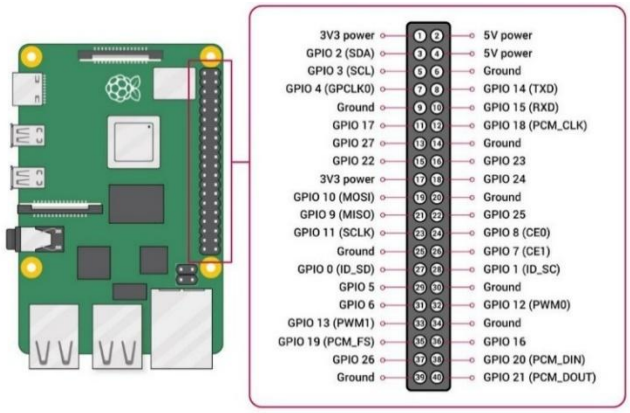

Fig. 5. External GPIO pins on rPi.

D. Testing Sensors

The Raspberry Pi 3 Model B+ Camera Module with a 5 MP resolution was chosen as the test camera because it connects via the CSI (Camera Serial Interface), similar to the cameras used in delivery vehicles, as shown in Fig. 6. This camera is classified as a MIPI (Mobile Industry Processor Interface) camera and connects directly to the VideoCore video chip through a CSI-2 (Camera Serial Interface-2) port, which helps conserve the Raspberry Pi's system resources, leaving USB ports available for other peripherals.

To test the camera's functionality, it must be confirmed that the camera can capture an image directly from the Raspberry Pi board. This involves configuring the camera in the system and installing Python libraries such as picamera for camera access and pillow for image processing. A test case was then created with the following logic: an image is captured using the camera, saved to the operating system as a file, then loaded and validated (ensuring the file is a valid image). Based on this validation, a report is generated indicating whether the test passed (Pass) or failed (Fail).

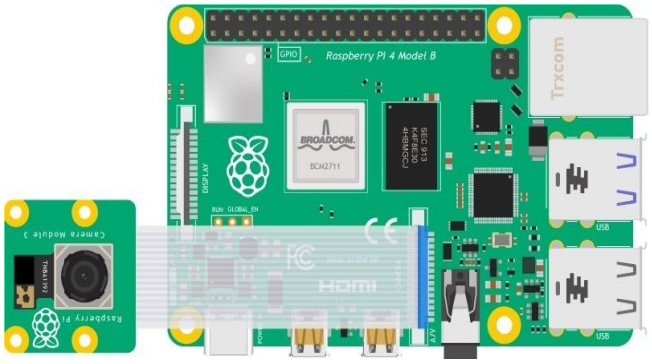

Fig. 6. The raspberry Pi 3 Model B+ camera module.

LiDARs are used for scanning and mapping the environment, aiding autonomous delivery vehicles in navigating safely. However, the diversity of LiDAR types and their operation in varying conditions complicates the development of universal testing procedures. Delivery vehicles typically use mechanical LiDARs. These feature a laser emitter (usually at a 905 nm wavelength) and a photodetector mounted on a rotating platform. This high pulse density enables the LiDAR to generate a visual 3D map of the surrounding area using a cloud of reflected points. The denser the laser pulses, the more detailed the point cloud.

Accelerometers in delivery vehicles measure acceleration along the X, Y, and Z axes. The accelerometer connects to the control electronics through the following pins:

- Power (V): Connected to the microcontroller's operating voltage.
- Ground (G): Connected to the microcontroller's ground.
- Data Signal (D): The data pin for the I²C bus, connected to the microcontroller's SDA pin.
- Clock Signal (C): The clock pin for the I²C bus, connected to the microcontroller's SCL pin.

To read values accurately from the accelerometer, the data for each axis is stored in high and low bytes. These must be combined into a single 16-bit value by performing a bit shift operation and adding the low byte to the shifted high byte.

In this section, functional testing was conducted to verify the operation of key sensors in the autonomous delivery vehicle. For instance, for testing the Wi-Fi wireless interface, a test was implemented to connect to a network using the Linux Network Manager, the most popular system for managing network connections on Linux systems. The next step involves testing the developed automated test cases.

IV. Results

A. Testing Boards

Before starting the test, ensure that the STM32F401RE board is connected to the Raspberry Pi 3. Begin by reading and verifying the board's ID. Next, test the two microcontroller pins, PA5 and PA6. Set PA5 on the STM32 to 1 (HIGH) and read the state of the corresponding pin on the Raspberry Pi. Verify that PA5 is set to 1, then similarly set and verify 0 (LOW). Repeat the same process for PA6. Finally, upload the firmware to the board and confirm that it has been successfully written, as shown in Fig. 7.

The UrJTAG utility is used for JTAG testing, allowing direct interaction with boards through the GPIO pins of the Raspberry Pi. Custom keywords were defined to structure the tests and avoid code duplication, such as opening and closing the JTAG interface and retrieving the state of a GPIO pin. The interaction with API libraries is considered but it also allows for precise fault localization, simplifying diagnostics and repair; however, its reliance on boundary scan capabilities limits its applicability to boards designed with JTAG support, potentially excluding legacy systems or simpler PCBs without such interfaces.

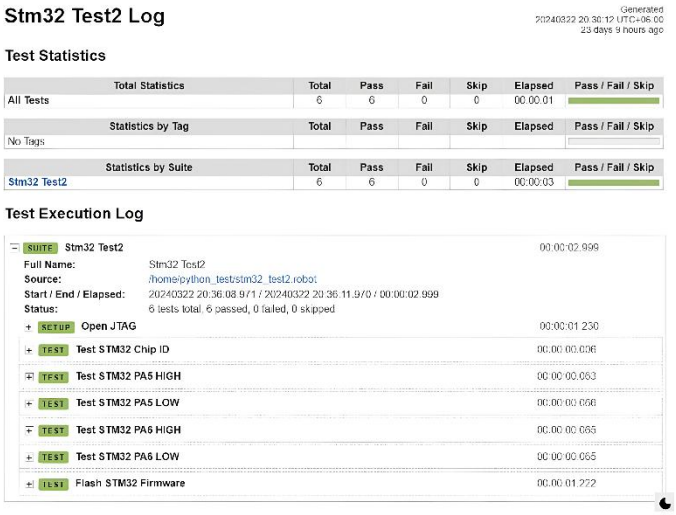

Fig. 7. JTAG testing log file.

Robot Framework tests are written in files with the .robot extension. These files use a BDD-like syntax, and the test file is named stm32_test2.robot. Test cases and keywords from the stm32_test.robot file interact with libraries by using methods belonging to those libraries.

- The jtag.py file is a library designed for working with the JTAG interface.
- The init method initializes the process for JTAG operations and sets non-blocking reading mode.
- The _set_nonblock method configures the stdout read descriptor to non-blocking mode for asynchronous interaction.
- The send method sends commands to the JTAG process, ensuring data transmission and calling flush for immediate delivery.
- The recv method reads data from the JTAG process, handles potential errors, and returns a tuple containing the execution status and response text.
- The bsdl, set_extest, and set_signal methods are used for configuring the BSDL, switching to EXTEST mode, and setting a signal on a pin, respectively.

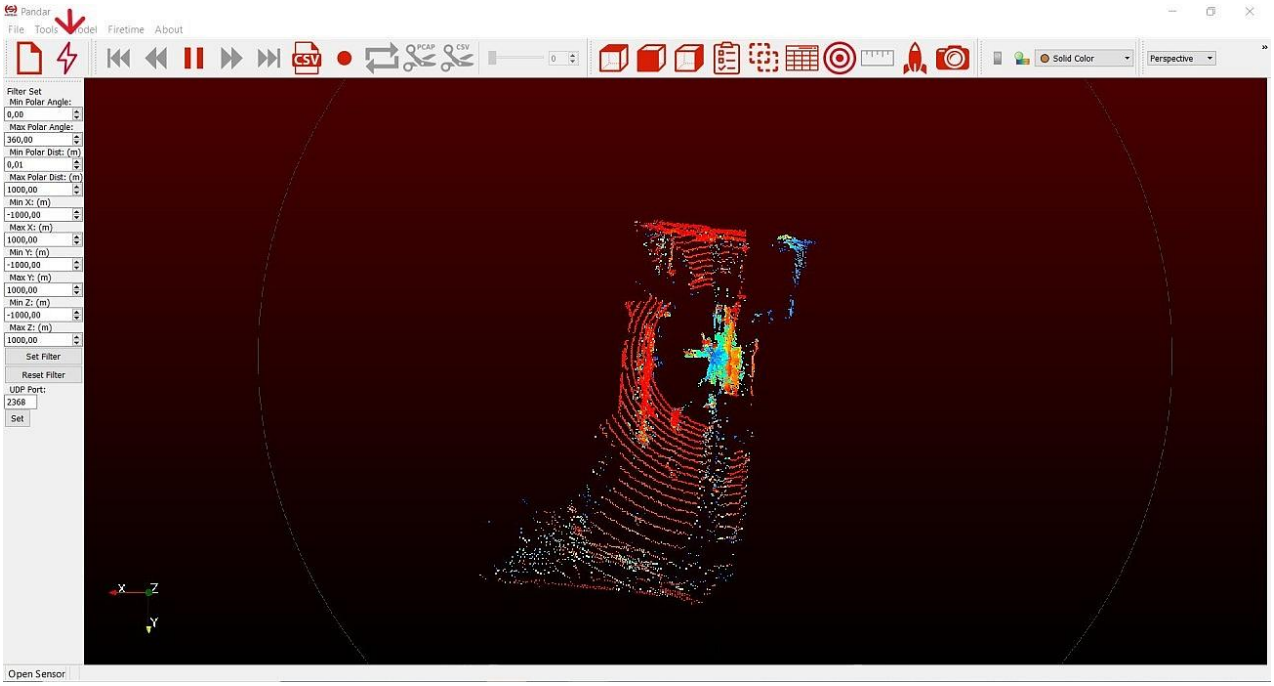

Fig. 8. LiDAR point cloud.

The detect_id method checks whether a device with a specified identifier (ID) is connected. It sends a detect command to the JTAG process and analyzes the response to determine if the specified ID is listed among the detected devices. The quit method ensures the proper termination of the JTAG process. It sends the quit command to the process and waits for it to exit. Python-based frameworks like Robot Framework has proven effective for evaluating key components such as cameras, LiDARs, and accelerometers; however, while it supports modular testing, it requires careful configuration and additional effort for integrating new device-specific libraries.

B. Testing Functional Parts

The LiDAR under test should be inspected for external mechanical damage and the condition of its lens. Prepare the necessary equipment:

- LiDAR;
- Laptop or PC with Ethernet, equipped with software for viewing the point cloud (e.g., PandarView);
- HESAI Interface Box;
- HESAI power supply;
- Ethernet patch cord.

Open PandarView and click "Receive Data from Ethernet." A point cloud should appears as in Fig. 8. This testing methodology was developed to verify the LiDAR's functionality and ensure the proper operation of its mechanical components, including the laser receiver and emitter.

We ensured that the LiDAR is not vibrating. Strong vibrations and low-frequency mechanical oscillation sounds can indicate issues with the bearings. Testing under poor visibility conditions should include assessments in fog, rain, and snowfall. A fog machine can be used to simulate these weather conditions. The greater the number of laser pulses, the denser the LiDAR point cloud. Based on various point clouds, the autonomous delivery vehicle's computational system constructs objects that form a three-dimensional representation of the surrounding environment.

Using a vibration test bench is a more effective method for assessing vibration resistance compared to driving over various road surfaces, as it allows testing under controlled, consistent conditions. Therefore, the parameters of the vibration test bench must be calculated to ensure optimal testing. Testing for mechanical factors, particularly vibration, requires preliminary calculations to select the most suitable equipment in terms of technical specifications and cost-effectiveness.

The vibration test bench is the core component and actuator of the vibration system, reproducing a specific type of vibration and transmitting it to the test object. Tests are typically conducted on a vibration stand equipped with one or more shakers, which register the sample's response to a predefined vibrational load. The market for vibration test benches is extensive and includes a wide variety of models. As a result, decisions often lean towards purchasing the most powerful vibration test bench available. For this purpose, the Tira vibration test bench, as shown in Fig. 9, with a thrust force of up to 32k, is selected as it meets the necessary requirements.

Fig. 9. Vibration test bench.

Thus, the developed system has successfully passed all tests and is suitable for testing real devices. However, for comprehensive testing of an autonomous delivery vehicle, it is insufficient to assess only its electronic modules using JTAG testing and functional tests. It is essential to conduct vibration resistance testing to evaluate the durability of electronic, electrical, and mechanical modules under vibrational stress. This is crucial as delivery vehicles may encounter potholes, gravel, and cobblestones, which impose vibrational and impact loads that could lead to the failure of individual modules or the entire vehicle [23]. The results of the developed automated tests are presented in Table II.

TABLE II. TEST CASES OF THE DEVELOPED SYSTEM

Test Name	*Steps*	*Expected Result*	*Test Passed*
All pins connected	Connect the test board to the test bench. Run. Wait for the test to complete.	Pass	Yes
Camera test (connected)	Connect the camera to Raspberry Pi. Run the test.	Pass	Yes
One pin disconnected	Disconnect PA5, run test, check result.	Fail: PA5 HIGH $0 \neq 1$	Yes
Camera test (disconnected)	Disconnect camera, run test, check result.	Fail: Photo not captured	Yes
Accelerometer test	Connect accelerometer, run test, check result.	Pass	Yes
WiFi test (disconnected)	Disable network device, run test, check result.	Fail	Yes
Vibration test	Place device on Tira, run Tira, visual check.	No cracks	Yes
EMC test	Execute EMC protocol, check connetion	Device stays connected	Yes

Environmental conditions are typically described using statistical variables such as temperature, humidity, air quality, and so on. These factors are critical for the functionality and lifespan of delivery vehicles, and manufacturers must ensure that their modules can operate within specified conditions while maintaining their stated performance characteristics.

Most climate tests are conducted in a climate chamber, as shown in Table III, which can simulate changes in temperature, humidity, dew, and frost. Additional conditions, such as dust and solar radiation exposure, are tested using dedicated chambers. Commonly measured parameters for determining the electrical safety of delivery vehicle modules include current, voltage, leakage path length between conductors, and the energy of emitted waves. It is crucial to note that electrostatic discharge (ESD) is unacceptable for electronic modules when they are not yet enclosed in a protective casing.

TABLE III. THE RESULTS FOR CLIMATE CHAMBER TESTS

Test Name	*Testing Methodology*	*Result*
Temperature Testing	Climate chamber, temperature range: -40°C to +85°C; condensation cycles and frost formation.	Most components operate within -20°C to +60°C; failures occur at ±70°C; frost impacts 30% of components
Humidity Testing	Controlled humidity chamber, 10%–95% RH	Corrosion risk increases by 40% at 85% RH; short circuits above 90% RH; risk varies by material
Dust Exposure Testing	Dust chambers with varying particle size (ISO 12103-1), Arizona test dust	Dust penetration in enclosures above 5-micron particles; 20% degradation in 3 weeks
Solar Radiation Testing	UV and infrared radiation exposure tests	UV exposure causes 15% material degradation over 1000 hours; discoloration starts at 500 hours
Electrical Safety Testing	High-voltage insulation resistance testing	Leakage current below 1mA at 1000V; insulation resistance >10MΩ meets IEC standards
Electrostatic Discharge (ESD) Testing	ESD simulator testing at 2kV–15kV discharge levels	Devices withstand up to 10kV discharge; failures start above 12kV

Once the delivery vehicle is fully assembled, it must withstand electrostatic discharge, as all electronic components are securely shielded by the casing. However, the reliance on specialized equipment introduces significant costs and operational constraints, especially for small-scale manufacturers; additionally, vibration testing under controlled conditions may not fully replicate the complexities of real-world terrain.

V. DISCUSSION

The developed testing system demonstrates significant advancements in ensuring the reliability and functional stability of autonomous delivery systems. By combining JTAG testing, functional testing, and environmental assessments, the system provides a comprehensive framework for identifying vulnerabilities and verifying the performance of key modules under diverse conditions. However, while the system achieves its primary objectives, there are opportunities for enhancement and certain limitations to address.

One notable strength of the system lies in its use of JTAG testing, which offers a highly efficient and cost-effective method for verifying PCB integrity. Unlike manual or in-circuit testing methods, JTAG testing eliminates the need for expensive test fixtures and reduces human error. It also allows for precise fault localization, simplifying diagnostics and repair. Although, its reliance on boundary scan capabilities restricts its applicability to boards designed with JTAG

support, potentially excluding legacy systems or simpler PCBs without such interfaces [24].

Functional testing, implemented through Python-based frameworks like Robot Framework, has proven effective for evaluating key components such as cameras, LiDARs, and accelerometers. The framework's human-readable syntax and Python integration streamline test development and maintenance, making it accessible to multidisciplinary teams. While Robot Framework supports modular testing, it requires careful configuration and additional effort for integrating new device-specific libraries, which may pose challenges for teams with limited resources or expertise.

Environmental testing introduces another layer of robustness by simulating real-world conditions in controlled environments [25]. The use of climate chambers for temperature, humidity, and frost testing, alongside vibration benches for mechanical stress evaluation, provides valuable insights into the durability of delivery systems. Nevertheless, the reliance on specialized equipment, such as the Tira vibration test bench, introduces significant costs and operational constraints, especially for small-scale manufacturers. Additionally, while vibration testing under controlled conditions is highly effective, it may not fully replicate the complexities of real-world terrain [26].

The inclusion of sensor-specific tests, such as those for LiDARs, camera, and accelerometers, highlights our focus on the core functionality of autonomous vehicles. Nevertheless, the diversity of sensor technologies and operational environments poses a challenge to the development of universal testing procedures [27]. For example, mechanical LiDARs with rotating components require different calibration and durability tests compared to solid-state LiDARs. Similarly, environmental factors like fog or heavy rain can disproportionately affect sensor performance, requiring further refinements to testing methodologies. The system also incorporates EMC testing to ensure devices can operate without interference [28]. This is particularly important for delivery vehicles, which rely on seamless communication between components. While the system's EMC tests have been effective, integrating real-time data collection and analysis during such tests could provide additional insights and improve overall reliability.

Despite these strengths, the system has limitations in scalability and regulatory compliance. The absence of standardized testing protocols for autonomous delivery vehicles means that manufacturers may face challenges in aligning their testing processes with emerging regulatory requirements. Furthermore, the system's reliance on high-performance test equipment, such as climate chambers and vibration benches, may not be feasible for all manufacturers, especially those operating in cost-sensitive markets.

Opportunities for improvement include the integration of machine learning algorithms to optimize test procedures and predict potential failures based on historical data [29]. Additionally, developing lightweight and portable testing solutions could reduce costs and improve accessibility for smaller manufacturers. The system could focus on expanding its adaptability and automation capabilities. Automated test execution and data analysis could significantly reduce the time and effort required for repetitive testing tasks, particularly for high-volume production scenarios. For example, integrating automated tools for capturing and analyzing LiDAR point clouds or accelerometer data could provide deeper insights into module performance under specific conditions.

Moreover, the testing framework could be extended to include real-time monitoring and diagnostics during operational testing. This critical opportunity lies in the development of modular testing architectures. Modular designs would also support scalability, allowing the testing framework to be adapted to different vehicle types or system configurations without significant reconfiguration. This would allow for dynamic adjustments in testing parameters, ensuring that modules are evaluated under a broader range of conditions, including unexpected environmental factors or system interactions [30]. Such an approach could also help detect intermittent faults that might not appear under standard test scenarios.

The incorporation of cloud-based testing and analytics could further enhance the system's capabilities [31]. A centralized platform for storing, analyzing, and sharing test results would enable manufacturers to benchmark performance across multiple production cycles or facilities. Additionally, cloud integration could facilitate collaborative development of standardized testing methodologies, allowing manufacturers to align their processes with industry best practices and emerging regulatory standards.

While the current framework emphasizes hardware testing, extending the scope to include software validation would provide a more holistic approach to system reliability. Autonomous delivery vehicles rely heavily on complex algorithms for navigation, object detection, and decision-making [32]. Testing these algorithms in simulated environments that mimic real-world scenarios could complement the hardware testing process, ensuring seamless integration and overall system robustness.

Finally, addressing regulatory alignment remains a critical area for improvement. By engaging with industry stakeholders and regulatory bodies, the system could be tailored to meet specific compliance requirements, paving the way for broader adoption in global markets [33]. Collaboration with regulatory bodies to define standardized testing frameworks could enhance the system's applicability and acceptance in the industry. Such efforts would also help establish the system as a benchmark for testing autonomous delivery vehicles, contributing to the standardization of quality assurance practices in this rapidly evolving field [34].

Overall, the developed system effectively addresses many challenges associated with testing autonomous delivery systems, further innovations in automation, modularity, and regulatory alignment will unlock new possibilities. By embracing these opportunities, the framework has the potential to become a solution for ensuring the safety, reliability, and functionality of autonomous delivery vehicles in diverse operational environments.

VI. Conclusion

The developed testing system provides a robust framework for assessing the functionality and reliability of autonomous delivery systems, combining JTAG testing, functional evaluations, and environmental assessments. It ensures comprehensive testing of critical components, including PCBs, sensors, and wireless interfaces, while maintaining cost-effectiveness through automation and streamlined processes.

However, the system has limitations. The reliance on specialized equipment like vibration benches and climate chambers can be cost-prohibitive for smaller manufacturers. Additionally, the absence of standardized protocols for autonomous delivery vehicles limits its regulatory alignment, and the diversity of sensor technologies complicates the development of universal testing methods.

Future work should focus on enhancing scalability and adaptability through modular and portable testing setups, integrating machine learning for predictive diagnostics, and expanding the framework to include software validation alongside hardware testing. Collaboration with regulatory bodies to establish standardized testing protocols and incorporating real-time data analytics will further strengthen the system's applicability and industry relevance.

AI-Powered Intelligent Speech Processing: Evolution, Applications and Future Directions

Ziqing Zhang
University International College, Macau University of Science and Technology, Macau 999078, China

***Abstract*—This paper provides an overview of the historical evolution of speech recognition, synthesis, and processing technologies, highlighting the transition from statistical models to deep learning-based models. Firstly, the paper reviews the early development of speech processing, tracing it from the rule-based and statistical models of the 1960s to the deep learning models, such as deep neural networks (DNN), convolutional neural networks (CNN), and recurrent neural networks (RNN), which have dramatically reduced error rates in speech recognition and synthesis. It emphasizes how these advancements have led to more natural and accurate speech outputs. Then, the paper examines three key learning paradigms used in speech recognition: supervised, self-supervised, and semi-supervised learning. Supervised learning relies on large amounts of labeled data, while self-supervised and semi-supervised learning leverage unlabeled data to improve generalization and reduce reliance on manually labeled datasets. These paradigms have significantly advanced the field of speech recognition. Furthermore, the paper explores the wide-ranging applications of AI-driven speech processing, including smart homes, intelligent transportation, healthcare, and finance. By integrating AI with technologies like the Internet of Things (IoT) and big data, speech technology is being applied in voice assistants, autonomous vehicles, and speech-controlled devices. The paper also addresses the current challenges facing intelligent speech processing, such as performance issues in noisy environments, the scarcity of data for low-resource languages, and concerns related to data privacy, algorithmic bias, and legal responsibility. Overcoming these challenges will be crucial for the continued progress of the field. Finally, the paper looks to the future, predicting further improvements in speech processing technology through advancements in hardware and algorithms. It anticipates increased focus on personalized services, real-time speech processing, and multilingual support, along with growing integration with other technologies such as augmented reality. Despite the technical and ethical challenges, AI-driven speech processing is expected to continue its transformative impact on society and industry.**

Keywords*—*Intelligent speech recognition; AI speech synthesis; speech processing; AI technology

I. INTRODUCTION

With the iterative upgrading of artificial intelligence technology, the application fields of AI technology are also expanding and developing, and at the same time, intelligent voice interaction, personalized speech generation, and other technologies are getting more and more attention in this process [1]. Among them, speech processing, as an important technology and means of personalized speech generation, involves speech signal processing, artificial intelligence, pattern recognition, phonetics, and other disciplines, and is the hot spot and difficult point in the field of speech processing research, and in the rapid development of AI technology, this field has also become a key research direction. Therefore, along with the development of the Internet and big data technology, voice processing technology (TTS), speech recognition technology (ASR), and other intelligent voice technologies are gradually maturing, the production, dissemination, and storage mechanism of the sound produces changes, and the application scenarios of AI voice are increasing, and voice products such as automobile navigation, video dubbing, intelligent speakers, cell phone assistants and so on are emerging in an endless number, and have already been realized to correspond to specific application Scenarios. Nowadays, there are two main parts of intelligent voice processing according to the function of the application scenes in social life, namely, AI synthesized voice is mainly composed of "AI voice narration" scenes without human-computer interaction, and "AI voice assistant" scenes with human-computer interaction. The two parts of the scene [2].

A. Significance of the Study

Language, as a unique tool for human communication, permeates all aspects of life, contains the rich and important emotional value, and plays an important role in the construction of civilized society, while emotion, as a characteristic unique to human beings, is usually difficult to be accurately conveyed in the process of speech processing. The development of AI technology makes it possible for the part of the speech processing process concerning human-specific expressive characteristics such as emotional value to be learned and applied by the machine, which is expected to have a profound impact on speech processing. Learn and apply, which is expected to have a profound impact on speech processing [3].

Speech, as a direct carrier of language, is the most natural way of communication among human beings and a key part of information transfer in daily life. With the rapid development of artificial intelligence research, speech recognition technology, which is carried by computers, cell phones, tablets, etc., is rapidly advancing. In the field of Human-Computer Interaction (HCI), recognizing individual phonemes or utterances of specific speakers can no longer meet the needs of learning and development of AI technology, so recognizing the hidden emotional state in speech has become a new trend in speech processing research under the rapid development of current AI technology. Therefore, the study of how to use this technology to assist speech processing to achieve intelligence in the current rapid development of AI technology is an urgent problem to be solved nowadays.

B. Conceptual Identification

1) Speech processing: Broadly speaking, people change the voice in the voice of the speaker's personality characteristics of voice processing technology collectively referred to as voice processing, which can be obtained, broad voice processing can be divided into two categories: non-specific person voice processing and specific person voice processing. Non-specific speech processing refers to the technical processing that makes the converted speech no longer sound like the original speaker's voice. In practical research and application, speech processing usually refers to the technology that changes the voice personality characteristics, such as spectrum and rhythm, of one speaker, i.e., the source speaker, to make it have the personality characteristics of another specific speaker, i.e., the target speaker, while keeping the semantic information unchanged. Generally speaking, the technical difficulty of person-specific speech processing is higher than that of non-person-specific speech processing.

The current research on linguistic AI mainly focuses on language understanding and language output, which are called "Natural Language Understanding" (NLU) and "Natural Language Generation" (NLG) respectively. "Natural Language Understanding (NLU) and Natural Language Generation (NLG). Natural Language Understanding allows computers to understand human natural language (including its intrinsic meaning) through a variety of analysis and processing, while Natural Language Generation focuses on how to allow computers to automatically generate natural language forms or systems that humans can understand. The relationship between the research contents of natural language processing and the corresponding human language ability is shown in the Table I.

TABLE I. CORRESPONDENCE TABLE BETWEEN NATURAL LANGUAGE AND HUMAN LANGUAGE ABILITY

No.	Research in Natural Language Processing	Linguistic competence of counterparts
1	Information retrieval	Language Understanding
2	Information filtering	
3	Information extraction	
4	Machine translation	Linguistic Generation
5	Automatic digest	
6	Document classification	Language Understanding
7	Text/Data mining	
8	Public opinion analysis	
9	Text editing and automatic proofreading	
10	Automatic scoring of essays	
11	Question and answer system	Linguistic Generation
12	Metaphorical computing	Language Understanding
13	Optical character recognition, OCR	
14	Speech recognition	
15	Text-to-language conversion	Linguistic Generation
16	Speaker identification/authentication/verification	Language Understanding

Using the degree of development of AI technology as a classification criterion, AI can be categorized into weak AI, strong AI, and super AI. Weak AI, also known as narrow AI. Its main features are: (1) does not have self-consciousness, its action depends on the instructions given by humans; (2) and human beings are significantly different from each other, there is still a huge gap in appearance and other aspects, it is very easy to identify; (3) cannot learn and innovate on its own, it is essentially a tool that relies on human beings to be upgraded. The above characteristics determine that weak artificial intelligence should not be qualified as a legal subject. Strong artificial intelligence, also known as general artificial intelligence, is complete artificial intelligence. Strong AI can think like a human being and is not just a tool for humans. Because it possesses the consciousness of rights, claims of rights, and the ability to realize autonomy, as well as the ability to assume responsibility relatively independently, and has a certain substantive connection with human beings, it meets the conditions for having limited legal subject qualification.

Super Artificial Intelligence, defined by Nick Bostrom as an intelligence that outperforms the human brain in almost every domain, these domains include scientific innovation, general intelligence, and social skills. This definition is open-ended. The possessor of superintelligence can be a digital computer, a computer network integration, or an artificial neural organization without regard to whether it has subjective consciousness or experience. It seems that super-artificial intelligence should be given a higher level of legal status, but this idea is still debatable due to the human fear of the risks posed by the unknown and the adherence to ethics.

Therefore, another commonly accepted classification standard at present is to categorize AI based on different application modes of AI, i.e., to classify AI into generative AI and discriminative AI. According to China's Interim Measures for the Administration of Generative Artificial Intelligence Services, which came into effect on August 15, 2023, generative AI technology refers to models and related technologies that can generate content such as text, pictures, audio, video, and so on. It has become a milestone in the history of AI because it

transcends the scope of traditional AI, is capable of generating natural language understandable to humans, performs tasks that should only be accomplished by human intellectual guidance, and is deeply involved in human daily life. Discriminative AI, also known as discriminative AI or decision-making AI, aims to train machine learning models to classify or predict based on input features. This approach is well suited for tasks such as regression and sequence labeling in areas such as image recognition, speech recognition, and natural language processing. One of the main advantages of discriminative AI is its ability to make efficient and accurate predictions, but it cannot typically generate new samples and an understanding of the generative mechanisms behind the data.

C. Purpose of the Synthesis

This paper will focus on analyzing the latest progress of intelligent speech processing technology in the wave of artificial intelligence technology and the consequent profound changes that will be brought to this research field. With the rapid development of AI technology, intelligent speech processing technology has moved from the laboratory to the road of wide application has gradually penetrated daily life, and has profoundly affected the current life and the mode of operation of various industries. The purpose of this paper is to comprehensively show the technological development of intelligent speech processing technology in terms of speech recognition accuracy, speech processing naturalness, and natural language processing intelligence by systematically combing domestic and foreign research results and application cases, and exploring how the development of AI technology will have a transformative impact on the field of intelligent speech processing, and at the same time, to look forward to the future development of intelligent speech processing. In addition, this paper will also discuss the impact of possible pitfalls in data security, privacy, and law brought about by the ongoing research in the field of intelligent speech processing, to obtain thoughts and inspiration on the impact of the development of AI technology. Overall, the research objective of this paper is to comprehensively sort out the development of intelligent speech processing technology under the development of AI technology, assess its transformative impact on the society and economy, and provide valuable reference and guidance for future research and application.

D. Structure of the Paper

This paper aims to study the development of an intelligent speech-processing technique based on AI technology and to discuss the technical and legal issues that are currently faced as well as the outlook for the future. The following is the Section structure of this thesis:

Section II mainly elaborates on the current status of intelligent speech processing, which firstly gives an overview of the relevant research progress at home and abroad, and then summarizes, combs, and summarizes the current research results at home and abroad, mainly including the overview of the achievements in the fields of speech recognition, speech processing, and speech learning paradigm.

Section III analyzes the key problems faced by the current intelligent speech processing technology based on AI technology, mainly from the main tasks and problems of speech processing technology, firstly, the tasks of the current speech processing technology are clarified, and then the completion of the speech processing tasks are analyzed in-depth by the current problems of speech processing technology, to the problems faced by the intelligent speech processing technology based on AI technology A detailed exposition is carried out.

Section IV describes the development issues in the field of intelligent speech processing based on AI technology, and this Section further explores the public data security and ethical and legal issues brought about by the technological development on top of the technological development issues in Section 3, and this Section analyzes the current intelligent speech processing field outside of the technology that may be encountered in the field of intelligent speech processing, mainly from the perspective of three aspects, namely, data privacy and security, data algorithmic discrimination and bias, and accountability and responsibility problems.

Section V provides an outlook on the future of intelligent speech processing based on the development of current technologies and application scenarios, mainly analyzing and looking forward to both technology and application levels.

Section VI concludes with a summary, which summarizes the significance of the development of intelligent speech processing technology, as well as further summarizes the technological development discussed in the content of the above Sections and the problems that may be faced, and discusses the future research direction, indicating the outlook for the future development of intelligent speech processing technology based on AI technology.

II. The Current Status of Research in the Field of Intelligent Speech Processing

A. Overview of Domestic and International Research

The work related to speech processing research can be traced back to the 1960s and 1970s, and there have been more than 50 years of research history, but it is only in the last decade or so that it has received extensive attention from both academia and industry. In recent years, the advancement of technologies such as speech signal processing and artificial intelligence deep learning, in addition, due to the explosive growth of information, the field of big data has also been developed significantly, and a considerable amount of learning and analyzing text has been obtained, therefore, the improvement of big data acquisition ability and large-scale computational performance has likewise given a strong impetus to the research and development of speech processing technology. Among them, the most important role is still the rise of speech processing methods based on artificial neural networks (Artificial neural networks, ANN), which makes the quality of speech processing further improved by the mode of deep learning. Institutions in China that have conducted speech processing research earlier include the Chinese Academy of Sciences, the University of Science and Technology of China, the National University of Defense Technology, Microsoft Research Asia, IBM China Research Institute, and so on. In recent years, many universities such as Southeast University, Nanjing University of Posts and Telecommunications, South China University of Technology, Soochow University, Harbin Institute of Technology,

Northwestern Polytechnical University, Army Engineering University, and many other companies such as Tencent, KDDI, and Baidu have also begun the research on this technology, and have successively achieved several research results. In 2016, scientists in the field of speech processing from China, Japan, and the United Kingdom organized the VCC2016. VCC2016 was organized by scientists from China, Japan, Britain, and other countries, which provided a data platform and performance scale for speech processing research. 2018 VCC2018 was also held as scheduled, and based on the world's cutting-edge artificial intelligence technology, the speech processing methods were once again pushed forward, and accordingly, the quality of speech processing was once again significantly improved. Enhancement. According to the key breakthroughs in speech recognition technology, Table II summarizes the development of speech processing and recognition technology in different time periods.

TABLE II. SPEECH PROCESSING TECHNOLOGY DEVELOPMENT

Period	Key Technology Breakthroughs	Application Areas	Main features
1950s	Syllable Recognition System	Specific Speech Conversion	Relies on hard coding with limited recognition capabilities
1960s-1970s	Rule-based and statistical modeling	Continuous speech stream processing	Recognition improved but was still limited by noise, etc.
1980s-1990s	Deep learning techniques, neural network models	Processing complex speech streams	Automatic learning capability to handle non-standard pronunciation
Early 21st century to the present	Mobile Internet and smartphone penetration	Multi-language, multi-accent recognition	Dealing with noise, accents, and speed of speech variations, a wide range of applications

B. Synthesis of Main Research Results

1) Development of speech recognition technology: For a long time, the dominant approach for speech recognition has been the Gaussian Mixture Model-Hidden Markov Model (GMM-HMM), which is based on context-dependent generative models of GMM and HMM. Neural networks were also a popular method used for speech recognition, however not as effective as GMM-HMM. Deep learning started to make an impact in the field of speech recognition after a close collaboration between academia and industry in 2010. The collaboration began with a phoneme recognition task, and the results demonstrated the capabilities of the DNN architecture and subsequent convolutional and recurrent network architectures. Their work also demonstrated the importance of moving away from the widely used MFCC features to lower-level raw speech spectrum features. Their collaboration has also yielded good results on large-vocabulary recognition tasks. The main reason for the success of DNN on large-vocabulary speech recognition tasks is that similar to the speech units in GMM-HMM, DNN uses a large-scale output layer structure. The reason for using this structure is that speech researchers expect to take advantage of context-dependent phoneme modeling techniques, which are very effective in GMM-HMM, and that this structure allows for as little change as possible to the highly efficient decoder software architecture developed for GMM-HMM. The work on large-vocabulary speech recognition by the DNN has also demonstrated that, if a large amount of labeled data can be exploited, a pre-training process similar to that for a deep confidence network is not necessary. the training process is unnecessary. Deep learning has been successful in both industry and academia in the field of speech recognition, and this success has been due to three main factors: (1) deep learning significantly reduces the speech recognition error rate compared to the best previous GMM-HMM systems; (2) due to the use of phonemes as the output of DNNs, deploying DNN-based speech recognizers requires only a small portion of the decoder to be changed; and (3) DNNs Powerful modeling capability reduces the complexity of speech recognition systems. After the success of the DNN-HMM system for speech recognition, researchers have proposed many new architectures and nonlinear units for improving speech recognition accuracy. Yu et al. proposed a tensor version of DNN by replacing one or more layers in a traditional DNN by using dual projection layers and tensor layers. The dual projection layer projects each input vector into two nonlinear subspaces. In the tensor layer, the two subspace projections interact with each other and jointly project the next layer of the entire depth architecture. The researchers also propose a method to map the tensor layer to a traditional sigmoid layer, so the tensor layer can be trained in a similar way to the sigmoid layer. The idea of time-domain convolution originated from a time-delay neural network (TDNN), which was used as a shallow network in early speech recognition. Recently when researchers used deep convolutional neural networks for phoneme recognition tasks, they found that weight sharing in the frequency domain is more compared to weight sharing in the time domain [4]. A research report also states that convolutional neural networks help in large-vocabulary continuous speech recognition tasks and that multilayer convolutional neural networks using a large number of convolutional kernels or feature maps give greater performance gains [5]. Sainath et al. explored a large number of variations of deep convolutional neural networks and found that when combined with several new methods, deep convolutional neural networks achieved the best results on several large-vocabulary speech recognition task results [6]. The most notable deep structures for speech recognition tasks are recurrent neural networks and their deep versions [7]. Although RNNs were first successful in phoneme recognition, however, due to the complexity of training RNNs, it was difficult to scale RNNs to larger speech recognition tasks [8]. Since then the learning algorithms for RNNs have been improved and better results have been achieved using RNNs on several tasks, especially using bidirectional LSTM RNNs [9]. In addition to innovations

in deep learning models for speech recognition, a large amount of work has investigated how to develop and implement better nonlinear units. The sigmoid function and the tanh function are the most commonly used nonlinear functions in DNNs, however both have limitations. For example, when the neuron nodes are close to saturation, the error function has a small value of the gradient concerning the parameters, at which point the network is slow to train. To overcome the shortcomings of the sigmoid and tanh functions, Jaitly and Hinton first used ReLU in speech recognition.

Another effective unit for speech recognition is the maxout unit, which is used to construct deep maxout networks. Deep max-out networks generate hidden layer activation values by performing a max operation or max-out operation on a fixed number of weighted inputs. This operation is the same as the maximum pooling operation in convolutional neural networks. These maximum values are the outputs of the previous layer. Thereafter, Zhang et al. generalized the max-out unit into two new types. Both of these types have been shown computationally and experimentally to work better than the ReLU units described in the previous section.

2) Research and development of speech processing technology: The goal of speech processing is to generate speech directly from text as well as additional information. To overcome the shortcomings of statistical parameter-based speech-processing algorithms, researchers have applied deep learning to the field of speech processing. Earlier speech processing techniques were mainly based on rules and rule sets, where computers converted text into speech according to predefined rules. This method requires a lot of human intervention and the results of synthesized speech are not satisfactory. Subsequently, statistical parametric speech processing appeared in the mid-1990s and became the main approach in the field of speech processing [10]. In this approach, the relationship between the text and the corresponding acoustic realizations is represented by a set of stochastic generative acoustic models, which presents three modules that are very important for speech processing: the language model, the acoustic model, and the vocoder. Among them, the task of the language model is to extract the input text into linguistic features utilizing natural language processing techniques, which have the linguistic information needed by the back-end acoustic model. The acoustic model is responsible for converting linguistic features into acoustic features, and then a separate vocoder completes the conversion of acoustic features to the original speech waveform. Hidden Markov models based on decision tree clustering, contextual correlation, and output states satisfying a Gaussian distribution are the most popular generative acoustic models. However, due to the use of shallow HMMs, this acoustic model is not adequately modeled. Some recent studies use deep learning to overcome this deficiency.

Ling et al. used Restricted Boltzmann Machine (RBM) and Deep Confidence Network as generative models to replace the traditional Gaussian model and achieved significant improvement in both subjective and objective evaluation of synthesized speech [11]. Kang et al. used the Deep Confidence Network as a generative model to represent the joint distribution of linguistic features and acoustic features and used the Deep Confidence Network to replace the decision tree and Gaussian model joint distribution of features and used deep confidence networks instead of decision trees and Gaussian models. This approach is similar to using deep confidence networks to generate digital images [12].

With the development of AI deep learning technology, speech processing technology has made a leaping breakthrough, and the iconic technology representative is the Tacotron model proposed by Google in 2017, which is an end-to-end speech processing model based on the self-attention mechanism, where the input side consists of text, which is generated by a text encoder to generate contextual text vectors with robustness, and the decoder side uses an attention-based mechanism based autoregressive decoder at the decoder side, which outputs N frames of Mel Spectrum speech features at a time. The so-called autoregressive decoding means that the N frames output in the first step become inputs in the second step, and this is repeated to generate the complete Mel Spectrogram. The Mel Spectrogram is then passed through the final high-speed convolution module of the Tacotron to generate a linear spectrogram, which is then passed through the Griffin-Lim algorithm to obtain the synthesized speech waveform. Recently, DeepMind announced its latest research breakthrough WaveNet in speech processing [13]. Subsequently, the Tacotron Generation 2 model proposed by Google Inc. in 2018 replaces the high-speed convolution module of the generation algorithm with a 3-layer long and short-term memory module and replaces the vocoder part from the GriffinLim algorithm with the deep-learning WaveNet algorithm, which is noteworthy for its synthesized quality, which is already able to reach the level of falsetto on the subjective evaluation. WaveNet utilizes real human voice clips and corresponding linguistic and phonetic features to train a convolutional neural network to be able to discriminate between linguistic and phonetic audio patterns. When using the WaveNet system, new textual information is input and the WaveNet system regenerates the entire original audio waveform to describe this new textual information.WaveNet is capable of simulating any human voice and generates speech that sounds more natural than the best speech-processing systems available today.WaveNet reduces the discrepancy between simulated-generated speech and the human voice by 50% or more [14].

The Tacotron model can generate high-quality speech processing, however, due to its autoregressive generation structure, the training speed and inference speed are not ideal [15]. Thus, in 2018, Transformer TTS proposed by the University of Electronic Science and Technology of China and Microsoft Research Asia, among others, utilized the self-attention mechanism Transformer to replace the original traditional content-based attention mechanism to accomplish non-autoregressive generation [16]. Subsequently, the FastSpeech1 and Fastspeech2 architectures proposed by Zhejiang University and Microsoft Research Asia in 2019 and 2020, respectively, succeeded in end-to-end non-autoregressive generation, which not only improved the inference speed, but also possessed a duration predictor, a pitch predictor, and an

energy predictor that could accomplish the fine-grained control of the output speech duration, pitch, energy, etc. and at the same time improves the errors of lost words and repeated words that Tacotron2 can make [17].

The VITS model is a 2021 highly expressive speech processing model that combines variational inference, normalized streaming, and adversarial training and is currently comprised of most of the speech processors used on major self-promotion platforms. VITS is the first truly end-to-end speech processing model that does not require an additional vocoder to reconstruct the waveform and directly maps characters or phonemes to waveforms. This synthesis improves the versatility of speech processing by cascading the vocoder and acoustic model of speech processing through hidden variables instead of the spectrum of the previous model [18].

3) Learning paradigms for speech recognition: In speech recognition, model training methods mainly include supervised learning, self-supervised learning, and semi-supervised learning. Traditional supervised learning employs video speech as well as corresponding labeled data and uses the loss function of label prediction for model optimization. Self-supervised learning frameworks, on the other hand, are usually divided into two phases: pre-training and fine-tuning. In the pre-training phase, unlabeled audio and video data are first utilized to train the model based on agent tasks such as mask loss prediction or audio-video cross-modal comparison learning to extract generic deep representations from the audio and video data. Then in the fine-tuning phase, supervised learning and optimization are performed for speech recognition tasks using labeled audio and video data. Semi-supervised learning, on the other hand, utilizes a portion of the labeled data to first train the speech recognition model, followed by pseudo-labeling of unlabeled audio and video speech using the trained model, and subsequently training the model jointly with all audio and video data.

The first is supervised learning. General end-to-end speech recognition directly uses text labels to train the model, and depending on the sequence-to-sequence model framework used, CTC loss, RNNT loss, or cross-entropy loss is used as the objective function for model optimization. To further constrain the model during the model training process, the researchers proposed the use of an auxiliary objective as a regularization term for training. This approach can also be regarded as a kind of multi-task learning. Sterpu et al. proposed the use of lip shape-related articulatory action units (action units) as auxiliary training targets for visual representations based on the AVAlign model to enhance audio-video modal alignment [19]. Ma et al. proposed a method based on audio representations as auxiliary training targets in a lip recognition task [20]. In this, the audio representation target is obtained by extracting the middle layer representation of the encoder using a trained speech recognition model.

The second is self-supervised learning. With the development of the self-supervised learning paradigm in recent years, speech recognition methods based on audio and video self-supervised learning have also received more and more attention. Early audio-video self-supervised learning focuses on the learning of local audio-video features, and most of the methods utilize the natural alignment properties between audio-video modalities to supervise each other's information, representative methods include AVTS, XDC, and local-global audio-video comparative learning methods, etc. LiRA proposes a cross-modal self-supervised learning method based on the pre-trained audio self-supervised learning model PHASE extracts audio representations as targets to train a visual representation extraction module [21]. Audio self-supervised learning methods have developed rapidly in the recent past, and researchers have been inspired by them and extended them to audio-video self-supervised learning, which includes AV-HuBERT based on the HuBERT model extended to audio-video speech, and AV-data2vec based on the data2vec model extended to audio-video speech. Based on the model of AV-HuBERT, Zhu et al. further introduced additional text modalities to realize the joint learning of audio, video, and text modal representations [22]. u-HuBERT further introduced additional unimodal speech in AV-HuBERT and could theoretically introduce more modalities of data [23]. The AV2vec model and the RAVEn models, on the other hand, use a teacher model based on an exponential sliding average approach to multimodal self-distillation learning for student models in training [24]. Audio-video self-supervised speech recognition has achieved better results in lip recognition as well as speech recognition tasks, and many current studies have used pre-trained self-supervised models to initialize the parameters of speech recognition models [25].

Then comes semi-supervised learning. Semi-supervised speech recognition methods are mostly inspired by semi-supervised learning methods for audio speech recognition. The Auto-AVSR model generates pseudo-labels for unlabeled speech recognition datasets using pre-trained speech recognition models and then trains the speech recognition models using a combination of labeled and pseudo-labeled data [26]. The AV-CPL method, on the other hand, proposes a semi-supervised based on continuous pseudo-label update learning method, which continuously employs the updated model for continuous optimization of pseudo-labels on unlabeled audio and video [27]. Self-supervised learning methods are limited by less labeled data, so the results are generally worse than semi-supervised learning. However, the self-supervised learning method can be combined with semi-supervised learning, i.e., using self-supervised learning at the beginning to obtain an initial speech recognition model, then using the initial model to generate text pseudo-labels for unlabeled data, and then jointly optimizing the recognition model with labeled data, which generally achieves better speech recognition results. The summary of speech recognition learning paradigms is shown in Table III.

TABLE III. SUMMARY OF SPEECH LEARNING PARADIGMS

Learning paradigm	Descriptive	Typical models or methods	Vintage	Drawbacks
Supervised learning	Using labeled speech data to train the model, the model learns the mapping relationship from speech signal to text	LSTM+CTC, DNN-HMM, RNN-HMM, etc.	1. can directly optimize the speech recognition performance 2. is effective in the case of sufficient annotation data	1. Labelling data is costly and time-consuming 2. Difficulty in covering all possible speech variations and noise environments
Self-supervised learning	Using unlabeled speech data to learn useful speech representations by designing assistive tasks	Siamese Networks, Generative Adversarial Networks (GANs), Self-Encoders	1. does not require large amounts of labeled data 2. can learn more generalized speech features 3. helps to improve the generalization ability of the model	1. complex model structures and training strategies may be required 2. The design of ancillary tasks has a large impact on performance
Semi-supervised learning	Combining labeled and unlabeled speech data for learning to improve the accuracy and generalization of models	Clustering-based methods, bias correction-based methods, etc.	1. exploits the richness of unlabeled data 2. enables improved performance with limited labeled data	1. need to balance the use of labeled and unlabeled data 2. may require complex model fusion strategies

III. KEY ISSUES IN INTELLIGENT SPEECH PROCESSING BASED ON AI TECHNOLOGY

A. Main Tasks of Speech Processing Technology

1) Speech matching: Speech matching refers to the automatic retrieval of all speech segments that have the same content as the query speech segment from a given speech database, so the extracted speech features are crucial for the speech-matching task. Since speech matching automatically retrieves all speech segments with the same content as the query speech segment from a given speech database, it can be regarded as a class of content-based speech retrieval applications, which have been widely used in music retrieval, song recommendation, and speech intelligence analysis. At the same time, speech matching is a class of unsupervised learning tasks, and the techniques applicable to speech matching can be applied to other unsupervised learning tasks in the field of machine learning, thus the study of speech matching algorithms has important academic value. According to the above scenario, it can be seen that the speech matching task is a typical class of speech processing tasks because the key to speech matching is the extraction of speech features.

2) Multimodal speech recognition: Human-computer interaction interfaces for intelligent machines, such as smartphones, home robots, and self-driving cars, are becoming more and more common in daily life. Speech recognition that is robust to noise is the key to achieving effective human-machine interaction [28]. Multimodal speech recognition is considered one of the effective solutions for robust speech recognition. In human-computer interaction systems, the machine can not only receive the operator's speech signal, but also observe the operator's behavioral information, such as body movement and changes in mouth shape, and this behavioral information can help the machine recognize the operator's speech signal, and the study of multimodal speech recognition has an important application value in human-computer interaction systems [29]. In addition, multimodal speech recognition is a supervised learning task that involves the fusion of information from multiple sources, which has important academic research value. Multimodal speech recognition is also a typical speech-processing task [30].

B. Technical Issues in Intelligent Speech Recognition and Processing

In recent years, with the continuous increase of current training data, deep learning models, and learning paradigms, the effect of speech recognition has been greatly improved. However, there are still many challenges in speech recognition, and future research needs to pay more attention to the following points. First, current speech recognition still performs poorly in more open and complex environments, such as home scenarios and multiple people talking freely [31]. Currently, most studies are still overly focused on the LRS2 and LRS3 datasets, but lip recognition as well as speech recognition on these two datasets are already saturated with word error rates, e.g., Auto-AVSR has a speech recognition word error rate of 0.9% on LRS3 [32]. Under other more challenging scenario test sets, such as MISP2021 and Google's YTDEV, speech recognition remains poor. In the MISP2021AVSR competition, the word error rate of the winning team was still as high as 24.6% [33]. Therefore, future research in speech recognition needs to focus on the performance of datasets with more complex conditions and avoid overfitting to single or multiple similar scene datasets [34]. Second, the performance of speech recognition in small languages with sparse data still needs to be improved. Similar to speech recognition, there are still many challenges in small-language speech recognition [35]. Compared to mono-speech, audio and video data in small languages are more difficult to capture, and many small languages even face the challenge of not being able to capture video data [36]. How to deal with this situation of missing visual data and very low resources to improve speech recognition in small languages is still a problem that needs to be further researched and solved. Third, speech recognition is relatively computationally intensive and incurs high inference computation costs in practical application deployments. Under many high signal-to-noise ratio conditions, the improvement of speech recognition relative to audio speech recognition is not significant and brings little benefit [37]. Therefore, how to further reduce the computational burden of speech recognition, achieve lightweight computation of the vision module, and at the same time realize effective dynamic computation for environmental noise conditions is one of the important issues to be solved for the practicalization of speech recognition [38]. Fourth, the robustness of speech recognition in the case of missing video modalities and faces being occluded needs to be further improved [39]. Recently, researchers have

begun to pay more and more attention to such problems of speech recognition in practical applications, and the proposed methods have improved the robustness of speech recognition to some extent [40]. However, these challenges have not been fully addressed, especially when there are cases of video damage, occlusion, etc. outside the training set distribution, speech recognition may still be worse than unimodal speech recognition. Ideal speech recognition maximizes the use of incremental information in the video while avoiding the effects of distracting information that appears in the video. How best to achieve this goal remains the open question.

IV. Development Issues in the Field of Intelligent Speech Processing based on AI Technology

AI technology in the development process is accompanied by lingering controversies, such as ChatGPT since its inception has been full of controversial copyright issues, as well as the existence of a large number of the use of AI voice cloning technology on the network to clone the voices of some of the singers and secondary creation of content, which belong to the "gray area" [41 These are all "gray areas" [41]. These contents not only involve copyright issues but also bring some difficult ethical problems. The current rapid development of AI technology has led to three major problems as summarized in Table IV.

TABLE IV. AI-Based Intelligent Speech Processing Problem

Type of problem	Explicit description	Frequency/number of reports
Data Privacy and Security	Voice data is being collected on a large scale, increasing the risk of privacy breaches	In recent years, an average of dozens of related privacy breaches have occurred each year, affecting millions of users.
Algorithmic bias and discrimination	Bias in training data leads to unfair recognition results	Several studies have reported that at least half of intelligent speech-processing systems suffer from varying degrees of algorithmic bias.
Responsibility and accountability	Difficulty in defining the responsible party when there is a problem with the speech recognition system	Every year there are dozens of legal disputes caused by errors in voice recognition systems, most of which involve unclear delineation of responsibility.

1) Data privacy and security issues: Generative AI models require a large amount of data for training at the initial stage, and data privacy issues are involved in whether the source of the data is traceable, authentic, and licensed by the information source. In the process of training generative AI models, the protection of user data is very important and must be done when conducting experiments. Several protection measures can be taken to address this issue. First, the data can be anonymized, the user data can be desensitized, and sensitive information, such as name, address, phone number, etc., can be deleted or replaced while ensuring accuracy, and encryption technology can be used to encrypt the user data to ensure that only authorized personnel can access it [42]. Second, user data can be stored in an isolated environment, data access rights can be set, and secure communication protocols can be used for transmission. Based on this, training data selection is performed by choosing appropriate training data in the dataset and avoiding the use of training data containing sensitive information, such as publicly available datasets or using processed data [43]. Again, the security of the model should be ensured, and after the model training is completed, the model needs to be evaluated for security to ensure that the model will not leak user data or have adverse effects. Finally, relevant laws and regulations, such as the Data Security Law of the People's Republic of China and the Personal Information Protection Law of the People's Republic of China, need to be strictly observed to ensure that user data are legally used and protected. In conclusion, a series of measures are needed to protect the security and privacy of user data when training and using generative AI.

2) Algorithmic bias and discrimination issues: If there is bias in the training data, then the generative AI may replicate that bias, leading to discriminatory decisions. American news commentator and social critic Lippmann famously proposed the "agenda-setting theory", which argues that "the news media influences 'the images we have in our minds about the world'", and this is also the case in generative AI [44]. For example, in 2016 Microsoft launched Tay, a conversational bot that was "portrayed" as racist only 16 hours after it went live and engaged in a conversation with a user, after which Microsoft urgently took the account offline [45]. The fact that it took only 16 hours from posting to taking the account offline suggests that a series of measures need to be taken to deal with this kind of problem. The first is the cleaning and filtering of data containing bias and discrimination during the data collection and processing phase [46]. This step involves removing or correcting inaccurate, outdated, or discriminatory data and, during the data collection process, ensuring that the data is diverse and inclusive. This means collecting data from different backgrounds, genders, ethnicities, and other characteristics to reduce the possibility of algorithmic bias and discrimination [47]. During algorithm design and training, ensure that the model is fair and unbiased. This includes the use of fair evaluation criteria, unbiased training data and algorithms, and a transparent decision-making process [48]. Algorithms also need to be audited periodically after the model has begun to perform computations to ensure that they meet the requirements of impartiality and fairness [49]. This includes examining the design of the algorithm, the training data, and actual runs, as well as assessing its impact on different populations. Bias detection and correction techniques can also be used to identify and correct bias in algorithms, where available [50]. This includes the use of techniques such as unsupervised learning, semi-supervised learning, or reinforcement learning to improve

the performance of the model and reduce bias. In terms of personnel requirements, there is a need to educate and train algorithm designers and users to increase their awareness of bias and discrimination issues and equip them with the skills to recognize and address these issues.

3) Responsibility and accountability issues: When AI systems lead to undesirable consequences, how to pursue responsibility is a complex issue. Similar to how to select the author of the textual content produced by generative AI, there are many controversies around this issue, some scholars believe that the responsibility should be borne by the AI system, and some scholars believe that it should be borne by the program developer, after all, the entire algorithmic mechanism is from the developer's hand [51]. It can be seen that pursuing responsibility is a complex issue that needs to be considered from several aspects. First, it is necessary to determine who the owners and users of the AI system are, i.e., the responsible subjects. This involves multiple parties such as hardware and software vendors, data providers, application developers, and users. Second, it is necessary to understand information about the operation mechanism, algorithm design, training data, and actual application scenarios of the AI system. This helps to analyze the causes of adverse consequences and attribute responsibility. Again, it is important to assess the extent of the impact of the adverse consequences of the AI system on individuals, organizations, and society for a specific time, including economic losses, privacy leakage, security issues, etc. Finally, it is important to determine the type of responsibility, including technical, legal, ethical, and other responsibilities, based on the adverse consequences and impacts of AI systems [52]. The discussion of this issue, should not stop at determining the responsible person, but should also look for solutions, based on the type of responsibility and the actual situation, including compensation for losses, improvement of system design, correction of algorithms, and strengthening of supervision. At the same time, an accountability mechanism should be established to hold AI systems accountable for adverse consequences. There is a need to establish internal accountability systems, implement transparent and traceable management programs, and strengthen regulation and legal sanctions. In addition, there is a need to strengthen cooperation and communication, mainly among government departments, enterprises, social organizations, and other institutions, to jointly solve problems that are likely to arise from AI systems.

V. Future Outlook for Intelligent Speech Processing

A. Forecast of Technology Development Trends

The future development of speech-processing technology will mainly rely on the continuous development of deep learning and neural network technology. With the continuous upgrading of hardware equipment and the continuous optimization of algorithms, the quality and naturalness of speech processing technology will continue to improve. The current speech processing technology can already realize realistic speech processing, but there are still some shortcomings, such as the rhythm and rhyme of the voice is not natural. Future speech processing technology will pay more attention to the improvement of these aspects to realize more realistic speech processing. Future speech-processing technology will pay more attention to personalized services and experiences. With the continuous development of artificial intelligence technology, future speech processing technology will be able to personalize speech processing according to the user's needs and preferences, and can synthesize any person's voice based on small or zero samples, providing speech processing services that are closer to the user's needs. Future speech processing technology will pay more attention to real-time speech processing. Real-time speech processing can provide users with a more natural and smooth voice interaction experience, providing a broader application space for the development of voice interaction technology.

B. Forecast of Application Development

With the development of artificial intelligence technology and other related technologies, the field of intelligent speech processing will increasingly focus on the personalized needs and experiences of users. Future speech processing technologies will be able to better provide personalized services and experiences, such as personalized speech processing based on user needs and interests, thereby increasing user satisfaction and loyalty.

In addition, multilingual support and cross-cultural communication will be facilitated by deep learning from a large amount of text and data. Speech-processing technology will be expected to support more languages and dialects so that it can better meet the needs of users from different countries and regions and realize cross-cultural communication [53]. Further, speech processing technology will also realize automatic translation and conversion between multiple languages, providing users with more convenient and diversified services. At the same time, the future speech processing technology will be able to better combine with other integrated media technologies, such as images, videos, text, etc., to realize richer and more vivid forms of media expression [54]. For example, in TV news, speech processing technology can be combined with video and text to realize more vivid and intuitive news broadcasting. Based on the above applications, it is foreseeable that future speech processing technology is expected to be combined with augmented reality technology to realize a more intelligent and convenient user experience. Based on the trend of deep integration of speech processing technology and artificial intelligence technology, the key applications of technology in the future may be concentrated in the following areas, as shown in Table V:

TABLE V. KEY APPLICATION AREAS FOR INTELLIGENT SPEECH PROCESSING

Application Areas	Specific application	Key technologies
smart home	Smart speaker, smart appliance control	Speech Recognition, Speech Synthesis, Internet of Things
smart city	Intelligent Transportation, Intelligent Security	Deep learning, computer vision, big data analytics
health care	Disease diagnosis, drug development	Natural language processing, machine learning, big data analytics
financial	Intelligent Risk Control, Intelligent Investment	Machine learning, natural language processing, big data analytics
teach	Intelligent Tutoring, Language Learning	Speech Recognition, Natural Language Processing, Intelligent Recommender Systems

VI. CONCLUSION

Intelligent speech processing technology has made significant progress under the impetus of AI technology, which not only realizes a qualitative leap in speech recognition and speech processing accuracy but also promotes the innovation of human-computer interaction. Through advanced technologies such as deep learning, intelligent speech processing systems can more accurately understand the emotional and semantic information in human speech and generate natural and smooth speech. With the continuous maturation of technology and the expansion of application scenarios, intelligent speech processing technology will play an important role in more fields, and at the same time, its wide application has also brought about profound impacts on social structure, occupational structure, and privacy laws. Looking ahead, intelligent speech-processing technology will continue to innovate and develop, bringing more convenience and possibilities to human society.

An Enhanced Whale Optimization Algorithm Based on Fibonacci Search Principle for Service Composition in the Internet of Things

Yun CUI
Hebei Chemical & Pharmaceutical College, Shi Jiazhuang 050026, China

***Abstract*—Service composition in the Internet of Things (IoT) poses significant challenges owing to the dynamics in IoT ecosystems and the exponential increase in service candidates. This paper proposes an Enhanced Whale Optimization Algorithm (EWOA) by introducing the Fibonacci search principle for service composition optimization to overcome certain shortcomings of conventional approaches, including slow convergence and being stuck in local optima, in addition to imbalanced exploration-exploitation trade-offs. The proposed EWOA combines the application of nonlinear crossover weights with a Fibonacci search to optimize the global exploration and local exploitation searches of the basic version, thereby producing a better solution. Several simulations were performed for IoT functions. Among the experiments involving different QOS-based service compositions, the results show that the EWOA achieves superior and faster convergence capability with enhanced convergence compared to recent methods.**

***Keywords*—Service composition; Internet of Things; quality of service; whale optimization; Fibonacci search**

I. INTRODUCTION

The Internet of Things (IoT) is driving a revolution in modern technologies, enabling the world to grow further connected, and billions of devices can communicate and share data effectively [1]. This rapid growth of services has led to a vast repository of functionalities that address different application areas [2]. However, this immense size and dynamism introduce a severe challenge: efficiently composing multiple IoT services to satisfy user demands [3]. Efficient service composition guarantees the realization of desired functionalities and optimizes the quality attributes of execution time, reliability, and cost in dynamic IoT ecosystems [4].

Traditional optimization methods and swarm-intelligence-based algorithms offer great promise for solving service composition problems [5]. However, these methods typically incur severe limitations due to slow convergence rates, premature stagnation at local optima, or failure to balance exploration and exploitation efficiently [6]. These challenges impede efficient solutions, particularly for large-scale and complex IoT service composition problems; hence, advanced approaches are required to ensure their robustness and scalability [7].

This paper presents an improved QoS-based service composition using a new metaheuristic approach. The contribution of this work is to improve the solution accuracy, accelerate convergence, and overcome local optima entrapment by addressing the limitations of existing algorithms. Thus, this work aims to find a globally optimal balance between local exploitation and global exploration and ensure a more effective and efficient service composition in dynamic IoT environments.

These include the development of the Fibonacci search principle to improve the performance of the WOA on global optimization problems and applying nonlinear weights in the WOA to maintain balance within its processes. In general, this contributes to reaching the optimality of a solution by increasing exploration during the initialization stage, thus creating faster convergence, whereas adopting this modified WOA to tackle the optimal solution in IoT service composition. Intensive validation showed the excellent performance of this algorithm owing to better convergence speed and stability in results, hence providing a concrete base for more challenging tasks within IoT service optimization processes.

The remainder of this paper is organized as follows: Section II presents a comprehensive literature review, discussing previous studies and existing optimization techniques for IoT service composition. Section III details the proposed algorithm. Section IV describes the experimental setup and presents the simulation results. Section V provides a critical discussion and comparative analysis of the findings. Finally, Section VI concludes the study, summarizing key contributions and outlining potential future research directions.

II. LITERATURE REVIEW

The authors in study [8] propose an Artificial Neural Network-based Particle Swarm Optimization (ANN-PSO) hybrid algorithm for cloud-edge computing to improve QoS factors. They utilized a formal verification process through functional transitions and constraint logic to ensure correctness regarding functional and non-functional aspects. Their approach shows enhanced memory, response time, availability, and price, yielding higher fitness values than others.

In study [9], a Hidden Markov Model (HMM) integrated with Ant Colony Optimization (ACO) was suggested for IoT service composition. HMM was trained for QoS prediction, and the Viterbi approach enhanced the emissions and transitions. The ACO algorithm identified optimal service paths, achieving better response time, reliability, energy consumption, and cost than prior approaches.

The authors of study [10] developed a semantic middleware to address IoT service composition challenges, incorporating contextual service search and semantic analysis. Automated, scalable service composition enhanced scalability, validated on innovative city scenarios, with improved service discovery, selection, and composition metrics versus existing methods.

In study [11], a fuzzy-driven hybrid algorithm combining ACO and Artificial Bee Colony (ABC) methods was proposed for cloud-fog IoT service composition. The approach optimized QoS metrics, including energy consumption, availability, reliability, and cost, achieving significant performance improvements over contemporary techniques.

Moreover, in study [12], a service composition technique based on Grey Wolf Optimization (GWO) within the MapReduce methodology was presented for QoS-aware IoT applications. The model achieved energy savings, reduced response times, and enhanced availability and cost metrics, with average performance gains over baseline algorithms.

The authors in study [13] proposed an enhanced ABC with a dynamic dimensionality reduction-inspired mechanism for IoT Service Composition. Further, the dimensions of disparity adjustment among solutions enable a method that has improved convergence rates and a more balanced exploration of solution exploitation. This significantly facilitates energy consumption to enhance availability and reliability with cost metrics.

In study [14], the Discrete Adjustable Lion Optimization Algorithm (DALOA) was proposed for composing IoT services, employing sub-populations and operators like roaming, mating, and migration. The approach provided a strong balance between exploitation and exploration, achieving near-optimal QoS-aware compositions in reduced execution time. A QoS-aware service discovery, developed using WOA and GA, is proposed in study [15]. This bioinspired technique has proven efficient in selecting a way of optimally utilizing energy, data access time, and cost-effectiveness in IoT service discovery.

While some existing approaches, as summarized in Table I, represent significant advances in IoT service composition, several critical gaps remain. Most of these approaches, such as HMM-based or semantic middleware-based, are not sufficiently adaptive for wider-scale IoT environments because of computational overhead or energy inefficiency in IoT devices. The majority of them experience performance bounds in highly dynamic IoT scenarios.

TABLE I. RECENT LITERATURE IN IOT SERVICE COMPOSITION

Algorithm	Key features	Performance gains	Shortcomings
ANN-PSO [8]	Hybrid approach combining ANNs for QoS enhancement and PSO for candidate service selection. Formal verification using labeled transition systems ensures correctness.	Achieved better response time, availability, and cost efficiency. Demonstrated improved fitness function values compared to other algorithms.	High computational complexity due to the hybrid approach and formal verification methods.
HMM + ACO [9]	The hidden Markov Model predicts QoS metrics based on emissions and transitions optimized by the Viterbi algorithm. ACO is used for service path identification.	Enhanced QoS regarding energy usage, cost, reliability, and response time. Outperformed prior techniques in availability and efficiency.	Limited scalability for real-time large-scale IoT environments due to the computational overhead of HMM.
Semantic middleware [10]	Modular and context-aware semantic abstraction for discovering IoT services, semantic filtering, and lightweight automatic service composition. Validated in smart city scenarios.	Improved scalability of service discovery by 15%, selection by 20%, and composition by 40% compared to state-of-the-art methods.	It focuses primarily on scalability but lacks energy efficiency and response time optimizations.
ACO + ABC (Fuzzy-based hybrid) [11]	A hybrid algorithm combining ACO and ABC algorithms with a fuzzy logic system. Focuses on energy-aware and QoS-based service selection in cloud-fog architectures.	Reduced energy utilization by 17%, improved availability by 8%, enhanced reliability by 4%, and lowered cost by 21% on average.	Increased complexity due to hybridization and dependency on parameter tuning for optimal performance.
GWO + MapReduce [12]	Combines GWO with the MapReduce framework to enable large-scale IoT service composition optimization. Targets QoS metrics like response time, cost, and energy savings.	Achieved a 24% reduction in cost, an 11% gain in availability, a 14% drop in response time, and a 40% energy savings.	MapReduce overhead may impact performance in highly dynamic IoT scenarios.
ABC with dynamic reduction [13]	The enhanced ABC algorithm introduces a dynamic reduction mechanism. Adjusts dimension disparities among solutions dynamically for better exploration-exploitation balance.	Decreased energy consumption by 17%, increased availability by 10%, improved reliability by 8%, and lowered cost by 23% compared to alternatives.	Potential convergence issues if initial dimension disparities are not set optimally.
DALOA [14]	Discrete adaptive lion optimization algorithm with unique operators (roaming, mating, migration). Balances strong global exploration through nomad roaming and efficient local exploitation via pride searching.	Achieved the best trade-off between exploration and exploitation. Reduced execution time and provided near-optimal IoT service compositions.	Increased complexity due to multiple operators and higher execution time for larger populations.
WOA + GA [15]	Integrates WOA with genetic algorithm for efficient IoT service discovery and selection. Bio-inspired optimization enhances QoS awareness in dynamic environments.	Optimized energy utilization, reduced data access time, and improved cost-effectiveness compared to traditional methods.	Lacks adaptability to large-scale IoT environments due to limited scalability and high computational cost.

In addition, the optimal balance between exploitation and exploration limits the possibility of obtaining a globally optimal solution with high efficiency. This study attempts to fill these gaps by incorporating the Fibonacci search principle into the WOA to leverage its global optimization strengths to enhance the convergence rates, stability, and QoS outcomes in IoT service composition.

III. PROPOSED METHODOLOGY

A. Problem Formulation and Statement

An IoT service refers to functional components within the IoT environment that facilitate the interaction and exchange of information between devices [16]. These services can be defined as a triple (TDP, FDP, $QoSDP$) where TDP stands for the text description of services, providing a semantic explanation of its functionality; FDP represents the functional description of services, detailing its operations and capabilities; and QoSDP refers to the Quality of Service (QoS) characteristics associated with IoT services, describing non-functional properties like execution time, cost, reliability, and trust. The QoS attributes provide measurable criteria for assessing service performance and ensuring non-functional requirements are met. These attributes are particularly crucial when selecting services for specific tasks in IoT applications.

Abstract IoT services represent a set of service instances that perform similar or identical functions. These services are abstracted into individual tasks within a requirements workflow and ensure functional compatibility but differ in their QoS values, making them key candidates in the service composition process [17].

As shown in Fig. 1, the composition of IoT services can follow various control logic structures based on user requirements. In the loop, certain tasks are repeated iteratively for a specified number of iterations (Fig. 1(a)). In the selection fashion, tasks are chosen based on specific conditions or decision points (Fig. 1(b)). In the parallel way, multiple tasks are executed simultaneously to improve performance (Fig. 1 (c)). Lastly, in the sequential approach, tasks are executed one after the other in a predefined order (Fig. 1 (d)). Given the focus on simplicity and efficiency, this paper exclusively considers sequential structures for IoT service composition.

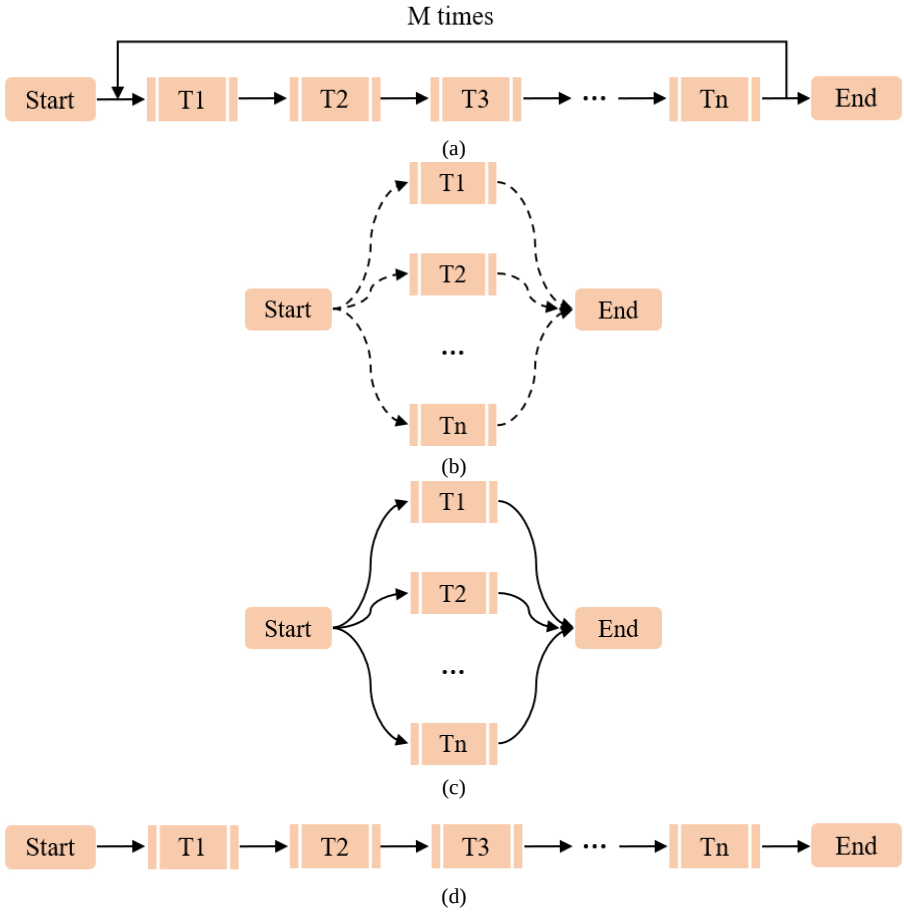

Fig. 1. IoT service composition structures: (a) Loop, (b) Selection, (c) Parallel, and (d) Sequential.

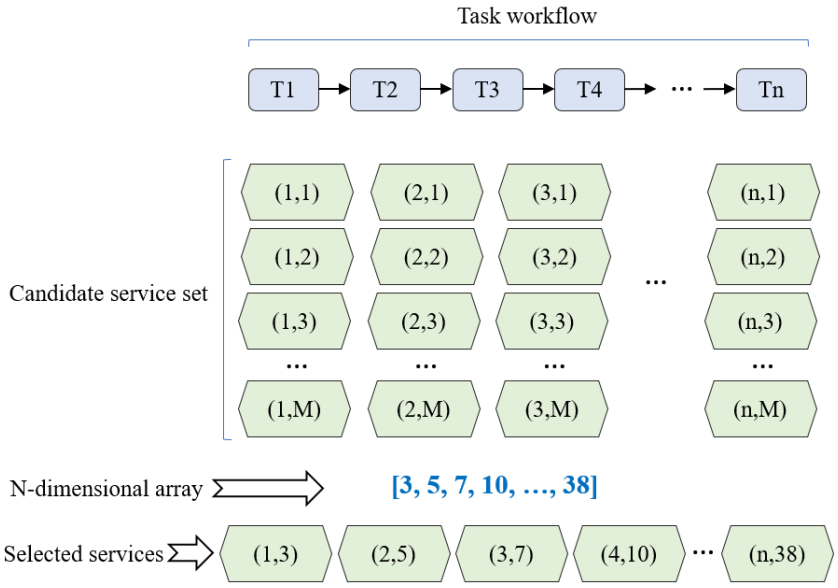

Fig. 2. Optimization process for selecting optimal IoT services from candidate sets.

The IoT service composition involves selecting specific services from a large pool of candidates to satisfy user requirements and QoS constraints. As illustrated in Fig. 2, the optimization process begins with a task workflow $T_1, T_2, \ldots, T_n$, where each task represents an abstract IoT service. For each task T_i, there exists a candidate service set $S(i, M)$, from which the most optimal service must be selected. Each task Ti has several service options $S(i, 1)$, $S(i, 2)$, …, $S(i, M)$. The selected services from all tasks are represented as an array [3, 5, 7, 10, …, 38], where each number corresponds to the selected service for a specific task. For a system with n tasks and M service candidates per task, the total number of possible combinations is M^n. This combinatorial complexity makes the service composition problem an NP-hard optimization challenge.

Several key QoS metrics are considered to evaluate the effectiveness of an IoT service composition, including reliability, credibility, service cost, and execution time. Reliability indicates the likelihood that the IoT service composition can complete tasks successfully without failure, calculated using Eq. (1) [18].

$$Q_r = \prod_{i=1}^{n} q_i^r \tag{1}$$

Credibility measures the user's trust level in the service composition based on factors such as reputation, expressed by Eq. (2) [19].

$$Q_c = \frac{1}{n}\sum_{i=1}^{n} q_i^c \tag{2}$$

Service cost refers to the monetary cost incurred by the user for utilizing the IoT service composition, calculated by Eq. (3) [20].

$$Q_{co} = \sum_{i=1}^{n} q_i^{co} \tag{3}$$

Execution time represents the total time required for the service composition to execute, including the processing time of all tasks, calculated by Eq. (4) [21].

$$Q_t = \sum_{i=1}^{n} q_i^t \tag{4}$$

The aggregated QoS value of an IoT service composition is calculated as a weighted sum of the above QoS metrics using Eq. (5).

$$Q = \sum_{k\epsilon\{r,c,co,t\}} Q_k \omega_k \tag{5}$$

Where ω_k denotes the weight assigned to each QoS metric. This weight reflects the relative importance of the corresponding attribute in the overall composition.

The objective is to select one service instance for each task in the workflow such that the aggregated QoS value Q is maximized. This optimization ensures that the composition meets user-defined QoS requirements and achieves the best possible performance in terms of execution time, cost, credibility, and reliability.

B. Enhanced Whale Optimization Algorithm

The WOA, introduced by Mirjalili and Lewis [22], is a heuristic optimization approach inspired by the hunting behavior of humpback whales. The algorithm mimics the whales' bubble-net feeding strategy as its central mechanism for solving optimization problems. The overall process of WOA is illustrated in Fig. 3. WOA consists of three main phases: encircling prey, bubble-net feeding, and searching for prey.

These phases emulate the whales' local exploitation and global exploration strategies, making WOA a versatile optimization framework.

The first phase of WOA involves encircling the prey, which represents the best solution found so far. Whales are assumed to position themselves around the prey to prepare for attack. Mathematically, this behavior is modeled using Eq. (6) and (7).

$$\vec{D} = \left|\vec{C}.\vec{X}_{best}(t) - \vec{X}(t)\right| \quad (6)$$

$$\vec{X}(t+1) = \vec{X}_{best}(t) - \vec{A}.\vec{D} \quad (7)$$

Where $\vec{A}$ *and* $\vec{C}$ are coefficient vectors, $\vec{D}$ stands for the distance between the whale and the prey, $\vec{X}(t)$ is the current position of the whale, and $\vec{X}_{best}(t)$ is the position vector of the best solution (prey) at iteration t. The vectors $\vec{A}$ and $\vec{C}$ are computed using Eq. (8) and (9).

$$\vec{A} = 2.\vec{a}.\vec{r}_1 - \vec{a} \quad (8)$$

$$\vec{C} = 2.\vec{r}_2 \quad (9)$$

Where $\vec{r}_1$ and $\vec{r}_2$ range between [0, 1], and $\vec{a}$ drops linearly from 2 to 0 with increasing iterations.

The bubble-net feeding phase simulates whales' two simultaneous strategies to capture prey: shrinking, encircling, and spiral updating. These strategies reflect both global and local search mechanisms.

Shrinking encircling reduces the distance between whales and prey over time by decreasing the range of $\left|\vec{A}\right|$. This is accomplished by progressively lowering the value of $\vec{a}$. Spiral updating mimics the spiral-shaped trajectory of whales around their prey. This phenomenon is represented mathematically using Eq. (10) and (11).

$$\vec{X}(t+1) = \vec{D}_p.e^{bl}.cos(2\pi l) + X_{best}(t) \quad (10)$$

$$\vec{D}_p = \left|\vec{X}_{best}(t) - \vec{X}(t)\right| \quad (11)$$

Where $\vec{D}_p$ refers to the distance between the whale and the prey, b defines the shape of the logarithmic spiral, and l signifies a random number in the range [-1, 1].

To combine these two strategies, WOA uses a probabilistic mechanism where a random number P determines which behavior is applied in each iteration, calculated using Eq. (12).

$$\vec{X}(t+1) = \begin{cases} \vec{D}_p.e^{bl}.cos(2\pi l) + X_{best}(t), & P < 0.5 \\ \vec{X}_{best}(t) - \vec{A}.\vec{D}, & P \geq 0.5 \end{cases} \quad (12)$$

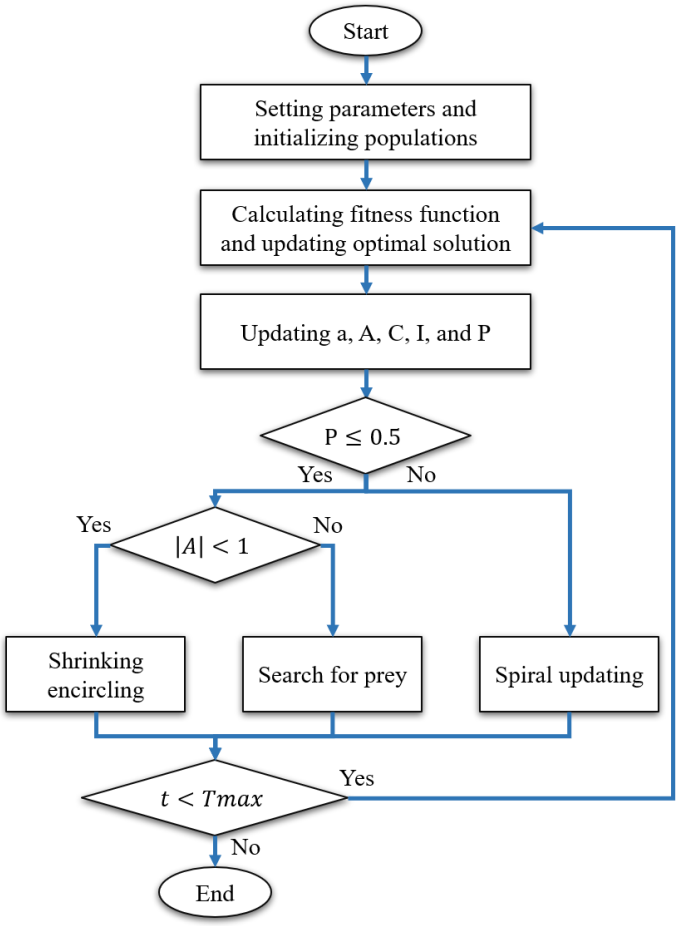

Fig. 3. WOA flowchart.

This probabilistic combination of behaviors balances global exploration and local exploitation. The final phase focuses on exploration by searching for prey. When the condition $|\vec{A}| \geq 1$ is satisfied, and whales move randomly for better solutions. This behavior is modeled using Eq. (13) and (14).

$$\vec{D} = \left|\vec{C}.\vec{X}_{rand}(t) - \vec{X}(t)\right| \quad (13)$$

$$\vec{X}(t+1) = \vec{X}_{rand}(t) - \vec{A}.\vec{D} \quad (14)$$

Where $\vec{X}_{rand}(t)$ is the position vector of a randomly selected whale. This phase prevents WOA from getting stuck on local optimum and enhances the algorithm's global search capability.

The enhanced WOA (EWOA) builds upon the original WOA by addressing its inherent shortcomings, such as slow convergence, poor accuracy, and proneness to local optima. This improvement is achieved by integrating a nonlinear cross-weight mechanism and the Fibonacci Search Method (FSM). The enhanced algorithm ensures optimal equilibrium between diversification (exploration) and intensification (exploitation), key components of any robust optimization method. Fig. 4 presents the pseudocode of the EWOA.

Input:
Initialize population $X = \{X_1, X_2, \ldots, X_n\}$
Define objective function $f(X)$
Set algorithm parameters: maximum iterations (T_{max}) and control parameters (α, A, C, I, P)
Step 1: Initialize and Evaluate
Evaluate the fitness of each solution in the population.
Identify the best solution $BEST_{sol}$.
Step 2: Iterative optimization
While iteration t is less than T_{max}
Update control parameters.
Exploration and exploitation decision:
if $P \leq 0.5$ (Exploration phase):
if $|A| < 1$:
Perform shrinking encircling mechanism to update position.
Else $|A| \geq 1$:
Conduct random search for prey to enhance exploration.
Else if $P > 0.5$ (Exploitation phase):
Perform spiral updating to refine solution accuracy.
Boundary Verification:
Check if any search agents exceed the search space limits and correct their positions if necessary.
Fitness Evaluation and Update:
Calculate the fitness of each solution.
If a better solution is found, update $BEST_{sol}$.
Increment iteration count $t = t + 1$.
End While
Output:
Return the best solution found $BEST_{sol}$

Fig. 4. Pseudocode of the EWOA.

Diversification explores the entire search space to identify global optima, while intensification involves focusing on local regions for fine-tuning solutions. The original WOA struggles with achieving an optimal balance between these two processes, often leading to stagnation at local optima. EWOA addresses this by introducing a nonlinear crossover weight to enhance solution diversity during exploration and incorporating the FSM for a more efficient local search, improving solution accuracy and convergence speed.

The EWOA incorporates crossover weights during location updates. The revised position update model is defined using Eq. (15).

$$\vec{X}(t+1) = \begin{cases} (\vec{X}_{best}(t) - \vec{A}.\vec{D}).CR1, & if\ a < 0.5 \\ \vec{D}'.e^{bl}.cos(2\pi l).CR2 + \vec{X}_{best}(t).(1 - CR2), & if\ a \geq 0.5 \end{cases} \quad (15)$$

Where $\vec{D}'$ stands for the distance between the current and best solutions, $CR1 = exp\left(tan\left(rand(1,N)\right)\right)$, $CR2 = 3.\left(0.5 - rand(1,N)\right).f$, and $f = exp\left(-\frac{Iteration}{Max\_iteration}\right)$. This mechanism ensures that solutions generated during exploration maintain sufficient diversity while enabling convergence during exploitation.

FSM is incorporated into EWOA to improve local search efficiency. FSM minimizes the search space by applying Fibonacci sequences, which guide the selection of optimal intervals. It operates as follows:

Generate Fibonacci numbers: The Fibonacci sequence $F = [F_1, F_2, \ldots, F_n]$ is expressed by Eq. (16).

$$F_n = F_{n-1} + F_{n-2},\ \ F_0 = 1,\ \ F_1 = 1 \quad (16)$$

Calculate initial points: Two points t_1 and t_2 are defined in the search range [LL, UL] using Eq. (17).

$$t_1 = LL + \frac{F_{n-2}}{F_n}.(UL - LL)$$
$$t_2 = UL - \frac{F_{n-2}}{F_n}.(UL - LL) \quad (17)$$

Where UL and LL define the upper and lower bounds of the range.

Evaluate function values: Compare the function values at t_1 and t_2:

If $(t_2) > (t_1)$, shift the range to the left.

If $(t_1) > (t_2)$, shift the range to the right.

IV. RESULTS

The effectiveness of the proposed EWOA was evaluated for optimizing the QoS-based IoT service composition optimization problem. EWOA effectiveness was evaluated against standard WOA [22], DALOA [14], and Genetic Algorithm (GA) [23] using three key evaluation criteria: effectiveness, convergence, and stability. The tests were carried out in a Windows 10 system powered by an Intel Core i7-12700F processor, 16 GB RAM, and PyCharm Community Edition 2022.3.

The experiments used randomly generated datasets based on the QoS value ranges defined in Table II. Four QoS attributes, including execution time, service cost, credibility, and reliability, were evaluated for candidate IoT service instances. The dataset scales were represented as $A \times I$, where A denotes the number of abstract service tasks, and I signifies the number of candidate services per task. The datasets included the following scales: 10×50, 10×100, 20×50, 20×100, 30×50, and 30×100. Each experiment was repeated 100 times to ensure robustness, and the results were analyzed to measure the algorithm's performance under varying scales and iterations.

TABLE II. QOS VALUE RANGES

Attributes	Reliability	Credibility	Service cost	Execution time
Ranges	(0.1,1]	(2,10]	(0,100]	(0,60]

The effectiveness of the algorithms was assessed by the average fitness values obtained after 100 global iterations. EWOA demonstrated significantly higher efficacy than WOA, DALOA, and GA, as shown in Table III and Fig. 5-7. Key observations include:

- For smaller scales (e.g., 10×50), EWOA slightly outperformed other algorithms, achieving higher-quality solutions.
- For larger scales (e.g., 30×100), EWOA's advantage became more evident, delivering higher fitness values with a broader margin.

TABLE III. FITNESS VALUES FOR VARIOUS SERVICE COMPOSITION SCALES

No. of abstract service tasks	No. of candidate services	Fitness values			
		GA	DALOA	WOA	EWOA
10	50	3.75	4.13	4.22	4.92
	100	4.02	4.21	4.36	4.85
20	50	6.49	6.75	7.06	9.53
	100	7.16	7.53	8.12	9.61
30	50	9.15	9.91	10.58	13.91
	100	10.13	11.54	12.02	14.05

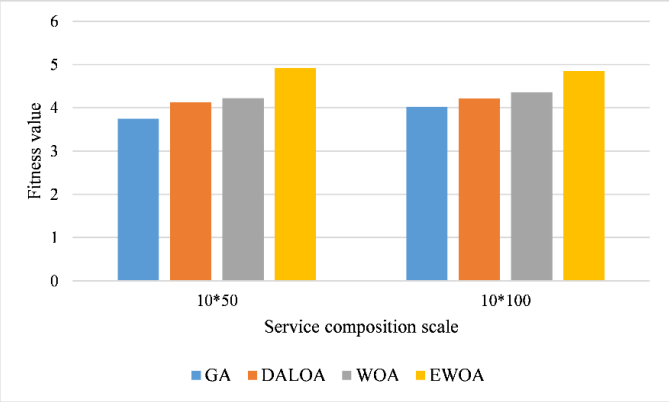

Fig. 5. Fitness value comparison for 10 service tasks.

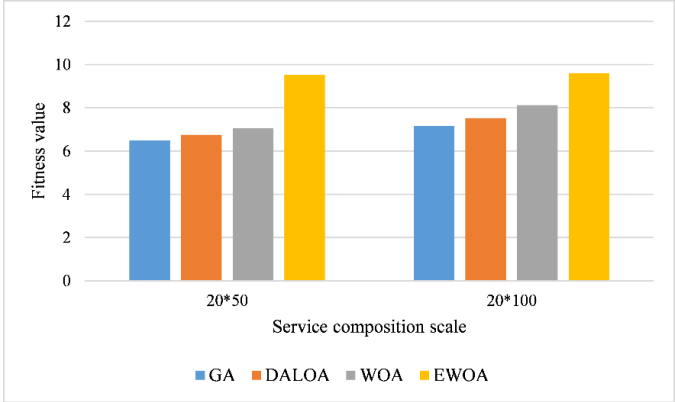

Fig. 6. Fitness value comparison for 20 service tasks.

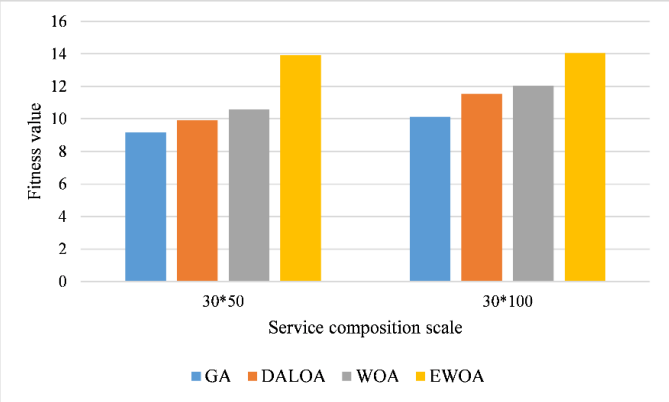

Fig. 7. Fitness value comparison for 30 service tasks.

The nonlinear crossover weights dynamically adjust exploration/exploitation, ensuring sufficient solution diversity at the beginning and accurate refinement in later iterations. The Fibonacci search strategy effectively narrowed the search space, leading to higher solution accuracy and better optimization of QoS attributes.

The convergence performance of the algorithms was analyzed based on their fitness values over iterations, as depicted in Fig. 8 – Fig. 10. EWOA consistently converged faster and to better solutions than WOA, DALOA, and GA. Notable findings include:

- At smaller scales (e.g., 10×50), EWOA achieved convergence within fewer iterations than other algorithms.
- At larger scales (e.g., 30×100), EWOA showed a significant fitness advantage and faster convergence speed.

The nonlinear crossover weights ensured efficient exploration in the early iterations, preventing premature convergence to local optima. The Fibonacci search strategy refined the best solutions in the exploitation phase, accelerating convergence toward the global optimum.

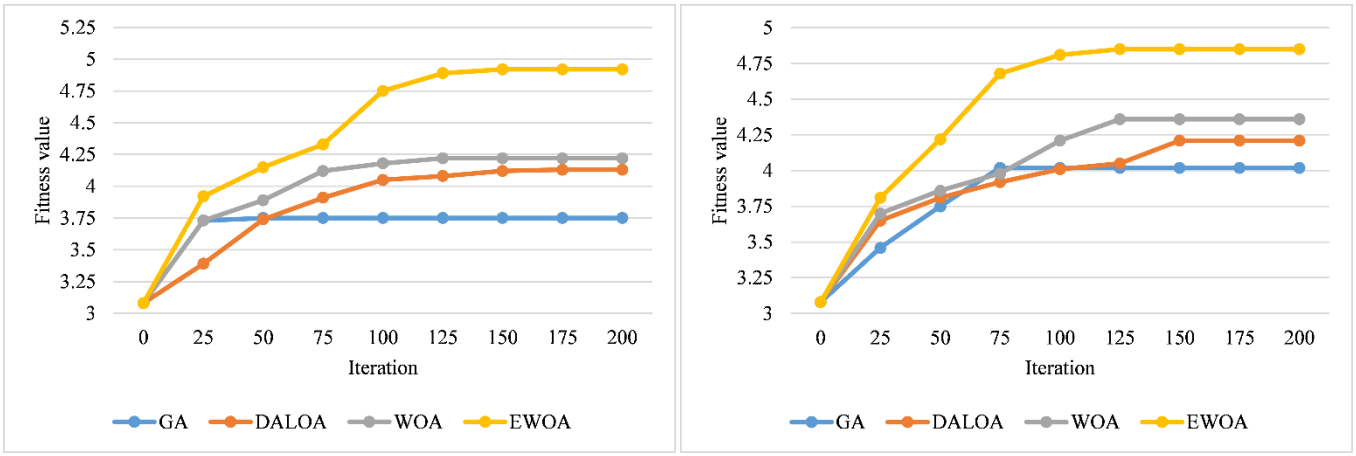

Fig. 8. Convergence performance comparison: (a) 10 service tasks and 50 candidate services, (b) 10 service tasks and 100 candidate services.

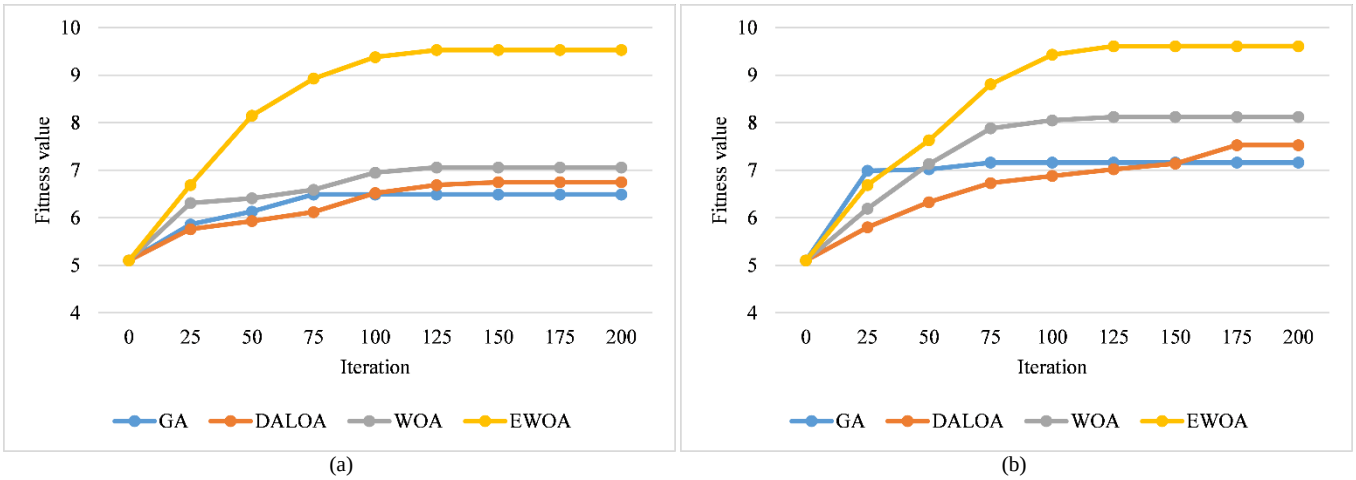

Fig. 9. Convergence performance comparison: (a) 20 service tasks and 50 candidate services, (b) 20 service tasks and 100 candidate services

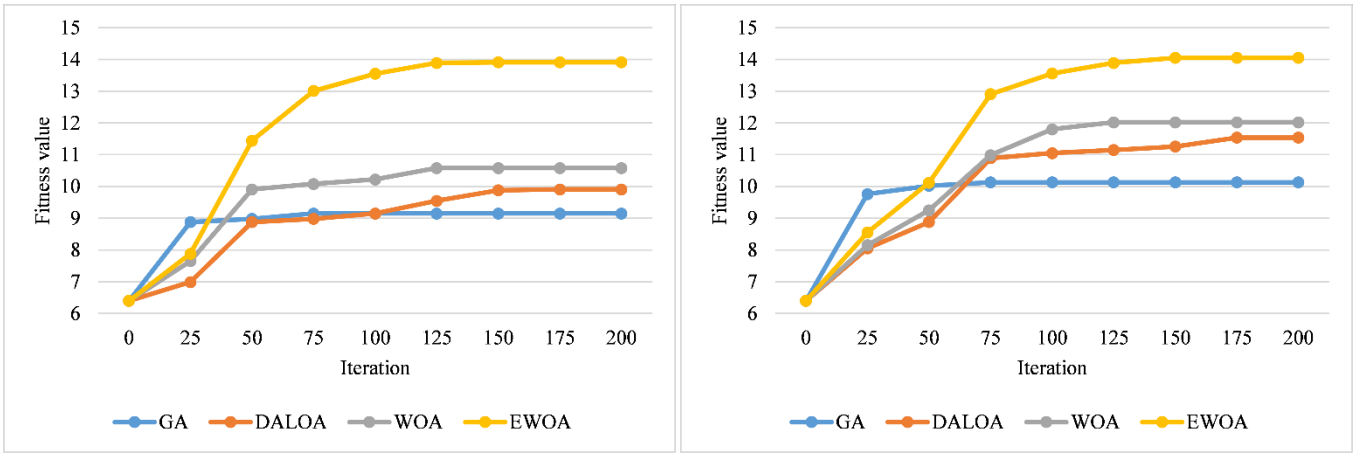

Fig. 10. Convergence performance comparison: (a) 30 Service tasks and 50 candidate services, (b) 30 Service tasks and 100 candidate services.

TABLE IV. STANDARD DEVIATION FOR VARIOUS SERVICE COMPOSITION SCALES

No. of abstract service tasks	No. of candidate services	Standard deviation			
		GA	DALOA	WOA	EWOA
10	100	0.0831	0.0526	0.0415	0.0089
20	100	0.1173	0.1085	0.1019	0.0269
30	100	0.1569	0.1503	0.1494	0.0612

The stability of the algorithms was measured in terms of standard deviation of optimal fitness values across 100 experiments, as shown in Table IV and Fig. 11. Lower standard deviation values indicate higher stability. Key findings include:

- EWOA exhibited significantly lower standard deviation values compared to WOA, DALOA, and GA, particularly at larger scales (e.g., 30×100).
- As scales increased, the standard deviation of all algorithms rose. However, EWOA maintained superior stability, consistently delivering reliable results with minimal variation.

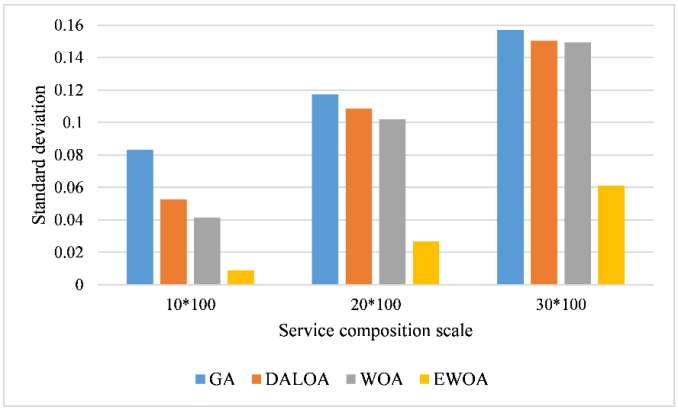

Fig. 11. Standard deviation comparison.

The nonlinear crossover weights provided adaptive adjustments, ensuring robustness against variations in initial population diversity. The Fibonacci search strategy reinforced solution refinement, minimizing the impact of random fluctuations in search trajectories.

V. DISCUSSION

The results demonstrate that the proposed EWOA significantly improves the optimization of QoS-based IoT service composition compared to standard WOA, DALOA, and GA. One of the key advantages of EWOA is its superior performance across various dataset scales, particularly for larger problem instances, where it consistently achieved higher-quality solutions. The nonlinear crossover weights effectively balanced exploration and exploitation, preventing premature convergence and ensuring sustained search diversity. Additionally, the integration of the Fibonacci search strategy enabled precise solution refinement by efficiently narrowing the search space, ultimately leading to better fitness values and improved QoS attribute optimization. These results validate the effectiveness of the proposed modifications, particularly in handling complex IoT service composition scenarios where scalability and solution accuracy are critical.

Furthermore, the convergence analysis confirms that EWOA consistently outperforms its counterparts in both speed and solution quality. The rapid convergence observed in smaller-scale datasets indicates that EWOA is highly effective even for less complex problems. However, its performance advantage becomes more pronounced as the problem scale increases, demonstrating its robust scalability. Additionally, stability analysis reveals that EWOA maintains lower standard deviation values, signifying its ability to deliver consistent and reliable results across multiple runs. This is primarily due to the adaptive adjustments of nonlinear weights, which dynamically regulate search behavior, and the Fibonacci search refinement, which enhances exploitation precision. The findings underscore the suitability of EWOA for large-scale IoT service

composition problems, offering a highly efficient, stable, and scalable optimization framework.

VI. CONCLUSION

This study proposed EWOA to resolve the QoS-based IoT service composition optimization problem. EWOA mitigated some disadvantages of conventional optimization algorithms, particularly slow convergence, the tendency toward local optima, and inability to balance exploration and exploitation. With nonlinear crossover weights combined with the Fibonacci search strategy, the EWOA optimized global exploration and local exploitation, providing outstanding performance in achieving optimization. The experimental test validated the efficiency of EWOA under different composition scenarios, from small-scale to large-scale problems. EWOA had better fitness, higher convergence speed, and more substantial stability than WOA, DALOA, and GA in all cases. Dynamic adjustment of the nonlinear crossover weights regulated solution diversity and refinement during optimization, whereas the Fibonacci search strategy improved efficiency in local search and prevented falling into suboptimal solutions.

EWOA proved to be especially helpful in large-scale composition, while its ability to handle increased problem complexity led to significant gains over existing algorithms. Moreover, its computational efficiency and stability over multiple runs indicated the appropriateness of real-world IoT scenarios. Future work will focus on integrating the EWOA with dynamic composition models to handle real-time and evolving QoS requirements. This could be further enhanced by hybridizing the EWOA with other metaheuristics for optimization problems that are highly complex and multidimensional. Given its capability, the EWOA represents a promising trend toward development in the field of optimization solutions within an IoT context.

***Abstract*—Artificial Intelligence (AI) is considered a big turning point for the financial industry. Introducing Artificial General Intelligence (AGI) enhances the capability of all the areas where AI shows its power. The development of AGI is directly proportional to the need for more advanced automation by enhancing the features quick responsive, customization/personalization and the refined decision making capabilities in different industries. The current study aims to discuss the respondent's views on the adoption of an AGI-enabled Sustainability, Quick responsiveness, Risk management, Customer-centric, and Data privacy (SQRCD) system in Digital Financial Inclusion System (DFIS). A total of 630 responses were collected from the respondents belonging to 90 different finance institutes. The result shows that SQRCD had a significant positive relationship with the attitude to adopt an AGI enabled-SQRCD system. The three cultural dimensions of Hofstede's theory power distance index, collectivism-individualism, and uncertainty acceptance are also taken as moderators. The effect of moderators is seen in the different relationships. The study develops a direct hypothesis to analyze the adoption of a new financial system which includes the mentioned factors. The result of the study is beneficial in the development of a renewed financial system where the mentioned parameters are essential for Industry 5.0.**

Keywords*—Artificial General Intelligence (AGI); Digital Financial Inclusion System (DFIS); industry 5.0; customer-centric; sustainability

I. Introduction

AI is considered as a big turning point for the financial industry. It plays an important role in process automation, consumer service and risk management [1]. Introducing AGI enhances the capability of all the area where AI is showing its power. AGI is the domain of AI which can perform tasks as human do and can learn and solve the problem in various domains. With the new upcoming technologies like big data, machine learning, cloud computing scientists are able to form many newer AI algorithms which are able to analyze the large amount of data and can predict and learn human intelligence [2]. The development of AGI is directly proportional to the need of more advanced automation by enhancing the feature quick responsive, customization/personalization and the refine decision making capabilities in different industries. Financial inclusion is the practice of making less expensive financial services and products in reach to both consumers and businesses is termed as financial inclusion. It seeks to guarantee that everyone, especially those with low incomes or disadvantages, get financial services in reduced cost. The use of digital technologies to offer financial services to under privileged people is known as DFIS. For people who are currently unbanked or financially marginalized, DFIS seeks to make financial services sustainable, reasonable and accessible. Among the many advantages of DFIS are reduced expenses, a decreased chance of financial crimes, and economic empowerment. A new stage of industrial development called Industry 5.0 highlights collaboration and cooperation between intelligent machines and people [3]. A civilization where digital technology is pervasive and permeates every part of daily life is known as a digital society. It is distinguished by the use of information and communication technology (ICT) for communication, teaching, purchasing, and selling, among other purposes. The paper is organized as follows. The literature review is covered in Section II, the proposed methodology is presented in Section III, the results and discussion are covered in Section IV, and finally, the conclusion is presented in Section V.

II. Literature Review

AI algorithm analyse a large amount of data to identify the pattern by which a fraudulent activity can be predict [4]. AI tools are playing an important role in the area of customer service to assist customer in various field. Personalization is one of the features of AGI. Advance AI algorithms are able to find the patterns and can predict the behaviour of customer and according to that can suggest service that suits to a particular customer. This is the way to fulfil everyone's need according to the choice and it will enhance the financial planning. Automation is another feature of AGI [5]. AGI can examine the large amount of data and enable the financial institution to take quick decisions about the information, service, product, investment, fraud etc. It will improve the efficiency of finance sector as well as it leads to reduced human error. Many insurance businesses have large data quantities that are difficult to handle due to some semi-automated or use of error-prone manuals. Managing human and machine-generated data is tedious because it lacks a uniform Master Data Management (MDM) system. Myriad technologies drive it challenging to provide data accuracy, consequently, steadfast systems are directed toward wisdom that can be used. Thus, it shows the need for AI and ML keys to enhance productivity. AI and ML are changing insurance businesses by enhancing functioning efficiency, increasing fraud detection, personalizing customer interactions, predictive perspicuity through the processing of big data, and enhancing sales approaches [6]. These advances offer tailored

solutions, resulting in higher customer satisfaction by providing more immediate service and lessened costs. By improving customer experience, personalization, data processing, fraud detection, and operational effectiveness. AI and ML are improving the insurance industry. As revealed by Ageas UK's image identification for cutting expenses, auto claims, delays and automation expedites claim processing. An algorithm that enhances fraud detection is US Lemonade, the US's anti-fraud algorithm. AI-based chatbots and virtual assistance enhance Customer satisfaction. AI improves goal-oriented marketing, increasing industry profitability and inducing leads [7]. According to the researcher, e-finance is a fast-developing topic that needs prevention from financial disasters to reduce financial errors. It concentrates on vital topics like the growing prominence of FinTech, bankruptcy prediction, fraud detection, decision-making, and creditworthiness evaluation. ML models like Support Vector Machines (SVM), Random Forest (RF), and K-Nearest Neighbors (KNN) have proven to be very predictive in the field of finance. It shows how AI is being used in finance. The work presented offers a complete study of AI's revolutionary impact on digital banking. It also spotlights the possible current and future developments [8]. The author [9] compares that how AGI is different from ANI and ASI. He discusses about the methods to achieve AGI which include human brain emulation and AIXI (a theoretical model). The paper analyzes the requirement and feasibility of each method based upon technologies and finds that integrated cognitive architectures are the most appropriate option for achieving AGI. The author [10] highlight the ethical and social challenges in the transition from machine learning to AGI. The author [11] states that the prime focus of AGI is to replicate human cognitive abilities in various domain. Although the technologies like big-data and deep learning are in development process but the achievement of AGI is still uncertain. The research describes about the role of AI in finance sector. Like it automates operations, improve efficiency and reduce cost. It also offers personalized service. By analysing data in real time AI helps in detecting fraud and assess risks. By improving risk management, automating repetitive operations, streamlining financial procedures, boosting investment management, guaranteeing regulatory compliance, and facilitating improved decision-making, the incorporation of AI technology in corporate finance offers substantial benefits [12] [13]. The author [14] state about the different domain of AI like ANI-weak AI and AGI-strong AI. Further [15] describes about the difference of ANI and AGI by stating that ANI specializes in specific tasks and AGI can perform tasks in multiple domains as human-like level. AGI is more versatile as compare to ANI. The potential of AGI in Industry 4.0, Industry 5.0 and Society 5.0 is discussed by [16]. AGI has potential to revolutionize the whole sectors by improving productivity, creativity and customization. Although the number of obstacles is there for its implementation including ethics, safety, data privacy, trust etc. For appropriate development of AGI a multidisciplinary strategy which include government, academia and civil society is needed. In China, the author [17] examines the alleviating impacts of digital inclusive finance on the financing restrictions encountered by small and medium enterprises (SMEs). It implements a statistical technique in a two-fold fixed effect model. It is responsible for data collection from individuals and firms and considers both i.e. time-specific and entity-specific effects. This model helps to reduce the constraints in digital inclusive finance. It also underlines the different characteristics of this alleviation such as regional mismatches, domain, and attributes in traditional financial services. The work finalizes that digital inclusive finance improves SMEs' inner funding origins by declining financing costs and managing leverage levels. To assess the credibility of AI in finance, the author introduces a cluster of integrated metrics named as SAFE stands for (Sustainability, Accuracy, Fairness, Explainability). It employs two statistical techniques Lorenz curve and Lorenz Zonoids. The work spotlights the limitations of ML in real-time d, notably concerning extreme data events and the demand for vital metrics. The author [18] expand earlier work to develop metrics. The SAFE framework has outperformed traditional metrics as per the practical demonstration using bitcoin price data. The suggested metrics seek to help stakeholders, financial authorities as well as asset management firms by delivering reliable evaluations of AI methods in finance, eventually improving conviction in AI applications. The author [19] examines the role of AI in improving access to digital finance within the inclusive financial system. The paper focuses on the significant benefits of employing robo advisor, while also discussing the potential risks posed by AI like market manipulation and system risks. Employing automated services will restrict the high commission charges thus lowering the costs and increasing accessibility for moderate savers. The research emphasizes the importance of a robust legal and regulatory framework that prioritizes market safety, consumer protection, and market integrity while promoting financial inclusion. The research work also highlights the requirement of prudent AI that strikes a balance between the rights of individual privacy and regulatory. It concerns the possibility of RegTech where AI is the regulatory technology. Sustainability, resilience and human-centric are the foundation of Industry 5.0 discussed by the author [20]. These three points help in creating a balanced industrial environment that incorporates state-of-the-art technologies with social and environmental stewardship. The employment of AI and ML in digital finance delivers improved efficiency [21], enhanced risk management, improved customer experience, and notable cost savings. It allows organizations to concentrate on strategic missions, stimulating invention in business pinnacles. Also increases the customer satisfaction by streamlining operations. To fight against monetary cybercrime via effectual peculiarity detection, automatic feature extraction, and real-time analytics can be enhanced through deep learning. As per [22] it processes enormous datasets, facilitating organizations to pinpoint deceitful stirs promptly and accurately. The author [23] discusses improved productivity and sustainability in manufacturing by incorporating human intelligence with robots. The focus is on human-robot collaboration, environmental sustainability, and the formation of unique roles like Chief Robotics Officer. The authors [24] [25] discusses the losses for users and institutions caused due to credit card fraud that significantly impacts the financial sector. The various challenges related to data are also focused such as

limited public data, high false alarm rates, growing fraud tactics, class imbalance, etc. It scours deep learning strategies compared to traditional algorithms for showing superior performance, and fraud detection, indicating real-world potential on three financial datasets. The author in [26] analyzes the influence of AI on cybersecurity, it examines the nine-banking data in Qatar's banking sector, emphasizing AI's role in improving security, challenges in enactment, potential hazards from AI mishandling, and susceptibilities in AI instruments. It highlights the demand for a competent workforce and regulatory obedience. AGI analysis applies myriad cognitive architectures however their underlying operational likenesses suggest the potential of a unified software framework, enabling easier implementation, analysis, and comparison. Developing such a framework could accelerate AGI's progress through code reuse and standardization [27] [28] [29].

III. Proposed Methodology

The main key features of industry 5.0 are shown in Fig. 1.

1) Human centric approach: Human demands and interests are central to the production process in an industry that is human-centric. Industry 5.0 asks what technology can do for workers rather than what workers can achieve with modern technology.

2) Sustainability goal: By creating circular economy procedures, a sustainable industry assists companies in lessening their environmental effect. Reducing waste, energy use and greenhouse gas emissions, as well as preventing the depletion and deterioration of natural resources, are other sustainability changes.

3) Resilience and adaptability: A resilient industry has a high level of resilience in its industrial production. It can support vital infrastructure during emergencies and is well-prepared for outages.

4) Integration of advanced technologies: Emerging of new technologies like AI, IoT, Blockchain are one of the major key features in Industry 5.0. Lots of new technology should be able to collaborate to achieve the theme of Industry 5.0 [30] [31].

A. Theoretical Foundation

For any new technology, service, or business to be adopted, it is critical to comprehend the culture. Because culture is multifaceted, there are many different meanings for it [32]. Numerous important people made contributions to cultural theory. "The collective mental programming that sets one group of people apart from another" is how Greek philosopher Hofstede defines culture. It has been established through research that culture affects how people adopt new or emerging technology. The culture has an impact on how new technologies are adopted. In order to explore the field of information theory, Hofstede proposed a theory. The power distance index, collectivism vs. individualism, uncertainty avoidance index, masculinity vs. femininity, and long-term vs. short-term are the five national cultural variables that form the basis of the Hofstede's theory [33] [34] [35]. While examining the adoption of technology, the author provided research on the significance of culture. The author claims that people's attitudes and perceptions of different technology are influenced by their culture [36]. It follows that the acceptance of a new, creative autonomous decision-making system depends on the inclusion of cultural factors. Among the five culture-dimensions three-culture dimension is used in the investigation. Fig. 2 shows the conceptual framework based on the proposed hypothesis.

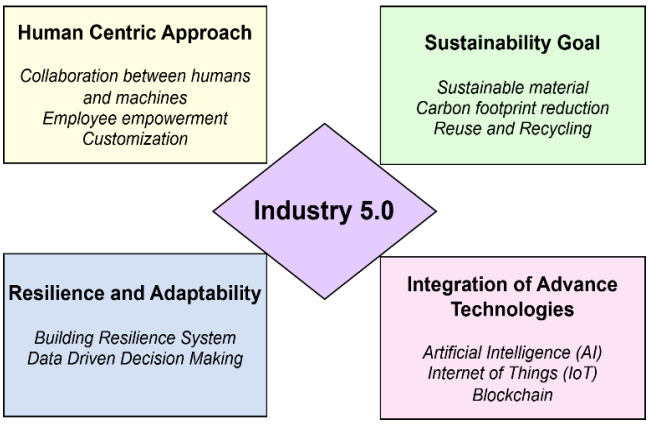

Fig. 1. Key components of industry 5.0.

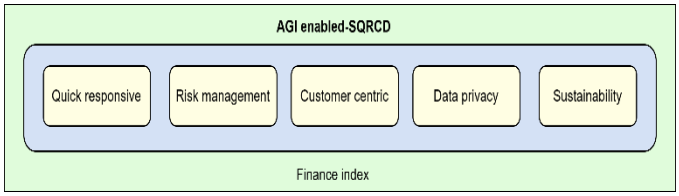

Fig. 2. Conceptual framework.

B. Conceptual Framework and Hypothesis Development

The variable quick responsive, risk management, customer centric, data privacy and sustainability influence the attitude of finance index towards the acceptance of an AGI enabled-SQRCD system. Hofstede's cultural variables power distance index, collectivism-individualism and uncertainty-avoidance moderate these relations. Table I shows the list of survey variable and Table II shows the abbreviation of the variables.

C. Hypothesis Proposed for Finance Index

Fig. 3 shows the conceptual detail framework based on the proposed hypothesis for finance prospective.

H_{qr} Quick responsive: It refers to the response time. The term quick responsive H_{qr} influence positively to the attitude of the finance index towards the acceptance of an AGI enabled- SQRCD.

H_{rm} Risk management: It refers to the capability of risk management. The term risk management H_{rm} influence positively to the attitude of the finance index towards the acceptance of an AGI enabled-SQRCD.

H_{cc} Customer centric: It refers to the process which focus about customer. The term customer centric H_{cc} influence positively to the attitude of the finance index towards the acceptance of an AGI enabled-SQRCD.

TABLE I. SURVEY VARIABLES

Variables	Items
Quick responsive	Finance index should be able to find an AGI enabled-SQRCD system where system is quick responsive while accessing service/product. Finance index should be able to find an AGI enabled-SQRCD system where system is quick responsive while dealing with customers queries.
Risk management	Finance index should be able to find an AGI enabled-SQRCD where system where risk can be managed specially while funding.
Customer centric	Finance index should be able to find an AGI enabled-SQRCD where system is design more in a customer centric way rather than a product centric way.
Data privacy	Finance index should be able to find an AGI enabled-SQRCD system where system where system is able to maintain privacy of data.
Sustainability	Finance index should be able to find an AGI enabled-SQRCD system where the system is able to take challenge to simulate sustainable development.
Power distance index	People who belongs to different income group should be able to find an AGI enabled-SQRCD system
Collectivism	People who belong to collectivist culture will more influence to adopt an AGI enabled-SQRCD system. Individual should be able to find an AGI enabled-SQRCD system
Uncertainty avoidance	People should be able to find an AGI enabled-SQRCD system where instructions are very clear and detailed what to do. People should be able to find an AGI enabled-SQRCD system where instructions and procedures are followed strictly.

TABLE II. ABBREVIATION OF VARIABLES

Variables	Abbreviations
Quick responsive	H_{qr}
Risk management	H_{rm}
Customer centric	H_{cc}
Data privacy	H_{dp}
Sustainability	H_{sn}
Power distance index	H_{pdin}
Collectivism	H_{col}
Uncertainty avoidance	H_{uav}
Attitude	H_{attd}

H_{dp} Data privacy: It refers to the capability of the process where data privacy is one of the important factors. The term data privacy H_{dp} influence positively to the attitude of finance index towards the acceptance of an AGI enabled-SQRCD.

H_{sn} Sustainability: Financial institute has to play very important role to address sustainable development. The term sustainability H_{sn} influence positively to the attitude of the finance index towards the acceptance of an AGI enabled-SQRCD.

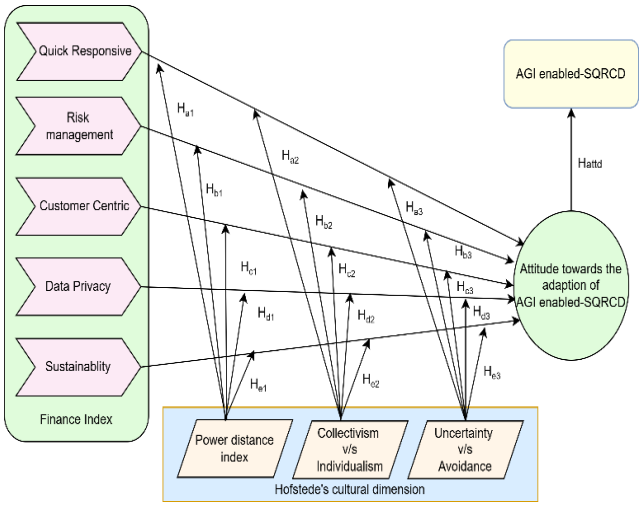

Fig. 3. Conceptual framework for finance index.

Table III shows the hypothesis created for the three constructs taken from the Hofstede's Cultural Dimension.

Fig. 4 shows the flowchart of Customer-Centric. It outlines a structured approach to enhancing customer experience and satisfaction within a financial inclusion system. It starts by identifying target customer segments, focusing on their unique needs and preferences.

TABLE III. HYPOTHESIS CREATED FOR HOFSTEDE'S CULTURAL DIMENSION

Hofstede's Cultural Dimension variables	Items	Description
H_{pdin}	H_{a1}	The relationship between the quick responsive and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in the society belongs to high/low both power distance index.
	H_{b1}	The relationship between the risk management and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in the society belongs to high/low both power distance index.
	H_{c1}	The relationship between the customer centric process and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in the society belongs to high/low both power distance index.
	H_{d1}	The relationship between the term data privacy and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in the society belongs to high/low both power distance index.
	H_{e1}	The relationship between the term sustainability and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in the society belongs to high/low both power distance index.
H_{col}	H_{a2}	The relationship between the quick responsive and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in both collectivism and individualism cultural.
	H_{b2}	The relationship between the risk management and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in both collectivism and individualism cultural.
	H_{c2}	The relationship between the customer centric process and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in both collectivism and individualism cultural.
	H_{d2}	The relationship between the term data privacy and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in both collectivism and individualism cultural.
	H_{e2}	The relationship between the term sustainability and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in both collectivism and individualism cultural.
H_{uav}	H_{a3}	The relationship between quick responsive and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in uncertainty avoidance cultural.
	H_{b3}	The relationship between risk management and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in uncertainty avoidance cultural.
	H_{c3}	The relationship between the customer centric process and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in uncertainty avoidance cultural.
	H_{d3}	The relationship between the term data privacy and the attitude towards the adaption of an AGI enabled-SQRCD system is stronger in uncertainty avoidance cultural.
	H_{e3}	The relationship between the term sustainability and the attitude towards the adaption of an AGI enabled SQRCD system is stronger in uncertainty avoidance cultural.

The next step involves collecting information through surveys and feedback mechanisms to assess customer expectations. Based on this information, personalized financial products and services are developed to ensure alignment with customer requirements. The chart emphasizes the importance of leveraging technology to provide tailored communication and support. The system incorporates regular measurement of customer satisfaction and service effectiveness, allowing for data-driven improvements using feedback process. Finally, the flow chart highlights the iterative nature of the process, ensuring that customer feedback is consistently integrated to refine offerings, enhance relationships, and foster loyalty, ultimately creating a responsive and adaptive financial service environment.

Fig. 5 shows the flowchart of sustainability-focused financial inclusion system. It outlines a structured approach to enhancing access to financial services for underserved populations while promoting environmental and social responsibility. It begins by identifying the target demographic and assessing their specific financial needs through community engagement. Next, inclusive financial products are developed, leveraging technology for accessibility and personalized education. Partnerships with local organizations are established to build trust and facilitate outreach. Financial literacy programs empower customers with knowledge, while engagement strategies foster strong relationships. The system emphasizes measuring impact through customer satisfaction metrics, allowing for continuous improvement based on feedback. Additionally, it promotes sustainable practices within financial offerings. The iterative process ensures that the system evolves to meet changing customer needs, ultimately creating a comprehensive framework that empowers individuals and communities while supporting sustainable development goals.

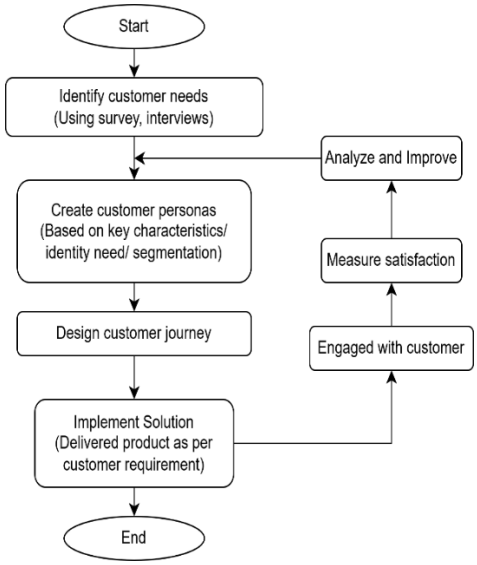

Fig. 4. Flow-chart customer centric focused intelligence financial inclusion system.

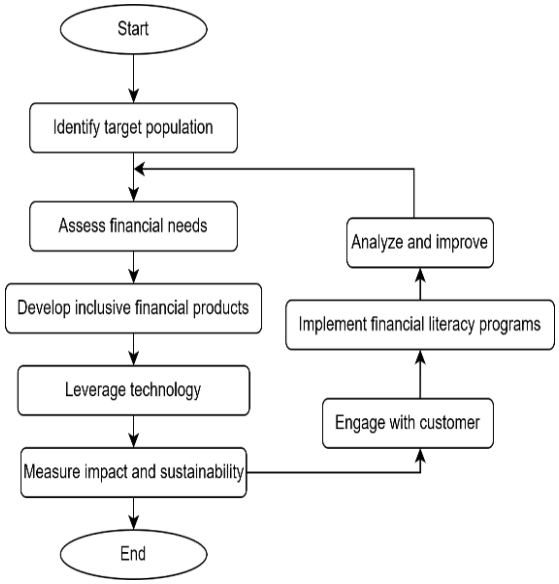

Fig. 5. Flow-chart sustainability focused intelligence financial inclusion system.

IV. Result Analysis

Using a quantitative research approach and a purposive selection technique, 630 financial service providers from various socio-economic backgrounds were selected for the sample. Table IV shows the demographic profile. Specifically, the sample design focused on people who had previously engaged with AI algorithms. Participants were invited to participate using online questionnaires. Five-point Likert scale is used for the value of survey variables, from strongly disagree to strongly agree. 1 is used as strongly disagree and 5 is used as strongly agree. This provided the data needed for a thorough analysis and understanding of the correlation between the constructs and the AGI enabled-SRQCD and also the adaption of AGI enabled-SQRCD.

TABLE IV. Demographic Profile

Type of Bank	
Public	13
Private	21
Foreign	44
Small finance	12
Total Number of Respondents (630)	
Public	91
Private	147
Foreign	308
Small finance	84

Before moving towards the thoroughly analysis the validation of each item's reliability is important. There are total five items are listed in conceptual model which are independent and one is dependent. Three items are taken from Hofstede's cultural dimension as moderators. Descriptive analysis is done to find a true picture of data involved in the study. Descriptive statistics of variable used in survey for study is shown in Table V. The graphs of mean, median, mode and std. deviation are shown in Fig. 6.

TABLE V. Descriptive Satistics

	Mean	**Median**	**Mode**	**Std. Deviation**	**Min**	**Max**
H_{qr}	4.253174603	4.25	4.5	0.54084908	1.25	5
H_{rm}	3.974206349	3.97	4.25	0.506348179	1.5	4.75
H_{cc}	3.929365079	4.25	4.5	0.730313157	1.25	5
H_{dp}	4.180952381	4.5	4.5	0.561052311	1.25	5
H_{sn}	3.986714286	4	4	0.524437011	1.33	5
H_{pdin}	4.104666667	4	4	0.582995499	1.67	5
H_{col}	4.098111111	4	4	0.510755001	1.33	5
H_{uav}	4.043253968	4.25	4.25	0.613032585	1.5	5
H_{attd}	4.253174603	4.25	4.5	0.54084908	1.25	5

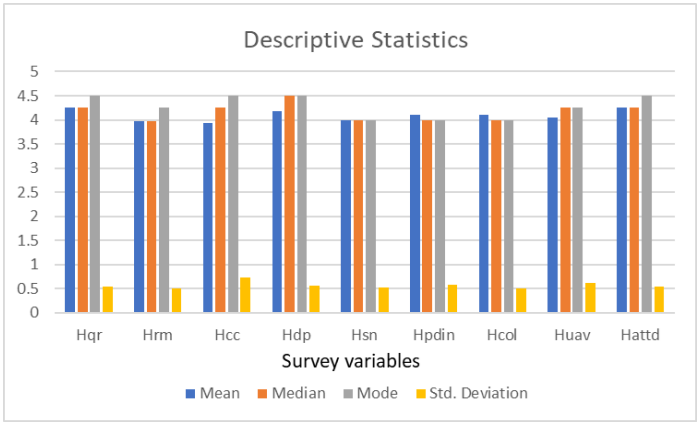

Fig. 6. Descriptive statistics.

Factor loading of each item are shown in Table VI. The value of factor loading exceed 0.7 is maintaining the guideline.

TABLE VI. FACTOR LOADING

Variable	Items	Factor Loadings
H_{qr}	H_{qr1}	0.866
	H_{qr2}	0.823
	H_{qr3}	0.777
	H_{qr4}	0.701
H_{rm}	H_{rm1}	0.711
	H_{rm2}	0.753
	H_{rm3}	0.84
	H_{rm4}	0.781
H_{cc}	H_{cc1}	0.735
	H_{cc2}	0.849
	H_{cc3}	0.842
	H_{cc4}	0.766
H_{dp}	H_{dp1}	0.76
	H_{dp2}	0.804
	H_{dp3}	0.846
	H_{dp4}	0.738
H_{sn}	H_{sn1}	0.781
	H_{sn2}	0.805
	H_{sn3}	0.852
	H_{sn4}	0.71
H_{pdin}	H_{pdin1}	0.719
	H_{pdin2}	0.82
	H_{pdin3}	0.838
	H_{pdin4}	0.711
H_{col}	H_{col1}	0.754
	H_{col2}	0.809
	H_{col3}	0.855
	H_{col4}	0.732
H_{uav}	H_{uav1}	0.822
	H_{uav2}	0.843
	H_{uav3}	0.88
	H_{uav4}	0.725
H_{attd}	H_{attd1}	0.738
	H_{attd2}	0.803
	H_{attd3}	0.854
	H_{attd4}	0.728

Cronbach's Alpha is calculated for each variable used in study and shown in Fig. 7. If the value of Cronbach's Alpha is found greater than 0.7 state that variable is reliable and can be used for further analysis.

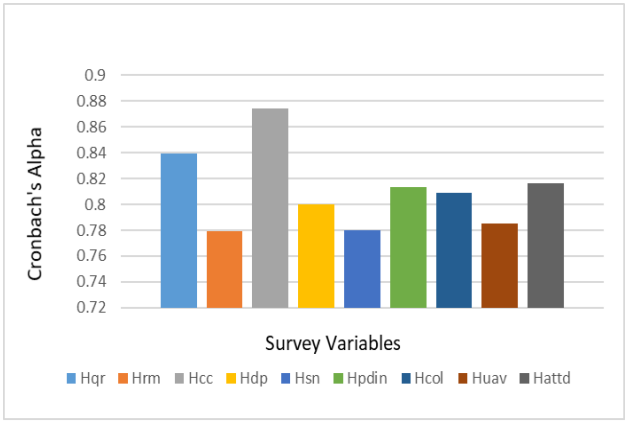

Fig. 7. Cronbach's alpha.

As shown in Table VII the value of all the variable exceed the cut off value indicate that the variables are reliable.

TABLE VII. CRONBACH'S ALPHA

Variable	Cronbach's Alpha
H_{qr}	0.839
H_{rm}	0.779
H_{cc}	0.874
H_{dp}	0.8
H_{sn}	0.78
H_{pdin}	0.813
H_{col}	0.809
H_{uav}	0.785
H_{attd}	0.816

Composite reliability of all used variables is shown in Fig. 8.

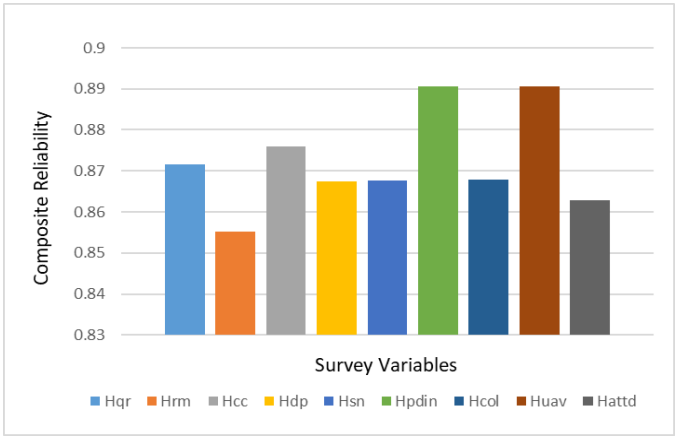

Fig. 8. Composite reliability.

Table VIII shows that the composite reliability also exceeds 0.7 states that items and variables are reliable. The Cronbach's alpha value and composite reliability exceed 0.7 confirm the guideline made by the authors [37].

TABLE VIII. COMPOSITE RELIABILITY

Variable	CR
H_{qr}	0.871597798
H_{rm}	0.855163124
H_{cc}	0.875925089
H_{dp}	0.867347575
H_{sn}	0.867622012
H_{pdin}	0.89058948
H_{col}	0.867908711
H_{uav}	0.89058948
H_{attd}	0.862774646

Average Variance Extracted (AVE) of the study variables are shown in Fig. 9.

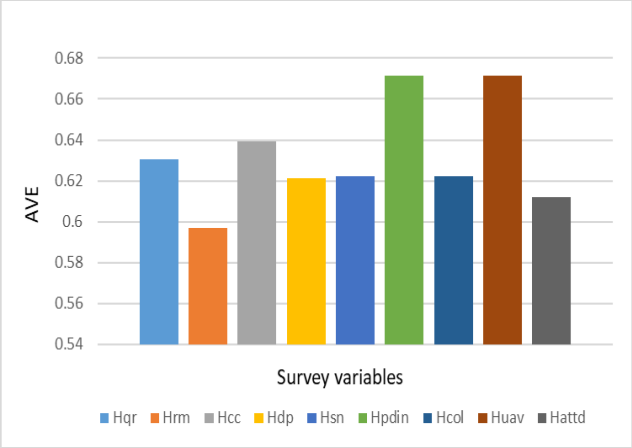

Fig. 9. Average variance extracted (AVE).

TABLE IX. AVERAGE VARIANCE EXTRACTED

Variable	AVE
H_{qr}	0.63060375
H_{rm}	0.59702275
H_{cc}	0.6391865
H_{dp}	0.621094
H_{sn}	0.6219975
H_{pdin}	0.6715895
H_{col}	0.6224615
H_{uav}	0.6715895
H_{attd}	0.61218825

Discriminant table is shown in Table X. The inter construct correlation values are less than the square root value of the Average Variance Extracted values of the respective variables shown in Table IX, thus it validates discriminant validity.

TABLE X. DISCRIMINANT TABLE

	H_{qr}	H_{rm}	H_{cc}	H_{dp}	H_{sn}	H_{pdin}	H_{col}	H_{uav}	H_{attd}
H_{qr}	.794								
H_{rm}	.71	.772							
H_{cc}	.60	.63	.799						
H_{dp}	.71	.68	.59	.788					
H_{sn}	.35	.34	.38	.72	.789				
H_{pdin}	.70	.69	.51	.58	.44	.774			
H_{col}	.55	.58	.62	.34	.56	.34	.788		
H_{uav}	.41	.50	.71	.55	.34	.56	.26	.810	
H_{attd}	.51	.56	.52	.63	.45	.59	.60	.35	.782

Initially, direct relationships tested between H_{qr}, H_{rm}, H_{cc}, H_{dp}, H_{sn} and H_{attd}. H_{qr} ($\beta = 0.43$, $p < 0.001$), H_{rm} ($\beta = 0.37$, $p < 0.001$), H_{cc} ($\beta = 0.65$, $p < 0.001$), H_{dp} ($\beta = 0.36$, $p < 0.001$), H_{sn} ($\beta = 0.68$, $p < 0.001$), H_{attd} ($\beta = 0.78$, $p < 0.001$). It states that the hypothesis H_{qr}, H_{rm}, H_{cc}, H_{dp}, H_{sn} and H_{attd} receives the support. The statistical analysis done for the examination provide the support for all six direct relations. Secondly moderator's H_{pdin}, H_{col} and H_{uav} influence checked on the relationship between H_{qr}, H_{rm}, H_{cc}, H_{dp}, H_{sn} and H_{attd}. The effects of H_{qr} X H_{pdin}, H_{rm} X H_{pdin}, H_{cc} X H_{pdin}, H_{dp} X H_{pdin}, H_{sn} X H_{pdin}, H_{qr} X H_{col}, H_{rm} X H_{col}, H_{cc} X H_{col}, H_{dp} X H_{col}, H_{sn} X H_{col}, H_{qr} X H_{uav}, H_{rm} X H_{uav}, H_{cc} X H_{uav}, H_{dp} X H_{uav}, H_{sn} X H_{uav}. H_{a1}, H_{b1}, H_{c1}, H_{d1} and H_{e1} examined with H_{pdin} as moderator. H_{a2}, H_{b2}, H_{c2}, H_{d2} and H_{e2} examined as H_{col} as a moderator. H_{a3}, H_{b3}, H_{c3}, H_{d3} and H_{e3} examined as H_{uav} as a moderator. The effect of H_{pdi} and H_{col} is Not Significant on above mention relation. The effect of H_{uav} is all were significant and supports the hypothesis.

V. FUTURE PERSPECTIVE

The future perspective of SQRCD (Sustainability, Quality, Resilience, Customer-centricity, and Digitalization) within the setting of building feasible and customer-centric DFIS for the Industry 5.0 era speaks to a major move towards making frameworks that coordinated progressed innovation, human-centric solutions, and sustainability goals. Sustainability isn't fair and natural concern but a foundational guideline for future DFIS. Within the Industry 5.0 era, which emphasizes the integration of people and machines, DFIS must consolidate eco-friendly practices, vitality effectiveness, and economical trade models. Quality affirmation will utilize AI-driven arrangements that automate testing, approval, and compliance to diminish human errors. As cyber dangers advance, securing DFIS with progressed encryption, multi-factor confirmation, and AI-driven extortion avoidance instruments is significant. Combining human imagination with machine accuracy will empower DFIS to offer versatile financial items and administrations custom-made to particular needs.

VI. Conclusion

The study proposed the direct hypotheses to analyze the adoption of an AGI enabled-SQRCD system among respondent belongs to financial service provider institute. Artificial intelligence has gained a very important place in the field of finance sector. It has been seen that that survey variables (i.e. quick responsive, risk management, customer centric, sustainability and data privacy) has positive association with the attitude of adoption of an AGI enabled-SQRCD system. Studies do not always same as actual behaviour so future work can be done to see the actual behaviour to see the adoption of AGI enabled-SQRCD system.

***Abstract*—In recent years, personalized federated learning (PFL) has garnered significant attention due to its potential for safeguarding data privacy while addressing data heterogeneity across clients. However, existing PFL approaches remain vulnerable to privacy breaches, particularly under adversarial inference and client-side data reconstruction attacks. To address these concerns, we propose DP-FedSim, a novel PFL framework incorporating adaptive differential privacy mechanisms. First, to mitigate the limitations posed by fixed-layer personalization strategies, we evaluate parameter significance using the Fisher information matrix. By selectively retaining parameters with higher Fisher values, DP-FedSim reduces the noise impact, enabling more efficient dynamic personalization. Second, we introduce a layered adaptive gradient clipping method. By leveraging the mean and standard deviation of the gradients within each layer, this method allows DP-FedSim to automatically adjust clipping thresholds in response to real-time privacy demands and model states, enhancing the adaptability to various model structures. This ensures a more accurate balance between privacy preservation and model performance. Furthermore, we present a model similarity-based aggregation method utilizing cosine similarity. This technique dynamically adjusts each client's contribution to the global model update, prioritizing clients with models more similar to the global model. This improves the global model's performance and generalization by allowing DP-FedSim to better handle a variety of data distributions and client model attributes. Experimental results on multiple SVHN cifar-10 datasets show that DP-FedSim outperforms the state-of-the-art PFL algorithm by an average of 5% when data heterogeneity is at its strongest. The efficiency of the suggested modules is validated by ablation tests, and the visualization results shed light on the reasoning behind important hyperparameter settings.**

I. INTRODUCTION

A distributed machine learning approach called federated learning (FL) [1] allows several separate devices to work together to train a single model without explicitly sharing local data, protecting privacy and avoiding data leaks. Only model updates are sent to a central server within the FL framework; each participant trains a model separately using their own local data. This decentralized method lowers network communication cost while also protecting data privacy. The performance of traditional federated learning models can be severely harmed by participant data that frequently exhibits non-independent and identically distributed (non-IID) features in real-world applications [2][3][4][5], which can significantly degrade the performance of conventional federated learning models [6][7][8][9]. To address this challenge, Personalized Federated Learning (PFL) algorithms [10][11][12][13] have been developed, incorporating personalization techniques to better accommodate the unique data distributions of individual participants. Despite the notable advances in PFL, privacy concerns remain unresolved. Specifically, model updates exchanged between clients and the central server remain vulnerable to inference and reconstruction attacks that can compromise the privacy of client data [14][15][16][17]. Therefore, integrating robust privacy-preserving techniques, particularly user-level differential privacy [18][19][20][21], is essential to ensure the security and reliability of PFL systems while protecting the privacy of sensitive data.

Despite significant progress, PFL still faces numerous challenges related to the implementation of differential privacy mechanisms. The current PFL techniques [10][22][23] frequently make strong assumptions about parameter partitioning, where clients share a set percentage of the model parameters while the rest are customized. This static approach lacks flexibility in parameter division and fails to fully account for the diversity in client data, which can hinder the performance of personalized models.

Within the context of differential privacy, gradient clipping is a key mechanism used to limit the size of gradients, thereby preventing sensitive information leakage and mitigating the issue of gradient explosion. Gradient clipping also reduces sensitivity, allowing for more efficient privacy budget usage without substantially degrading model performance [25]. However, traditional methods typically employ a fixed clipping threshold c, which can result in either over-clipping or under-clipping under different conditions, potentially impairing the performance of the model.

In most federated learning (FL) frameworks, after a client's local training round is completed, the client sends the model updates, typically in the form of gradients, to a central server responsible for aggregation. The standard aggregation method often relies on a simple averaging of the received gradients. However, in practice, not all clients participate equally in the model training process [26]. Some clients may contribute less due to factors such as limited data, weak computational resources, or unstable network connections. This imbalance can result in the global model becoming overly dependent on clients with larger data volumes or stronger computational capabilities [27], which can hinder the model's ability to capture broader data trends, thus compromising the generalization and convergence of the global model.

However, existing studies still have obvious shortcomings in addressing the above problems. On the one hand, although some studies try to protect privacy through differential privacy techniques, they fail to adequately address the problems of inflexible parameter partitioning and overly fixed gradient trimming strategies in personalized federated learning. On the other hand, the improvement of the aggregation method also fails to effectively take into account the heterogeneity of client data and the difference in model quality, resulting in limited global model performance. Therefore, how to achieve more flexible parameter personalization, more accurate gradient tailoring, and more effective aggregation strategies under the premise of privacy protection has become a key problem to be solved in the field of personalized federated learning.

To address these challenges, we draw inspiration from the work "FedFisher: Leveraging Fisher Information for One-Shot Federated Learning" [28], which employs the Fisher information matrix to facilitate dynamic personalization of model parameters. The square of the first-order derivative of the log-likelihood function is calculated in the core mechanism to assess the contribution of parameters to the curvature of the loss function. In essence, this process captures the information content carried by each parameter. Leveraging this principle, we assess the significance of each client's model parameters through the Fisher information matrix before training begins. By retaining parameters that carry the most information, we mitigate the adverse effects of noise addition in differential privacy settings and avoid potential optimization issues stemming from inappropriate global model parameters.

Building on this, we propose an adaptive gradient pruning strategy, which introduces a hierarchical adaptive gradient clipping method. This approach automatically adjusts the clipping threshold according to the current privacy preservation requirements and the real-time state of the model. In contrast to traditional differential privacy methods that use fixed clipping bounds, this adaptive approach offers greater flexibility and can better accommodate diverse network structures and training environments. It also provides a more accurate response to privacy leakage risks. Furthermore, by allowing the use of larger learning rates, adaptive gradient clipping accelerates convergence and enhances model training performance.

Additionally, we introduce a model similarity-based aggregation method, which utilizes cosine similarity to dynamically adjust each client's contribution to the global model based on the similarity of its parameters to those of the global model. This technique is designed to better align with the data distributions and model quality of different clients, rather than simply assigning equal weight to all updates. By prioritizing updates from clients with models more similar to the global model, this method improves the overall performance and generalization of the global model, as these more similar models are likely to better capture the broader patterns and trends in the data. The following are this paper's main contributions:

- We introduce DP-FedSim, a personalized federated learning framework with adaptive differential privacy. DP-FedSim effectively integrates personalized learning with adaptive gradient tailoring, making it ideal for situations involving a high degree of client data variety and diversity.
- To address the limitations of fixed-layer approaches in traditional personalized federated learning, we leverage the Fisher information matrix to enable a dynamic approach to customization. The Fisher information matrix quantifies the importance of parameters, and under the same additive noise, parameters with higher Fisher values are more sensitive to noise, resulting in greater performance degradation. In order to lessen the effect of noise and improve model performance, we maintain parameters with higher Fisher values.
- We propose a novel adaptive gradient clipping method based on the mean and standard deviation of gradients within each layer. This method accelerates the training process and improves model performance while ensuring privacy protection. In addition, we introduce a model similarity-based aggregation strategy that effectively combines model updates from diverse clients. This method addresses the challenge of heterogeneous client data, where updates may differ significantly, by dynamically adjusting the contributions of client models based on their similarity to the global model.

This paper's remaining sections are organized as follows: We evaluate relevant work in Section II. Section III outlines the foundational concepts relevant to this study. Section IV describes the proposed methods in detail, including the implementation of the three key approaches. Section V presents a performance comparison of DP-FedSim with state-of-the-art methods, and Section VI concludes the paper.

II. Related Work

A. Personalized Federal Learning

A machine learning paradigm called Personalized Federated Learning (PFL) allows a central server to plan model training for dispersed clients without having direct access to their data. The primary objective of PFL is to address data heterogeneity by learning customized models for each client. Mainstream PFL approaches include LG-FedAvg [23], FedBABU [30], PPSGD [29], and FedBN [31]. Both FedBABU [30] and LG-FedAvg [23] adopt fixed local

parameters to exploit local data performance for personalization. However, their static partitioning approaches limit the flexibility required for handling diverse data distributions. The FedPer algorithm [10] introduces personalization layers, which are appended to the base model. During training, the base model's parameters are globally aggregated, while the parameters of the personalization layers remain local and are not aggregated. Similarly, FedBN [31] incorporates one or more batch normalization (BN) layers, which remain fixed during training and do not participate in global aggregation. By keeping certain layers locally, these methods improve customization while better accommodating local data peculiarities, however they might not be as flexible in terms of model adaption.

Additionally, algorithms such as GPFL [32], pFedMe [24], and FedAMP [33] aim to learn both global and personalized feature representations. These methods strike a balance between global model consistency and local personalization, allowing models to capture common features across clients while preserving unique, client-specific information. Despite their effectiveness, these approaches are still constrained by the inflexibility of their personalization mechanisms and may see a decrease in performance as a result of using noisy global parameters directly under the differential privacy (DP) technique.

B. Differential Privacy

Differential privacy (DP) is a crucial technique for protecting data privacy, designed to minimize the risk of identifying individual records when statistical information is shared. In the context of federated learning, user-level differential privacy has been widely adopted [18][19][20][34]. This technique quantifies privacy preservation through two key parameters, (ε, δ), where smaller values of ε and δgenerally imply stronger privacy guarantees but add extra noise, which might impair model performance, to the federated learning process. In federated learning, user-level DP is usually accomplished in two steps: first, local updates are clipped and noise is added before being sent to the server. Clipping reduces the effect of local updates, further improving privacy, and the noise is adjusted based on the sensitivity of the function being assessed. Although these steps greatly improve privacy, the required noise addition and gradient clipping may cause performance issues and delayed convergence.

Recent studies have explored ways to mitigate the negative impact of noise and clipping on performance. Sparsification and uniform regularization approaches, for example, are used by LUS and BLUR [19] to mitigate the impacts of noise and accelerate model convergence. The DP-FedSAM [20] algorithm enhances robustness to noise by employing the Sharpness-Aware Minimization (SAM) optimizer, which identifies more reliable places of convergence. Furthermore, PPSGD [29] uses customisation to enhance performance without compromising privacy. In spite of the progress in these methods, research on gradient pruning and clipping within personalized federated learning remains limited. In this paper, we aim to optimize personalized federated learning algorithms through adaptive gradient tailoring, contributing to the ongoing development of personalized federated learning approaches.

C. Federated Learning Aggregation Algorithm

Model aggregation is a core component of federated learning, where the local models from clients are aggregated in each communication round to generate an updated global model. There are two main types of aggregation: parameter-based aggregation and output-based aggregation, with the distinction based on the aggregation target. One of the first and most popular federated learning algorithms is FedAvg [1], which aggregates models by average parameters from all clients, weighted by the size of each client's dataset. The FedProx algorithm [35] modifies the aggregation process by introducing a proximal term in the objective function to control the impact of local models and ensure convergence. Meanwhile, FedNova [36] improves upon FedAvg by normalizing and scaling local updates based on each client's local iteration count, which helps achieve fairer aggregation. A data agnostic distributional fusion model, which depicts the client's heterogeneous data distribution as a global collection comprised of multiple virtual fusion components with varying parameters and weights, is used by the FedFusion algorithm [37] to characterize the global data distribution.

Although these methods contribute to the development of model aggregation in federated learning, challenges remain. For instance, the FedNova algorithm introduces additional computational complexity due to the need to track and adjust local iteration counts, which increases the computational burden on both the clients and the server, ultimately affecting model convergence speed.

III. Preliminary

A. Personalized Federal Learning

In personalized federated learning (PFL), the primary objective is to train a model that can adapt to the unique data distribution of each client while preserving a degree of global consistency across all clients. This is typically achieved by decomposing the model parameters into two distinct components: one set of globally shared parameters and another set of client-specific personalized parameters, as illustrated in Fig. 1.

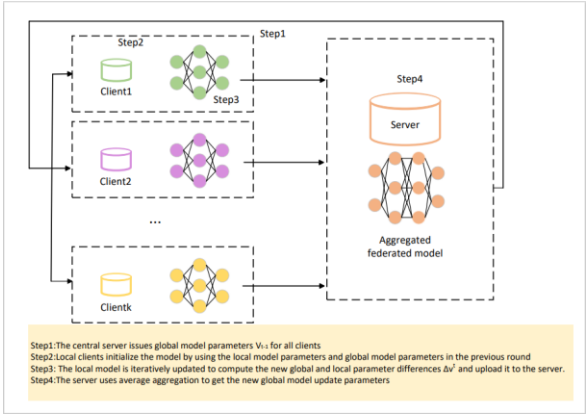

Fig. 1. The key processes of traditional personalized federated learning are depicted. First, a central server publishes global model parameters for use by clients. The model is then repeatedly updated by the client using local data to calculate parameter variances, which are then uploaded to the server. Finally, the server creates global model updates by integrating the variances using an average aggregation approach.

Suppose we have k clients, each possessing a unique dataset, denoted as $D_k = \{(x_i, y_i)\}_{i=1}^{N_k}$, where N_k is the size of the dataset for client k, and i indexes the data samples. In common personalization methods, the model parameter vector w_i is typically decomposed into two components: a local part and a global part, represented as w = (u, v). The objective of personalized federated learning is to update the model parameters according to a specific optimization process, as outlined in Eq. (1).

$$\min_{\nu, u_{1:k}} \left\{ f(\nu, u_{1:k}) := \frac{1}{m} \sum_{i}^{k} f_i(\nu, u_i) \right\} \tag{1}$$

Let $u_{1:k}$ denote $(u_1, \ldots, u_k)$, and let $f_i(v, u_i)$ represent the average loss of parameters v and u_i over the entire dataset D_i for client i, where $i = 1, \ldots, N_k$. The personalized differential privacy mechanism involves two iterative steps:

Local Iteration: During the local iteration, each client i receives the global model parameters v^{t-1} from the server while retaining the local parameters $u_{1\,i}^{t-}$ from the previous round. The model is initialized as $w_{1\,i}^{t-} = (v^{t-1}, u_{1\,i}^{t-})$. The client then performs local updates, iteratively optimizing the parameters to obtain the updated model $w_i^t = (v_i^t, u_i^t)$. The global update $\triangle v^t$ is computed as the difference between v_i^t and v^{t-1}.

Global Update: In the global update phase, all clients transmit their local updates $\triangle v^t$ to the server. The server then aggregates these updates by averaging them across all clients, updating the global parameter as follows:

$$v^t \leftarrow v^{t-1} + \frac{1}{k} \sum_{i=1}^{m^t} \Delta v_i^t \tag{2}$$

The new global parameter v^t is then sent back to all clients to initiate the next round of updates.

B. User-Level Differential Privacy

In personalized federated learning, differential privacy offers a robust protection mechanism that effectively addresses the issue of privacy leakage. As a comprehensive privacy protection framework, differential privacy aims to facilitate the analysis of overall dataset properties while safeguarding individual information. This is achieved at the cost of a certain degree of data accuracy, thereby ensuring stringent privacy protection for user data. The ultimate goal is to prevent adversaries from determining whether a specific individual is represented in the dataset.The concept of differential privacy [38] is defined mathematically to delineate this probability gap, as articulated in Definition 1:

Definition 1 (ε, δ). Differential Privacy A randomization mechanism M satisfies (ε, δ)-Differential Privacy (ε > 0, δ > 0) if and only if, for any adjacent input datasets S and S', and for any possible set of output values R, the following holds:

$$Pr[M(S) \in R], e^{\varepsilon} \cdot Pr[M(S') \in R] + \delta \tag{3}$$

Here, δ denotes the probability of a failure in privacy protection. A randomized algorithm M satisfies (ε, δ)-DP if, for any pair of neighboring datasets D and D' differing by a single record, and for any output subset S in the range of M.

Definition 2 L2 Sensitivity Given a function M and two neighboring datasets D and D', the L2 sensitivity is defined as follows:

$$\Delta f = \max \| M(D) - M(D') \|_2 \tag{4}$$

User-level differential privacy is a specific classification within the broader framework of differential privacy. Noise must be added to the model updates that are locally calculated by each user in order to apply user-level differential privacy to customized federated learning. This approach ensures compliance with user-level differential privacy requirements. Specifically, users must incorporate noise into the gradient or model parameter updates derived from their local datasets after training.

Based on this theoretical foundation, user-level differential privacy is effectively achieved through gradient cropping and noise addition. Gradient cropping is primarily employed to regulate the model's sensitivity to individual data points. By mitigating the influence of outlier samples during a given training round, it helps protect data privacy.

However, much of the existing research focuses on fixed gradient cropping methods. If the cropping threshold is set too high, most gradients may fail to exceed this threshold, rendering the cropping process ineffective. Conversely, setting the threshold too low may excessively constrain gradient updates, hindering the model's ability to glean valuable information from the data. This can diminish the training efficiency and, ultimately, the predictive performance of the model.

Therefore, this paper investigates adaptive gradient cropping within the context of personalized federated learning. A detailed exploration of this topic is presented in Section IV.

IV. Methodology

In this study, we offer a differential privacy federated learning system that combines model similarity-based aggregation, adaptive gradient cropping, and customization based on Fisher information matrices. The proposed approach consists of three key components: Fisher personalized federated learning, adaptive gradient cropping for differential privacy, and aggregation based on model similarity.

When the client gets the global model from the server, the procedure starts. Each local client then computes the Fisher information vector F_i using the Fisher information matrix. Subsequently, the client generates computational binary masks M_{1i} and M_{2i} based on the F_i vector and a set of parameters λ. These parameters are crucial in determining which model parameters should be deemed informative and retained throughout the personalization process.

Once the binary masks M_{1i} and M_{2i} are established, they are utilized to update the local model parameters $w_{1\,i}^{t-}$. The updated model parameters w_i^t are then obtained through further training using these masks.

Next, the cropping thresholds T_s are computed by leveraging the mean and standard deviation of the gradients corresponding to each layer. The gradient parameter $\| g_i \|$ is subsequently calculated, followed by the computation of the cropping factors c_s based on the defined cropping thresholds T_s. These cropping factors are employed to control the scaling of the gradient, yielding the adjusted gradient $g_i^{'}$. The complete gradient is computed by summing the cropped gradients across all layers l.

Finally, model similarity-based aggregation is achieved by calculating the cosine similarity between the global model parameters and the parameters of the i-th client model. Specifically, we first compute the similarity S_i for each client model, followed by summing and weighting all computed similarities. This cumulative similarity is then utilized to update the global model accordingly.

The detailed algorithmic procedure is illustrated in Algorithm 1 and Fig. 2.

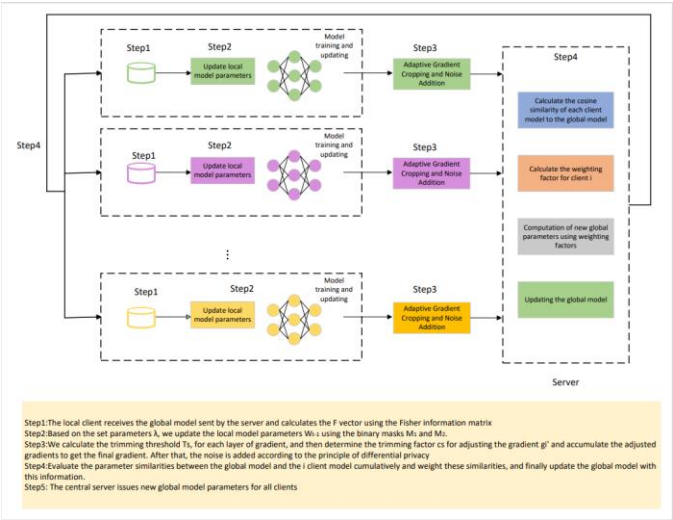

Fig. 2. An overview of DP-FedSim. The client first receives the global model and computes the F vector, then updates the local model parameters. Next, the gradient is adjusted by set thresholds and factors, and noise is added to maintain differential privacy. Finally, the server synthesizes the parameter similarities across clients and updates the global model.

A. Based on Fisher Personalized Federal Learning

Motivation: The motivation for personalization in federated learning is underscored by the use of the Fisher information matrix. The Fisher information matrix serves as an effective tool for quantifying the importance of model parameters; specifically, a larger Fisher value indicates a greater significance of the parameter in the model's predictive performance. This observation leads to the conclusion that parameters with elevated Fisher values contribute to a more substantial degradation of model performance when subjected to the same additive noise.

In conventional personalization approaches, after receiving the global model from the server, clients typically designate specific fixed layers within the network as personalization layers. However, this method is inherently limited, as it fails to account for the differential impact of noise on various parameters. To address this limitation, we propose the introduction of Fisher values as a metric for assessing the importance of model parameter information across each layer.

Fisher Personalization: To alleviate the current inflexibility issues associated with personalized federated learning, we implement a dynamic personalization strategy based on the Fisher information matrix. This approach enhances the model's adaptability to the non-independent and identically distributed (non-IID) data characteristic of individual clients. The procedure is as follows: each client i receives the distributed global model w^{t-1} from the server and subsequently computes the Fisher value F_i based on its local private dataset D_i. The retention of the previous round's local parameters is denoted as $w_{1\,i}^{t-} = (v^{t-1}, u_{1\,i}^{t-})$. In $w_{1\,i}^{t-}$, the diagonal approximation of the true Fisher value for each parameter indexed by j is calculated as:

$$F(w_{ij}) = \left(\frac{\partial \log L(w_i, D_i)}{\partial w_{ij}} \right)^2 \tag{5}$$

This formula illustrates how sensitive the model's predictions are to changes in parameter w_j and serves as a foundational element in enhancing the personalization process.

where $L(w_i, D_i)$ denotes the log-likelihood function of w_i. Then by normalizing each parameter j in layer s layer by layer, the value of fisher's F_s is achieved as

$$\hat{F}_{s,j} = \frac{F_{s,j}}{\sum_j F_{s,j}} \tag{6}$$

After we generate the layer-by-layer Fisher values f_s by the above operation, we generate two binary masks M_1 and M_2 for dynamic selection of parameters. In the event that a parameter's Fisher value is larger than or equal to λ, it is set to 1, otherwise the value is set to 0. For each parameter j in layer s, the mask is defined as follows:

$$M_1[j] = \text{sgn}(\hat{F}_{ij} - \lambda) \quad \text{and} \quad M_2[j] = 1 - M_1[j] \tag{7}$$

To choose the right parameters for customization, we next carry out an elemental multiplication between these masks and parameters. In other words that is, the parameters that had a greater Fisher value locally in the previous round are kept through the masking operation. The remaining parameters are replaced with global parameters.

$$w_i^t = M_1 \odot w_i^{t-1} + M_2 \odot w^{t-1} \tag{8}$$

where M_1 and $w_{1\,i}^{t-}$, M_2 and w^{t-1} serve as the Hadamard product, i.e., the point-by-point product between the elements. The global parameter supplied by the receiving server is w^{t-1}, whereas the local personalization parameter kept from the previous round is $w_{1\,i}^{t-}$. Updating with this method effectively retains the more informative parameters as personalized parameters, and the less informative parameters are updated by the corresponding informative global parameters.

B. Adaptive Gradient Tailoring Differential Privacy

Motivation: In the realm of differential privacy, traditional fixed gradient cropping methods exhibit inherent limitations, particularly when applied to diverse datasets and model architectures. These methods often lack the flexibility to adapt to varying circumstances, leading to issues of over-cropping or under-cropping. Such discrepancies can adversely affect both the training efficacy and the final performance of the model.

The primary motivation behind the adaptive gradient cropping (AGC) technique is its capacity to dynamically adjust cropping thresholds in response to the statistical characteristics of the weights at each layer. This dynamic adjustment mechanism enhances the stability of model training and offers the flexibility to accommodate different network architectures and training configurations, thereby allowing for more precise control over the risk of privacy leakage. A further significant advantage of the AGC technique is its facilitation of larger learning rates, which is critical for accelerating model convergence. This capability can substantially enhance the efficiency and performance of model training, resulting in a more expedient training process and improved model outcomes while maintaining robust privacy protection.

Algorithm 1: Heading

$$w_i \leftarrow \frac{S_i}{S_{sum}}$$

$$\Delta w_i^t \leftarrow \Delta w_i^t + w_i \Delta w_i$$

End

$$w^t \leftarrow w^{t-1} + \Delta w_i^t$$

For $i = 1, 2, ..., m^t$ do

Send w^t to client i^{th}

End

End

In the context of Federated Learning (FL), the heterogeneity of data across different clients often results in substantial discrepancies in the model updates submitted by each client. Such variations may lead to excessively large or small gradient updates for some clients, consequently impacting the training stability of the global model and increasing the risk of privacy breaches. This paper presents the AGC approach, which dynamically modifies the cropping threshold according on the statistical characteristics of the gradient at each layer in order to address these issues. This method effectively addresses the complications arising from heterogeneous data, enhancing both training stability and privacy assurance.

1) Calculation of gradient trimming threshold: The fundamental principle of adaptive gradient trimming lies in performing gradient trimming on each layer's parameters of the global model while dynamically adjusting the trimming threshold to accommodate gradient variations across different data distributions. Specifically, for each layer parameter θ_i of the model, we first compute the mean μ_s and standard deviation σ_s of the corresponding gradient g_s in that layer. These statistical measures provide insight into the concentration and distribution characteristics of the gradients within that layer. The cropping threshold T_s is then calculated as follows:

$$T_s = b \times \left(1 + \frac{\sigma_s}{|\ \mu_s| + \grave{o}}\right) \tag{9}$$

where b represents a predetermined base cropping threshold, which governs the overall intensity of cropping, and ϵ is a small positive constant introduced to prevent division by zero errors. In this formulation, a larger standard deviation of the gradient for a given layer suggests a more dispersed gradient distribution, indicating the potential presence of outliers or noise. In such cases, the cropping threshold will be correspondingly elevated to mitigate excessive cropping. Conversely, when the standard deviation is small, the cropping threshold will be relatively low, thereby enforcing a stricter control over the size of the gradient.

2) Gradient trimming process: Following the determination of the cropping threshold for each layer, we proceed to trim the gradient g_s for each respective layer. Specifically, we first calculate the norm $\| g_i \|$ of the gradient, after which the cropping factor c_s is computed based on the previously established cropping threshold T_s.

$$c_s = \min\left(1, \frac{T_s}{\square g_s \square + \partial}\right) \tag{10}$$

The cropping factor cs governs the scaling of the gradient, ensuring that the cropped gradient does not exceed the predefined threshold. Ultimately, the cropped gradient $g_i^{'}$ for this layer can be expressed as follows:

$$g_s^{'} = g_s \times c_s \tag{11}$$

The complete client-side gradient is expressed as the aggregation of the cropped gradients from all layers. Assuming there are L layers, each with a corresponding cropped gradient $g_i^{'}$, the complete gradient for the client can be formulated as follows:

$$G_{\mathrm{i}} = \sum_{l=1}^{L} g_s^{'} \tag{12}$$

where G' represents the complete client-side gradient, and $g_{\mathrm{l}}^{'}$ denotes the cropped gradient for layer l.

This method preserves much of the information found in normal gradients while successfully reducing the negative impacts of anomalous gradients on the global model. As a result, it improves model training stability and reduces information loss.

Gradient update and noise addition after cropping: To further enhance privacy protection, noise is introduced to the cropped gradient $g_i^{'}$. This addition adheres to the principles of differential privacy, with the standard deviation σnoise calculated based on the base cropping threshold b and the noise multiplier noise_multiplier:

$$\sigma_{\mathrm{noise}} = \sqrt{\frac{\mathrm{b}^2 \times noise_{\mathrm{m}} ultiplier^2}{N}} \tag{13}$$

where N denotes the number of clients participating in federated learning. The noise addition process involves incorporating Gaussian noise into the gradient update at each layer, represented by the following formula:

$$g_i^{\mathrm{update}} = G_i + \mathrm{N}\ (0, \sigma_{\mathrm{noise}}^2) \tag{14}$$

This process ensures that the model's privacy is further reinforced while maintaining the integrity of the gradient through cropping. By appropriately calibrating the noise intensity, we can maximize the privacy of user data without compromising the accuracy of the model.

C. Aggregation Based on Model Similarity

Motivation: In the realm of federated learning, the selection of an appropriate aggregation strategy is pivotal to the ultimate performance of the model. The classical Federated Averaging (FedAvg) algorithm simply averages the model weights of all participating clients, with the averaging weighted by the volume of data each client holds. However, in personalized federated learning scenarios, the model updates from clients may exhibit substantial variability due to the inherent heterogeneity of their respective datasets. Consequently, straightforward weighted averaging may result in diminished global model performance or inadequate personalization.

To alleviate this problem, we propose a model similarity-based aggregation method, the core of which is to dynamically adjust the client's contribution weight in federated learning by measuring the consistency of update directions between the client's local model and the global model. The method adopts cosine similarity as the similarity metric: firstly, the parameter update vectors of the client model are cosine similar to the global update direction. The advantage of cosine similarity is that it focuses on the vector direction rather than the magnitude, which can effectively capture the synergy of the model updates, e.g., clients with high similarity in the update direction are consistent with the global trend, which can be given a higher aggregation weight to inhibit the bias caused by non independent identically distributed data leads to biased updates. Compared with Euclidean distance or Pearson correlation coefficient, cosine similarity is more robust to amplitude changes in high-dimensional sparse model parameter space, and the computational efficiency is more suitable for distributed scenarios. Through this mechanism, local model updates compatible with the global objective can be filtered out to improve the convergence speed, while retaining the client's personalized features, ultimately achieving a balanced optimization of global model performance and personalization.

3) Calculation of model similarity: In model similarity-based aggregation methods, it is essential to first quantify the similarity between each client model and the global model. In this paper, we employ cosine similarity as a measure of the degree of similarity between the client model and the global model. Cosine similarity is a widely utilized metric that computes and normalizes the inner product of two vectors, thereby deriving the angular similarity between them. In this approach, we treat the parameter vectors of the global model and each client model as high-dimensional vectors. We then compute the cosine similarity between these vectors layer by layer, ultimately taking the average similarity across all layers.

Specifically, let w_g denote the parameters of the global model and w_i represent the parameters of the i-th client model. The similarity between these two can be defined as

$$S(\mathbf{w}_i, \mathbf{w}_g) = \frac{< \mathbf{w}_i, \mathbf{w}_g >}{\square \mathbf{w}_i \square\square \mathbf{w}_g \square} \tag{15}$$

where $<w_i, w_g>$ denotes the inner product of the parameter vectors w_i and w_g, while $\|w_i\|$ and $\|w_g\|$ represent their Euclidean norms, respectively. This similarity metric assesses the directional consistency of the model updates from clients relative to the global model. In our implementation, we establish a similarity metric mechanism by calculating the cosine similarity between the parameters of the client model and the global model layer by layer.

4) Aggregation methods for similarity weighting: In the traditional Federated Averaging (FedAvg) approach, the contribution of each client to the global model update is typically determined by the proportion of its data volume. Nevertheless, the degree of similarity between the client models and the global model over several training rounds is

not taken into consideration by this strategy. To address this limitation, we propose an adjustment to the aggregation process by incorporating the cosine similarity between the client models and the global model as a weighting factor.

This process ensures that the model's privacy is further reinforced while maintaining the integrity of the gradient through cropping. By appropriately calibrating the noise intensity, we can maximize the privacy of user data without compromising the accuracy of the model.

During each training round, we first calculate the cosine similarity between each client model and the global model. To ensure the resulting weights are reasonable, we normalize these similarity values so that the sum of the weights of all clients equals 1. This normalization process effectively adjusts the contributions of the clients, allowing updates from clients that exhibit higher similarity to the global model to carry greater weight in the aggregation process, while minimizing the impact of clients with lower similarity on the global model updates.

Let S_i denote the similarity of the i-th client model. The corresponding weighting factor w_i is then computed using the following equation:

$$w_i = \frac{S_i}{\sum_{j=1}^{N} S_j} \tag{16}$$

where N represents the total number of clients participating in the training, and S_j is the similarity of the j-th client model. This weighting method facilitates a dynamic weighted aggregation strategy based on similarity, enhancing the efficiency and effectiveness of the model training process.

5) Polymerization update: Building upon the weights calculated from model similarity, this paper employs a weighted aggregation strategy to update the global model parameters. Each client model's updated value is weighted and superimposed according to its corresponding weights, resulting in the final updated value of the global model. The aggregation process is outlined as follows:

First, for each client model's update result, the update is multiplied by its corresponding weighting factor. Subsequently, the weighted update values of all clients are accumulated layer by layer. Specifically, let the update value of the i-th client be denoted as Δw_i. The update value of the global model, Δw_g, is then computed using the following formula:

$$\Delta w_g = \sum_{i=1}^{N} w_i \cdot \Delta w_i \tag{17}$$

Where w_i is the weight of the i-th client, and Δw_i represents its corresponding model update value. The aggregated update value Δw_g is subsequently applied to the global model to complete each round of model updates.

By utilizing this similarity-weighted aggregation strategy, the global model not only synthesizes data features from diverse clients but also dynamically adjusts the influence of each client based on model similarity. In the presence of diverse data distributions, this method improves the model's generalization performance.

V. Experiments

A. Experimental Setup

1) Dataset and models: We assessed DP-FedSim's performance against cutting-edge algorithms in a federated learning environment on a variety of image recognition tasks. Fashion-MNIST [39], SVHN [40], and CIFAR-10 [41] were among the datasets used in this assessment.A test set of 10,000 samples and a training set of 60,000 samples make up the Fashion-MNIST dataset. A 28 × 28 grayscale picture linked to a label from a total of 10 classes represents each sample. The 60,000 color, 32 × 32 pixel pictures that make up the CIFAR-10 dataset are divided into 10 different classes, with 6,000 images in each class. The digit classification-focused SVHN dataset, which consists of 26,032 test samples and 73,257 training samples, is taken from Street View photos. Every sample is a 32 x 32 color picture that shows the numbers 0 through 9.

For the model architectures, FEMNIST employs a simple convolutional neural network (CNN) comprising 2 convolutional layers and 2 fully connected layers. CIFAR-10, on the other hand, has a more intricate architecture that consists of three convolutional layers and three fully linked layers. The SVHN dataset is processed using a straightforward model featuring 2 convolutional layers, 1 pooling layer, and 2 fully connected layers.

2) Benchmarks: We evaluate DP-FedSim's performance against a number of cutting-edge federated learning techniques, including FedAvg [1], DP-FedAvg[42], DP-FedSAM [20], and DP-FedSAM-top [20]. The FedAvg algorithm serves as a baseline federated learning method that operates without noise. In contrast, DP-FedAvg guarantees client-level differential privacy (DP) by applying a Gaussian mechanism directly to the local updates. The DP-FedSAM algorithm addresses the adverse effects of differential privacy through the utilization of gradient perturbations, specifically incorporating a Sharpness Aware Minimization (SAM) optimizer to produce locally flat models that exhibit improved stability and robustness against weight perturbations. Additionally, DP-FedSAMtopk is a variant of DP-FedSAM that employs a top-k update thinning technique, further minimizing the magnitude of random noise by updating only the most significant portions of the model updates, thereby enhancing model performance while preserving privacy.

3) Implementation details: For our experiments involving the Fashion-MNIST, SVHN, and CIFAR-10 datasets, we model data heterogeneity across client datasets by partitioning local data from the original dataset using a Dirichlet sampling process. The sampling parameter α controls the degree of imbalance in data distribution among clients; larger values of α correspond to weaker data heterogeneity, while smaller values imply stronger heterogeneity. Our primary evaluation metric is global accuracy. In comparisons with other

algorithms, we assess accuracy under varying degrees of non-independent and identically distributed (non-IID) data partitioning, proving that our customized federated learning approach is successful in handling non-IID data.

For the Fashion-MNIST, SVHN, and CIFAR-10 datasets, we set the learning rate to 1×10^{-3} and λ to 0.4. The parameters for differential privacy are set to $\varepsilon = 2$ and $\delta = 1\times10^{-5}$. We establish the number of global rounds at 100, local update rounds at 4, and batch size at 64, with the number of clients set to 100 and a sampling rate of 0.1.

The following sections of this paper are organized into three main parts: first, we conduct a comparative analysis of our algorithm against existing differential privacy federated learning methods. Second, we perform two ablation studies focusing on adaptive gradient cropping and model similarity-based aggregation to validate their effectiveness. Finally, we present a hyperparameter analysis to further elucidate the model's performance.

B. Performance Evaluation

1) Comparative analysis: In Table I, we evaluate the global accuracy of four baseline algorithms across three datasets: Fashion-MNIST, SVHN, and CIFAR-10. To assess the impact of data heterogeneity on the performance of these algorithms, we compare all baselines while varying α within the range of {0.05, 0.1, 0.2}. The results summarized in Table 1 indicate that our proposed algorithm demonstrates superior accuracy and generalization ability under standard noise conditions. This finding underscores the enhanced performance of personalized federated learning with differential privacy.

TABLE I. OPTIMAL TEST ACCURACY OF DP-FEDSIM AND CENTRALIZED BASELINES AT DIFFERENT NON-IID SETTINGS

Data	α	FedAvg	DP-FedAvg	DP-FedSAM	DP-FedSAM-top-k	DP-FedSim
Fminst	0.05	85.12	54.48	58.37	58.64	69.36
	0.1	93.25	62.10	65.95	66.51	71.68
	0.2	93.41	64.99	71.60	72.13	72.93
SVHN	0.05	85.47	77.12	50.21	53.01	84.27
	0.1	86.27	85.28	65.89	66.78	85.83
	0.2	88.64	86.16	72.69	74.53	86.79
Cifar10	0.05	54.62	51.69	45.28	45.78	60.63
	0.1	58.86	55.76	56.78	57.02	63.01
	0.2	64.98	61.44	58.41	59.77	64.07

For instance, in the non-independent identically distributed (non-IID) setting with α= 0.2, the accuracy achieved by our algorithm on the FEMNIST dataset is 78.93%, 86.79% on the SVHN dataset, and 64.07% on CIFAR-10. It is evident that the optimal accuracies of DP-FedSim consistently surpass those of the other baseline algorithms in most cases, highlighting the effectiveness of our approach in improving computational accuracy.

Furthermore, Table I illustrates the robustness and generalization capabilities of our algorithms under varying levels of non-IID distribution, specifically with α set at 0.05, 0.1, and 0.2. The heterogeneous distribution settings among local clients complicate the training and convergence of the global model. Notably, among the four baseline algorithms, the adverse effects of heterogeneous distribution become more pronounced as α decreases.

On the SVHN dataset, our proposed algorithm (Algorithm 1) exhibits superior convergence and generalization compared to DP-FedAvg as the non-IID level diminishes. When $\alpha = 0.05$, the accuracy of Algorithm 1 exceeds that of DP-FedAvg by 7.15%, indicating a greater adaptability of Algorithm 1 in handling non-independent homogeneous distributions. Additionally, on the CIFAR-10 dataset, Algorithm 1 demonstrates differences in non-independent homogeneous distribution of 2.38% and 1.06% at varying levels of α, which are notably lower than the 4.07% and 5.68% observed for DP-FedAvg, and significantly less than the 11.24% and 2.75% exhibited by DP-FedSAMtopk. These results confirm that, despite the challenges posed by heterogeneous data, Algorithm 1 remains resilient and exhibits enhanced robustness and stability.

C. Ablation Experiment

We carried out a number of ablation tests to clarify the role that each element of our strategy had in the overall performance. Our proposed method encompasses two key components: adaptive gradient cropping (AGC) and model similarity-based aggregation (MSA). To assess their individual impacts, we explored several variant configurations, including the removal of both adaptive gradient cropping and model similarity-based aggregation, the removal of adaptive gradient cropping while retaining model similarity-based aggregation, and the removal of model similarity-based aggregation while utilizing only adaptive gradient cropping.

- In the first variant, we eliminated both adaptive gradient cropping and model similarity-based aggregation, opting for the commonly employed differential privacy and simple average weighted aggregation methods based on fixed gradient cropping. This configuration serves as the baseline model for our comparative analysis.
- In the second variant, adaptive gradient cropping was removed, and we employed the conventional differential privacy method utilizing fixed gradient cropping for training, while maintaining model similarity-based aggregation for server-side aggregation. This setup allows us to evaluate the effectiveness of the model similarity-based aggregation method.
- The third variant involved the removal of the model similarity-based aggregation component, utilizing a simple average weighted aggregation method to assess

the effectiveness of the adaptive gradient cropping technique.

In this context, for the first variant, the differential privacy aspect implemented fixed gradient cropping with a cropping threshold c set to 0.4. All other parameter settings remained consistent with those outlined in Section V. The specific experimental results are presented in Table II.

TABLE II. ABLATION STUDY WITH DIFFERENT PRIVACY BUDGETS

Data	ACG	MSA	ε=2	ε=4	ε=8
Fminst			57.74	60.21	62.40
		✓	58.34	61.14	62.67
	✓		70.21	72.82	74.01
	✓	✓	72.31	73.62	74.78
SVHN			72.19	73.17	74.51
		✓	73.59	75.24	77.51
Cifar10			45.77	48.31	49.46
		✓	47.44	49.09	49.74
	✓		61.12	63.84	65.73
	✓	✓	64.62	65.88	67.26

The experimental data reveal that the removal of both modules resulted in a notable decrease in model accuracy, thereby underscoring the importance of each component in the modeling framework. Adaptive Gradient Cropping. The implementation of adaptive gradient cropping significantly enhances accuracy across various privacy budgets. Adaptive gradient cropping significantly improves accuracy across all privacy budgets when used in customized federated learning (as seen in the third row of each dataset in Table 2 as opposed to the baseline model (first row of each dataset). This finding validates the effectiveness of adaptive gradient cropping in bolstering the model's performance.

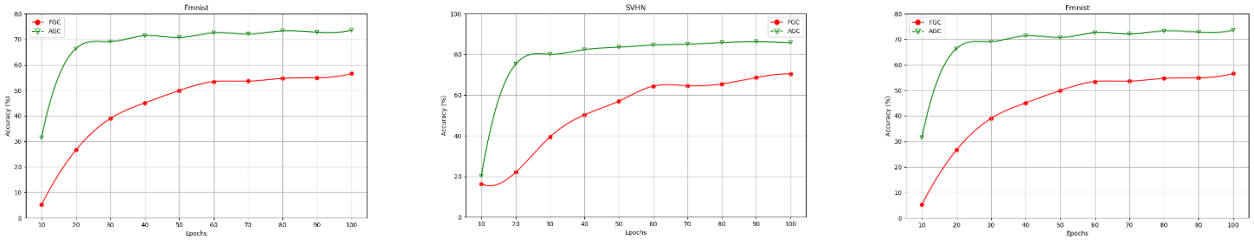

Fig. 3. Fixed gradient cropping and adaptive gradient cropping accuracy plots.

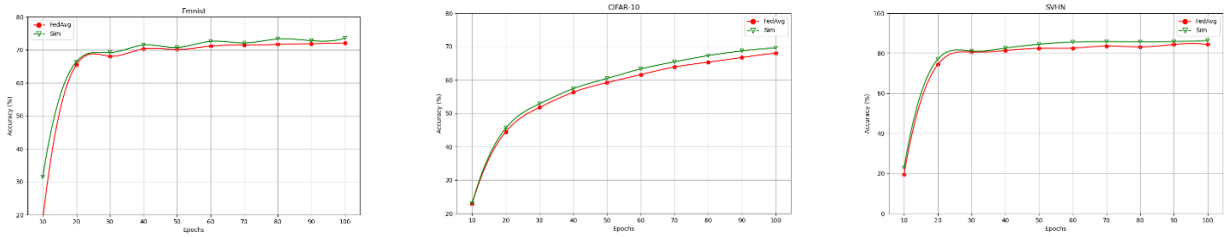

Fig. 4. Weighted average aggregation and model similarity based model accuracy plots.

Model Similarity-Based Aggregation. Similarly, when personalized federated learning relies solely on model similarity-based aggregation (as illustrated in the second row of each dataset in Table 2, there is a marked improvement in accuracy across the privacy budgets relative to the baseline model. This result further corroborates the effectiveness of model similarity-based aggregation within this framework.

Moreover, when both adaptive gradient cropping and model similarity-based aggregation are utilized in tandem (as shown in the fourth row of each dataset in Table 2), the accuracy demonstrates improvement across different privacy budgets compared to the baseline model, the model utilizing adaptive gradient cropping alone, and the model employing model similarity-based aggregation alone. The results clearly indicate that both adaptive gradient cropping and model similarity-based aggregation significantly contribute to the overall performance of the model under varying privacy budgets. The synergistic combination of these two components yields optimal results, thereby enhancing the effectiveness of our proposed algorithm.

D. Hyperparametric Analysis

In experiments concerning personalized federated learning with differential privacy, the selection of hyperparameters significantly influences both the performance and training efficiency of the model. This paper specifically examines the impact of the hyperparameter related to the number of clients on model performance, conducting tests across two distinct datasets.

As illustrated in Figures 5, when the number of clients is set to 5, 10, and 20 for both the Fashion-MNIST and CIFAR-10 datasets, the experimental results indicate a positive correlation between the number of clients and the overall accuracy of the model. The participation of a larger number of clients enables the system to leverage a broader range of local data, thereby enhancing the global model's generalization capability. Furthermore, an increased client count results in a data distribution that more closely reflects real-world scenarios, which helps mitigate the adverse effects of individual client data biases on the model's performance.

However, this increase in client numbers is accompanied by a significant rise in training time. This phenomenon is primarily attributed to the augmented participation of clients in local computations and model aggregation during each training round, leading to increased communication overhead and computational demands. Notably, with the implementation of differential privacy mechanisms, as the number of clients rises and the volume of data per client decreases, the number of communication rounds necessary to achieve a comparable level of convergence may increase, thereby exacerbating the overall training time.

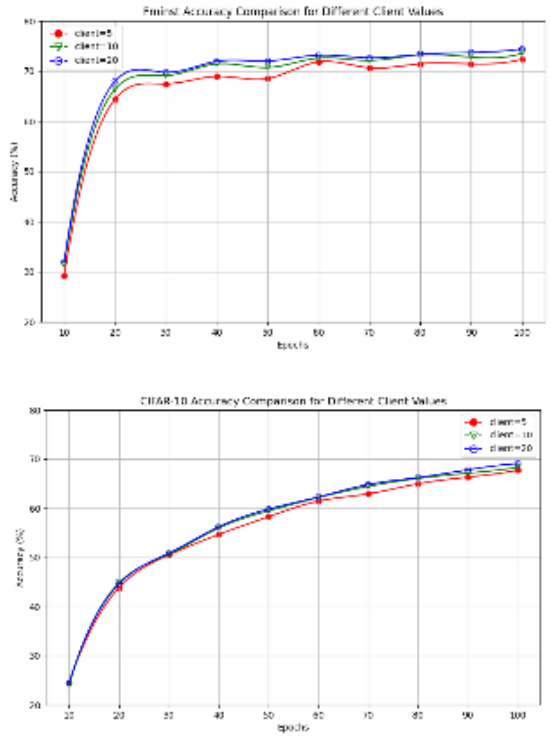

Fig. 5. Accuracy curve for different number of clients.

Consequently, selecting the optimal number of clients necessitates a careful balance between model performance and training efficiency. In scenarios where accuracy is paramount, increasing the number of clients can substantially enhance the model's generalization ability. Conversely, in time-sensitive training contexts, it is imperative to regulate the number of clients to mitigate computation and communication overhead. In practical applications, the number of clients can be adjusted according to specific requirements to achieve an optimal trade-off between performance and efficiency.

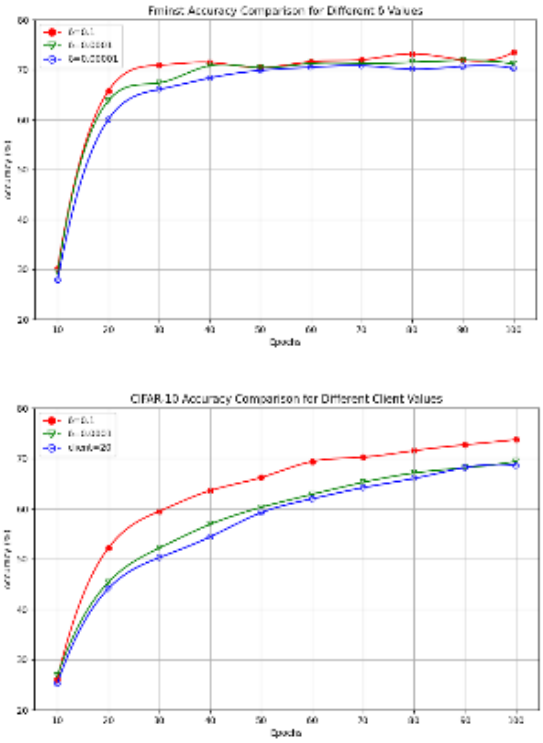

Fig. 6. Accuracy curve for different values of δ.

In Figures 6, we investigate the impact of varying δ-values (0.1, 0.0001, and 0.00001) on the performance of our model using the Fashion-MNIST and CIFAR-10 datasets. The experimental results demonstrate that model accuracy improves as the δ-value increases. This observation can be attributed to the fact that a larger δ-value signifies weaker privacy protection, resulting in reduced noise interference during the training process. Consequently, the model is able to extract useful information from the data more effectively, thereby enhancing its overall accuracy.

However, while a higher δ-value may yield performance benefits, it is crucial to acknowledge that it cannot be set excessively high within the framework of differential privacy. According to the principles of differential privacy, the δ-value represents the probability that the algorithm may violate the privacy budget. A large δ-value consequently diminishes the security of the differential privacy mechanism. If δ is set too high, the efficacy of privacy protection becomes questionable, potentially exposing sensitive data to the risk of leakage.

Therefore, in practical applications, the choice of parameter δ needs to be based on the differential privacy framework, which is a trade-off between model accuracy and privacy protection strength. Differential privacy achieves privacy protection by adding noise or data perturbation, and its privacy budget parameter ε and relaxation parameter δ together determine an upper bound on the risk of privacy leakage. Specifically, δ denotes the probability threshold that the algorithm cannot satisfy strict ε-differential privacy; a smaller

value of δ enhances the privacy guarantee but may lead to a decrease in the model's utility; conversely, increasing δ may enhance the model's performance but increase the likelihood of sensitive information exposure. For example, a decrease in the noise scale will reduce the perturbation to the training data distribution, but will weaken the strictness of the privacy boundaries. Therefore, it is recommended to experimentally quantify the effects of different (ε,δ) combinations on the model metrics according to the sensitivity requirements of the application scenarios, and ultimately choose the optimal parameter configurations that can satisfy the privacy authentication criteria while maintaining the model usability.

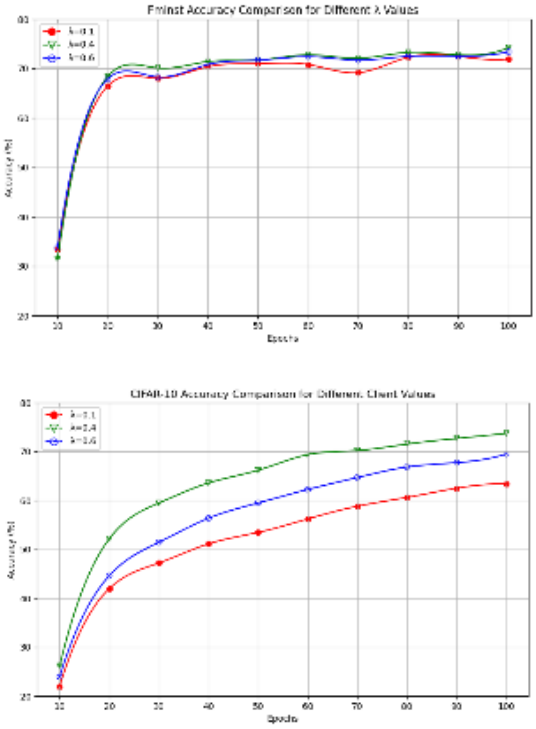

Fig. 7. Accuracy curve for different values of λ.

The value λ is a crucial hyperparameter in customized federated learning, affecting the weight balance between the global and local models in the experiment shown in Figure 7. By adjusting λ, the system can regulate the extent of fusion between the global model and the personalized model during the aggregation process. In our experiments, we set λ to values of 0.1, 0.4, and 0.6 and evaluated the model's performance across different datasets.

The results indicate that setting λ to 0.4 yields the best performance, achieving high accuracy on both the Fashion-MNIST and CIFAR-10 datasets. Specifically, when λ is 0.4, the model strikes an optimal balance between global generalization and local personalization, effectively maintaining a degree of personalization while retaining the shared knowledge encapsulated in the global model. This finding suggests that a moderate fusion of global and local models can enhance the overall performance of personalized federated learning, highlighting the importance of carefully selecting λ to achieve the desired model efficacy.

VI. Conclusion

DP-FedSim is a customized federated learning system with adaptive differential privacy that we present in this paper. This framework effectively addresses the limitations of traditional personalized federated learning, particularly its inflexibility in handling data heterogeneity, while also mitigating the adverse effects of additive noise associated with differential privacy on model performance. DP-FedSim leverages the properties of Fisher's information entropy matrix to accurately quantify the significance of model parameters, allowing for the retention of parameters with larger Fisher values. This strategy reduces the detrimental impact of noise addition on model efficacy. From the perspective of differential privacy, we introduce a hierarchical adaptive gradient cropping method that enables the system to automatically adjust the cropping threshold based on current privacy protection requirements and the real-time state of the model. During the model aggregation phase, the server evaluates the similarity between model parameters by computing metrics such as cosine similarity and dynamically modifies the contribution of each client model to the global model update. This adaptive approach enhances the framework's ability to accommodate the diverse data distributions and model qualities present among different clients. We apply the proposed algorithm to the Fashion-MNIST, SVHN, and CIFAR-10 datasets, demonstrating that our model achieves superior accuracy compared to other differential privacy algorithms, as evidenced by comparative experiments against state-of-the-art models. Furthermore, we conduct ablation experiments to analyze the contribution of each component to the overall performance of the model, while also discussing the rationale behind our hyperparameter settings through detailed hyperparameter analysis.

Smart Night-Vision Glasses with AI and Sensor Technology for Night Blindness and Retinitis Pigmentosa

Shaheer Hussain Qazi, M. Batumalay
Faculty of Data Science and Information Technology, INTI International University, Nilai, Malaysia

***Abstract*—This paper presents the conceptualization of Smart Night-Vision Glasses, an innovative assistive device aimed at individuals with night blindness and Retinitis Pigmentosa (RP). These conditions, characterized by significant difficulty in seeing in low-light or dark environments, currently have no effective medical solution. The proposed glasses utilize advanced sensor technologies such as LiDAR, infrared, and ultrasonic sensors, combined with artificial intelligence (AI), to create a real-time, visual representation of the surroundings. Unlike conventional camera-based systems, which require light to function, this device relies on non-visible, non-harmful rays to detect environmental data, making it suitable for use in pitch-dark conditions. The AI processes the sensor data to generate a simplified, user-friendly view of the environment, outlined with clear, cartoon-like visuals for easy identification of objects, obstacles, and surfaces. The glasses are designed to look like regular prescription eyewear, ensuring comfort and discretion, while a button or trigger can switch them to "night mode" for enhanced vision in low-light settings. This concept aims to improve the independence, safety, and quality of life for individuals with night blindness and RP, offering a transformative solution where no medical alternatives currently exist. However, challenges such as sensor miniaturization, power consumption, and AI integration must be addressed for successful implementation. Beyond its direct benefits for users, the device could have broader societal and economic impacts by enhancing accessibility, reducing nighttime accidents, and fostering technological innovation in assistive wearables. The paper also discusses future directions for research and refinement of the technology while supporting the Process Innovation.**

Keywords*—Night-vision; glasses; night blindness; Retinitis Pigmentosa (RP); IoT; assistive technology; sensor technology; AI; data processing; low-light navigation; wearable devices; process innovation

I. Introduction

Night blindness and Retinitis Pigmentosa (RP) are significant visual impairments that severely restrict an individual's ability to navigate and function in low-light or nighttime environments. Night blindness, also known as nyctalopia, is a condition that reduces the eyes' ability to adjust to dim lighting, making it challenging for affected individuals to see clearly in conditions such as dusk, poorly lit areas, or complete darkness. Similarly, Retinitis Pigmentosa is a progressive degenerative disorder that damages the retina's photoreceptor cells, leading to tunnel vision, difficulty in perceiving peripheral objects, and eventual loss of night vision. Studies estimate that RP affects approximately 1 in 4,000 people globally, making it one of the leading causes of inherited blindness. Additionally, night blindness is a widespread symptom of various eye conditions, including Vitamin A deficiency and congenital disorders, impacting millions worldwide. These visual impairments significantly limit an individual's independence, mobility, and overall quality of life, underscoring the urgent need for effective assistive solutions.

Despite advancements in medical science, no definitive cure exists for either night blindness or RP. Current interventions focus on managing symptoms or slowing the progression of RP through dietary supplements, light therapy, or experimental gene therapy. However, these approaches do not restore functional vision or significantly improve navigation ability in low-light conditions. As a result, individuals with these conditions often rely on assistive devices or human aid to perform everyday tasks.

Technological solutions, such as night-vision goggles and camera-based systems, have been developed to assist individuals in low-visibility scenarios. However, these technologies come with inherent limitations. Night-vision goggles, widely used in military and industrial applications, amplify existing light but are often bulky, expensive, and unsuitable for daily civilian use. Camera-based systems, while more compact, require some amount of ambient light to function effectively, making them unreliable in complete darkness. They are also prone to latency issues, glare interference, unidentifiable environment in sight and privacy concerns, limiting their practicality for visually impaired individuals. These shortcomings highlight the pressing need for an innovative, accessible, and efficient solution tailored to individuals with night blindness and RP.

The primary objective of this research is to conceptualize a novel assistive device: Smart Night-Vision Glasses. These glasses are designed to empower individuals with night blindness and RP by enabling them to perceive their surroundings in low-light and no-light conditions. Unlike existing solutions, this concept utilizes advanced sensor technologies and artificial intelligence (AI) to create a real-time representation of the user's environment. The device would rely on non-visible, non-harmful rays, such as LiDAR or infrared, to gather environmental data without depending on visible light. This data would then be processed by AI

algorithms to generate a simplified, cartoon-like visualization of the surroundings, displayed directly on the glasses' lenses.

The glasses aim to be lightweight, discreet, and easy to use, closely resembling conventional eyewear. A user-friendly interface would allow individuals to switch between regular and night-vision modes with the press of a button, ensuring seamless integration into daily life. This approach not only offers functional assistance in darkness but also caters to aesthetic and comfort considerations for regular use.

The proposed smart glasses represent a significant leap forward in assistive technology for low-vision individuals. Unlike traditional camera-based night-vision systems, which rely on ambient light or emit visible light, this concept leverages non-visible rays such as LiDAR or infrared, which are both safe and effective in complete darkness. These sensors can create a detailed map of the environment by detecting surfaces, objects, and movement, irrespective of lighting conditions.

The innovation lies in the integration of AI-powered processing to transform raw sensor data into a cartoon-like outlined visual representation that can be projected on lenses of glasses. By simplifying complex environmental data into outlines and clear distinctions, the glasses can provide users with an intuitive and easily interpretable view of their surroundings. This approach is inspired by the visualization techniques used in video games and animated media, where objects and characters are outlined with thick lines for better differentiation.

Moreover, the glasses are designed to prioritize accessibility and practicality. Their discreet appearance and lightweight design address the stigma and inconvenience often associated with assistive devices. By incorporating real-time processing and a seamless mode-switching mechanism, the glasses aim to provide users with an enhanced sense of independence and confidence in various scenarios, from nighttime walks to driving and navigating unfamiliar environments.

This concept aligns with the United Nations Sustainable Development Goal (SDG) 9, which emphasizes fostering innovation and developing sustainable infrastructure. By focusing on Internet of Things (IoT) integration, advanced sensor technologies, and AI, this project promotes the creation of inclusive, forward-thinking solutions that enhance quality of life and address unmet needs in the assistive technology sector. The smart glasses not only represent a technological innovation but also hold the potential to transform how we approach visual impairments, particularly in conditions where no medical solutions currently exist.

II. Literature Review

The evolution of assistive technologies for visually impaired individuals has led to the development of various smart glasses and wearable devices aimed at improving mobility, navigation, and environmental perception. These technologies integrate artificial intelligence (AI), computer vision, and Internet of Things (IoT) components to assist users in performing daily activities independently. Despite these advancements, significant limitations persist, particularly concerning cost, usability, and effectiveness in low-light or nighttime conditions. This section critically examines existing assistive technologies, their shortcomings, and potential areas for improvement.

A highly sophisticated AI-based smart glasses design is presented by [1] that integrates multiple vision correction functionalities along with advanced navigation and security features. The proposed glasses dynamically adjust for far vision, computer use, and reading through ultrasound-based mechanisms while incorporating night-vision-enabled cameras for obstacle detection and environmental awareness. The inclusion of motion detection, explosive-trace identification, and blind-corner monitoring through strategically placed cameras and sensors highlights the potential of AI-driven wearable technology in enhancing both accessibility and security. While our conceptual design does not rely on cameras or auditory feedback, [1]'s work reinforced the importance of real-time environmental awareness and adaptive visual augmentation. His approach to integrating AI-based obstacle detection helped refine our understanding of non-visual sensing methods, particularly how sensor-based data interpretation could be leveraged to provide a seamless navigation aid for individuals with night blindness and RP.

The Internet of Things (IoT) continues to emerge as a transformative technology, facilitating solutions that improve human life. A significant portion of the global population faces disabilities that complicate daily activities, particularly those with visual impairments. While various assistive tools have been developed to aid individuals with blindness, many of these solutions fall short in terms of accessibility and efficiency. Integrating artificial intelligence (AI) into such assistive devices emphasized by [2] significantly enhances their utility by offering users a simulated sense of vision, ultimately promoting independence. However, despite advancements, challenges persist regarding affordability, compact design, and the incorporation of essential functionalities.

Assistive technology (AT) plays a crucial role in improving the daily lives of individuals with disabilities by enabling greater independence. It encompasses a wide range of devices and services tailored to specific needs, including mobility aids, vision-enhancing products, and cognitive assistance tools. The importance of AT in bridging the accessibility gap for visually impaired individuals is underscored by [2], highlighting how modern innovations in AI-driven object detection and real-time voice feedback are redefining the scope of such technologies.

One of the primary challenges faced by visually impaired individuals is navigation in public spaces. According to [2], IoT-based solutions are increasingly addressing these challenges, introducing a variety of navigation aids designed specifically for users with limited or no vision. The development of smart glasses equipped with advanced sensors and deep learning algorithms presents a promising avenue for enhancing mobility and independence. The functionality of such smart glasses was explored by [3], emphasizing the role of adaptive algorithms and deep learning techniques in object recognition and real-time environmental interpretation. The ability of such devices to process visual data accurately enables

visually impaired users to interact with their surroundings more effectively.

Moreover, [3] highlights the growing importance of functional analysis and statistical mechanics in assessing the strengths and limitations of smart glasses. These analytical methods provide a deeper understanding of how AI-driven assistive devices operate in real-world conditions, paving the way for future advancements. The practical application of smart glasses extends beyond functional performance, as [3] notes that usability, ergonomic design, and social acceptability are equally vital considerations. A seamless integration into daily life, coupled with a lightweight and comfortable design, enhances the practicality of these devices for both indoor and outdoor use.

Beyond navigation, AI-powered image processing algorithms are instrumental in improving object recognition and text-to-speech conversion capabilities. Convolutional Neural Networks (CNNs) and its ability to enable smart glasses to detect and classify objects in real time is detailed by [3]. Similarly, Haar Cascade Classifiers, which rely on machine learning for object detection, are particularly effective in identifying specific patterns such as faces and gestures. These technological advancements underscore the growing precision of AI-driven visual assistance tools.

Obstacle detection and avoidance remain fundamental features of smart glasses designed for visually impaired individuals. Additionally, [3] discusses how these systems leverage a combination of sensors, algorithms, and feedback mechanisms to enhance navigation safety. Technologies such as LiDAR (Light Detection and Ranging) and time-of-flight (ToF) sensors provide real-time depth measurements, allowing users to navigate around obstacles more effectively. Additionally, computer vision techniques, including edge recognition and object segmentation, further improve the glasses' ability to analyze surroundings and guide users through audio or tactile feedback. Machine learning algorithms, such as CNNs, contribute to distinguishing obstacles from the background, enhancing accuracy and minimizing the risk of collisions.

The development of AI-powered smart glasses aimed at enhancing the independence and social integration of visually impaired individuals was explored by [4]. Their design incorporates multiple assistive functionalities, including text reading, currency recognition, color differentiation, obstacle detection, and facial recognition. By focusing on discreet and user-friendly features, the authors address the psychological and practical concerns of individuals who may prefer less conspicuous assistive devices. While our conceptual design does not involve cameras or facial recognition, this work provided valuable insight into the broader scope of smart glasses as accessibility tools. In particular, their emphasis on seamless obstacle detection reinforced the need for intuitive, real-time feedback, shaping our approach to integrating non-visual environmental awareness through LiDAR and ultrasonic sensing.

A comprehensive analysis of the integration of Artificial Intelligence (AI) and Visible Light Communications (VLC) in assistive technologies for visually impaired individuals was provided by [5]. Their work explores how VLC, an emerging communication technology using modulated light signals, can be leveraged for navigation and environmental awareness, complementing AI-driven assistance. By reviewing existing solutions and outlining a roadmap for AI-VLC integration, the authors highlight the transformative potential of these technologies in enhancing accessibility. While our concept does not incorporate VLC, this study broadened our perspective on alternative sensing methods beyond traditional camera-based or infrared solutions. The discussion on AI-driven early disease detection was particularly insightful, reinforcing the importance of optimizing assistive devices to cater to diverse visual impairments.

A smart glasses system designed to assist blind individuals by converting written English text into audio output using artificial intelligence was presented by [6]. Their approach integrates Optical Character Recognition (OCR), the EAST text detector, and ultrasonic sensors to capture and interpret text efficiently. Additionally, the use of motion sensors and RFID technology enables indoor navigation, particularly in structured environments like classrooms and lecture halls. While their device focuses on reading assistance rather than environmental awareness, it provided valuable insights into sensor-based guidance and real-time AI processing. This study reinforced the importance of designing intuitive and responsive assistive devices, which influenced our decision to prioritize real-time sensor data processing for enhanced navigation in low-light conditions. Our conceptual design doesn't have such features as our concept focusses on Night Blindness and Rp patients specifically.

SMART_EYE, a smart assistive technology was introduced by [7], aimed at helping visually impaired individuals navigate unfamiliar environments and detect obstacles using AI and sensor integration. Their system leverages a mobile application for image classification, while ultrasonic sensors handle real-time obstacle detection, providing auditory feedback via voice commands. A key contribution of their work is the emphasis on cost-effectiveness, addressing the affordability barriers that often limit the adoption of assistive devices. While our concept diverges by focusing on night vision enhancement rather than image-based classification, their research reinforced the importance of integrating real-time sensor feedback for seamless navigation. Their findings also highlighted the necessity of lightweight, user-friendly solutions, which further validated our approach of ensuring ergonomic and intuitive design in our Smart Night-Vision Glasses.

A comprehensive overview of how artificial intelligence, particularly deep learning, is transforming both the diagnosis of eye diseases and the development of assistive visual aids was conducted by [8]. Their research underscores the dual role of AI in early disease detection and the enhancement of everyday accessibility tools for visually impaired individuals. While our concept does not focus on AI-driven diagnostics, their discussion on smart devices reinforced the potential of AI in wearable assistive technologies. Their work highlighted the rapid advancements in deep learning applications, which further supported our decision to integrate AI-driven sensor processing for real-time navigation assistance. Additionally, their insights into the future directions of AI-assisted visual

technologies provided a broader perspective on how such innovations could evolve, aligning with our goal of leveraging AI to enhance spatial awareness for individuals with night blindness.

The challenges of object detection in low-light environments were explored by [9], emphasizing the limitations of traditional surveillance methods and the advantages of deep learning-based approaches using thermal infrared imaging. Their study highlights the difficulties of maintaining high detection accuracy at night due to poor illumination, a challenge that aligns with the core problem our concept aims to address. While their research is focused on security and surveillance, the insights on leveraging thermal imaging for object recognition reinforced the feasibility of using infrared sensors in our conceptual design of Smart Night-Vision Glasses. Their findings validated our approach of relying on non-visible light sources rather than conventional cameras, demonstrating the effectiveness of alternative sensing technologies for enhancing visibility in dark environments. Additionally, their discussion on deep learning's role in feature extraction and classification provided useful perspectives on potential future enhancements for intelligent obstacle recognition in assistive wearables.

An innovative approach was presented by [10] to self-powered sensor systems by leveraging triboelectric nanogenerators (TENG) for energy harvesting and signal processing, addressing key challenges in wearable technology, such as power sustainability and deployment flexibility. Their discussion on TENG's ability to convert mechanical stimuli into electrical signals offers valuable insights into potential advancements in assistive technology. While our proposed Smart Night-Vision Glasses do not incorporate sound recognition or energy harvesting, their research highlights the growing trend of integrating self-driven sensors with AI for real-time data processing, which could be relevant for future iterations of assistive wearables. The study reinforces the importance of low-power, intelligent sensor networks, aligning with our concept's focus on developing a compact and efficient solution for individuals with night blindness. Moreover, their exploration of machine learning applications in sensor signal processing provides a broader perspective on how AI can enhance the accuracy and responsiveness of wearable devices.

A comprehensive review of the key enabling technologies that drive advancements in autonomous vehicles (AVs) is provided by [11], focusing on the integration of IoT, edge intelligence, 5G, and blockchain to enhance safety, security, and efficiency. Their discussion of sensor networks and real-time data processing is particularly relevant to assistive technologies like our proposed Smart Night-Vision Glasses, which also rely on sensor fusion and AI-driven decision-making. While our concept does not involve vehicular automation, the paper highlights the broader potential of IoT-enabled systems in improving real-time navigation and obstacle detection—principles that align with our device's goal of enhancing spatial awareness for individuals with night blindness. Furthermore, their exploration of edge intelligence emphasizes the benefits of decentralized processing, reinforcing the importance of efficient, low-latency data handling, a crucial aspect for wearable assistive devices.

The role of computer vision and AI algorithms in autonomous driving was explored by [12], highlighting their application in scene perception, obstacle detection, and intelligent decision-making. Their discussion on sensor integration and real-time image processing resonates with the conceptual framework of our Smart Night-Vision Glasses, which also rely on AI-driven perception for enhanced visibility in low-light conditions. While our design does not incorporate computer vision for autonomous navigation, the paper underscores the significance of real-time data acquisition and preprocessing, key principles that inform our approach to sensor-based environmental awareness. The emphasis on obstacle detection and avoidance further reinforces the importance of adaptive assistive technologies, validating our decision to integrate multi-sensor fusion for enhanced spatial perception.

Some papers were considered beyond the scope of our concept, in order to get as many intuitive ideas as possible while designing a concept of future technology in human assistance. The role of digital technologies in optimizing energy grid integration is discussed by [13], emphasizing predictive analytics, monitoring, and control systems that enhance stability and efficiency. While our proposed Smart Night-Vision Glasses do not directly relate to energy management, the concept of real-time data processing and intelligent decision-making aligns with our approach to sensor-driven environmental awareness. The paper's insights into predictive analytics reinforce the importance of proactive adaptation in assistive technologies, much like how our design leverages AI to interpret sensor data and provide real-time feedback for improved night vision and obstacle detection.

By integrating cutting-edge AI technologies with wearable assistive devices, researchers continue to push the boundaries of accessibility and independence for visually impaired individuals. The growing body of literature in this domain highlights the potential of smart solutions to revolutionize how users interact with their environment, offering not only enhanced perception but also a deeper sense of autonomy.

A. Existing Assistive Technologies

Several smart solutions designed for visually impaired users have emerged in recent years, incorporating features such as object recognition, text reading, and navigation assistance. Notable products include SMART_EYE, OrCam, eSight, and Aira smart glasses. These devices leverage AI-driven image processing to enhance the user's understanding of their surroundings. For example, OrCam MyEye utilizes a small, camera-equipped module that attaches to traditional eyewear, allowing users to receive real-time audio descriptions of their environment. eSight employs high-resolution cameras to capture images and magnify them for individuals with low vision, while Aira connects users to remote human assistants who provide navigation guidance.

In addition to camera-based solutions, some assistive technologies integrate advanced sensors such as LiDAR (Light Detection and Ranging) and ultrasonic sensors. These technologies are particularly beneficial in low-light environments, as they generate depth maps and detect obstacles regardless of ambient lighting. However, despite their

potential, they are not widely adopted in wearable devices for visually impaired users.

B. Limitations of Current Systems

While the aforementioned technologies have contributed significantly to improving mobility for visually impaired individuals, they exhibit critical shortcomings that hinder widespread adoption. One of the primary issues is the over-reliance on light-dependent cameras. Most existing smart glasses function optimally in well-lit environments but fail to perform adequately in darkness or poor lighting conditions. Since night blindness and Retinitis Pigmentosa predominantly affect individuals' ability to see in low-light conditions, these devices do not fully address their needs.

Another major limitation is the reliance on audio-based feedback. Many smart glasses provide auditory cues to guide users, which can be problematic in noisy environments or situations where the user must remain aware of external sounds, such as traffic. Overloading the auditory senses can reduce situational awareness and pose safety risks.

Cost is another prohibitive factor. Many commercially available smart glasses are expensive, often exceeding several thousand dollars. This restricts accessibility for a large portion of the visually impaired population, particularly in developing countries where affordability is a significant concern.

Moreover, many of these devices are cumbersome, requiring additional hardware such as handheld controllers, smartphones, or external batteries. This lack of seamless integration into daily life reduces user adoption rates. In addition, devices that rely on cloud-based AI processing introduce latency issues, making real-time navigation less effective and frustrating for users.

C. Why Certain Technologies have Failed to Gain Widespread Adoption

Despite the promise of AI and IoT in assistive technology, several solutions have struggled to achieve mainstream adoption. One reason is the lack of personalization in existing systems. Current technologies often take a one-size-fits-all approach, failing to consider the varying degrees of visual impairment among users. Additionally, user interfaces are often unintuitive, requiring extensive training before users can fully benefit from the technology.

Another critical reason for limited adoption is the failure to address social and psychological barriers. Many visually impaired individuals prefer discreet assistive devices that blend seamlessly into everyday life. Bulky or conspicuous designs contribute to social stigma and discourage users from adopting the technology.

Battery life also remains a concern. Many smart glasses consume significant power due to continuous image processing and AI computations. Frequent recharging requirements and limited operational hours reduce their practicality for all-day use.

Furthermore, privacy concerns associated with camera-based systems deter users. Devices that continuously capture and process visual data may be perceived as intrusive in social or professional settings, raising ethical and legal considerations regarding data security and consent.

D. Opportunities for Improvement

The shortcomings of current assistive technologies highlight several areas where innovation is necessary. The most pressing issue is the need for improved night-vision capabilities. Future solutions should prioritize the integration of non-visible ray-emitting sensors, such as infrared (IR) and LiDAR, which can accurately detect objects and depth in complete darkness. LiDAR, in particular, has shown remarkable success in autonomous vehicles, where real-time spatial mapping is critical for navigation. Implementing similar sensor-based approaches in wearable assistive devices would significantly enhance their reliability in low-light environments.

Another area for improvement is the development of multi-modal feedback systems. Instead of relying solely on audio cues, future assistive devices should incorporate haptic feedback and visual overlays to guide users. Augmented reality (AR) displays that outline obstacles and objects in a simplified, high-contrast format could provide a more intuitive navigation experience while reducing dependence on sound-based instructions.

Reducing hardware bulk and enhancing user comfort should also be prioritized. Advances in miniaturization and power-efficient AI processing could lead to the creation of lightweight, discreet smart glasses that resemble traditional eyewear. Wireless charging and extended battery life would further enhance their usability.

Furthermore, affordability must be a key consideration in the development of next-generation assistive devices. Open-source software and cost-effective hardware solutions could make high-quality assistive technology more accessible to a broader audience.

Finally, privacy concerns must be addressed through on-device processing rather than cloud-based computation. Edge AI technologies, which allow real-time data analysis without transmitting information to external servers, could enhance security and alleviate users' concerns about continuous surveillance.

E. Conclusion

The review of existing literature highlights the progress made in assistive technologies for visually impaired individuals, particularly through AI-driven smart glasses. However, critical gaps remain, particularly regarding low-light performance, reliance on auditory feedback, high costs, and limited user adoption due to social and usability concerns. Future innovations should focus on sensor-based night-vision solutions, multi-modal feedback systems, ergonomic designs, and affordability to maximize the impact of assistive technologies.

By leveraging LiDAR, infrared, and other advanced sensors, wearable assistive devices can evolve beyond their current limitations and provide an effective, all-encompassing solution for individuals with night blindness and Retinitis Pigmentosa. This research aims to bridge these gaps by

conceptualizing an intelligent, sensor-driven smart glasses system that enhances mobility and independence while maintaining user comfort and discretion.

III. Conceptual Design of Smart Night-Vision Glasses

A. System Architecture

The proposed Smart Night-Vision Glasses present a conceptual solution aimed at enhancing mobility and spatial awareness for individuals with night blindness and Retinitis Pigmentosa (RP). By leveraging advanced sensor technology and AI-driven data processing, the system is designed to provide users with a real-time, visually intuitive representation of their surroundings, even in complete darkness. Unlike traditional night-vision solutions, which rely on cameras or amplified light, this design is entirely sensor-based, ensuring reliable performance across varying environmental conditions.

The core architecture of the glasses integrates multiple sensor modalities, including LiDAR (Light Detection and Ranging), infrared (IR), and ultrasonic transducers. These sensors can collaboratively construct a detailed environmental map, with LiDAR providing precise depth perception, IR capturing heat signatures, and ultrasonic sensors supplementing obstacle detection. The AI-powered processing unit interprets this data to generate a simplified, cartoon-like outline of the surroundings, which is then projected onto the glasses' lenses. The visual output on the lens of glasses can mirror the style of video games or cartoons, where objects and characters are outlined with bold, thick lines, ensuring easy differentiation. For example, walls might appear as clearly outlined flat surfaces, trees as simple silhouettes, and people or animals as distinctive shapes with identifiable boundaries. This approach ensures that users can perceive objects, obstacles, and spatial boundaries through an intuitive, high-contrast visual representation, enhancing navigation and situational awareness.

A key challenge in such an architecture is real-time processing, as sensor data must be collected, analyzed, and displayed with minimal latency to ensure a seamless user experience. The AI system must handle vast streams of depth, thermal, and ultrasonic data, transforming them into an intelligible format without noticeable delay. To achieve this, edge AI processing techniques are considered, allowing computations to be performed directly within the glasses rather than relying on external cloud-based processing. This not only reduces latency but also ensures uninterrupted functionality in all environments, including remote or offline settings.

B. Sensor Technology and Power Efficiency

The reliance on LiDAR, infrared, and ultrasonic sensors eliminates the need for traditional camera-based systems, addressing common issues such as sensitivity to glare, poor weather performance, and privacy concerns. LiDAR emits laser pulses that reflect off objects, allowing the system to construct a 3D depth map, while infrared detects heat-emitting entities, making it particularly useful for identifying living beings. Ultrasonic sensors provide an additional safety layer, especially in detecting obstacles in close proximity where LiDAR and IR may have limitations.

Fig. 1 shows how LIDAR is being used in today's Autonomous Vehicles and how it detects its surrounding obstacles. Whereas Fig. 2 shows what an Infrared vision looks like, with High Heat signature (Red-Orange) being mostly Living Creatures like humans, and Low Heat Signature (Blue-Green) being surrounding objects. If the sensors work together to collect data, it can be quite an efficient strategy to merge their data and get combined result using cutting-edge AI processing.

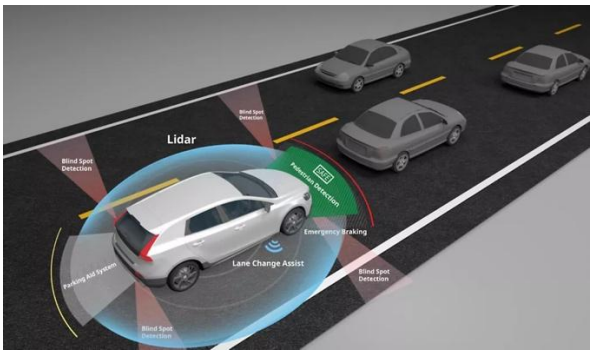

Fig. 1. LIDAR working in self-driving vehicles.

Fig. 2. Infrared vision.

However, one of the primary concerns in implementing these sensor technologies in a wearable device is power consumption. LiDAR systems, while highly accurate, can be power-intensive, depending on the scanning frequency and resolution. Infrared sensors also require continuous energy input, particularly when detecting thermal variations over a wide field of view. Ultrasonic sensors, although relatively low-power, still contribute to overall battery drain. To ensure prolonged battery life without compromising performance, the Smart Night-Vision Glasses would incorporate several power management strategies, such as:

- Adaptive Sensor Activation: Instead of running all sensors continuously, the system dynamically activates specific sensors based on the detected environment. For instance, LiDAR may operate at full resolution in complex spaces but switch to a lower-power mode in familiar environments.
- Efficient AI Processing: The AI model is optimized to minimize redundant computations, using compressed

depth mapping techniques and selective rendering to process only the most relevant visual elements.

- Low-Power Display Technology: The projection system within the lenses could employ energy-efficient micro-OLED or e-paper technology to reduce power consumption while maintaining high visibility.
- Rechargeable, High-Capacity Batteries: Advanced lithium-polymer batteries with optimized energy density would provide extended usage, supported by rapid charging mechanisms for convenience.

By incorporating these strategies, the Smart Night-Vision Glasses aim to strike a balance between high-performance sensing and practical battery life, ensuring users can rely on the device throughout their daily activities without frequent recharging.

C. AI Implementation and Data Processing

At the core of the proposed system lies an advanced AI model designed to process multimodal sensor data and generate an intuitive, real-time visual output. Unlike conventional AI-driven vision systems that rely on image recognition, this model could function exclusively on depth, thermal, and ultrasonic data, reconstructing a scene based purely on environmental contours and object boundaries. The AI processing pipeline can follow several key steps:

- Data Fusion and Preprocessing: The system first aggregates raw data from LiDAR, IR, and ultrasonic sensors. Noise reduction techniques, such as Kalman filtering and temporal smoothing, are applied to enhance signal clarity and reduce measurement inconsistencies.
- Edge Detection and Scene Reconstruction: Using deep learning-based edge extraction techniques, the AI can identify object contours and spatial structures. This can be achieved through modified Convolutional Neural Networks (CNNs) trained specifically on depth and thermal datasets. Unlike traditional image-based edge detection, this method could operate on geometric point clouds and thermal differentials.
- Cartoon-like Rendering and Display Optimization: The extracted object boundaries can then be stylized into a high-contrast visual format, resembling bold outlines in a simplified 3D space. This representation can be rendered using lightweight GPU-based processing or custom-designed FPGA hardware for minimal latency.
- Latency Optimization and Edge AI Deployment: Given that real-time responsiveness is critical, the AI model can be deployed on an embedded system featuring an ARM-based neural processing unit (NPU). This will reduce computational overhead and ensures that the glasses can function autonomously without reliance on external computing resources.

A significant challenge in this implementation can be to maintain real-time performance while handling large volumes of sensor data. LiDAR alone can generate millions of data points per second, and without efficient processing, the system could introduce delays. To counter this, the AI can employ hierarchical processing, prioritizing essential objects and filtering out irrelevant background data. Additionally, by leveraging sparsity-aware algorithms, the system could ensure that only critical edge information is rendered, thereby reducing computational load without sacrificing accuracy.

D. Visual Representation of System Design

To further clarify the conceptual framework of the Smart Night-Vision Glasses, the following simple diagrams illustrate the data flow, operational process, and system's architecture. These visual aids provide a structured understanding of how the proposed technology integrates various components to enhance night vision capabilities for individuals with night blindness and Retinitis Pigmentosa (RP).

The data flow diagram in Fig. 3 illustrates the sequence in which data moves through the system, ensuring real-time processing and visualization. When night vision mode is active, the Sensors continuously scan the environment, collecting depth, obstacle, and ambient light information. This data is transmitted to the Microcontroller, which aggregates and formats the input before passing it to the AI Processing Unit. Here, advanced machine learning algorithms analyze the data, filter out noise, and generate a simplified yet accurate spatial representation of the surroundings. The processed information is then transmitted to the Display Lenses, enabling users to visualize objects and obstacles in their path. Additionally, User Controls provide input that alters processing settings, allowing for adaptive visual representation based on user preferences or environmental conditions.

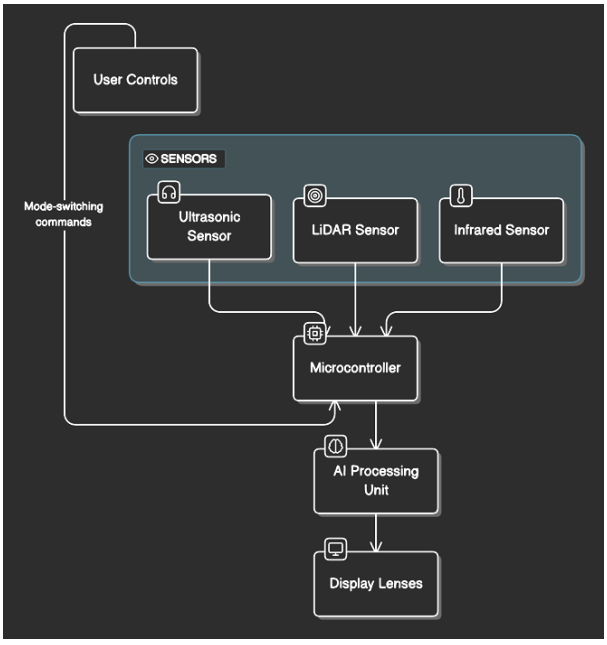

Fig. 3. Conceptual data flow diagram.

The flowchart in Fig. 4 details the step-by-step operational process of the Smart Night-Vision Glasses, from activation to data visualization and user interaction. The user can manually switch between normal and night vision modes via User Controls. When the user activates the night vision, the system initiates sensor data collection, where LiDAR, infrared, and

ultrasonic sensors gather environmental depth and object proximity information. The data is then processed by the AI-driven computational unit, which generates a structured visual overlay displayed on the lenses. This structured flow ensures efficient operation with minimal latency.

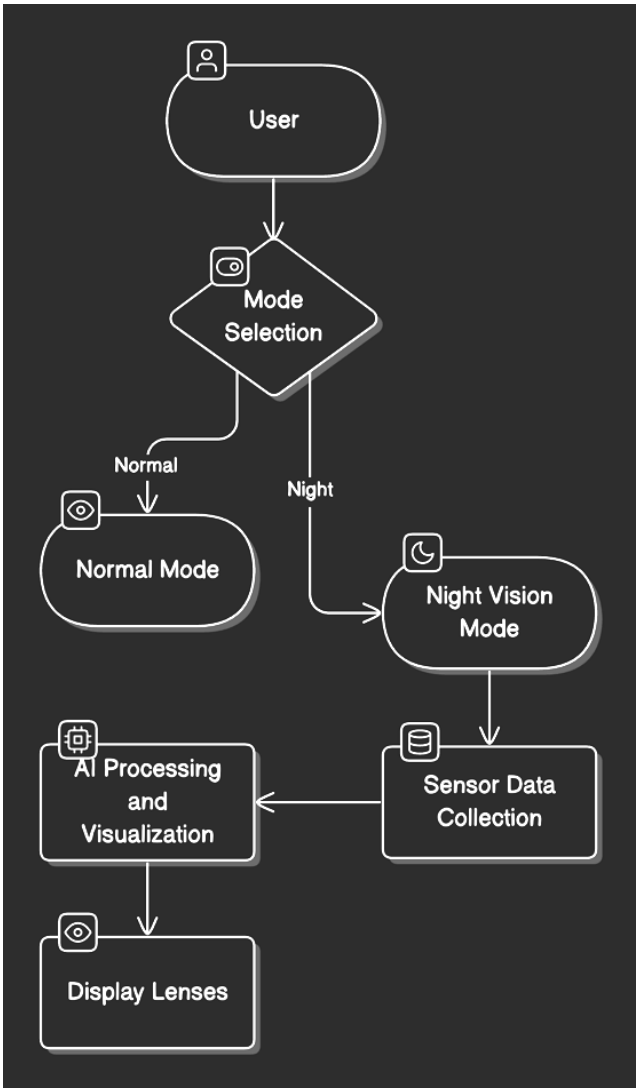

Fig. 4. Conceptual operational flow diagram.

The system architecture diagram in Fig. 5 presents a high-level overview of the key hardware and functional components of the Smart Night-Vision Glasses. The device consists of multiple sensors, including LiDAR, infrared, and ultrasonic sensors, which capture environmental data in low-light conditions. This data is transmitted to a Microcontroller, which serves as the central processing hub, relaying raw information to the AI Processing Unit for real-time interpretation and visualization. The processed data is then displayed on transparent Lenses of the glasses, allowing users to perceive a structured representation of their surroundings. A Power Supply Unit ensures continuous operation, while User Controls facilitate switching between normal and night vision modes. This modular architecture ensures a seamless and efficient user experience while maintaining a compact and lightweight form factor.

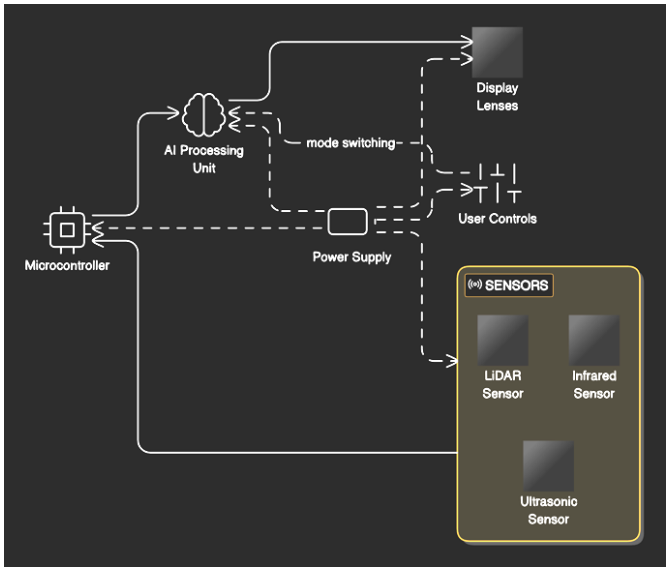

Fig. 5. Conceptual system architecture diagram.

These conceptual visual representations provide a comprehensive overview of the system's functionality, technical integration, and user interaction, reinforcing the feasibility of the proposed concept while acknowledging the need for future research and development.

E. Usability and Experience

A key design consideration for the Smart Night-Vision Glasses is their ease of use and seamless integration into daily life. The glasses are conceptualized to closely resemble standard prescription eyewear, ensuring that users feel comfortable and confident wearing them in any social or professional setting. The frame is designed to be lightweight yet durable, allowing for extended use without discomfort or fatigue.

A critical feature that enhances usability is the mode-switching mechanism, which enables users to seamlessly transition between normal vision and AI-enhanced night vision. This transition can be facilitated by an ergonomically positioned button or touch-sensitive trigger embedded in the frame. With a simple press, the device shifts from standard eyewear mode to night vision mode, activating the sensor suite and AI processing system. This instantaneous switch ensures adaptability to various lighting environments, such as moving from a well-lit indoor space to a completely dark outdoor setting.

In normal mode, the glasses are to function as standard eyewear, which can accommodate prescription lenses if required. The transparent display remains inactive in this mode, ensuring that the glasses look and feel like conventional spectacles. In night vision mode, the LiDAR, infrared, and ultrasonic sensors begin scanning the surroundings, while the AI system processes this data to generate an outlined, cartoon-like representation of objects and surfaces. This visual output can then be projected onto the lenses in real-time, providing users with an intuitive spatial awareness of their environment.

To enhance accessibility, the glasses could integrate haptic feedback mechanisms to alert users of mode changes or

provide additional contextual awareness about their surroundings. For instance, subtle vibrations in the frame could indicate the presence of nearby moving objects or sudden changes in terrain. Additionally, users could have the ability to fine-tune the displayed visuals through adjustable settings, such as contrast levels, edge thickness, or depth emphasis, ensuring an optimized and personalized viewing experience.

Simplicity and user-friendliness remain central to the design philosophy. The system can be envisioned to operate autonomously, without requiring manual calibration or technical adjustments. The goal will be to create a device that enhances mobility and independence for individuals with night blindness or RP, enabling them to navigate their surroundings with confidence and ease.

F. User Testing and Feedback Mechanisms

While the technological advancements behind the Smart Night-Vision Glasses are crucial, their real-world effectiveness depends on user experience and adaptability. Given the conceptual nature of this design, ensuring that it meets the needs of individuals with night blindness and RP would require iterative testing and feedback-driven refinements. Potential user testing approaches would involve the following stages:

- Simulated Virtual Testing: Before physical prototypes are developed, a virtual simulation environment could be used to evaluate the AI's rendering capabilities. Individuals with visual impairments could interact with the simulated display to provide feedback on contrast levels, object clarity, and usability.
- Controlled User Trials with Functional Prototypes: Once a working prototype is available, selected users could test the glasses in controlled environments such as indoor pathways, urban streets, and dimly lit areas. These trials would focus on ease of navigation, reaction time, and cognitive load assessment.
- Iterative Feedback and Design Optimization: Continuous feedback loops would allow developers to refine edge thickness, object emphasis, and dynamic adjustments based on user preferences. Customization options could be introduced, allowing users to fine-tune aspects like contrast intensity and depth sensitivity.
- Longitudinal Studies on Adaptation and Learning Curve: Since adapting to a new visual representation takes time, long-term studies would track how users adjust to the glasses over weeks or months, identifying patterns in usage and potential areas for enhancement.

Another critical factor is social acceptability. The design must not only be functional but also aesthetically discreet, ensuring that users feel comfortable wearing the glasses in various social settings. Unlike bulky assistive devices that may draw unwanted attention, the Smart Night-Vision Glasses aim to resemble conventional eyewear, reinforcing confidence and normalizing their usage in everyday life.

IV. Potential Applications and Benefits

A. Everyday Life

The Smart Night-Vision Glasses have the potential to transform the daily lives of individuals with night blindness and Retinitis Pigmentosa (RP) by addressing the fundamental challenge of navigating in low-light or completely dark environments. Everyday tasks that most people take for granted such as walking through a dimly lit room, taking an evening stroll, or finding their way through a darkened parking lot can be hazardous and stressful for individuals with these conditions. These glasses could serve as a life-changing solution by enabling users to perceive their surroundings clearly, regardless of ambient lighting.

Consider a real-world scenario where an individual with night blindness needs to walk through a dark alley to reach a bus stop after work. Without assistance, they might struggle to detect obstacles such as curbs, trash bins, or uneven pavement, increasing the risk of falls or injury. With the Smart Night-Vision Glasses, the path ahead would be outlined in a clear, cartoon-like format, making obstacles and surface transitions instantly recognizable. This enhanced spatial awareness could instill confidence and encourage greater independence.

Another case study could involve a person with RP navigating a crowded subway station at night. Since RP often reduces peripheral vision, individuals with the condition may have difficulty detecting people or objects approaching from the sides. The glasses, by outlining and emphasizing moving objects in their field of view, could help them avoid collisions and safely navigate through dense crowds.

Driving at night is another area where these glasses could offer significant benefits. Individuals with night blindness often struggle with reduced contrast sensitivity and difficulty perceiving road markings, pedestrians, and other vehicles. The glasses could enhance nighttime driving safety by clearly outlining road edges, lane markings, and potential hazards, reducing anxiety and improving reaction time. While this would not replace standard vehicle lighting or existing driver-assist technologies, it could provide an additional layer of visual clarity for those with night vision impairments.

Beyond mobility and transportation, the glasses could enhance nighttime social engagement. Attending concerts, dining in dimly lit restaurants, or even engaging in outdoor activities such as hiking or camping often presents challenges for individuals with night blindness. With the aid of the glasses, they could experience a newfound sense of inclusion, participating in nighttime activities with greater ease and confidence.

B. Specialized Applications

Beyond personal use, the Smart Night-Vision Glasses could be invaluable in various specialized fields that require enhanced vision in low-light conditions.

For instance, in firefighting, visibility is often compromised by thick smoke and darkness, making it difficult for first responders to locate victims and navigate burning structures.

The glasses, using LiDAR and infrared sensors, could highlight structural outlines, detect heat-emitting bodies, and improve situational awareness. Firefighters could move more efficiently and safely through hazardous environments, increasing the chances of successful rescues while reducing the risk of injury.

Similarly, in military and law enforcement applications, the glasses could serve as a lightweight, energy-efficient alternative to traditional night-vision goggles. Unlike existing solutions that rely on image intensification technology, the Smart Night-Vision Glasses would generate a high-contrast, simplified outline of the environment, enabling soldiers or officers to identify threats, maneuver through unfamiliar terrain, and conduct surveillance with greater precision.

Search-and-rescue operations, particularly those conducted at night or in disaster-stricken areas, could also benefit from this technology. Rescuers navigating through collapsed buildings or forests at night could detect obstacles, locate missing individuals, and assess environmental hazards more effectively, potentially saving lives.

In addition to emergency response and defense, professionals working in remote or extreme environments such as deep-sea researchers, cave explorers, or Arctic scientists could use the glasses to navigate terrain where traditional lighting solutions are ineffective. The ability to perceive surroundings clearly without reliance on external illumination could enhance safety and efficiency in these challenging environments.

C. Social and Economic Impact

The Smart Night-Vision Glasses could have a profound societal impact, particularly for individuals with night blindness and RP. By enabling safer and more independent mobility, they could drastically improve the quality of life for users and reduce reliance on caregivers or mobility assistance programs.

One of the most significant potential benefits is a reduction in nighttime accidents. Falls, collisions, and other visibility-related incidents could be significantly decreased, leading to fewer emergency room visits and hospitalizations. This reduction in injury rates could, in turn, lower healthcare costs associated with treating fractures, concussions, or other accident-related conditions.

From an economic standpoint, these glasses could help individuals with night blindness and RP maintain employment opportunities that require nighttime mobility. Workers in industries such as transportation, security, and emergency response could remain active in their fields without being restricted by their visual impairments. The ability to work more independently could also lead to increased earnings and reduced dependency on disability benefits, contributing to economic self-sufficiency.

Employers could benefit as well by fostering a more inclusive workforce. With assistive technologies like these glasses, businesses might find it easier to accommodate employees with vision impairments, reducing workplace accessibility barriers and promoting diversity.

Educational institutions could also see advantages. Students with night blindness or RP might struggle with evening classes, fieldwork, or extracurricular activities held in low-light conditions. The Smart Night-Vision Glasses could enable them to participate more fully, ensuring that their academic experience is not limited by their condition.

Overall, the potential applications and benefits of the Smart Night-Vision Glasses extend far beyond personal convenience. Whether empowering individuals with visual impairments, enhancing public safety, supporting professionals in high-risk fields, or reducing healthcare costs, this concept represents a significant step toward greater accessibility and inclusion. By leveraging cutting-edge sensor and AI technologies, this innovation envisions a future where vision impairments no longer dictate the boundaries of human potential.

D. Simulated Visual Examples Demonstrating the Potential Benefits

The following examples highlight how smart glasses with advanced sensor integration can significantly improve visibility in dimly lit environments. These conceptual illustrations showcase enhanced edge detection, offering a clear, outlined view of surroundings to aid individuals with night blindness or low vision.

1) Example 1: Staircase in a Dimly Lit Lounge

Fig. 6 depicts a round staircase located in the lounge of a house. The environment is either dimly lit or captured during nighttime, creating significant challenges for individuals with difficulty perceiving in low-light conditions. In such settings, the edges of the stair steps are nearly indistinguishable, posing a risk of missteps or even falls. Additionally, any objects or hazards on the ground blend into the dimly lit surroundings, further exacerbating the risk of accidents.

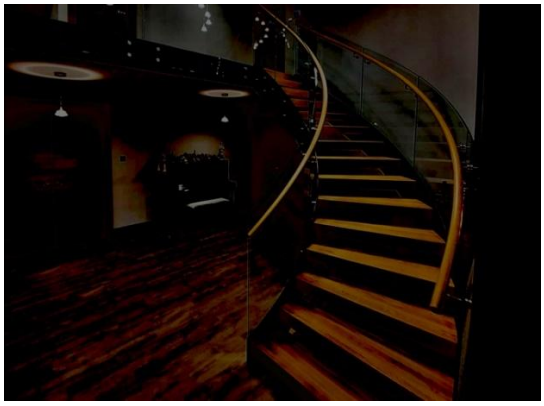

Fig. 6. Staircase in a dimly lit lounge.

Fig. 7 illustrates the same lounge but with a proposed outlined visualization generated by the smart glasses. In this outlined version, the edges of the staircase, furniture, and any other objects in the room are clearly highlighted. The high-contrast outlines allow users to discern each step and object with precision, even in near-complete darkness. This visualization demonstrates how the project's concept could significantly enhance safety and mobility in poorly lit environments, ensuring that users navigate their homes with confidence and ease.

Fig. 7. Conceptual view of the staircase in a dimly lit lounge.

2) Example 2: Sidewalk with Broken Path-Blocks

Fig. 8 captures a section of a sidewalk partially shaded by a tree and an overhanging shop canopy. The broken path-blocks in this area are hard to detect due to the interplay of light and shadows, creating a potential tripping hazard for anyone, especially individuals with reduced night vision or low-light perception.

Fig. 8. Sidewalk with broken path-blocks.

In Fig. 9, the same sidewalk is shown with the concept's outlined visualization. Here, the broken path-blocks, as well as the edges of nearby curbs and other elements, are distinctly outlined, offering a detailed, high-contrast representation of the environment. This enhanced visual information would allow users to easily identify and avoid hazards, improving their safety while walking on shaded or poorly illuminated paths. By providing a clear and real-time depiction of obstacles, the smart glasses concept can empower users to navigate public spaces with greater autonomy and reduced risk of injury. It's something that camera-based solution can't do.

Fig. 9. Conceptual view of the sidewalk with broken path-blocks.

3) Example 3: Dark-Colored Staircase Against a Wall

Fig. 10 shows another staircase situated against a wall within a home. The deep, dark brown color of the staircase steps makes them difficult to visually distinguish from one another, especially under dim lighting conditions. This scenario presents a significant tripping hazard, as users may struggle to gauge the height and depth of each step, increasing the likelihood of accidents.

Fig. 10. Dark-colored staircase against a wall.

Fig. 11 demonstrates the same scene but with the outlined visualization that could be generated by the proposed system. The outlines clearly separate each step and highlight the edges of the surrounding environment, providing a vivid and easily interpretable view of the staircase. This outlined representation ensures that users can confidently ascend or descend the stairs without the fear of losing their footing, even in low-light settings. Such an enhancement highlights the practical benefits of the project, emphasizing how its implementation could transform challenging environments into navigable spaces for individuals with night blindness or similar conditions.

Fig. 11. Conceptual view of the dark-colored staircase against a wall.

These outlined images, while simulated, effectively demonstrate the potential of the proposed solution. By transforming real-world environments into easily distinguishable visual outlines, the concept showcases a promising direction for improving safety and independence for visually impaired individuals.

E. Alignment with SDG Goal 9: Innovation, Industry, and Infrastructure

The concept of Smart Night-Vision Glasses exemplifies a commitment to advancing innovation within the realm of assistive technologies by leveraging cutting-edge developments in IoT, AI, and sensor technology. The concept represents a significant departure from conventional camera-based solutions, adopting a more advanced approach that integrates non-visible, non-harmful sensors such as LiDAR and infrared with sophisticated AI-driven data processing. This combination creates a user-friendly, real-time representation of the environment that is both intuitive and practical, showcasing how emerging technologies can be adapted to meet specific needs in the field of accessibility.

This innovation directly aligns with Sustainable Development Goal (SDG) 9, which emphasizes the role of technology in fostering inclusive and sustainable industrial development. By addressing a critical gap in assistive devices for individuals with night blindness and RP, the glasses contribute to the creation of accessible technologies that empower marginalized groups. Their potential to enhance independence, safety, and mobility underscores the importance of designing solutions that are both innovative and equitable.

Moreover, the proposed system's reliance on efficient, scalable sensor technologies like those used in autonomous vehicles demonstrates its potential for broader applications and integration into existing infrastructure. This versatility positions the concept as a steppingstone toward more comprehensive IoT ecosystems, where assistive devices are seamlessly interconnected with other smart technologies, promoting inclusivity and sustainability.

V. Challenges and Future Directions

The development of Smart Night-Vision Glasses presents a range of challenges spanning technical, user adoption, and economic considerations. Addressing these hurdles will require multidisciplinary advancements in sensor technology, AI optimization, material science, and human-computer interaction.

A. Technological Challenges

One of the primary technical challenges is sensor miniaturization. Embedding LiDAR, infrared, or ultrasonic sensors into a form factor as small and lightweight as regular glasses requires advanced engineering. These sensors must not only be compact but also maintain high accuracy in various environmental conditions, including fog, rain, and extreme temperatures. Current LiDAR and infrared modules used in autonomous vehicles or industrial applications are too large for wearable integration. A potential solution lies in developing micro-electromechanical systems (MEMS)-based LiDAR or solid-state LiDAR, which could offer the same functionality in a smaller footprint.

Another significant challenge is real-time AI processing and latency reduction. The glasses need to process sensor data instantly to generate a clear and intuitive visual representation without noticeable lag. AI models for object detection, edge enhancement, and depth perception must operate at high speed while consuming minimal power. Solutions may involve algorithmic optimizations, such as employing efficient neural network quantization techniques to reduce the computational burden. Additionally, specialized AI hardware accelerators, such as edge TPU (Tensor Processing Unit) chips, could enable efficient on-device processing without excessive energy consumption.

Power efficiency is another critical issue. Continuous operation of sensors and AI computations demands substantial energy, yet integrating large batteries would compromise the device's weight and comfort. Potential solutions include low-power AI chips, optimized power management algorithms, and energy-harvesting technologies (e.g., thermoelectric generators or solar cells embedded in the frame). Additionally, modular battery packs that allow users to swap or recharge batteries externally could provide extended usability.

Finally, data fusion and calibration pose challenges. The glasses rely on multiple sensor inputs to construct a meaningful visual representation, requiring precise sensor synchronization and dynamic calibration algorithms that adapt to environmental conditions in real-time. Advances in sensor fusion algorithms and adaptive AI models will be key in ensuring accurate perception under varying lighting conditions.

B. User Adoption Challenges

Even if the technical barriers are overcome, widespread adoption depends on user comfort, ease of use, and adaptability.

Ergonomic design and comfort are paramount, as users may need to wear the glasses for extended periods. Unlike traditional night-vision goggles, which are bulky and used intermittently, these glasses must be lightweight, aesthetically appealing, and customizable for different face shapes and prescription lens requirements. Research into advanced lightweight materials, such as graphene-reinforced polymers or titanium alloys, could help reduce weight while maintaining durability.

Learning curve and usability present another hurdle. Users with night blindness or RP may need time to adapt to the AI-generated visual output. The glasses must provide an intuitive and natural visual experience that does not overwhelm or confuse the user. A possible solution is an adaptive AI system that gradually customizes the display output based on the user's preferences and past behavior. In addition, incorporating a guided onboarding process (e.g., interactive tutorials or gradual exposure modes) could ease the transition for new users.

Additionally, public perception and stigma surrounding assistive technologies may impact adoption. If the glasses appear too conspicuous or resemble medical devices, some users may feel self-conscious wearing them in social settings. A sleek, inconspicuous design that mimics standard eyewear will be crucial in normalizing their use and encouraging widespread adoption.

C. Economic and Market Challenges

The affordability of the glasses is a significant factor in market viability. Advanced sensors and AI hardware are expensive, and integrating them into a consumer-grade wearable device may result in high manufacturing costs.

Cost-effective production methods will be essential to making the glasses accessible to a broad audience. Potential strategies include:

- Scaling manufacturing through mass production, which could drive down costs.
- Exploring alternative materials that offer a balance between affordability and performance.
- Leveraging modular hardware designs to allow users to upgrade specific components without purchasing a completely new device.

Market positioning and funding also present challenges. Unlike traditional night-vision goggles, which are typically aimed at military or industrial markets, these glasses target individuals with night blindness and RP. This is a relatively niche consumer base, meaning financial incentives such as insurance coverage, government subsidies, or assistive technology grants may be necessary to ensure widespread adoption. Partnering with healthcare providers, vision impairment advocacy groups, and public health agencies could facilitate market entry.

D. Future Research

To transform this concept into a viable product, a structured research and development (R&D) roadmap is necessary. The following timeline outlines key phases of development:

1) Short-Term (0–2 Years): Foundational Research and Prototyping:

- Conduct feasibility studies on sensor integration and power-efficient AI processing.
- Develop early-stage prototypes focusing on real-time data visualization and sensor fusion.
- Collaborate with materials scientists to design a lightweight, ergonomic frame.
- Begin small-scale user testing to gather feedback on usability and comfort.

2) Mid-Term (3–5 Years): Iterative Development and Field Testing:

- Optimize miniaturized LiDAR/infrared technology for compact, consumer-friendly use.
- Enhance AI models for low-latency, edge-device processing.
- Implement personalized AI adaptation, allowing the glasses to tailor their visual output to individual users.
- Expand user trials, partnering with vision impairment organizations to refine functionality.
- Conduct regulatory assessments and seek approval from assistive technology regulatory bodies.

3) Long-Term (6–10 Years): Commercialization and Widespread Deployment:

- Scale up manufacturing processes for mass production.
- Secure insurance coverage and reimbursement options for affordability.
- Expand the market by integrating cross-platform compatibility (e.g., optional smartphone connectivity for advanced settings).
- Continue AI refinement through real-world data collection to enhance adaptability and accuracy.

Beyond this timeline, future iterations could explore additional innovations such as haptic feedback integration, augmented reality (AR) overlays, or brain-computer interface advancements to further improve accessibility and user experience.

The development of Smart Night-Vision Glasses presents a compelling opportunity to enhance the mobility, safety, and quality of life for individuals with night blindness and RP. However, significant challenges must be addressed, including sensor miniaturization, real-time AI processing, and affordability. Through an iterative R&D approach, leveraging advancements in wearable technology, machine learning, and human-centered design, these challenges can be systematically tackled.

By outlining a structured roadmap for future research and development, this concept moves beyond theoretical discussion into the realm of practical feasibility. If successfully developed, Smart Night-Vision Glasses could redefine accessibility, enabling individuals with vision impairments to navigate the world with confidence and independence.

VI. Conclusion

The Smart Night-Vision Glasses concept represents a transformative leap in assistive technology, offering a non-invasive, AI-driven solution for individuals with night blindness and Retinitis Pigmentosa (RP). By integrating advanced sensor technologies such as LiDAR and infrared, the design proposes an innovative method for enhancing vision in

low-light and dark environments—one that does not rely on traditional camera-based systems or visible light sources. This unique approach not only prioritizes user privacy and security but also ensures optimal functionality in all lighting conditions without being affected by glare, reflections, or light pollution.

A. Key Contributions of this Work

- Conceptualization of a novel assistive device that leverages sensor-based depth perception rather than camera-based vision, addressing privacy concerns and low-light visibility challenges.
- Integration of LiDAR, infrared, and ultrasonic sensing technologies to create real-time, AI-enhanced visual representations of the environment, improving spatial awareness for individuals with night blindness and RP.
- Development of an AI-driven visualization framework that simplifies complex sensory input into clear, user-friendly imagery, allowing for intuitive navigation.
- Exploration of power-efficient, compact hardware designs suitable for a wearable, lightweight form factor, ensuring comfort and prolonged usability.
- Discussion of technical, user adoption, and market challenges, offering practical solutions for sensor miniaturization, AI processing, and affordability to facilitate real-world implementation.
- Proposal of a structured research and development roadmap, outlining future directions in prototyping, AI optimization, field testing, and large-scale deployment over the next decade.

B. Call to Action

While this paper presents a conceptual framework rather than a functional prototype, it lays the foundation for an entirely new class of sensor-based assistive eyewear. To bring this vision to reality, collaboration across multiple disciplines is essential. Researchers, engineers, AI specialists, medical professionals, and assistive technology advocates are encouraged to explore the feasibility of this design, contribute to prototype development, and refine the system through user testing.

Furthermore, industry stakeholders, wearable tech manufacturers, healthcare institutions, and policymakers should consider funding and supporting research into next-generation assistive devices. Addressing the mobility challenges of individuals with vision impairments is not just a technological endeavor; it is a step toward fostering greater accessibility, inclusivity, and independence for millions worldwide.

By advancing this research, we move closer to a future where vision impairments no longer dictate limitations, and individuals with night blindness or RP can navigate their world with confidence, safety, and autonomy.

Comparative Analysis of Cardiac Disease Classification Using a Deep Learning Model Embedded with a Bio-Inspired Algorithm

Nandakumar Pandiyan[1], Subhashini Narayan[2]*
Research Scholar, School of Computer Science Engineering and Information Systems, Vellore Institute of Technology, India[1]
Associate Professor, School of Computer Science Engineering and Information Systems, Vellore Institute of Technology, India[2]*

***Abstract*—Cardiac disease classification is a crucial task in healthcare aimed at early diagnosis and prevention of cardiovascular complications. Traditional methods such as machine learning models often face challenges in handling high-dimensional and noisy datasets, as well as in optimizing model performance. In this study, we propose and compare a novel approach for heart disease prediction using deep learning models embedded in bioinspired algorithms. The integration of deep learning techniques allows for automatic feature learning and complex pattern recognition from raw data, while bioinspired algorithms provide optimization capabilities for enhancing model accuracy and generalization. Specifically, the cuckoo search algorithm and elephant herding optimization algorithm are employed to optimize the architecture and hyperparameters of deep learning models, facilitating the exploration of diverse model configurations and parameter settings. This hybrid approach enables the development of highly effective predictive models by efficiently leveraging the complementary strengths of deep learning and bioinspired optimization. Experimental results on benchmark heart disease datasets demonstrate the superior performance of the proposed method compared to conventional approaches, achieving higher accuracy and robustness in predicting heart disease risk. The proposed framework holds significant promise for advancing the state-of-the-art in heart disease prediction and facilitating personalized healthcare interventions for at-risk individuals.**

***Keywords*—Cardiac disease; heart disease; bio-inspired; machine learning; deep learning; prediction; classification**

I. Introduction

Over the years, people all around the world have fought many terrible illnesses, with heart disease [1] receiving the most attention and is widely recognized in medical studies. It's a well-known illness that strikes a lot of people in their middle or advanced years and can sometimes result in life-threatening complications. Men are more prone to heart disease than women are. A cardiac disease diagnosis is crucial to the prognostication process. Reducing health risks and averting cardiac arrests depends heavily on the early detection of heart disease. According to the World Health Organization (WHO) [2], 17.9 million people worldwide pass away from cardiovascular disorders each year, making it the top cause of mortality worldwide. One significant risk faced by healthcare institutions, including hospitals and clinics, is the provision of quality services at reasonable prices.

Medical professionals are currently using data mining and analytical modeling to learn about various unknown diseases in the future. The key challenges for deep learning include data collection, efficient and interpretable work, integration with other traditional approaches, maintaining imbalanced labels with multimodal data, and the release of new models with other multidisciplinary studies. In the future, this kind of work can be achieved by using the deep learning approach to either feature extraction, classification, or a combination of the two.

A subfield of machine learning known as "Deep Learning" [3] gained prominence in the world, particularly for the classification of diseases. The development of deep learning models has shown promising results in the classification and diagnosis of various cardiac conditions, including arrhythmia, myocardial infarction, and coronary artery disease. Convolutional neural networks (CNNs) [4], which are significant and potent deep learning models, can be improved with additional layers to create neural architecture designed especially for medical applications. The deep learning model can be further enhanced and we can obtain additional network performance in terms of learning rate and dropout rate by using novel data pre-processing, augmentation techniques, and hyperparameter optimization. These are the essential components of effective deep learning techniques in healthcare. The proposed concept focuses on evaluating how different deep-learning models predict and classify cardiac conditions. Several outcomes in the cardiac disease prediction process were discussed and examined in this article, along with their performance using different deep learning techniques. However, the performance of these models can be further enhanced through the integration of bio-inspired algorithms, which can optimize the model's architecture and hyperparameters, leading to improved accuracy and efficiency. This research paper aims to conduct a comparative analysis of cardiac disease classification using deep learning models embedded with bio-inspired algorithms.

The motivation behind this research lies in addressing key challenges in cardiac disease classification using AI-driven techniques. The conventional machine learning and deep learning approaches, while powerful, often require extensive hyperparameter tuning, suffer from model generalization issues, and may lack robustness when applied to diverse datasets. Moreover, high-dimensional medical data, such as ECG signals and cardiac imaging, introduce complexity in feature extraction and classification. Bio-inspired algorithms, including genetic

algorithms (GA), particle swarm optimization (PSO), ant colony optimization (ACO), and artificial immune systems (AIS), mimic natural evolutionary and adaptive processes to optimize model parameters, improve feature selection, and enhance classification accuracy. By embedding a bio-inspired optimization technique within a deep learning framework, the proposed approach aims to enhance model performance, improve computational efficiency, increase generalization ability, enable automated feature selection, and reduce dependence on large labeled datasets.

The integration of a bio-inspired optimization algorithm with deep learning for cardiac disease classification presents several benefits, including higher classification accuracy, efficient feature engineering, scalability and adaptability, reduction in false positives/negatives, and enhanced decision support in clinical settings.

The following is the proposed research work: First, in Section II, the study will review the current state of deep learning techniques in the field of cardiovascular disease diagnosis, highlighting the challenges and limitations of existing approaches. The review will also explore the potential of bio-inspired algorithms to enhance the performance of deep learning models. Next, in Section III, the paper will present the development of a novel deep-learning model integrated with a bio-inspired algorithm for the classification of cardiac diseases. The model will be trained and evaluated on a comprehensive dataset of electrocardiogram signals and other relevant clinical data. The comparative analysis will be conducted by evaluating the performance of the proposed model against other state-of-the-art deep learning architectures, both with and without the integration of bio-inspired algorithms is discussed in Section IV. The difficulties and potential future paths of the suggested effort are covered in Section V. The comparative analysis work is concluded in Section VI with recommendations for further research and use in real-time applications.

II. Literature Review

A review of the literature on machine learning-based heart disease prediction indicates that there is increasing interest in utilizing cutting-edge computational methods to improve the precision and effectiveness of heart disease detection and prediction. Here is a summarized overview of key findings and trends:

Electronic health records (EHRs) [5], clinical databases [6], and public repositories [7] are among the most often used datasets in research. Large-scale datasets make it easier to create solid machine-learning models. Feature selection and extraction strategies [8] are critical for improving model performance while lowering dimensionality. Demographic information, clinical characteristics, and medical history are among the most common components. Various machine learning algorithms are used, ranging from basic methods like logistic regression to more complex techniques like decision trees, support vector machines, and ensemble methods. Deep learning models, particularly neural networks, are becoming popular due to their capacity to automatically learn hierarchical representations. Model performance is often assessed using metrics such as accuracy, sensitivity, specificity, precision, recall, and area under the receiver operating characteristic curve (AUC-ROC). Cross-validation on independent datasets is a standard way to check generalization performance.

Ensemble approaches [9], such as random forests and gradient boosting, are commonly used to increase forecast accuracy and handle imbalanced datasets. Addressing class imbalance in heart disease datasets is a recognized concern, and researchers use strategies such as oversampling, undersampling, and cost-sensitive learning to address it. Some research emphasizes the necessity of using domain knowledge and clinical competence when selecting features, developing models, and interpreting results. With the introduction of wearable technologies and continuous health monitoring, there is a growing emphasis on building models for real-time cardiovascular disease prediction and monitoring [10]. As machine learning models are used in clinical settings, there is a greater emphasis on making algorithms interpretable and offering reasons for predictions, which improves confidence and acceptability among healthcare practitioners.

While machine learning and deep learning approaches have shown promise in heart disease prediction, each has its own set of demerits. The following enumerates the disadvantages of utilizing conventional machine learning techniques for heart disease prediction in contrast to deep learning:

Traditional machine learning frequently relies on human feature engineering, which necessitates domain knowledge to choose appropriate features. This can be time-consuming and may overlook complex patterns in the data. Machine learning methods may struggle to automatically learn complicated hierarchical characteristics from raw data, perhaps missing subtle patterns critical to good heart disease prediction. Scalability issues may arise for traditional machine learning methods when working with big and high-dimensional datasets. This shortcoming may impair their ability to manage the huge amount of heterogeneous data available in healthcare settings. Machine learning methods may struggle to detect nonlinear correlations between features in data. Heart disease prediction frequently involves complicated relationships, which typical machine-learning methods may fail to capture adequately. Traditional machine learning algorithms may fail to appropriately capture the temporal features of heart disease progression. Sequential patterns and time-dependent interactions may be required for reliable forecasts, although they are frequently difficult for these models.

Deep learning models, with their several layers, are excellent at automatically learning hierarchical characteristics from data. This enables them to record complicated linkages and representations, which may lead to better prediction performance. Deep learning models frequently require large amounts of labeled data for training, and performance may degrade if data is constrained. In contrast, traditional machine learning models can sometimes outperform smaller datasets. Deep learning models are computationally expensive, necessitating sophisticated hardware and substantial computational resources. This intricacy can be an impediment, particularly in resource-constrained contexts. Deep learning models are typically regarded as "black boxes," making it difficult to explain their decisions. In healthcare, interpretability is critical for building confidence with clinicians and patients,

and older machine learning models may be more interpretable. Deep learning models, particularly those with many parameters, are susceptible to overfitting, especially when training data is restricted. Regularization techniques are necessary, although they may not eliminate the risk.

The literature survey highlights the promising role of machine learning in heart disease prediction, with a focus on model performance, interpretability, and real-time monitoring. In summary, while deep learning has shown advantages in automatically learning complex features, it comes with challenges such as interpretability issues, computational complexity, and the need for large amounts of labeled data. Traditional machine learning methods may have limitations in capturing intricate patterns but offer advantages in terms of interpretability and scalability with smaller datasets. The healthcare application's criteria for interpretability, the resources at hand, and the characteristics of the dataset will determine which of the two techniques is best. Continued advancements in this field have the potential to significantly impact cardiovascular healthcare. This resulted in the addition of a bioinspired metaheuristic algorithm that powers the suggested work's feature selection and optimization processes. Bio-inspired algorithms [11], such as genetic algorithm, cuckoo search algorithm, particle swarm optimization, elephant herding optimization, simulated annealing, and ant colony optimization, among others, are computational techniques that mimic the behavior of natural systems or processes. These algorithms have been increasingly applied in various fields, including optimization problems in healthcare, such as predicting heart diseases. Here's how bio-inspired algorithms can help optimize dataset features for better accuracy in predicting heart diseases:

One of the key steps in building predictive models is selecting the most relevant features from the dataset. Bio-inspired algorithms can help identify the most informative features by mimicking natural selection processes. To evolve a population of possible feature subsets, for instance, one can utilize genetic algorithms [12], where each subset is a potential solution to the feature selection problem. The algorithm iteratively evaluates and evolves these subsets based on their performance in predicting heart diseases. High-dimensional datasets can lead to overfitting and increased computational complexity. Bio-inspired algorithms can be used for dimensionality reduction by finding a low-dimensional representation of the data that preserves its essential characteristics. Techniques like particle swarm optimization or ant colony optimization can optimize the selection of features or combinations of features that best represent the dataset while minimizing redundancy and noise. Bio-inspired algorithms can also be employed to optimize the parameters of machine learning models used for predicting heart diseases. For instance, genetic algorithms can search the parameter space of complex models such as neural networks or support vector machines to find the combination of parameters that maximizes prediction accuracy. Bio-inspired algorithms can facilitate the creation of diverse ensemble models [13] for predicting heart diseases. These algorithms can be used to generate multiple models with different subsets of features or different parameter settings. Ensemble approaches frequently outperform individual models in terms of prediction accuracy by aggregating the predictions of these several models.

Bio-inspired algorithms can automate the process of hyperparameter tuning, which involves selecting the optimal values for parameters that control the learning process of machine learning algorithms. By exploring the hyperparameter space efficiently, these algorithms can help optimize the performance of predictive models for heart disease prediction. Overall, bio-inspired algorithms provide powerful tools for optimizing dataset features and improving the accuracy of predictive models for heart diseases. By leveraging principles from nature, these algorithms can efficiently explore complex solution spaces and identify high-quality solutions that lead to more accurate predictions. The proposed model for cardiac disease prediction will be analyzed and compared with the deep learning model incorporating a bio-inspired algorithm in the following section.

III. Proposed Model of Cardiac Disease Prediction

Heart disease is one of the most significant ailments that must be treated early on. Humans are encouraged to investigate the AI-driven industry by advances in cardiac and medical technology, which are supported by deep learning models. Based on the statistics presented in the study, deep learning has become the new preferred option for researchers. Researchers are encouraged to explore novel ways of classifying heart diseases using deep learning models. The approach for diagnosing heart disease is based on numerous well-known datasets, including the Cardiovascular Health Study (CHS), Framingham Heart Study, Statlog Heart Disease, and UCI (Cleveland, Hungary, Switzerland). According to this study [14], bio-inspired algorithms can improve the accuracy of deep learning models that include heart disease. Bioinspired computing has the potential to grow and spread throughout several research communities. Future computing generations will surely be greatly impacted by the algorithms covered in the proposed work. It has been demonstrated that biocomputing offers a very natural answer to the issue that many wild animals and humans face. Fig. 1 shows the schematic diagram for the proposed task. It has four layers. The first layer analyses data through collection, preprocessing, and feature selection. The second layer consists of implementing a model, such as a deep learning model, training the model, and optimizing it using the bio-inspired algorithm. The third layer uses metrics including accuracy, precision, recall, and F1-score to assess performance through validation and testing. The fourth layer connects the generated results to the human interaction model, healthcare support systems, and user interfaces.

A. Comparative Analysis of Proposed Work

In this article, we examine two results for heart illness prediction. The first paper discusses how deep belief networks can embed the cuckoo search algorithm, while the second paper discusses how to use a convolutional neural network with the inception-resnet-v2 model. In the first work, the authors [19] employed the feature selection approach, which was followed by a hamming distance-based data-cleaning procedure. After being collected and evaluated, datasets on cardiac disorders are delivered to the cleaning process. The hamming distance feature

selection strategy is used during the data pre-processing stage to manage missing values and eliminate falsified, and unrelated features. Hamming distance is also used to calculate the distance between features from the heart disease dataset. Cross-validating the dataset using test and training data is the next stage. Machine learning methods for classification including logistic regression, Naïve Bayes, decision trees, and support vector machines are used to process the training data. A bioinspired cuckoo search technique combined with an optimized deep learning model classification like deep belief networks handles the testing set. Cuckoo search [21] refers to a significant population-based optimization technique developed by Xin-she Yang et al. in 2009. It works by permeating their oocytes inside the protection of various nourishing birds. Breeding behavior inspires cuckoo search, which is used to tackle a variety of optimization challenges. A cuckoo search is another nature-inspired method that is commonly used to solve various optimization problems across several engineering fields. Larochelle et al. developed deep belief networks [22] as probabilistic generative models acquired by stacked restricted Boltzmann machines in 2007. These networks offer an alternative to the discriminative character of classic neural networks. Two key features of deep belief networks are their ability to encode higher-request network topologies and their quick induction. It uses two probabilities to calculate yields autonomously. They have both coordinated and undirected layers and are made up of double inert components. Unlike previous models, deep belief networks learn all information at each layer. It can be used to record signal data, process images, create video sequels, identify clusters, and train nonlinear autoencoders. Fig. 2 depicts cardiac illness prediction utilizing deep belief networks and embedded cuckoo search.

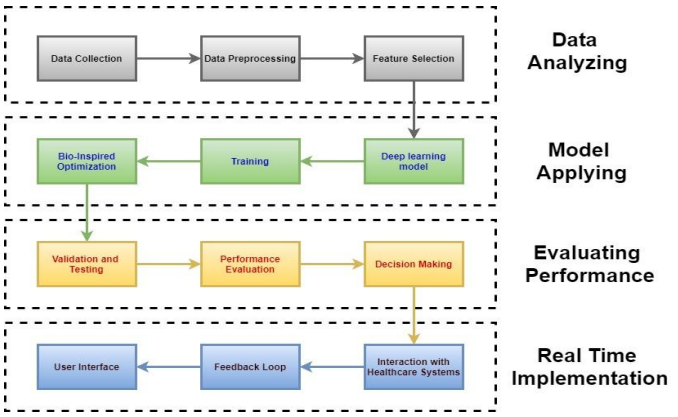

Fig. 1. The schematic diagram of the proposed work.

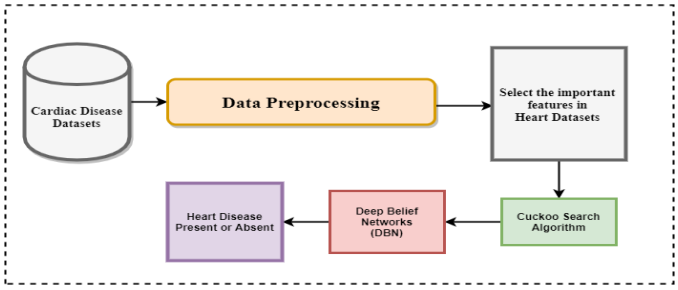

Fig. 2. Cuckoo search algorithm and deep belief networks for the identification of cardiac illness.

The mathematical model of deep belief networks is as follows:

A DBN with l hidden layers contains l weight matrices: $W^{(1)}, \ldots, W^{(l)}$

It also contains $l+1$ bias vectors: $b^{(0)}, \ldots, b^{(l)}$ where $b^{(0)}$ provide the biases for the visible layer.

The probability distribution for DBN is given by,

$$P(h^{(l)}, h^{(l-1)}) \propto exp(b^{(l)^T} h^{(l)} + b^{(l-1)^T} h^{(l-1)} + h^{(l-1)^T} W^{(l)} h^{(l)}) \quad (1)$$

$$P\left(h_i^{(k)} = 1 \middle| h^{(k+1)}\right) = \sigma\left(b_i^{(k)} + W_{:,i}^{(k+1)^T} h^{(k+1)}\right) \quad (2)$$

Where $\forall i, \forall k \in 1, \ldots, l-2$

$$P(v_i = 1 \mid h^{(1)}) = \sigma(b_i^{(0)} + W_{:,i}^{(1)^T} h^{(1)}) \quad \forall i. \quad (3)$$

In the case of real-valued visible units, substitute

$$v \sim N(b^{(0)} + W^{(1)^T} h^{(l)} \beta^{-1}), \quad (4)$$

With β diagonal for tractability $\sigma(x) = 1/(1+exp(-x))$

The weights from the trained DBN can be used as the initialized weights of a DNN,

$$h^{(1)} = \sigma(b^{(1)} + v^T W^{(1)}), \quad (5)$$

$$h^{(l)} = \sigma(b_i^{(l)} + h^{(l-1)^T} W^{(l)}), \forall l \in 2, \ldots, m \quad (6)$$

also, then, at that point, the entirety of the loads is tweaked by applying backpropagation or other discriminative models to enhance the efficiency of the entire network.

The mathematical models of the cuckoo search algorithm are as follows:

When generating new solutions $x^{(t+1)}$ for, say, a cuckoo i, a Lévy flight is defined by equation (7) as follows,

$$x_i^{(t+1)} = x_i^{(t)} + \alpha \oplus Levy(\lambda) \quad (7)$$

Where $x_i^{(t)}$ is the current location of the cuckoo, α is a step size and positive constant tuned according to the dimensions of the search space, $\oplus$ is the entry-wise multiplication and λ is the levy exponent.

The above equation is essentially the stochastic equation for a random walk. The random step length is drawn from a Lévy distribution defined in equation (8) as follows,

$$Levy(\lambda) \sim u = t^{-\lambda}, (1 < \lambda \leq 3) \quad (8)$$

Where λ is the levy exponent that defines the decay of the probability density function (PDF) with t. In most cases, $\alpha = 1$ and $\lambda = 1.5$.

Lévy-flight has the unique virtue of increasing population variety in stages, allowing the algorithm to efficiently exit the local optimum. The following equation (9) is calculated as Levy random numbers,

$$Levy\ (\lambda) \sim \frac{\phi \times u}{|v|^{1/\lambda}} \quad (9)$$

Where u and v are both standard normal distributions, then ϕ is defined in equation (10) as follows:

$$\phi = \left[\frac{\gamma\,(1+\lambda) \times sin\,(\pi \times \lambda/2)}{\gamma\,(((1+\lambda)/2) \times \lambda \times 2^{(\lambda-1)/2})}\right]^{1/\lambda} \quad (10)$$

where, γ is a standard gamma function and ϕ is a random angle used for convergence.

The suggested method outperforms alternative deep learning and machine learning models. Table I presents the latest research conducted by multiple authors on the use of a deep learning model integrated with bio-inspired algorithms to predict heart illness. The heart disease review study analyses the accuracy rates of numerous classification strategies used to detect or forecast it using deep learning models.

TABLE I. ANALYZING AND CONTRASTING DIFFERENT DEEP LEARNING MODELS FOR PREDICTING CARDIAC ILLNESS WITH DATASET INFORMATION

Author Name	Year	Models	Dataset	Accuracy
Girish S. Bhavekar, Agam Das Goswami [15]	2022	RNN, LSTM	UCI Cleveland	95.10%
A Bhardwaj et al., [16]	2023	DCNN	Physionet PCG data	93.07%
AL Golande, T Pavankumar [17]	2023	CNN, LSTM	PTB Diagnostic ECG Data	95.89%
Yunqing Liu et al., [18]	2023	EfficientNet-based network	ECG dataset	73.33%
Nandakumar P, Subhashini R [19]	2022	DBN-CSA	UCI Statlog	91.26%
Nandakumar P, Subhashini R [20]	2024	CNN-Inception-ResNet-v2-EHO	UCI Cleveland	98.77%

In this study [19], the authors employed Euclidean distance to preprocess data. This method is used to sanitize data. For feature selection, a metaheuristic technique such as elephant herding optimization is used. After selecting the best features, a convolutional neural network with the Inception-ResNet-v2 model is used to classify the output based on the chosen features. Elephant herding optimization [23] was used to choose features. Feature selection is viewed as a pre-processing stage in machine learning. One of the most difficult tasks is determining which feature subset in a large or complex dataset is the most relevant. It is now crucial to find important information or hidden patterns in vast amounts of data. It has been demonstrated that feature selection effectively eliminates superfluous features. It can also cut computing costs, increase storage capacity, and improve classifier performance. A convolutional neural network called Inception-ResNet-v2 [24] combines the Inception structure with Residual connections. Multiple convolutional filters of different sizes are combined with residual connections in the Inception-ResNet block. In addition to avoiding the degradation issue with deep structures, adding residual connections speeds up training. Using an Inception-ResNet-v2 model, this study classified the UCI heart disease dataset into two categories: present and missing, as shown in Fig. 3.

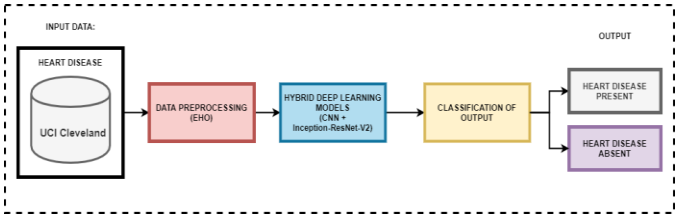

Fig. 3. The combined deep learning model for predicting heart disease.

The mathematical models of EHO begin with two basic notions, then introduce the velocity and separation strategies, and finally apply the elitism strategy to the entire algorithm.

As a result, for the elephant j in clan ci, the position can be updated as:

$$\mathrm{X_{new,ci,j}} = \mathrm{X_{ci,j}} + \alpha \times \left(\mathrm{X_{best,ci}} - \mathrm{X_{ci,j}}\right) \times \mathrm{r} \quad (11)$$

Where $X_{new,ci,j}$ and $X_{ci,j}$ are new and old positions for elephant j in clan ci, respectively. $\alpha \in [0,1]$ is a scale factor. $X_{best,ci}$ represents the best position in clan ci. $r \in [0,1]$ is a commonly distributed random number.

In Eq. (11), the matriarch's position has not changed. It can be updated as follows for the fittest individual:

$$\mathrm{X_{new,ci,j}} = \beta \times \mathrm{X_{center,ci}}, \quad (12)$$

$$\mathrm{X_{center,ci}} = \frac{1}{\mathrm{n_{ci}}} \times \sum_{\mathrm{j=1}}^{\mathrm{n_{ci}}} \mathrm{X_{ci,j}}, \quad (13)$$

where, $\beta \in [0,1]$ is a scale factor. $X_{center,ci}$ is the middle place in clan ci. n_{ci} is the number of elephants in clan ci. The positions of all the clan members may be observed to be modified by the matriarch.

Male elephants live alone after being separated from their group. The EHO method is designed to replace the worst elephant in each clan with a separation operator. The procedure can be shown in Eq. (14):

$$\mathrm{X_{worst,ci}} = \mathrm{X_{min}} + (\mathrm{X_{max}} - \mathrm{X_{min}} + 1) \times \mathrm{r}, \quad (14)$$

where, $X_{worst,ci}$ symbolizes the lousiest elephant in clan ci. The elephant position's upper and lower boundaries are X_{max} and X_{min}, respectively.

In this work, the input consists of one-dimensional data with $x = (x_1, x_2, x_3, \ldots\ldots, x_{n-1}, x_n, clabel)$ where $x_n \in R^d$ denotes the heart disease features and $clabel \in R$ denotes a class label used for the output of either heart disease present or absent. Conv1D is used to generate a feature map Fm. The convolution operation is then applied to the heart disease input data with filtering of $w \in R^{\mathrm{F}d}$ where F represents the intrinsic properties of the input data that will produce the final output after feeding it into the next input block.

From the set of features, the new feature map Fm is obtained as follows:

$$h\ell_i^{\mathrm{F}m} = tanh(w^{\mathrm{F}m} x_{i:i+\mathrm{F}-1} + b) \quad (15)$$

where, $h\ell$ is the filter employed for each set of heart disease input features F is defined as:

$$\{x_{1:\mathrm{F}}, x_{2:\mathrm{F}+1}, x_{3:\mathrm{F}+2}, \ldots\ldots, x_{n-\mathrm{F}+1}\} \quad (16)$$

From Eq. (16), the generated feature map is,

$$h\ell = [h\ell_1, h\ell_2, h\ell_3, \ldots, h\ell_{n-F+1}] \quad (17)$$

where, $b \in R$ denotes a bias term and the filter $h\ell \in R^{n-F+1}$.

In addition to numerous bio-inspired algorithms, they offer powerful optimization capabilities and are increasingly being applied in various fields to solve complex problems and improve system performance in real-time applications. The following part will describe the acquired results and compare them with other models.

IV. Results and Discussion

This section presents the findings and examines the various cardiac illness datasets that the proposed model has tested on. This study [19] used the benchmark datasets from the UCI machine learning repository. The authors introduced a feature selection approach combined with a deep belief network model to analyze and forecast heart illness. The data has been preprocessed, and the outcomes are beautifully categorized using distinct dataset features. The hamming distance feature selection method was used to gather and clean several cardiac datasets. After selecting crucial criteria, the data is transmitted to deep belief networks coordinated with varied degrees of depth cuckoo search bio-inspired algorithms, resulting in precise cardiac disease prediction. Furthermore, it was demonstrated that the proposed prediction model outperformed alternative machine learning models in terms of performance. This work's primary contribution is the diagnosis of heart disease using deep learning models, like the Deep Belief Network. The model was first tested with 100 random executions without using feature selection, and the results are reported in Table II. The model was again tested with 100 random executions using feature selection, and the results are reported in Table III. The bio-inspired technique is then optimized, increasing the accuracy of identifying heart disease. We obtained an accuracy of 91.2% from Statlog's heart disease dataset by utilizing a deep belief network and the Cuckoo search technique.

We have concentrated on the accuracy, and area under the receiver operating characteristic curve metrics to show the efficacy of heart disease prediction. Fig. 4 and Fig. 5 show the results achieved using the proposed model.

TABLE II. Performance of Classifiers without using Feature Selection on 100 Randomized Tests in UCI Statlog Dataset

Model	Sens (%)	Spec (%)	F1-Score (%)	Pre (%)	Acc (%)

The probability that a parameter will fall between two values around the mean is shown by a confidence interval. Confidence intervals quantify how reliable or uncertain a sampling technique is. They are often constructed with 95% confidence levels. In this work, an area under the curve is calculated by the variance, and 95% confidence intervals are evaluated to the performance metrics such as accuracy, error rate, runtime, AUC, and ROC by the quantile function of the normal distribution.

TABLE IV. Classification Performance of DBN with Confidence Intervals

Dataset	Error rate (CI)	Acc (CI)	Runtime (CI)	AUC (CI)	ROC (CI)
Cleveland	0.47	86.1	18.31	0.85	0.86
Hungarian	0.64	83.6	18.42	0.83	0.83
Statlog	**0.43**	**85.7**	**22.56**	**0.83**	**0.84**
Switzerland	0.56	85.6	21.57	0.83	0.82
South Africa	0.47	84.7	22.17	0.84	0.86
Z-Alizadeh Sani	0.64	85.6	22.14	0.85	0.84
Framingham	0.47	85.7	20.43	0.86	0.85

Table IV presents the classification performance of a Deep Belief Network (DBN) across various datasets, along with their respective confidence intervals (CI). The table includes the following columns: Dataset: The name of the dataset used for evaluation. Error Rate (CI): The proportion of incorrect predictions made by the model, accompanied by confidence intervals. Accuracy (CI): The percentage of correct predictions, also with confidence intervals. Runtime (CI): The time taken to run the model, including confidence intervals. AUC (CI): The Area Under the Curve, a performance measurement for classification problems at various threshold settings, with confidence intervals. ROC (CI): The Receiver Operating Characteristic curve, which illustrates the diagnostic ability of a binary classifier system, along with confidence intervals. The Cleveland dataset shows a relatively low error rate and high accuracy, indicating that the model performs well. The AUC and ROC values are also high, suggesting good discrimination ability. The Hungarian dataset has a higher error rate compared to Cleveland, resulting in lower accuracy. The AUC and ROC values are slightly lower, indicating a reduced ability to distinguish between classes. Statlog has the lowest error rate among the datasets, which correlates with a high accuracy. However, the runtime is longer, and the AUC and ROC values are slightly lower than Cleveland, suggesting a good but not exceptional performance. The Switzerland dataset shows a moderate error rate and accuracy. The AUC and ROC values indicate a decent performance, but the model is less effective compared to Cleveland and Statlog. Similar to Cleveland, the South Africa dataset has a low error rate, but the accuracy is slightly lower. The AUC and ROC values are strong, indicating good classification performance. This dataset has a higher error rate, which affects its accuracy. However, the AUC is relatively high, suggesting that while the overall accuracy is lower, the model can still effectively distinguish between classes. The Framingham dataset shows a low error rate and high accuracy, similar to Cleveland. The AUC and ROC values are also strong, indicating effective classification. Best Performance: Cleveland and Framingham datasets exhibit the best performance with low error rates and high accuracy. Moderate Performance: Statlog and South Africa datasets show good performance but with slightly longer runtimes. Lower Performance: Hungarian and Z-Alizadeh Sani datasets have higher error rates and lower accuracy, indicating room for improvement in classification.

The proposed DBN classifier with receiver operating characteristics curves is shown in Fig. 6 for Statlog dataset and Fig. 7 for Cleveland dataset. This work enhances the deep belief network approach employing cuckoo search optimization to get optimal hyper-tuning parameters for cardiac illness diagnosis from the benchmark dataset.

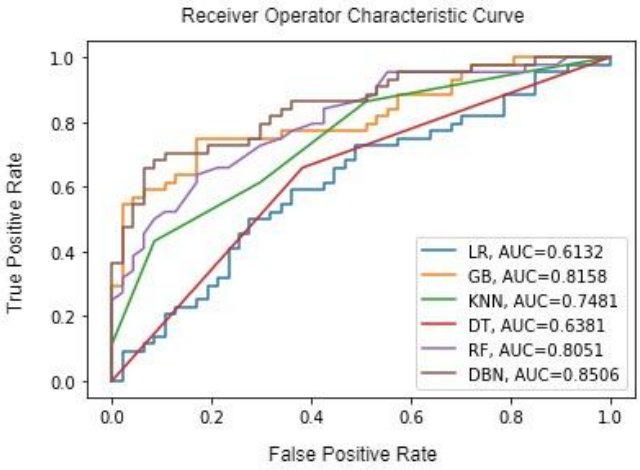

Fig. 7. Receiver operating characteristic (ROC) curves of DBN classifier for Cleveland dataset with other models.

People of all ages benefit greatly from early detection of heart disease. This study uses UCI datasets to increase heart disease prediction accuracy. This study [20] presents three key strategies for predicting heart disease: convolutional neural networks, elephant herding optimization, and Inception-ResNet-v2. After pre-processing the data with the standard Euclidean Distance approach, elephant herding optimization (EHO) is used to pick features and also to minimize the local optimal issue. Then, utilizing well-known UCI data sources like the Cleveland dataset, the popular classifier convolutional neural network with an Inception-ResNet-v2 is employed to classify heart disease. The initial part, data pre-processing, is carried out using the standard Euclidean Distance technique. The input features are then sent to the elephant herding optimization, which selects the relevant features for the classification models. The study also found that the elephant herding optimization strategy enhanced the number of selected features, convergence speed, and classification performance.

While Inception-ResNet-v2 is primarily designed for image classification tasks, it can still offer benefits in the classification of heart disease based on categorical data, although it might not be the most suitable choice compared to models specifically designed for tabular data. Heart disease classification often involves understanding complex relationships between various risk factors, symptoms, and medical history. Inception-ResNet-v2's deep architecture allows it to capture intricate patterns and dependencies within the data, potentially uncovering non-linear relationships that simpler models might overlook. Once trained, deep learning models like Inception-ResNet-v2 can be deployed in production environments to automate the classification of heart disease from categorical data. This scalability enables consistent and efficient processing of patient data, potentially improving healthcare outcomes by identifying high-risk individuals more quickly and accurately. For the Cleveland dataset, the proposed model achieved an accuracy of 98.77%, beating other cutting-edge techniques. When compared to existing meta-heuristic and deep learning models, the proposed hybrid model has significantly improved efficiency in classification and more solid outcomes.

Future modifications to the proposed model may include further unique metaheuristic-based techniques on large datasets for the early diagnosis of cardiac disease, which is a serious worry for those who have recovered from COVID-19. Future trials of EHO's efficacy will focus on increasingly demanding scientific and technical areas. Furthermore, the proposed model can be combined with ensemble models to increase performance metrics in the detection and prediction of various diseases. The model was tested, and the results of various performance metrics compared with other models are provided in Table V. Fig. 8 depicts the results achieved using a proposed model.

TABLE V. PERFORMANCE METRICS COMPARING THE PROPOSED MODEL WITH OTHER MODELS FOR THE CLEVELAND DATASET

Model	Sens (%)	Spec (%)	F1-Score (%)	Pre (%)	Acc (%)
RF	92.2	84.3	89.2	87.3	88.4
MLP	88.4	75.1	84.5	80.1	82.3
KNN	84.1	73.4	80.1	77.4	79.4
SVM	87.6	75.7	83.4	79.2	81.3
Adaboost	86.5	77.3	83.6	81.3	83.4
Proposed: CNN-Inception-ResNet-v2 model	93.3	85.2	90.5	87.4	98.7

The provided data from Table II, Table III, and Table V presents the performance metrics of various machine learning and deep learning models, including Decision Tree (DT), Random Forest (RF), K-Nearest Neighbors (KNN), Support Vector Machine (SVM), Artificial Neural Network (ANN), Deep Belief Network (DBN), Multi-Layer Perceptron (MLP), and Adaboost, as well as proposed models such as Convolutional Neural Network (CNN) and Inception-ResNet-v2. The evaluation metrics include Sensitivity, Specificity, F1-Score, Precision, and Accuracy. In the first set of results, the proposed DBN model outperforms the other models with the highest Sensitivity (90.5%), Specificity (91.4%), F1-Score (90.2%), Precision (91.5%), and Accuracy (91.2%). Notably, SVM and ANN also demonstrate competitive performance. In the second set of results, the proposed CNN- Inception-ResNet-v2 model exhibits the best performance across all metrics, with a Sensitivity of 93.3%, Specificity of 85.2%, F1-Score of 90.5%, Precision of 87.4%, and Accuracy of 98.7%.

In Work 2, the proposed CNN-Inception-ResNet-v2 model outperforms the other models in terms of sensitivity, specificity, F1-score, precision, and accuracy. The sensitivity of the proposed model is 93.3%, which is higher than the other models. Similarly, the specificity, F1-score, precision, and accuracy of the proposed model are also higher compared to the other models. Specifically, the specificity is 85.2%, the F1-score is 90.5%, the precision is 87.4%, and the accuracy is 98.7%. These values indicate that the proposed CNN-Inception-ResNet-v2 model demonstrates superior performance across all metrics in Work 2. This suggests that the proposed CNN model is particularly effective for the given task. The findings of this research will contribute to the ongoing efforts to improve the accuracy and reliability of cardiac disease diagnosis using advanced machine learning techniques. The integration of bio-inspired algorithms with deep learning models has the potential to enhance the clinical decision-making process, leading to more personalized and effective treatment strategies for patients with cardiovascular diseases.

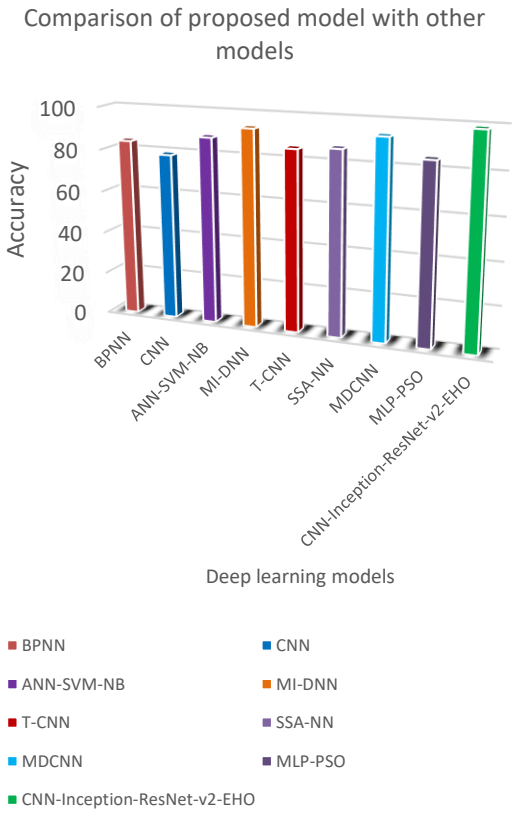

Fig. 8. Comparison of the CNN-Inception-ResNet-v2-EHO model with other methods.

TABLE VI. COMPARATIVE ANALYSIS OF COMPUTATIONAL COMPLEXITY OF DBN AND CNN

Aspect	DBNs	CNNs
Training Complexity	Higher due to Gibbs sampling and layer-wise training.	High due to convolution operations but often faster than DBNs.
Inference Complexity	Moderate; depends on the number of layers.	High; dominated by convolutional layers.
Parallelization	Difficult to parallelize.	Well-suited for parallelization on GPUs.
Scalability	Challenging for large datasets.	Highly scalable with optimized architectures.

From Table VI, DBNs are computationally intensive and less suited for large-scale tasks compared to CNNs, primarily due to the unsupervised pretraining and lack of efficient parallelization. CNNs, despite being computationally expensive, benefit from hardware accelerations like GPUs, making them more practical for real-world applications.

In summary, the evaluation of various machine learning and deep learning models reveals that the proposed DBN model in the first set of results and the proposed CNN- Inception-ResNet-v2 model in the second set of results outperform the other models in terms of Sensitivity, Specificity, F1-Score, Precision, and Accuracy that are shown in Fig. 9. These findings indicate the potential of these proposed models for the specific task at hand, demonstrating their effectiveness in comparison to traditional machine learning algorithms such as DT, RF, KNN, SVM, ANN, MLP, and Adaboost. These results provide valuable insights for selecting the most appropriate model for the given classification task, emphasizing the significance of considering proposed models in addition to established algorithms. By leveraging the complementary strengths of deep learning and nature-inspired algorithms, the proposed approach seeks to enhance the accuracy, efficiency, and robustness of AI-based cardiac disease detection systems when compared with the existing approaches. The findings of this research can contribute to the development of advanced clinical decision-support tools, ultimately improving early diagnosis and treatment outcomes for patients suffering from cardiovascular disorders.

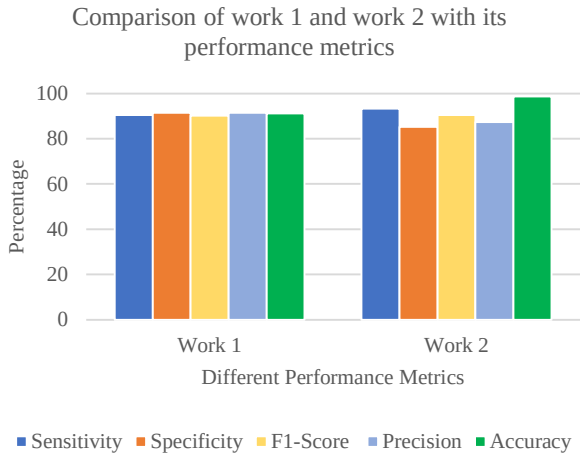

Fig. 9. Comparison of work 1 and work 2 with its performance metrics.

The deep learning incorporated bio-inspired algorithms for heart disease prediction offer various merits: The first and foremost one is improved accuracy. Deep learning models, with their ability to detain complex schemes and relationships in data, can enhance the accuracy of heart disease predictions. The integration of bio-inspired algorithms further refines model parameters, leading to better performance. The second is feature optimization. Bio-inspired algorithms aid in feature selection, optimizing the choice of relevant variables for prediction. This can enhance the efficiency of the model by addressing the most informative properties and lessening noise. The third is automated learning. Deep learning enables automated learning from data, allowing the model to adapt and improve its predictions over time without manual intervention. Bio-inspired algorithms contribute to automating the optimization process, making the system more adaptive.

The fourth is generalization. Deep learning models, when properly trained and validated, have the potential to generalize well to new, unseen data. This is crucial for the reliability of a heart disease prediction system, as it should perform well on diverse patient populations. The fifth is real-time monitoring. The integration of deep learning and bio-inspired optimization allows for the development of models that can provide real-time predictions. This is valuable for continuous monitoring of individuals and timely interventions. The sixth is personalized medicine. The ability to optimize models using bio-inspired algorithms allows for personalized and adaptive prediction models. This ensures that the system can cater to individual variations and provide more accurate risk assessments.

The seventh is efficient data utilization. Bio-inspired algorithms can optimize the use of available data, extracting meaningful information from large datasets. This efficiency is particularly important when dealing with healthcare data, which may be limited in size and complexity. The eighth is reduced human bias. Automated feature selection and optimization processes can help reduce human bias in decision-making. The model focuses on data-driven patterns, minimizing the impact of subjective judgment. The ninth is continuous improvement. The inclusion of bio-inspired optimization creates a continuous improvement loop. The model can be updated and refined over time as more data becomes available, ensuring that it stays relevant and effective. The tenth is interpretability. While deep learning models are often considered black boxes, the optimization process can provide insights into the importance of specific features, contributing to the interpretability of the model to some extent. The last and best thing about the proposed work is the early detection of the diseases. The predictive nature of the model, coupled with continuous monitoring, can contribute to the early detection of potential heart disease risks. Early intervention can significantly improve patient outcomes. It's important to note that while these merits are significant, challenges such as data privacy, interpretability of deep learning models, and ethical considerations need careful attention in the development and deployment of such systems in healthcare settings. Additionally, collaboration with healthcare professionals is crucial to ensure the clinical relevance and safety of the predictions made by the system.

V. Challenges and Future Directions

Heart disease prediction using deep learning embedded bio-inspired algorithms presents a unique set of challenges and offers exciting future directions. Here's a summary of challenges and potential avenues for further exploration in this specific context:

A. Challenges

To integrate bio-inspired algorithms with deep learning, certain hyperparameters must be tuned. The intricacy of optimizing both the deep learning architecture and the bio-inspired algorithm parameters might be daunting. The combination of deep learning and bio-inspired algorithms may produce models that are challenging to understand. Ensuring openness and interpretability in decision-making is critical, particularly in healthcare applications. Heart disease prediction frequently relies on many databases, such as medical history, and genetic information. Integrating these many data sources while including bio-inspired algorithms increases complexity and necessitates efficient preprocessing and feature extraction approaches. Deep learning models, particularly those integrated with bio-inspired algorithms, can be computationally costly. It is difficult to ensure accessibility and scalability, especially in resource-limited healthcare settings. As with any use of artificial intelligence [25] in healthcare, securing patient privacy, consent, and ethical data utilization is critical. The integration of bio-inspired algorithms should follow ethical principles and legislation.

B. Future Directions

Creating innovative hybrid architectures that smoothly blend deep learning and bio-inspired algorithms, leveraging the advantages of both approaches. This could include novel model architectures or optimization methodologies. Incorporating explainable AI approaches improves model interpretability. This entails creating bio-inspired algorithms that provide insights into their decision-making process, hence enhancing trust and understanding among healthcare professionals. Increasing the use of deep learning incorporated bio-inspired algorithms in real-time monitoring and personalized treatment. This could entail continuously monitoring patient data and dynamically adjusting predictive algorithms depending on individual health trajectories.

Ensure that models are reliable across diverse populations, demographics, and healthcare contexts. The models must be generalized beyond the training data to be useful in a variety of clinical settings. Leveraging the growing popularity of wearable devices for continuous health monitoring. Integrating bio-inspired deep learning models with wearable data could yield useful insights into early identification and prevention of heart disease. Addressing the difficulty of unbalanced datasets in heart disease prediction by using bio-inspired algorithms that are specifically intended to deal with class imbalances successfully. Conducting comprehensive clinical validation studies to evaluate the real-world performance of bio-inspired deep learning algorithms. Collaboration with healthcare professionals is critical to the successful implementation of these models in clinical practice.

The integration of deep learning with bio-inspired algorithms for cardiac disease prediction has enormous potential, but it must overcome hurdles such as model complexity, interpretability, data integration, and ethical considerations. Challenges include the requirement for standardized databases, ethical constraints, and the integration of multimodal data sources. Future research should focus on discovering novel solutions to these problems, ultimately increasing the usefulness and applicability of these models in healthcare settings. Future research directions include researching explainable AI [26], incorporating genome data [27], and improving the interpretability of deep learning models to increase clinical adoption.

VI. Conclusion

In conclusion, our study demonstrates the efficacy of employing deep learning models embedded with bio-inspired algorithms for the classification of cardiac diseases. Through a comparative analysis, we have shown that this approach outperforms traditional methods in accurately diagnosing cardiac conditions from medical data. The proposed model enhances the classification accuracy by effectively handling complex and high-dimensional data, extracting relevant features, and optimizing model parameters. This synergy exploits the benefits of both approaches, manipulating the powerful learning capabilities of deep neural networks and the optimization prowess of bio-inspired algorithms.

Furthermore, our findings suggest that the proposed methodology holds promise for improving clinical decision-making processes, enabling timely and accurate diagnosis of cardiac diseases. By providing reliable predictions based on diverse medical data sources, this approach can assist healthcare professionals in delivering personalized treatment strategies and improving patient outcomes. Overall, the successful application of the proposed work in cardiac disease classification underscores their potential for advancing medical diagnostics and contributing to the development of more efficient and effective healthcare systems. Future research endeavors should focus on further refining and validating these methods across global benchmark datasets to facilitate their integration into clinical practice. Deep learning is becoming a more prominent use of machine learning, with recent discoveries directing future research on prognostic models that can save many lives and enhance quality of life. This will save countless lives while also reducing the financial burden on individuals with regular earnings.

Quantum Swarm Intelligence and Fuzzy Logic: A Framework for Evaluating English Translation

Pei Yang*
Henan University of Economics and Law, HeNan, ZhenZhou, 450046, China

***Abstract*—This study introduces the Quantum Swarm-Driven Fuzzy Evaluation Framework (QSI-Fuzzy) for assessing English translation software across multiple domains and criteria. The principal aim is to develop a scalable, adaptive, and interpretable evaluation framework that optimizes dynamic weight assignments while managing linguistic uncertainties. A major challenge in translation software evaluation lies in ensuring accurate and unbiased assessments of semantic accuracy, fluency, efficiency, and user satisfaction, particularly across diverse domains such as Legal, Medical, and Conversational contexts. To address this, QSI-Fuzzy integrates Quantum Swarm Intelligence (QSI) for dynamic weight optimization with fuzzy logic for handling linguistic uncertainties, ensuring robust and adaptive decision-making. Experimental results demonstrate that QSI-Fuzzy outperforms benchmark algorithms including Genetic Algorithm (GA), Particle Swarm Optimization (PSO), and Simulated Annealing (SA), achieving faster convergence (55 iterations on average vs. 120 for SA) and exhibiting greater robustness under noisy conditions (maintaining a performance score of 0.80 at 20% noise, compared to 0.70, 0.68, and 0.65 for GA, PSO, and SA, respectively). These findings confirm that QSI-Fuzzy provides an efficient, scalable, and high-performance solution for translation software evaluation, with broader implications for real-time systems, complex decision-making, and multi-domain optimization challenges.**

Keywords*—English translation software; quantum swarm intelligence; fuzzy logic; multi-domain evaluation; optimization; linguistic performance analysis

I. Introduction

The rapid development in the field of NLP has, therefore, caused an unprecedented rise in the development of software intended for English translation. Regarding this, tools like Google Translate, DeepL, and Microsoft Translator have become omnipresent due to their capabilities in overcoming linguistic barriers and fostering communication across the world. The cultural nuances, the contextual accuracy, and syntactical variations in a language make such a translation system a grand challenge for evaluation. The traditional metrics are BLEU [1] and METEOR [2] that give quantitative assessments, but still fall short to show the qualitative aspects of translation; hence, new methodologies have to be designed for a more holistic evaluation.

Quantum-inspired swarm intelligence is one of the recent fields in computational intelligence which provides an attractive way of optimizing complex systems. Inspired by the principles of quantum mechanics, these algorithms have performed better in optimization problems in machine learning and logistics fields [3], [4]. This hybrid could be combined with fuzzy logic, a mathematical approach for dealing with uncertainty and imprecision, to establish a robust framework for the evaluation of translation software [5]. The combination of Quantum Swarm Intelligence, which has the capability of optimization, with the flexibility of fuzzy systems, makes it an appropriate methodology to be applied for dealing with those thorny issues involved in the quality assessment of translation.

Recent studies demonstrate that these hybrid models function effectively when applied to decision-making problems [6]. For example, hybrid quantum swarm algorithms have been employed in areas such as image processing [7], supply chain optimization [8], and medical diagnosis [9] with highly satisfactory results. Similarly, fuzzy logic has been proved to function effectively within linguistic fields such as sentiment analysis and text classification, all of which are definitely dependent upon subjective judgment [10, 11]. This research stretches further in these developments by suggesting a hybrid quantum swarm intelligence model with fuzzy logic that can evaluate the semantic accuracy, fluency, and contextual relevance in English translation software [12].

The uniqueness of the model proposed is the ability to combine strengths of quantum swarm intelligence together with fuzzy logic for an enhanced decision-making process. It is the integration along such lines that makes the model particularly effective in adapting the fluidity of language with a view to addressing the intrinsic uncertainties inherent in linguistic evaluation. This work, in fact, is underpinning an ability to be demonstrated by this hybrid model for providing a wholesome and reliable assessment model compared to those from traditional frameworks. The contribution of this study will lie in the adoption of state-of-the-art computational approaches for setting a new benchmark in the evaluation of translation systems, further enriching vast areas of natural language processing and decision science.

The remainder of this paper is structured as follows: Section II presents the related works, providing an overview of existing translation evaluation frameworks and optimization techniques. Section III details the methodology, explaining the design of the proposed QSI-Fuzzy framework, its components, and the optimization process. Section IV discusses the results and evaluation, highlighting the comparative performance of QSI-Fuzzy algorithms. Finally, Section V concludes the study, summarizing key findings and outlining potential future research directions.

II. Related Work

There is a growing body of research related to the evaluation and improvement of machine translation software, especially due to recent developments in the area of computational intelligence. A few recent works deal with new metrics and hybrid models to improve the quality of translation and evaluation. Along this line, Mohiuddin and Joty [13] introduced the first end-to-end metric for machine translation that deeply looks into contextual embeddings and proves to have much stronger correlation with human judgments than those in existing metrics. This paper, emphasizing the importance of contextual information, proposes a superior approach to estimate semantic coherence in translation. In a somewhat related concept, Zhang et al. [14] introduce a transformer-based framework in translation quality assessment that involves both semantic consistency and syntactic alignment. All these approaches taken together provide a base for involving more automation and interpretability in the evaluation processes associated with translation.

In the general case, quantum-inspired computational methodologies were pointed out as one of the most promising ways to tackle complex optimization problems both in translation and outside. Suresh et al. [15] implemented quantum-enhanced swarm optimization to solve tasks of natural language processing and demonstrated higher efficiency while evaluating translation software. This research recognized the possibility of using quantum principles for the expansion of search space and reduction of computational loads. Besides, Cai et al. [16] came up with the multi-objective quantum optimization algorithm, which would be powerful in bringing out its own capability to optimize different types of objectives that conflict with each other, underlining its importance regarding linguistic applications. Indeed, all these developments bring into view the adaptability of quantum methodologies in the solution of intricacies related to natural language processing.

Besides, the integration of fuzzy logic into the computational frameworks has been amazing, hence yielding effective results in dealing with uncertainties arising intrinsically in performing the translation tasks. Zhou et al. [17] discussed hybrid quantum and fuzzy models for decision-making over complicated systems to deal directly with challenges that arise owing to impreciseness in translation quality assessment. Dash et al. [18] presented a hybrid swarm optimization-based fuzzy clustering method that resolves linguistic ambiguities to have a better clustering with semantic analysis. Such schemes depict that the use of fuzzy logic with computation intelligence improves reliability and interpretability of translations generated during evaluation.

More recent studies in neural machine translation have, therefore, shaped the way evaluation models have been designed. Vaswani et al. [19] came up with the Transformer model later, which revolutionized machine translation by introducing better modeling of long-range dependencies through its attention mechanism. Using this architectural design as a source of inspiration, Yang et al. [20] proposed the contextual evaluation frameworks that make use of attention-based metrics to assess coherence between source and target translations. These frameworks have brought in a solid methodology of capturing global and local dependencies within the translation quality assessment and increased the accuracy of the automatic assessments.

The modern concept applies hybrid models of quantum-inspired algorithms with fuzzy decision-making processes, exploring the capability of being applied in multi-criteria decision scenarios. Such models have been effectively tried in handling linguistic ambiguities using quantum-inspired evolutionary algorithms, reinforcing the process of decision making, by Tarik et al. [21]. Along the same line, other works, such as Gupta et al. [22], have applied hybrid approaches to machine translation system evaluation, including fuzzy logic for representing semantic nuances. These results imply that hybrid quantum-fuzzy models can contribute significantly to enhancing translation evaluation with robustness, efficiency, and interpretability to tackle challenges at both computational and linguistic levels.

III. Methodology

The section outlines a methodological framework in adopting a hybrid model combining Quantum Swarm Intelligence with fuzzy decision-making for evaluating English translation software. This would, by this means, enable the computational efficiency of QSI, along with the uncertainty management characteristics accorded by fuzzy logic, to be employed towards establishing a comprehensive evaluation framework for translation software. The pseudo code of the designed framework has been detailed in Table I.

A. Problem Formulation

Evaluation of English translation software represents a complex multi-domain multi-criteria decision-making problem. The translation tools need to perform optimally on diverse contexts, including legal, medical, and conversational domains, where the priorities and metrics for evaluation are significantly different. Besides, the evaluation has to take into consideration interdependencies of criteria, dynamic domain-specific requirements, and real-world constraints such as computational efficiency and scalability.

Let $S = \{s_1, s_2, \dots, s_n\}$ represent the set of n translation software tools under evaluation. Each software s_i is evaluated based on m criteria, $= \{c_1, c_2, \dots, c_m\}$, where c_j denotes the j-th evaluation metric. These metrics may include semantic accuracy, syntactic coherence, fluency, computational efficiency, and user satisfaction. Furthermore, the evaluation spans k domains, $= \{d_1, d_2, \dots, d_k\}$, each characterized by unique evaluation priorities and contextual factors [23].

The performance of software s_i under criterion c_j in domain d_k is denoted by x_{ij}^k. These scores form a three-dimensional evaluation tensor X, defined as:

$$X = \left\{ x_{ij}^k \mid i = 1, \dots, n; j = 1, \dots, m; k = 1, \dots, k \right\}, \quad (1)$$

where x_{ij}^k represents the quantitative performance measure of software s_i under criterion c_j in domain d_k.

To account for domain-specific priorities, each domain d_k is assigned a weight vector $w^k = \{w_1^k, w_2^k, \dots, w_m^k\}$, where w_j^k

reflects the relative importance of criterion c_j in domain d_k. The weights satisfy the constraints:

TABLE I PSEUDOCODE REPRESENTATION OF THE QUANTUM SWARM-DRIVEN FUZZY EVALUATION FRAMEWORK FOR MULTI-DOMAIN AND MULTI-CRITERIA EVALUATION

Input: Translation software $S = \{s_1, s_2, \ldots, s_n\}$, domains $D = \{d_1, d_2, \ldots, d_k\}$, criteria $C = \{c_1, c_2, \ldots, c_m\}$, performance scores $X = \{x_{ij}^k\}$, domain weights α_k, quantum parameters P, $T_{\max}$, and ϵ
Output: Optimized weights $W = \{w_j^k\}$ and aggregated software scores $\tilde{F}(s_i)$
Step 1: Initialization
for $k = 1$ to K (domains) **do**
  for $j = 1$ to m (criteria) **do**
    Initialize each quantum particle q_j^k with probability amplitudes α_j^k and β_j^k
    Initialize global best position g^k and personal best position p^k
  end for
end for
Step 2: Fitness Evaluation
for $t = 1$ to $T_{\max}$ **do**
  for each particle q_j^k in each domain d_k **do**
    Collapse quantum state to classical weight vector $w^k = \{w_1^k, w_2^k, \ldots, w_m^k\}$
    Compute fitness $F^k(w^k)$ for domain d_k:

$$F^k(w^k) = \frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{m} w_j^k \cdot x_{ij}^k$$

  end for
end for
Step 3: Quantum State Update
for each particle q_j^k in each domain d_k **do**
  Update probability amplitudes α_j^k and β_j^k:

$$\begin{bmatrix}\alpha_j' \\ \beta_j'\end{bmatrix} = \begin{bmatrix}\cos(\theta_j) & -\sin(\theta_j) \\ \sin(\theta_j) & \cos(\theta_j)\end{bmatrix}\begin{bmatrix}\alpha_j \\ \beta_j\end{bmatrix}$$

  Compute rotation angle $\theta_j = \eta \cdot \frac{\partial F(w^k)}{\partial w_j^k}$
end for
Step 4: Fuzzy Decision-Making
for each software s_i in each domain d_k **do**
  Compute fuzzy-adjusted score for s_i in d_k:

$$\tilde{F}_k(s_i) = \sum_{j=1}^{m} w_j^k \cdot \mu(x_{ij}^k)$$

end for
Step 5: Aggregation Across Domains
Compute overall score $\tilde{F}(s_i)$ for each software s_i:

$$\tilde{F}(s_i) = \sum_{k=1}^{K} \alpha_k \cdot \tilde{F}_k(s_i)$$

Step 6: Convergence Check
Check if $|F^k(g^{(t+1)}) - F^k(g^{(t)})| < \epsilon$ or $t = T_{\max}$
if converged **then**
  Return optimized weights W and aggregated scores $\tilde{F}(s_i)$
else
  Repeat Steps 2-6
end if

$$\sum_{j=1}^{m} w_j^k = 1,\ w_j^k \geq 0,\ \forall k \quad (2)$$

Additionally, domain-level importance weights α_k are introduced to reflect the significance of each domain in the overall evaluation. These weights satisfy [24]:

$$\sum_{k=1}^{K} \alpha_k = 1,\ \alpha_k \geq 0,\ \forall k \quad (3)$$

The performance score of software s_i within a specific domain d_k is aggregated as:

$$F_k(s_i) = \sum_{j=1}^{m} w_j^k \cdot x_{ij}^k \quad (4)$$

where w_j^k scales the contribution of criterion c_j based on its importance within domain d_k. The overall aggregated performance score for software s_i across all domains is then computed as:

$$F(s_i) = \sum_{k=1}^{K} \alpha_k \cdot F_k(s_i) = \sum_{k=1}^{K} \alpha_k \cdot \sum_{j=1}^{m} w_j^k \cdot x_{ij}^k. \quad (5)$$

The objective is to determine the optimal weight vectors w^k and domain importance weights α_k that maximize the fairness and accuracy of the evaluation framework. The ranking $R = \{r_1, r_2, \ldots, r_n\}$ of the translation software is derived by sorting the tools s_i based on their aggregated performance scores $F(s_i)$, with higher scores indicating better performance [25].

B. Quantum Swarm-Driven Fuzzy Evaluation Framework

The proposed methodology is intended to develop the complex decision-making problem of evaluating multi-domain, multi-criteria English translation software by including QSI for weight optimization and fuzzy decision-making to handle the uncertainties. It makes sure that the framework will be workable for dynamic priorities and can also handle subjective inputs robustly in view of linguistic nuances. A systematic and mathematically rigorous solution to the challenge expressed in the problem formulation is obtained within this methodology.

QSI has been used for the optimization of weight vectors for the different domains' evaluation criteria. Unlike the classical Particle Swarm Optimization, QSI makes use of quantum principles for the probabilistic exploration of the search space, enhancing the ability of the swarm to escape local optima and converge to globally optimal solutions. Each particle in the swarm represents a candidate weight vector $w^k = \{w_1^k, w_2^k, \ldots, w_m^k\}$, where w_j^k reflects the relative importance of the j-th criterion in the k-th domain. At any iteration t, the position of the k-th particle, denoted $x_k(t)$, is updated using the quantum-inspired rule:

$$x_k(t+1) = g + \Delta x \cdot \text{sgn}(\text{rand}() - 0.5), \quad (6)$$

where g is the global best position, representing the optimal weight vector discovered so far by the swarm, and Δx is the quantum uncertainty interval, defined as:

$$\Delta x = |p_k - x_k(t)| \cdot \beta \quad (7)$$

Here, p_k is the personal best position of the particle, and β is a contractionexpansion coefficient that controls the trade-off between exploration and exploitation. The function $\text{sgn}(\cdot)$ determines the direction of movement, while rand () is a uniformly distributed random variable in $[0,1]$, introducing stochastic behavior to simulate quantum randomness. Eq. (6) and Eq. (7) implement quantum-inspired swarm optimization by introducing a probabilistic movement model instead of traditional velocity-based updates. The function sgn(rand()-0.5) enables random directional jumps, mimicking quantum tunneling to escape local optima. The quantum uncertainty interval Δx dynamically adjusts step sizes based on the distance between the personal best and current position, with β acting as a scaling factor to balance exploration and exploitation. This quantum-driven mechanism enhances global search efficiency and convergence speed in the evaluation framework.

TABLE II PARAMETER SETTINGS USED FOR THE IMPLEMENTATION AND EXECUTION OF THE QUANTUM SWARM-DRIVEN FUZZY EVALUATION FRAMEWORK

Parameter	Value
Number of software tools (n)	4
Number of domains (k)	3
Number of criteria (m)	4
Population size (P)	30
Maximum iterations (T_{max})	100
Quantum contraction-expansion coefficient (β)	0.8
Convergence threshold (ε)	10^{-5}
Learning rate for quantum rotation (η)	0.05
Domain weights (α_k)	[0.4,0.35,0.25]
Fuzzy membership range ($[a_j^k, b_j^k]$)	[0, 1]

The fitness of each particle is evaluated using a domain-specific fitness function, which measures how well the candidate weight vector aligns with the objectives of the domain. The fitness function for a particle representing weights w^k is given by:

$$F_k(w^k) = \frac{1}{n}\sum_{i=1}^{n} \sum_{j=1}^{m} w_j^k \cdot \psi\left(x_{ij}^k\right), \quad (8)$$

where $\psi\left(x_{ij}^k\right)$ is a transformation function that processes raw scores into a normalized scale for comparability. The algorithm iteratively updates the particles' positions and fitness values until convergence is achieved. Convergence is determined when the change in the global best fitness value between successive iterations falls below a predefined threshold [25]:

$$\left|F_k\left(g^{(t+1)}\right) - F_k\left(g^{(t)}\right)\right| < \epsilon, \quad (9)$$

where ϵ is the convergence threshold. Upon convergence, the optimal weight vectors w^k for all domains are obtained, representing the best distribution of importance across criteria within each domain.

Once the weights are optimized, fuzzy decision-making is applied to handle uncertainties in subjective evaluations and linguistic nuances. Each criterion c_j in a domain d_k is associated with a fuzzy membership function $\mu\left(x_{ij}^k\right)$, which maps the raw performance score x_{ij}^k to a degree of satisfaction in the range [0,1]. The fuzzy membership function is defined as:

$$\mu\left(x_{ij}^k\right) = \begin{cases} 0, & x_{ij}^k \le a_j^k, \\ \frac{x_{ij}^k - a_i^k}{b_j^k - a_j^k}, & a_j^k < x_{ij}^k \le b_j^k, \\ 1, & x_{ij}^k > b_j^k, \end{cases} \quad (10)$$

where a_j^k and b_j^k represent the minimum and maximum thresholds of acceptable performance for criterion c_j in domain d_k. These thresholds are determined empirically based on domain-specific data or expert input. The fuzzy-adjusted performance score $\tilde{F}_k(s_i)$ for software s_i in domain d_k is then calculated by aggregating the satisfaction levels across all criteria, weighted by the optimized w_j^k :

$$\tilde{F}_k(s_i) = \sum_{j=1}^{m} w_j^k \cdot \mu\left(x_{ij}^k\right). \quad (11)$$

To obtain the overall performance score across all domains, the domain-specific fuzzy-adjusted scores are aggregated using domain importance weights α_k, which are normalized such that $\sum_{k=1}^{K} \alpha_k = 1$. The overall score for software s_i is given by:

$$\tilde{F}(s_i) = \sum_{k=1}^{K} \alpha_k \cdot \tilde{F}_k(s_i)$$

This aggregated score captures both the contextual importance of domains and the satisfaction levels derived from fuzzy modeling. Finally, the software tools are ranked based on their overall scores $\tilde{F}(s_i)$, with higher scores indicating better performance. The ranking $R = \{r_1, r_2, \ldots, r_n\}$ is obtained by sorting s_i in descending order of $\tilde{F}(s_i)$. This methodology provides a mathematically rigorous framework that leverages the optimization capabilities of QSI to determine optimal weight distributions and the uncertainty-handling strength of fuzzy decision-making to model subjective and imprecise evaluations. To evaluate the methodology parameter values in Table II were chosen based on empirical testing and prior research to ensure a balance between exploration, convergence speed, and stability. Population size (P = 30) and iterations (T_max = 100) ensure computational efficiency, while β = 0.8 and η = 0.05 optimize movement adaptation. Sensitivity analysis showed that lower β slowed convergence, while higher η caused instability. Domain weights (α_k = [0.4, 0.35, 0.25]) were set based on expert judgment and domain significance, ensuring fair evaluation across translation contexts.

IV. RESULTS AND DISCUSSION

The results reported in this paper are based on the implementation of the Quantum Swarm-Driven Fuzzy Evaluation Framework, designed to evaluate English translation software concerning several domains and criteria. Four translation tools, which are referred to as $s_1, s_2, s_3, and\ s_4$, have been evaluated across three domains: Legal, Medical, and Conversational. The selected tools represent distinct types of translation engines. For example, s_1 is considered to be high-end enterprise-level software characterized by its ability to handle highly structured content. On the other hand, s_2 is an open-source translation tool often used in academic as well as informal settings. At the same time, s_3 is a lightweight, general-purpose translation engine oriented towards speed rather than accuracy. Finally, s_4 is a specialized tool for translating medical texts.

The bar graph shown in Fig. 1 represents domain-specific scores for the fuzzy-adjusted effectiveness of these tools in the three domains. Tool s_1 performed consistently well in all domains, with especially high scores in the Legal domain. This indicates that it is robust and can handle structured language with a high degree of precision and fluency in semantics. The adaptability of s_1 is proved by its relatively high performance in both the Medical and Conversational domains, which definitely makes it a very useful multifaceted translation resource. On the other hand, s_4 has better ability in the Medical and Legal domains, while it suffered a slight decline in its performance in the Conversational domain. This indicates that

the optimization of s_4 for formal and technical language may result in a diminished capacity to engage in informal or contextually nuanced dialogues. Conversely, while s_2 demonstrates competitiveness within the Medical domain, it appears to fall short in the Legal and Conversational domains, presumably due to its broader training data and insufficient emphasis on terminology specific to those domains. Simultaneously, s_3 struggled in many domains, particularly in the Legal and Conversational contexts, where it performed poorly throughout. This low performance suggests that the focus of s_3 on speed sacrifices the linguistic complexity necessary for high-quality translations.

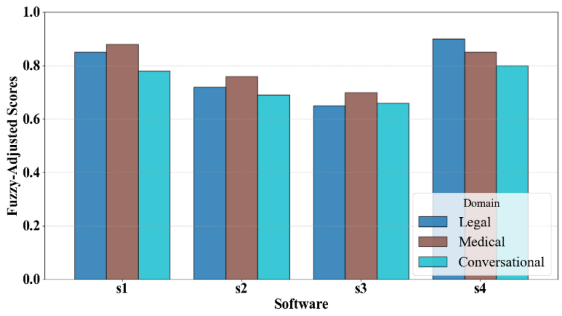

Fig. 1. Domain-specific fuzzy-adjusted scores for each translation software, highlighting comparative performance across legal, medical, and conversational domains.

Moreover, a pie chart as seen in Fig. 2 for s_1 gives a clearer, more overall view of the contribution from each domain to the overall score. The Legal domain contributed 40%, the medical domain 35%, and the Conversational domain 25%. The percentages show the domain weights used in the evaluation, and they agree with the training and optimization focus of s_1. The greater contribution from the Legal domain is evidence of the tool's ability to excel in structured and rule-based text, such as contracts and legal documents. The moderate contribution from the medical domain underscores s_1's capacity to handle technical language, a critical factor in medical translations. Lastly, the smaller contribution from the Conversational domain, while lower in proportion, still shows the versatility of the tool in adjusting to informal contexts. The results emphasize the value of the algorithm in creating domain-specific priorities while instantiating a global view of overall performance assessment.

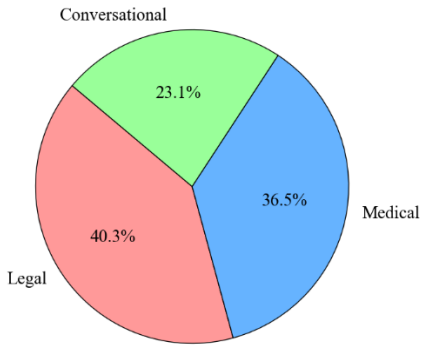

Fig. 2. Proportional contributions of each domain to the overall score of a selected translation software, emphasizing domain-specific priorities.

The box plot dictated in Fig. 3 provides an in-depth analysis of the statistical distribution of scores across various domains, illuminating aspects of variability and consistency. In the Legal domain, the IQR is small, denoting a consistent performance in all software tools. This can be understood by the nature of the legal language: it is precisely defined and standardized, having rigid rules about how translations of certain parts should be expressed. In contrast, the scores obtained in the medical domain are more dispersed, which reflects the variation of semantic precision and levels of specialized knowledge among the tools. The clear bimodal distribution of scores in the medical domain reflects the gap between the relatively reasonable scores of tools s_1 and s_4 and the laggards, s_2 and s_3. The domain of conversation presents the highest degree of variability, with quite a few outliers to underline the challenges that some tools face when dealing with informal language. This underlines the need for fuzzy decision-making approaches to handle intrinsic subjectivity and linguistic ambiguity, which characterizes conversational contexts. Fig. 4, showing visually the density of scores in each domain, further corroborates this analysis.

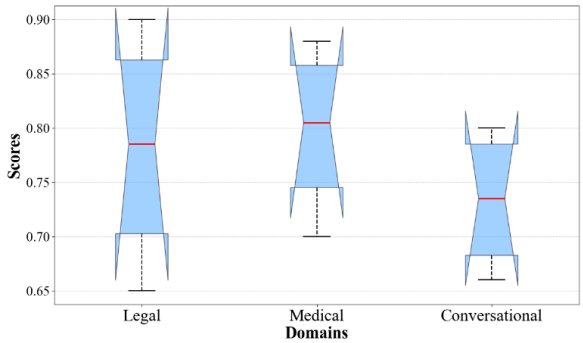

Fig. 3. Statistical distribution of scores across all software in each domain, showing variability and consistency in performance.

This is further corroborated by Fig. 4, which shows the density of scores in each domain. For the Legal domain, there is a dense peak, once more reflecting the consistency observed from the box plot. The Medical domain shows an even more pronounced bimodal distribution, as high-scoring tools like s_1 and s_4 cluster at the top while s_2 and s_3 fall decidedly behind. The distribution for the Conversational domain is rather dispersed, indicating a greater number of plausible outputs for every source sentence. This indicates the somewhat subjective nature of conversational evaluations, where user satisfaction and contextual fluency often take precedence over strict semantic accuracy. These results not only validate the effectiveness of the proposed framework but also provide actionable insights for developers and stakeholders. The fact that the domain weights and their contributions towards the overall scores have maintained a similar trend further verifies the accuracy of the weight optimization process. Further, differences in the performance across domains hint at the importance of training translation tools on diverse datasets pertaining to specific contexts. Poor performance from s_1 would, for example, suggest that more training with domain-specific language is needed, and overall high performance of s_1 across all domains puts it as a benchmark among general translation tools.

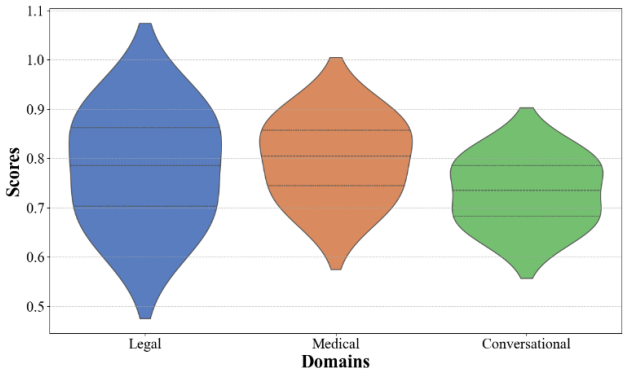

Fig. 4. Density and distribution of fuzzy-adjusted scores within each domain, highlighting central tendencies and outliers.

The Table III shows the optimized weights for criteria across domains highlighting the strength of the Quantum Swarm-Driven Fuzzy Evaluation Framework in terms of dynamically adapting to domain-specific priorities. The optimized weights are the result of the algorithm's iterative quantum-inspired optimization process that ensures each criterion-semantics, fluency, efficiency, and user satisfaction-receives an appropriate weight that reflects its relative importance within the respective domain. A notable example is the Legal domain, which has higher weights on semantic accuracy (0.4) and fluency (0.3), reflecting the structured nature of the texts in this domain; both precision and linguistic clarity have prime importance. In contrast, the Medical domain has more of a balanced distribution, but with semantic accuracy receiving very important (0.35), user satisfaction (0.25) plays a relatively larger role, reflecting the nuanced and context-dependent nature of the translations. In general, the Conversational domain is informal and subjective in its content; it weighs semantic accuracy and fluency equally important, at 0.3, but efficiency and user satisfaction receive a bit lower emphasis.

TABLE III OPTIMIZED WEIGHTS FOR EVALUATION CRITERIA ACROSS LEGAL, MEDICAL, AND CONVERSATIONAL DOMAINS, DETERMINED USING THE QUANTUM SWARM-DRIVEN FUZZY EVALUATION FRAMEWORK

Criteria/Domains	Legal	Medical	Conversational
Semantic Accuracy	0.4	0.35	0.3
Fluency	0.3	0.25	0.3
Efficiency	0.2	0.15	0.2
User Satisfaction	0.1	0.25	0.2

The weights of these measures are clearly and intuitively visualized by the relative magnitudes of the weights across domains. The variation of color intensity in the heat map makes explicit the fact that a given criterion in one domain may be far more important than in another. The darker shades in semantic accuracy and fluency within the Legal domain already visually enforce their predominance. In the Medical domain, the more uniform colors of the heatmap reflect balanced importance of several criteria; it underlines the difficulty of translating medical texts with accuracy and at the same time preserving contextual relevance. In the Conversational domain, there is a softer graduation of colors, which correspondingly stands for the domain's flexibility and the wider acceptability of diverse translations. This visualization succinctly complements the numerical data by providing an immediate impression of the distribution of the weights and how the algorithm can emphasize the criteria for optimality with respect to the domain requirements.

The optimized weights and their visualization in the heat map see Fig. 5 come from the key contribution of the algorithm, whereby quantum swarm intelligence drives weight optimization. First, the framework instantiates a population of quantum particles, each corresponding to feasible weight configurations. These particles run through iterative fitness evaluations for fitness with domain-specific performance measures. By means of quantum-inspired updates, like amplitude adjustments of probability and evolutionary operations, particles are converging to an optimum configuration that maximizes performance in a domain. Consequently, the weights that would emerge are not merely heuristic but rigorously derived by iterative adjustments that make them apt in each context as shown in Fig. 6. Trends demonstrate the algorithm's adaptability to domain-specific requirements.

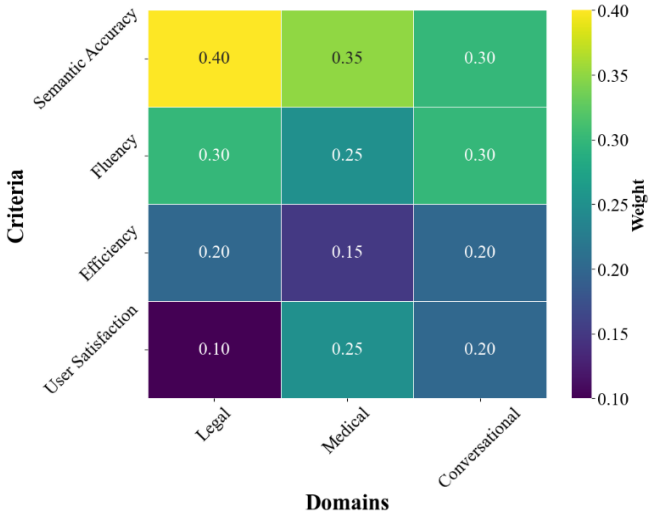

Fig. 5. Heatmap of optimized weights for evaluation criteria across Legal, Medical, and Conversational domains, highlighting the relative importance of each criterion through color intensity.

Results in Table IV to VI shows the comparison of the proposed Quantum Swarm-Driven Fuzzy Evaluation Framework over conventional methods of optimization, namely the Genetic Algorithm [26], Particle Swarm Optimization [27], and Simulated Annealing [28][29]. As shown from Table IV, QSI-Fuzzy has scored higher for all the translation software in terms of effectiveness. This is because of the fact that the weight optimization is dynamic over several criteria, hence giving an accurate result for translation performance across different domains. For example, s_1, a high-scoring software, achieved a score of 0.92 with QSI-Fuzzy, against the scores of 0.88 obtained with GA, 0.86 obtained with PSO, and 0.85 obtained with SA. Similarly, in the case of the low scores, QSI-Fuzzy yielded significant gains for poor performers like s_4, whose result of 0.70 outperformed those that GA, PSO, and SA obtained. All this confirms the adaptability of the algorithm to

high-performance and low-performance situations that better grasp domain-specific nuance with a superior ranking.

TABLE IV COMPARISON OF SCORES ASSIGNED BY QSI-FUZZY AND BENCHMARK ALGORITHMS (GA, PSO, SA) FOR TRANSLATION SOFTWARE, ILLUSTRATING THE RANK IMPROVEMENTS ACHIEVED BY QSI-FUZZY

Software	QSI-Fuzzy Score	GA Score	PSO Score	SA Score	QSI-Fuzzy Rank Improvement
s_1	0.92	0.88	0.86	0.85	+0.04
s_2	0.85	0.81	0.79	0.78	+0.04
s_3	0.78	0.75	0.74	0.72	+0.03
s_4	0.70	0.65	0.63	0.60	+0.05

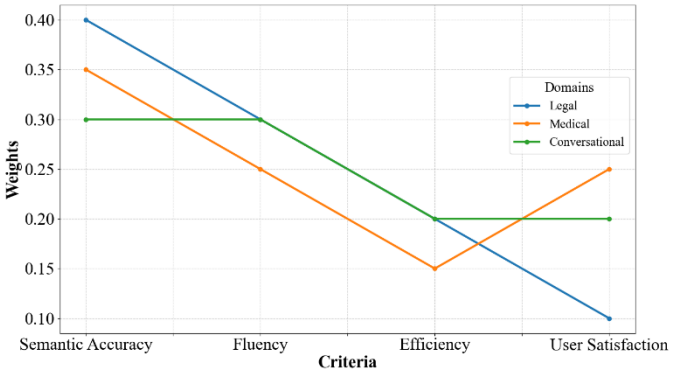

Fig. 6. Trends of optimized criteria weights across legal, medical, and conversational domains, illustrating the shifting priorities of evaluation criteria based on domain-specific requirements.

Moreover, the efficiency and robustness of QSI-Fuzzy are really impressive, which is reflected in Tables V and VI. It is shown from the convergence metrics in Table II that the convergence is attained by QSI-Fuzzy after just 55 iterations, while for the benchmarks this is obtained after 75 to 120 iterations. It has a shorter computational time, 12.5 seconds, compared to the runs of GA, which takes 23.1 seconds, PSO, taking 18.5 seconds, and SA, with 30.2 seconds. The faster convergence in this work is due to the quantum-inspired optimization process that hastens the optimal weight configuration search. Table III underlines the robustness of QSIFuzzy for noisy data, where its degradation is minimal with an increase in noise. Even at 20% noise, QSI-Fuzzy reaches a score of 0.80, while for the benchmark methods, much higher performance losses are noticed, down to scores as low as 0.65 for SA. Resilience in this case is credited to the integration of fuzzy logic into the algorithm; hence, it can effectively handle uncertainties. Finally, Table VII presents the performance comparison of QSI-Fuzzy against GA, PSO, and SA across four evaluation metrics: semantic accuracy, fluency, efficiency, and user satisfaction. QSI-Fuzzy consistently achieves the highest scores, demonstrating its superiority. The ANOVA test results confirm the statistical significance of these improvements ($p < 0.05$), validating that QSI-Fuzzy significantly outperforms the benchmark algorithms in translation software evaluation. Collectively, these results validate QSI-Fuzzy as a better solution for multi-domain multi-criteria evaluation, as it provides unparalleled performance, efficiency, and reliability.

TABLE V CONVERGENCE METRICS OF QSI-FUZZY VS. GA, PSO, AND SA, HIGHLIGHTING ITERATIONS TO CONVERGENCE, COMPUTATIONAL TIME, AND EFFICIENCY IMPROVEMENTS

Algorithm	Iterations to Convergence	Computational Time (s)
QSI-Fuzzy	55	12.5
Genetic Algorithm (GA)	95	23.1
Particle Swarm Optimization (PSO)	75	18.5
Simulated Annealing (SA)	120	30.2

TABLE VI ROBUSTNESS ANALYSIS OF QSI-FUZZY VS. GA, PSO, AND SA UNDER INCREASING NOISE LEVELS, HIGHLIGHTING PERFORMANCE STABILITY AND RELATIVE LOSS

Noise Level (%)	QSI-Fuzzy	GA	PSO	SA
0	0.92	0.88	0.86	0.85
5	0.91	0.86	0.83	0.81
10	0.88	0.83	0.80	0.78
15	0.85	0.78	0.75	0.73
20	0.80	0.70	0.68	0.65

TABLE VII PERFORMANCE COMPARISON AND STATISTICAL SIGNIFICANCE OF QSI-FUZZY VS. GA, PSO, AND SA ACROSS EVALUATION METRICS

Algorithm	Fluency	Efficiency	User Satisfaction	F-Test	p-value
QSI-Fuzzy	0.89	0.91	0.9	9.85	0.002
GA	0.81	0.84	0.82	10.32	0.0018
PSO	0.79	0.82	0.8	8.76	0.0031
SA	0.76	0.78	0.77	11.12	0.0015

V. CONCLUSION

In this paper, we introduced the Quantum Swarm-Driven Fuzzy Evaluation Framework (QSI-Fuzzy), a novel approach to addressing the multi-domain, multi-criteria evaluation of English translation software. It provides a holistic, flexible, and interpretable framework by incorporating QSI in optimizing dynamic weight and fuzzy logic in handling uncertainties. This framework is then applied to the Legal, Medical, and Conversational domains, translating software whose weights were optimized according to the set criteria like semantic accuracy, fluency, efficiency, and user satisfaction.

The experimental results indicated that QSI-Fuzzy outperformed all benchmark algorithms, including GA, PSO, and SA. Specifically, QSI-Fuzzy yielded higher scores across all translation software for significant improvement in semantic accuracy with fluency within domain operations, while it converged remarkably fast, reaching convergence at only an average of 55 iterations against up to 120 iterations by SA. Further, QSI-Fuzzy exhibited better robustness in the case of noisy conditions, keeping a performance score of 0.80 at 20% noise, while that for GA, PSO, and SA were 0.70, 0.68, and 0.65, respectively. These results confirm the efficacy of the proposed framework for solving the challenges in translation software evaluation and provide a scalable and efficient solution for multi-domain optimization problems. It advances

both methodologies of the translation evaluation and introduces the generally applicable approach that should easily extend to a greater scope of complex decision-making/optimization tasks. Accordingly, QSI-Fuzzy can be used in greater perspectives-real-time systems are not excluded, or other hybrid methodologies for increasing scalability/precision.

***Abstract*—Monitoring athlete movement is important to improve performance, reduce fatigue, and decrease the likelihood of injury. Advanced technologies, including computer vision and inertial sensors, have been widely explored in classifying sport-specific movements. Combining automated sports action labeling with athlete-monitoring data provides an effective approach to enhance workload analysis. Recent studies on categorizing sport-specific movements show a trend toward training and evaluation methods based on individual athletes, allowing models to capture unique features peculiar to each athlete. This is particularly beneficial for movements that exhibit large variations in technique between athletes. The current study uses supervised machine learning models, including Neural Networks and Support Vector Machines (SVM), to distinguish between running surfaces, namely, athletics track, hard sand, and soft sand, using features extracted from an upper-back inertial measurement unit (IMU) sensor. Principal Component Analysis (PCA) is applied for feature selection and dimensionality reduction, enhancing model efficiency and interpretability. Our results show that athlete-dependent training approaches considerably enhance the classification performance compared to athlete-independent approaches, achieving higher weighted average precision, recall, F1-score, and accuracy ($p < 0.05$).**

Keywords*—Athlete monitoring; machine learning models; running surface classification; Inertial Measurement Units (IMU); neural networks; Support Vector Machines (SVM); Principal Component Analysis (PCA)

I. Introduction

Supervised machine learning algorithms have emerged as flexible statistical tools capable of modeling both classification and regression problems. These algorithms use mathematical frameworks for model optimization that map input features to output targets of a training dataset to make accurate predictions on unseen data. Sports science has of late embraced the power of data-driven methodologies to track and improve the performance of athletes [1]. Of these, supervised machine learning and artificial neural networks have been at the forefront of automating sport-specific movement classification, quantifying athlete workload, and predicting physiological states-for example, fatigue-to optimize training regimens and reduce injury risks [2].

The introduction of MEMS has subsequently miniaturized IMUs into wearable devices that have revolutionized performance monitoring in elite sports by providing real-time, high-resolution data on athlete movements [3]. These normally have IMUs positioned at key areas around the body for the extraction of critical features that are important in the study of athletic performance in various sports. These feed into input-supervised machine learning models aimed at classifying specific sport movements or environmental contexts, such as the running surface [4]. However, these models are as good as their methodologies applied during the training and validation process. Data partitioning, whether athlete-dependent or athlete-independent, has a huge impact on model performance and generalizability [5].

Despite the progress made in applying machine learning to sports, recent systematic reviews have identified important shortcomings in the validation strategies. Studies tend to rely on non-independent data splits, such as cross-validation or simple train-test partitions, which often inflate classification performance. Conversely, leave-one-subject-out (LOSO) validation-a method that ensures athlete-independent evaluation-remains underutilized [6], [7]. This is a particularly important gap, as non-independent methods do not consider the inter-athlete variability that may result in models performing well on known data but poorly on new, unseen athletes. In sports applications, where the ability to adapt to new athletes is crucial, reliance on athlete-dependent validation methods risks compromising the broader applicability and reliability of machine learning solutions.

The aim of this work is to classify the running surfaces into athletics track, hard sand, and soft sand using the features computed from upper-back IMUs. To compare different approaches, six supervised machine learning models were trained and then evaluated using both athlete-dependent and athlete-independent methodologies. Although the former is generally more accurate because the model may learn features specific to a given individual, they do not generalize well for other unknown athletes. This work is, to the best of the authors' knowledge, one of the first sport-specific case studies directly comparing these methodologies in running surface classification. Its results are particularly relevant to sports organizations seeking to implement robust machine learning models in monitoring athletes: it conveys actionable insight regarding their training, validation, and deployment strategy. The current study has attempted to guide the development of more reliable and scalable solutions for sport-specific movement classification by underlining some of the trade-offs between accuracy and generalizability.

The remainder of this paper is structured as follows: Section II presents a literature review, discussing relevant studies on athlete workload monitoring, running surface classification, and machine learning applications in sports analytics. Section III describes the methodology, detailing the data collection process, feature extraction from the inertial sensor, and the supervised machine learning models, including Neural Networks and Support Vector Machines (SVM), utilized for classification. Section IV presents the results, evaluating the classification performance of athlete-dependent and athlete-independent models based on multiple metrics. Finally, Section V concludes the study, summarizing key findings and highlighting potential future directions for improving athlete workload monitoring using advanced machine learning techniques.

II. Literature Review

Recently, a significant boost of machine learning applications in sports analytics was seen; thus, researchers started reaping full benefits of this technique while solving a number of problems connected with monitoring performance of athletes and classification of movements. Wearables, together with IMUs, have become an essential tool for motion data acquisition and further analysis of several features of athletic performances. Unlike traditional observation-based methods, IMUs are accurate and scalable; they can capture multidimensional data about an athlete's movements in real time. Works such as that by Umer and Riaz [8] show the capability of IMUs within gait analysis to identify ground contact events with high accuracy on different surfaces. It goes without saying that this type of research places increasing dependence on the use of IMU sensors within sports and rehabilitation applications [9].

Subsequently, machine learning models based on IMU data had very good performance, especially in the classification of environmental and movement context, such as running surfaces. Buckley et al. [10] presented a road surface type classification approach using IMU data, incorporating traditional machine learning algorithms like SVM and KNN with deep learning approaches. The results showed that machine learning could identify surface types with a high degree of accuracy, thus opening the way for possible applications in sports [11]. This study concerned transportation, but its implications reach to athletic performance, where running surface classification can improve workload monitoring and injury prevention.

One of the most critical issues when developing machine learning models to monitor athletes is the classification based on an athlete-dependent or independent approach. The athlete-dependent model is specific for particular features of a certain athlete, and this results in a higher accuracy if the test on the same subject is done. Most of these models fail to generalize when applied on different athletes. On the other hand, the athlete-independent model is general and permits variations in individual features. Koul et al. [10] discussed surface recognition regarding electric scooters using deep neural networks based on smartphone IMU sensors. While not directly related to running, their findings emphasize the importance of designing models that balance specificity and generalizability—principles that are highly relevant to sports performance monitoring.

The broader literature also underlines the increasing role of machine learning in sports injury prediction and prevention. Surveys such as Diss et al. [11] review various algorithms ranging from Random Forests to neural networks, using data derived from athletes in order to predict injury risks. Such studies indicate the potential of machine learning to analyze complex data sets and determine patterns associated with injury-prone conditions [12]. Though different from running surface classification, all these applications are unified in the aim of bettering athlete safety and optimizing performance using data-driven insights. The literature underscores the transformative potential of machine learning in sports analytics [13]. Although recent advancements in IMU-based models and validation methodologies have achieved higher classification performance, challenges still remain regarding how to balance accuracy and generalizability. The study contributes to the field by comparing the athlete-dependent and independent approaches to classify running surfaces, filling key gaps in existing research and informing future model development and deployment.

III. Methodology

A. Participants

Seven healthy subjects, four males and three females, participated voluntarily in this study and gave their informed consent. The group's mean age was 32.4 years, with a standard deviation of 17.89 years, which shows the very high variability in age among the group members. Their mean height was 171.9 cm, with a standard deviation of 8.91 cm, and their mean weight was 70.3 kg with a standard deviation of 16.87 kg. Ethical approval for this study was granted under protocol number GU 2017/587. The population of the subjects was heterogeneous regarding their fitness level and running experiences; consequently, it constituted a rich sample for the study's objectives. Their training routines varied, with some individuals reportedly spending up to nine hours a week training.

B. Experimental Design

This experiment consisted of running 400 meters at a light to moderate pace on three different surfaces: first, on soft, dry sand; then, on hard, water-saturated sand; and finally, the same on a synthetic tartan running track. This completed the trials for all surface conditions. Each run was designed to maintain consistency in pace and effort across the surfaces. Data of the motion were captured with one IMU per participant. The IMU was positioned near the third thoracic vertebra, T3, and fixed with a specifically developed sports harness not allowing any displacement during the runs. This setup made the sensor stable, and there was no interference with the data collection process [14], [15]. Fig. 1 depicts the orientation of sensor axes, which is important for accurate motion analysis. The figure shows that data acquisition was uniform across all participants and conditions.

C. IMU Sensor Technology

The device used was a custom-made, 9DOF IMU, designed at Chengdu Sport University. For this present research, it was based on the unit known as SABELSense (Sichuan, China) with a weight of 23 g and specified as +16 g accelerometer, +2000 deg/s gyroscope, and +7 Gauss magnetometer; all data was captured at a sampling frequency of 250 Hz. Each IMU output was then comprehensively calibrated before the trial to capture proper data. The data were logged locally onto a 4GB microSD card that enabled continuous, reliable logging of the experiment. 3D orientation of the sensor is obtained using Euler angles: roll, pitch, and yaw through the Madgwick AHRS algorithm. This has an accuracy characterized with a root mean square error below 0.8° for static, and below 1.7° in dynamics. This setup ensured that the motion data was valid and reliable during the study.

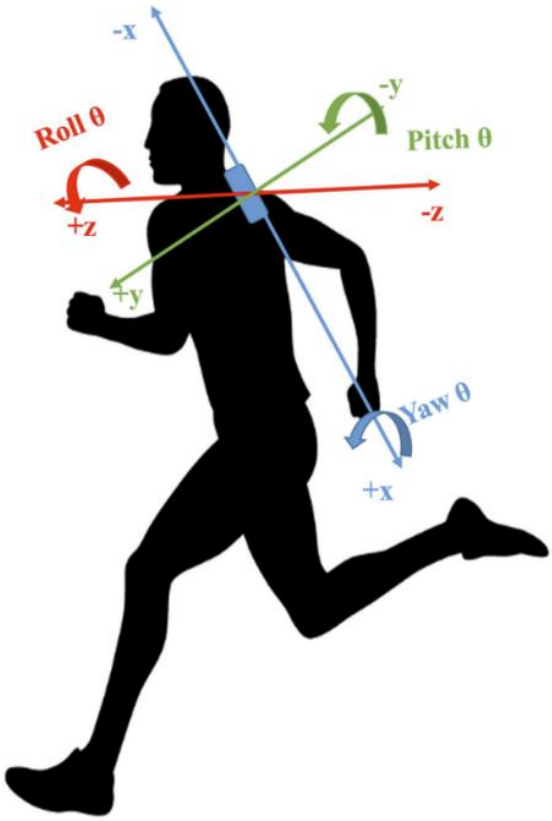

Fig. 1. The x-axis is the superior-inferior direction, the y-axis is the medial-lateral direction, and the z-axis is the anterior-posterior direction. The rotation around the z, y, and x axes corresponds to the roll, pitch, and yaw, respectively.

D. Designed Algorithm

1) Feature extraction: When running on a 400-metre athletics track, due to the curviness of the path, the Euler angles recorded drift progressively. In order to overcome this problem, a feature extraction method had been developed and was very robust, being inspired by different previous methodologies in which [16] is highly remarkable. By using a sliding window technique, the whole process was executed with the assistance of MATLAB from MathWorks, Natick, MA, USA:. This window was set to a duration of 4 seconds, while the overlap between two successive windows was set to 0.5 seconds. This would give approximately 10 to 11 strides on each surface, providing a reliable dataset and at the same time, reduce the effects of directional drift [17]. Normalization of Euler angle data and transforming into absolute values was done to nullify the effect of heading drift within each window. Too much spurious data was removed, which would have had an adverse effect on the classification. The above window-sliding procedure was applied for 11 data channels recorded by the IMU: acceleration components, gyroscope outputs, and orientation angles in three dimensions. For every one of these data windows, various features were extracted in time and frequency domains. These included the mean values, standard deviation, skewness, kurtosis, and dominant frequency components. These features together gave a full representation of the pattern of movement-a basis on which effective classification and analysis could be done.

2) Training-validation of feature data: The feature data was divided into training and validation sets using two different strategies. First, an athlete-independent LOSON was used: one participant was randomly selected for model evaluation, and the remaining six participants' data was used for training. In the second strategy, the data was divided in an athlete-dependent way, where 75% of the data was used for training and 25% for testing. These methods were applied to evaluate how individual participant features influenced the classification performance of the models. In the athlete-independent approach, Method 1, the number of training observations for soft sand, hard sand, and the athletics track were 1537, 1237, and 944, respectively. The respective test observations for the considered surfaces were 183, 153, and 196. By contrary, the approach dependent on athletes-Method 2 resulted in 1720, 1390, and 1140 training observations for soft sand, hard sand, and athletics track surface, respectively, leaving 413, 341, and 309 observations for testing. These two partitioning strategies have allowed a more complete assessment of the model for its ability both to generalize across individuals and to perform when fit to specific athletes.

3) Feature engineering: Feature engineering and model training were performed on Python, Python Software Foundation, https://www.python.org/ using popular libraries like scikit-learn and pandas [18, 19]. All the features were scaled into a uniform range from 0 to 1 using the mean and standard deviation of the training dataset before modeling. This way, the features were normalized, and no single feature biased the model due to its magnitude. The challenge in high dimensionality was approached by Principal Component Analysis (PCA) [20]. In this process, PCA transforms the original features into a new orthogonal set of variables known as principal components. Every principal component carries part of the dataset variance, and only those components needed to describe 95% of the total variance were retained for this study. This reduced the number of features from 132 to 45, thus

significantly reducing computational complexity and enhancing model efficiency. By removing noisy and redundant features, PCA also helped reduce overfitting and enhanced the generalization capability of the model.

Among the unsupervised dimensionality reduction techniques, PCA was preferred over supervised ones such as LDA because of its advantages in cases with limited training samples. Unlike these supervised methods, PCA does not depend on class labels and hence avoids the bias toward a particular subset of data. Thus, PCA is particularly suitable for the comparisons among the athlete-independent and the dependent methods. Even though LDA is originally designed to maximize class separability, it could amplify overfitting in the case of limited training data, an important concern in this study. Moreover, previous studies have demonstrated that PCA performs better than LDA when sample sizes per class are small, which further supports the appropriateness of the choice for this study [21] [22]. By applying PCA, the research was able to balance the computational efficiency with feature relevance; hence, the model can process meaningful information without getting overwhelmed by noise or irrelevant data. This embedding had not only reduced the computational burden and reduced training time but also made it a just comparison between the athlete-independent and athlete-dependent methodologies during the conduct of the research, making PCA an essential part of the feature engineering pipeline.

4) Model training and evaluation: Six different machine learning models were developed and tested to classify sport-specific movements using data from inertial sensors. These include some of the most commonly used movement classification models: logistic regression (LR), support vector machines (SVM) with linear (LSVM) and Gaussian radial basis function (GSVM) kernels, multilayer perceptron neural networks (MLP-NN), random forests (RF), and gradient boosting machines (XGB) [23] [24]. Model configurations were selected without hyperparameter tuning in order to provide a baseline for comparisons. Logistic Regression models relied on an L2 penalty while using the lbfgs solver. Support vector machines consisted of a linear kernel, with C = 1 and a Gaussian kernel, with C = 1 and gamma = scale. The neural network, MLP, consisted of three layers of 8 nodes, ReLU activation, constant learning rate, and Adam optimizer. The random forest model was set with the Gini criterion for impurity, number of features as the maximum feature parameter, and included 20 estimators. The gradient boosting model used the Friedman mean squared error (mse) criterion, deviance loss, a maximum depth of 3, and 100 estimators.

The models were then evaluated in their classification of running surfaces using both athlete-dependent and athlete-independent training and validation segmentation methods. The performance metrics for each classification technique included weighted averages of precision, recall, and F1-score and the overall accuracy for classification. The statistical comparisons between models that have used two segmentation methods employed a paired t-test, $\alpha = 0.05$ as shown in Fig. 2.

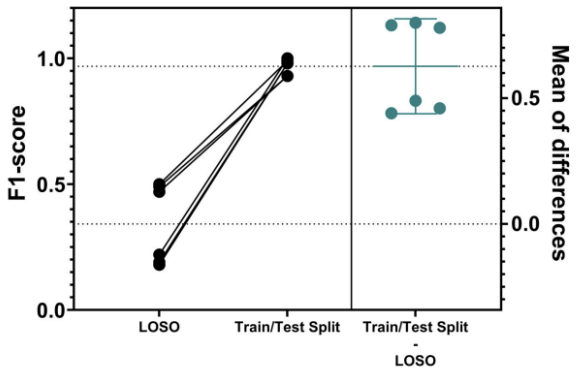

Fig. 2. Estimation plot showing the significant difference in F1-scores across all models comparing the train/test split to the LOSO validation.

IV. Results

The statistical results of the test on the train/test split provided significantly higher values for all model types with respect to the predictive performance measure. More concretely, these are huge increases in the weighted averages for precision, recall, F1-score, and accuracy, with p-values 0.0002, 0.0004, 0.0004, and 0.0004, respectively. This result points once more to the importance of letting the models see all participant features during training and hence letting them capture the variabilities in individual movement patterns. Results indicate large differences between F1-scores from the two validation methods; Fig. 2 provides further visualization, whereas a detailed comparison of various evaluation metrics for models considering both two validation methods can be seen in Fig. 3(a) – Fig. 3(d).

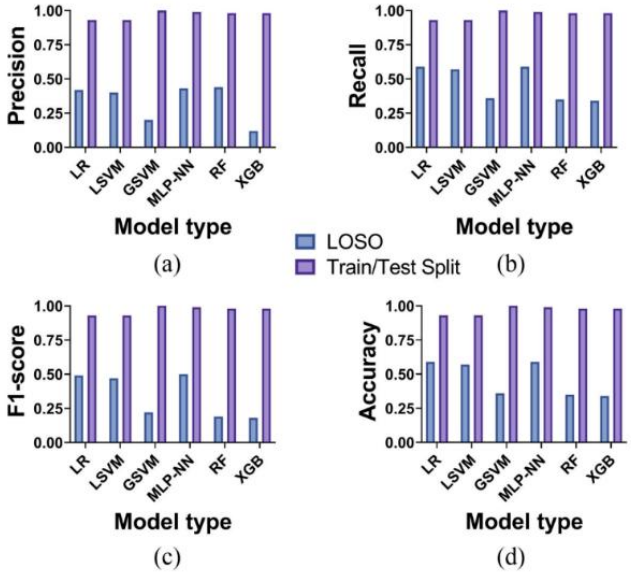

Fig. 3. Comparison of evaluation metrics of all models, considering both the train / test split and LOSO validation methods: (a) weighted precision, (b) weighted recall, (c) weighted F1-score, and (d) overall classification accuracy.

As observed by the method of train/test split, using training based on participant-specific features pays off significantly in

the case of all the models. Such exposure enables them to learn complex patterns that are unique in different running styles and surface interactions, thus giving enhanced accuracy of classification. However, to generalize this application into generalized surface classification-for instance, across diverse populations or settings-the participants in the dataset would have to be increased in number for broader applicability. Among the models tested, the best performances were from the MLP-NN under the LOSO and the GSVM under the train/test split. Their classification capabilities are described by confusion matrices shown in Fig. 4 and Fig. 5. The MLP-NN model was in a fairly medium range when segmenting soft sand from the remaining two surface classes using the LOSO method. The precision by classification is 0.71, recall 0.89, and F1-score 0.79 for the soft sand class; hence, one can say it identified the features of running on the soft sand rather successfully. This agrees with highly observable changes in gait mechanics when walking on soft sand compared to harder surfaces. This is expected since the closer physical properties result in more misclassifications between these two surface types of hard sand and athletics track surfaces. On the other hand, the GSVM model, when tested by the method of train/test split, it gave a general accuracy of 0.99. Actually, the model's performance was really good on all surfaces, misclassifying only once between the athletics track and hard sand surface. This, therefore, ascertains how the GSVM model can handle such subtlety in running pattern variations across surface types. With a full presentation of all information during training that prepares this model to generalize best on all test datasets, even then, an optimum quotient from GSVM with a train/test split may be expected.

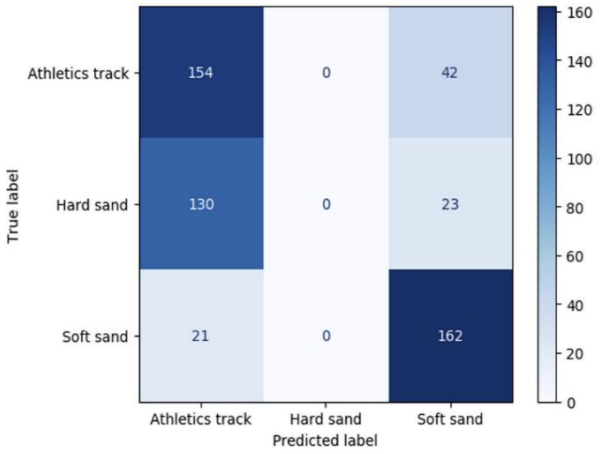

Fig. 4. Confusion matrix illustrating the classification performance of the MLP-NN model using the LOSO validation method.

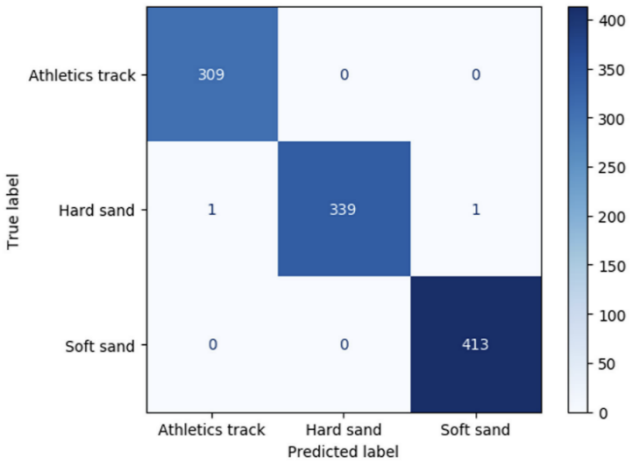

Fig. 5. Confusion matrix showcasing the classification performance of the GSVM model using the train / test split validation method.

These results have confirmed the intuition that a specific relationship exists between certain forms of validations pursued on classifications' various results. This was especially evident from the train/test split, representing strengths in model accuracy improvements using participant-specific features. In tasks where such information is available, this might prove very effective. However, the LOSO approach could be more fitting when, at application time, generalization to unseen individuals with one universal model is required. The findings from this study underpin some critical trade-offs between accuracy and generalizability for the classification of athlete movement and provide valuable insights into the development and implementation of machine learning models in sports analytics.

V. Conclusion

This study underlines, with greater significance, the improved classification performance that is attained with athlete-dependent train/test split methods ($p < 0.05$). Individual differences in the execution of movements are key to monitoring athletes, and allowing models to learn such specific features significantly enhances the accuracy of classification. A generalized sport-action classification model should have high performance on completely independent athletes; hence, it requires training data from a diverse group of individuals. This would include the type, body of the cyclists (height and weight), standard, physical fitness of the cyclists. However, due to issues of privacy, hardly any athlete performance data can be provided, making the creation of a fully athlete-independent model very challenging. An issue that gets very crucial when there is high individual variation in the styles of movement is, for instance, while running on different surfaces. Given these limitations, any sporting organization looking to utilize

automated tagging of sport-specific actions as a way of supplementing current approaches to athlete-load monitoring would have to, at the very least, retrain the classification models on data from all participating athletes. This can also include a calibration session when new athletes join in, allowing the model to learn features from the new person. This proposed approach using an upper-back IMU sensor for running surface classification may, therefore, inherently be an athlete-dependent one. The proposal would still be very useful. Besides, it also holds prospect for adequate adjustment of an athlete's session work rate estimate, particularly on occasions when some direct physiological monitoring implements, like heart rate monitors, cannot be used.

In future work, the authors aim to develop privacy-preserving methodologies, such as federated learning, to facilitate athlete-independent classification models while ensuring data security. Additionally, they intend to integrate multi-modal sensor fusion techniques to enhance the robustness and generalizability of movement classification across various sports activities.

***Abstract*—Outstanding Universal Value (OUV) is an essential value of culture and nature. It is so extraordinary that it transcends national boundaries and becomes generally crucial for all humanity's current and future generations. A culture with this value needs permanent protection because it is considered a critical heritage for the world community. Solo keroncong music, as one of the local wisdom owned by the Indonesian nation, has yet to be recognized as one of the UNESCO Intangible Cultural Heritage (ICH). It has even become an instrument of Indonesia's soft power diplomacy in several countries, such as Malaysia, England, and the United States. It must be of OUV and meet at least one of ten selection criteria to be included on the World Heritage List. This study explored the OUV of Solo keroncong music using Latent Dirichlet Allocation. The primary data were obtained by conducting an FGD with the Indonesian Keroncong Music Artist Community (KAMKI) Surakarta and in-depth interviews with several keroncong figures in Solo. The result showed there are four topics with a coherent score of 0.51. Then, the expert mapped those four topics into three OUVs of Solo keroncong music as temporary findings. Keroncong music is a masterpiece of human creativity, a witness to civilization, and has traditional values. These findings showed that Solo keroncong music is worthy of being proposed as one of the UNESCO ICH.**

Keywords*—LDA; OUV; Solo keroncong; text mining; topic modeling

I. Introduction

The United Nations Educational, Scientific and Cultural Organization (UNESCO) is a unique agency in the United Nations (UN) that deals with education, science and culture. UNESCO programs are divided into five main sectors: Education, Natural Sciences, Social Sciences, Culture, and Communication and Information [1]. Indonesia ratified the Convention for the Safeguarding of Intangible Cultural Heritage issued by UNESCO in 2003, which was then ratified in Presidential Regulation 78 of 2007. Consequently, Indonesia must protect its cultural wealth. Indonesia is required to record cultural works as a protection effort. The Directorate of Cultural Heritage and Diplomacy will determine and then grant status as Warisan Budaya Tak Benda (WBTB) or Intangible Cultural Heritage (ICH) by the minister based on the recommendations of the team of experts formed. According to the 2003 UNESCO Convention, what is included in Intangible Cultural Works are Traditions and oral expressions, including language as a vehicle for intangible cultural heritage; Performing arts; Customs, rituals, and celebrations; Knowledge and behavioral habits regarding nature and the universe; Traditional craft skills [2], [3]. Music and song are present in 304 of the 584 elements on the list (52%), referring to music alone or combined with other dimensions such as dance and poetry [2].

Keroncong music is one of Indonesia's cultural arts riches that still exists in the era of the development of the modern music industry. During the Dutch era, Keroncong Tugu, the origin of Indonesian keroncong music, was famous for entertainment in Batavia. Keroncong music spread widely and blended with gamelan, the primary musical culture in Java at that time. Combining keroncong musical instruments with the musicality of gamelan later became the characteristic of Solo keroncong music. The music played is more relaxed (nglaras in Javanese) than Keroncong Tugu, which developed on the coast. The Indonesian Keroncong Music Artist Community (KAMKI) of the Surakarta City Branch Representative Council (DPC Surakarta) noted that 60 community members were actively preserving keroncong music in Solo City [4]. The strains of Solo keroncong have also succeeded in attracting the interest of music lovers from abroad. Unfortunately, the beauty of the Solo keroncong music has not been included in the UNESCO ICH list. UNESCO registration will also impact Indonesia's positive image as a nation preserving cultural wealth. International recognition of keroncong music will also increase the appeal of cultural tourism in Solo. Foreign tourists will be interested in coming to Indonesia and directly enjoying the musical strains of Solo keroncong music and other local cultures.

Based on the background above, this study was designed to explore the feasibility of keroncong music as one of the ICH by exploring the Outstanding Universal Value (OUV) contained in Solo keroncong music. OUV is an essential value of a culture or nature that is so extraordinary that it transcends national boundaries and becomes generally crucial for all humanity's current and future generations.

Exploring the OUV of Solo Keroncong Music used ten criteria based on the Operational Guidelines for implementing the World Heritage Convention (OGIWHC) [1]. The research involved KAMKI Surakarta in gaining in-depth knowledge about Solo Keroncong Music. The results of discussions and interviews were processed into texts for use in LDA modeling.

The modeling results in several topics about the main values of Solo keroncong music. These main topics' values were evaluated based on OGIWHC to see whether Solo keroncong music meets the OUV criteria as a requirement for UNESCO ICH determination.

This study is organized into five sections. The first section briefly describes Keroncong music, the background to the problem area, the objective of the study, and the significance of the research output. The second section deals with previous studies on soft power diplomacy and topic modeling using LDA in terms of ICH. The third section discusses the methodologies used to conduct this study. The fourth section is about the analysis and results of this study. Finally, the last section discusses the findings and recommendations for future work.

II. Related Work

A. Soft Power Diplomacy

This study is anchored in the concept of soft power diplomacy, a framework developed by Joseph Nye. It posits that culture, politics, and foreign policy are the three pivotal sources of soft power. Effectively utilizing these sources is instrumental in determining diplomacy's success [5]. Soft power diplomacy is a strategy to influence foreign public opinion and behavior by utilizing the appeal of culture, values, and inclusive foreign policies. The implementation of soft power diplomacy pursues the goal of creating a positive image of the country and expanding its influence in the international world. A country's reputation and how the target public accepts it will determine the success of soft power diplomacy. The appeal and influence result from a social process involving both parties, so the effects of soft power will only occur if there is a mutually impactful relationship between the two parties [6].

Researchers have recently conducted studies using soft power to implement Indonesian diplomacy. Research on the peaceful message of the XX Papua National Sports Week (PON) was carried out to highlight sports as one of the instruments of soft power diplomacy [7]. The study results show the success of the government's soft power diplomacy in warding off security issues in Papua through the success of PON XX. The researcher also conducted a sentiment analysis of the news of the K-Pop concert on the 50th Anniversary of bilateral relations between Indonesia and South Korea. The positive sentiment of the Indonesian public explains that music can be an instrument of soft power diplomacy in harmonizing bilateral relations between Indonesia and South Korea [8]. Currently, the researcher is conducting research (ongoing) on the potential of keroncong music as cultural diplomacy between Indonesia and Malaysia [9]. Initial results found the public's love abroad, especially in Malaysia, for the beauty of the Solo keroncong music [9]. This is the background for the researcher to develop in a new study to find the primary value of Solo keroncong music. The researcher has conducted a study on the evolution of keroncong music in Richmond, Virginia. The Rumput Orchestra is an example of the rapid development of keroncong music outside Indonesia. This orchestra creates new music by combining various Keroncong music cultures, such as Javanese, Balinese, Sundanese, Appalachian, and Irish [10]. The research also involved the keroncong community in Solo City as one of the determinants of the success of Indonesia's soft power diplomacy. The involvement of non-state actors is an effective tool for implementing soft power more efficiently [11].

B. Topic Modeling using LDA in Terms of ICH

Reference [12] stated that the development of new media has enabled intangible cultural heritage to be disseminated through online platforms and attracted the attention of many contemporary young people. Classification and discussion on the value of intangible cultural heritage were essential ways to help with inheritance and dissemination. Real online reviews were collected using the Bilibili website as the research data source. A text-based BiGRU-Attention model was conducted to achieve value recognition and classification, and keyword statistics and topic analysis were performed for a score of more than 77%. The Cultural Value Perception (CVP) category has the best classification performance. Through the topic analysis of comments and keywords, the cultural value of intangible cultural heritage is its core connotation, social value is the primary purpose, and economic value is the power source [12].

Meanwhile, based on cultural identity and sovereignty, intangible cultural heritages (ICHs) are disappearing at an alarming rate and facing an existential crisis [13]. With the emergence of neural network models, the development of digital technology has revived many things that were on the verge of extinction. Traditional cultures and industries that initially seemed unrelated can take on new forms with the help of digital technology, thus enabling ICHs to find new ideas for development. The study took Huizhou ICH as an example and tried to design and construct a Huizhou ICH database and a digital map of Huizhou ICH, establishing a database for management and operation. The paper applies information space theory to study the use of ICH's digital resources under the threshold of the neural network. It employed digital information technology to recode, reconstruct, and interpret ICH. As a result, traditional ICH items were displayed digitally, improving the public's recognition of digital ICH items, thereby promoting the inheritance and dissemination of ICH [13].

The study in [14] designed and constructed a knowledge ontology framework for sports intangible cultural heritage (ICH) resources to support their preservation and inheritance by integrating and mining sports ICH resources. The study collected multiple data on sports ICH from various data sources and constructed ICH knowledge ontology using the CIDOC CRM metadata reference model and seven-step method. To enrich the content of the ontology, the TextRank algorithm was used to extract critical textual information and design a domain-specific NER model for sports NRL. In addition, the study adopted the VSM vector space model for text representation and used a proven hierarchical classification model for text categorization to improve classification accuracy. The study also explores the similarity calculation of concepts in the sports NRM ontology and proposes a semantic similarity calculation formula based on the ontology concepts. Respondents' willingness to pay was investigated through the conditional value method (CVM) to assess the value of sports NRM tourism resources. Finally, the factors influencing

respondents' willingness to pay were analyzed using statistical analysis and a logistic regression model, and it was found that they were mainly influenced by the degree of understanding of sports non-heritage resources and the level of education. The results of this study not only provide theoretical and methodological support for the effective integration and excavation of sports non-heritage resources and a new perspective on their protection, inheritance, and sustainable development [14].

ICH has important historical, cultural, and spiritual values. The study in [15] used the intangible cultural heritage of Yunnan Painting, the national architectural decoration of Dali, as the case study object. They crawled the consumer's comment text data to establish the Yunnan Painting consumer comment text dataset. Secondly, using the K-means method, they clustered high-frequency words from the dataset using text mining technology, TF-IDF keyword extraction, and LDA themes. Finally, they evaluated the economic potential of Yunnan Painting in terms of consumers' cognitive abilities and the emotional appeal of its products based on the extracted results. The study revealed that the dressmaking, painting, and tourism industries were the main economic activities of Yunnan color painting, with the tourism industry requiring further strengthening. According to the text mining of high-frequency words, the frequency of "product" in Yunnan painting was the highest at 296 times, followed by "culture," "technology," "cultural creativity," and "theme." Analyzing consumers' emotional text features reveals that most consumers have positive emotions towards Yunnan-colored paintings, while very few have negative emotions. The proposed economic optimization strategy is based on the results and provides a reference value for the economic development of other intangible cultural heritage [15].

The study in [16] conducted a paper's topic-tracking research based on the topic model. Firstly, the LDA model was used to extract the topic information from the news texts of different time windows. Then, the improved Single-Pass algorithm was used for topic tracking, in which the time decay function and the JS divergence were used to measure the similarity between the topics. Finally, the content and strength of the topics were analyzed for the results of topic tracking. They found that the topics discovered by the LDA model were more reliable than the k-means clustering in topic recognition. For topic tracking, the perplexity degree determined the optimal number of topics in the time window [16].

The combination of machine learning-driven topic modeling using Latent Dirichlet Allocation (LDA) and network analysis techniques examined a corpus of Korean and Japanese research papers on ICH [17]. LDA topic modeling identified three primary themes: technology and ICH, safeguarding ICH, and methodologies and approaches in ICH research.

Previous studies have been conducted related to analyzing [12] and exploring the value of ICH [14], [15] and its digitalization [13]. Unfortunately, no one discussed topic modeling to find UNESCO's Outstanding Universal Values of those ICHs. Topic detection or topic modeling has been conducted using LDA [16] and machine learning [17]. In terms of the dataset, this study used the primary data as the result of the FGD process, while the previous study used secondary data by crawling [15].

III. Methodology

This study explored the OUV of Solo keroncong music, which has not been explored before. Exploratory research helps develop a phenomenon that is not widely known or has little information [18]. Exploratory methods allow researchers to understand complex social phenomena more deeply before formulating specific research questions [19]. Fig. 1 shows the proposed methodology used in this study.

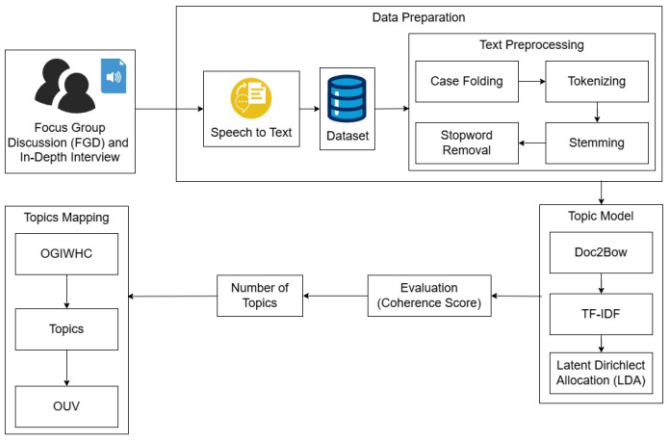

Fig. 1. Proposed methodology.

A. Data Collecting

The first step is to collect primary data. The study used primary data from conducting Focus Group Discussion (FGD) with the Surakarta Keroncong Music Artist Community (KAMKI) and in-depth interviews with several keroncong music figures and activists in Solo. FGD is a structured group discussion with various perspectives or experiences related to a particular research topic [20]. In-depth interviews are qualitative data collection methods that allow researchers to understand individuals' experiences, views, and perspectives related to the research topic [21]. FGD involved 40 people, and in-depth interviews involved five informants. They discussed the main values of keroncong music so that it can be recognized as UNESCO ICH. Initial data were obtained through audio recordings of FGD and in-depth interviews. There were six files of audio recordings.

B. Data Preparation

The recording results were then converted into text using TurboScribe.ai to create a dataset. The text obtained from TurboScribe.ai was then corrected for formats such as spaces, new lines, and inappropriate words. The informants verified the transcript to ensure the validity of the FGD and in-depth interview results. After the transcript (dataset) is verified, the following step is to prepare the data. The dataset contains eight documents. Text processing consists of case folding, tokenizing, stemming, and stopword removal. Case folding is the activity of removing special characters and changing them to lowercase. Tokenizing breaks down text based on spaces into a word (token). Stemming maps each token into a basic word form for nouns, verbs, and adjectives [22]. Stopword

removal is the activity of removing words that refer to words in a language (this study uses the Indonesian language) that are grammatically irrelevant to the content of the text, such as "*di*", "*yang*", "*dan*", "*maka*", and others [22]. The Sastrawi Python library implements the Nazief and Adriani algorithms used during the stemming and stopword removal process because it provides good results for the stemming process of Indonesian-language documents [23]. The results of this phase are transcripts datasets of the text on the FGD activities and in-depth interviews.

C. Modeling

Modeling begins by determining the corpus (collection of documents) using the Gensim Doc2Bow library. Then, text weighting and topic modeling follow.

Term (or text) weighting refers to calculating and determining weights. Term Frequency-Inverse Document Frequency (TF-IDF) is the most popular scheme in text weighting. The weight of words calculated by the TF-IDF scheme is proportional to the frequency of their occurrence in a particular text but inversely proportional to the frequency in other texts [22]. TF-IDF is an unsupervised statistical algorithm commonly used in information retrieval and text mining to assess the importance of words in a particular document in a corpus [15].

TF, or word frequency, represents the number of times a word appears in a given document, and this number is usually normalized to avoid TF bias towards long documents. Defining any word as T_i, the TF of the word T_i is formulated as [15]:

$$TF_{i,j}=\frac{N_{i,j}}{\sum_k N_{k,j}} \quad (1)$$

$N_{i,j}$ is the number of times the word T_i appears in a document D_j, and $\sum_k N_{k,j}$ is the total number of times all words appear in a document D_j.

IDF is the inverse document frequency, representing the distribution of documents containing a particular word in the corpus. The IDF of the word is formulated as [15]:

$$IDF_i=\log\frac{|D|}{1+|\{j:T_i\in D_j\}|} \quad (2)$$

$|D|$ is the total number of documents in the corpus, $1+|\{j:T_i \in D_j\}|$ is the number of documents containing the word T_i 1 is added to avoid the denominator being 0 (i.e., all documents do not contain the word).

A statistical-based technique is used to assess the importance of a word in a document to the corpus, namely Term Frequency-Inverse Document Frequency (TF-IDF). This technique calculates the weight of a word by measuring the frequency of its appearance in the document and its relevance to all documents in the corpus [22]. The calculation of TF-IDF is shown in (3). The larger the TF, the smaller the IDF is. In other words, the more times a word appears in a document, the fewer times the word appears in the corpus. The higher the value of TF-IDF, the more important the word is to this article and the more it can represent the article. TF-IDF is calculated as [15]:

$$TFIDF_{i,j}= TF_{i,j} \text{ x } IDF_i = \frac{N_{i,j}}{\sum_k N_{k,j}} \text{ x } \log\frac{|D|}{1+|\{j:T_i\in D_i\}|} \quad (3)$$

The results of TF-IDF weighting are in the form of a term-document matrix (TDM) and a list of essential words with the highest weight in each document. TF-IDF weighting is based on the corpus.

The next step is topic modeling. Topic modeling is one of the most widely used techniques in the unsupervised machine-learning field [24], [25], [26], [27]. According to [24], topic modeling assumes that a set of hidden topics structures each corpus document. Applying this method, researchers can uncover latent topics and find relationships among topics from textual data. Many social scientists have used topic modeling, especially Latent Dirichlet Allocation (LDA), the most popular method for topic modeling [27], [28], [29].

LDA is a generative probabilistic model of corpus. The LDA method, first introduced in [24], estimates the probability of topic distribution in documents and word distribution in topics [25]. LDA requires an input parameter (k) to determine the number of topics generated. For the LDA model, the number of topics (k) should be determined by researchers [24], [29]. This study determines the number of topics (k topics) by looking at the coherence score [26]. The coherence score indicates semantic similarity between words on a topic [30].

LDA is a method that assesses that each document is represented as a probability distribution over latent topics, and distribution over words characterizes each topic [24]. Words with the highest probability in each topic are usually used to determine its topic, which, in this case, are the main values. LDA can easily assign probability to a new document; no heuristics are needed for a new document to be endowed with a different set of topic proportions than those associated with the training corpus documents. Based on the cooccurrence of words in a large corpus, LDA algorithms simultaneously estimate topics and assign topic weights to each document. The outputs from a topic modeling algorithm are lists of weighted words, where each list is a topic and higher weighted words in a list are more indicative of that topic. It represents each document as a distribution over topics, which can be used to detect semantic patterns across all documents [24].

In Fig. 2, α and β are determined empirically. Meanwhile, z and θ are determined by the LDA model. M is the number of documents; N is the number of feature words in document m. α represents the priori parameter of the topic distribution over the entire document set. β represents the priori parameter of the word distribution across all topics.

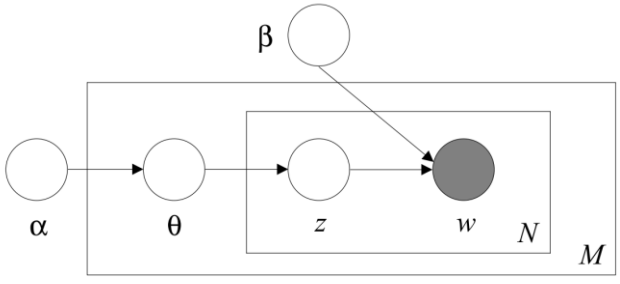

Fig. 2. LDA model diagram [24].

Based on α, the distribution θ of topics in the document is generated. θ is the polynomial distribution of the topic in document M. A topic z is selected from the distribution θ in a document. z is the topic of the n^{th} word in document m; w is the n^{th} word in document m [16]. Algorithm 1 shows the LDA generation process.

Algorithm 1: LDA Generating Model

1: **for all** topics k ∈[1, K] **do**
2: sample mixture components $\varphi_k \sim Dir(\beta)$
3: **end for**
4: **for all** documents m ∈ [1, M] **do**
5: sample mixture proportion $\theta_m \sim Dir(\alpha)$
6: sample document length $N_m \sim Poiss(\in)$
7: **for all** words n ∈ [1, N_m] **do**
8: sample topic index $z_{m,n} \sim Mult(\theta_m)$
9: sample item for word $w_{m,n} \sim Mult(\varphi_{z_{m,n}})$
10: **end for**
11: **end for**

D. Evaluation

LDA algorithms assume there are n topics across all documents to identify topics in a set of documents. The distributions of words determine the distributed k topics across all the documents. This study measures the number of topics (k topics) by the Coherence score [26]. Conversely, the coherence score shows the semantic similarity between words on a topic [30]. The coherence score is formulated as [30]:

$$score(v_i, v_j, \in) = \log \frac{D(v_i, v_j)+\in}{D(v_j)} \quad (4)$$

where,

$D(v_i,v_j)$ counts the documents containing the words v_i and v_j.

$D(v_j)$ counts the number of documents containing the word v_j.

E. Topics Mapping

The primary value is identified by examining the probability of weighing words by the number of topics determined. These main topics' values were evaluated based on OGIWHC to see whether Solo keroncong music meets the OUV criteria as a requirement for UNESCO ICH determination.

IV. Analysis and Result

The dataset used in this study consists of eight documents. After going through the text processing, 2,563 words were obtained, with details of 86 words in the first document, 217 in the second document, 322 in the 3rd document, 480 in the 4th document, 304 in the 5th document, 375 in the 6th document, 268 in the 7th document, and 511 in the 8th document. The weight of each word was then calculated using TF-IDF. Table I shows some examples of words with frequency and TF-IDF values.

TABLE I. Example of Term Frequency and TF-IDF Score

After the term was weighted, modeling was carried out with the LDA. Several experiments with topics 2 to 10 were carried out to obtain the best Coherence Score. Fig. 3 shows that the number of topics 4 obtains the best Coherence Score of 0.51.

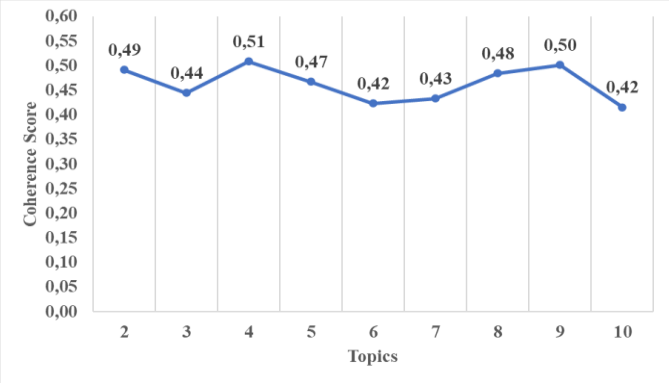

Fig. 3. Comparison of coherence score.

The higher the coherence score, the better the topic modeling interpretation results produced. Using four topics (k=4), the model gave the semantic similarity between words on a topic. Thus, every topic was visualized using pyLDAvis and the word cloud, which was needed in the analysis process.

The terms in the topic modeling are shown in the text, which is primarily frequent in the document. These were depicted by the circle size (as seen in Fig. 5, 7, 9, and 11). Representation of the result using a scatter plot would reveal the distance between topics, the distribution, and the relationship between topic levels. The distance between two or more topics approximates their semantic relationship. Note that close topics 1, 2, 3, and 4 are semantically related, which describes the terms in the topics. As observed in Fig. 5, 7, 9, and 11, the terms are described in the articles concerning the topic's distribution. This reveals that topics 1, 2, 3, and 4 are semantically distributed and have a relationship on topic levels. These reveal four selected topics from the topic model analyzed using the LDA model. The LDA model was one of the input arguments, along with the corpus and dictionary of the emerging terms used for the topic modeling. The slider (λ) in the web-based interactive visualization depicts the relevance metric of the rank terms. It is worth knowing that the terms of the topic are ranked in decreasing order by default following the topic-specific probability (λ = 1). Fig. 5, 7, 9, and 11 reveal the standard terms from the topic model when the slider is at full probability.

Fig. 4 shows the word cloud generated by topic 1, and Fig. 5 shows the model visualization. The comments containing the keywords "kait" and “naskah” appear the most often. In addition, expressions related to music such as “cengkok”, “biola”, “ritmis”, and “genre” are also frequently mentioned.

The model visualization of topic 1 (Fig. 5) reveals the top 30 most relevant terms for topic 1, highlighted with the red bar. These terms account for 49.6% of the overall term frequency, highlighted with the blue bar. Those terms are kait, naskah, masuk, karakter, catat, wakil, usul, ahli, lobi, presentasi, Menteri, WBTB, UNESCO, untung, budaya, kategori, seni, mohon, wayang, dinas, program, pihak, waris, sederhana, eksklusif, akademik, nyata, sapto and dulu.

Fig. 4. Word cloud of topic 1.

Fig. 6 shows the word cloud generated by topic 2, and Fig. 7 shows the model visualization. The comments containing the keywords "baku", “adaptasi”, “karakter”, and “patah” appear the most often. Other expressions related to the community such as “anggota”, “asosiasi”, “ahli”, “KAMKI”, and “perilaku” are also frequently mentioned.

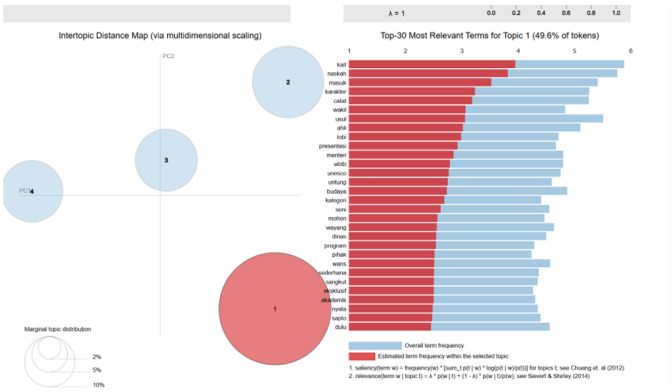

Fig. 5. Model visualization of topic 1.

Fig. 6. Word cloud of topic 2.

The model visualization of topic 2 (Fig. 7) reveals the top 30 most relevant terms for topic 2, highlighted with the red bar. These terms account for 20.2% of the overall term frequency, highlighted with the blue bar. Those terms are baku, adaptasi, patah, usul, KAMKI, cengkok, target, ciri, Moresko, seniman, anggota, gaya, perilaku, asosiasi, sriwedari, sumbang, wadah,

gemar, khas, ndak, ritmis, catat, sumbangsih, wayang, ahli, stimulant, budaya, artis, biola, and enggak.

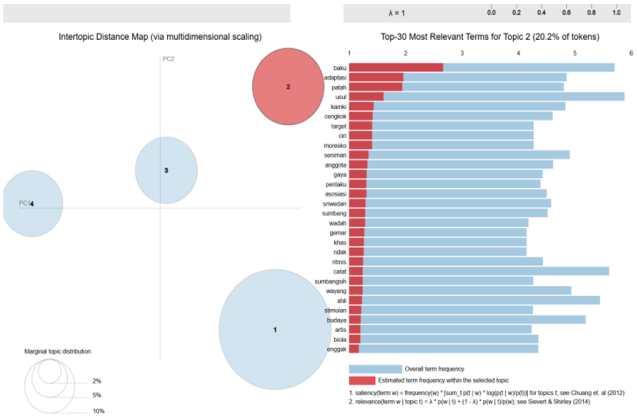

Fig. 7. Model visualization of topic 2.

Fig. 8 shows the word cloud generated by topic 3, and Fig. 9 shows the model visualization. The comments containing the keywords "ajar" and "Ramlee" appear the most often. Other expressions related to history and tradition, such as "Malaysia," "Melayu," "zaman," "kumpul," and "patriotik," are also frequently mentioned.

Fig. 8. Word cloud of topic 3.

The model visualization of topic 3 (Fig. 9) reveals the top 30 most relevant terms for topic 3, highlighted with the red bar. These terms account for 15.2% of the overall frequency, highlighted with the blue bar. Those terms are ajar, Malaysia, cengkok, ritmis, lagu, Ramlee, zaman, and biola. Topic 3 mostly contains terms related to music and the instrument such as cengkok, ritmis, lagu, biola, vokal, klasik, gitar, genre, akor, senggaan, and ngeroncongi; the value of education, tradition, and history such as ajar, Malaysia, zaman, Ramlee, Melayu, pakem, baku, patriotik, metode, kumpul, karakter, mula, and pengaruh.

Fig. 10 shows the word cloud generated by topic 4, and Fig. 11 shows the model visualization. The comments containing the keywords "rekam" and "abad" appear the most often. Other expressions related to the history such as "Hindia", "Belanda", "lokananta", and "historis" are also frequently mentioned.

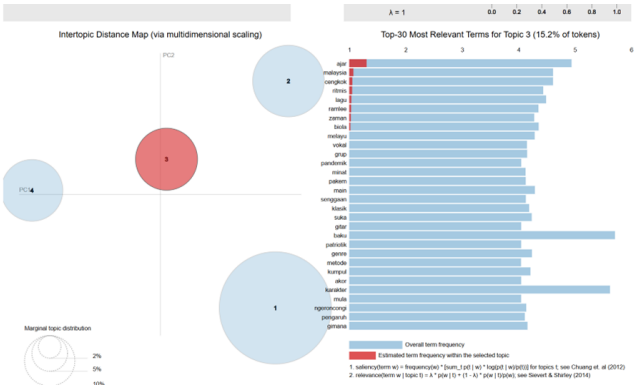

Fig. 9. Model visualization of topic 3.

Fig. 10. Word cloud of topic 4.

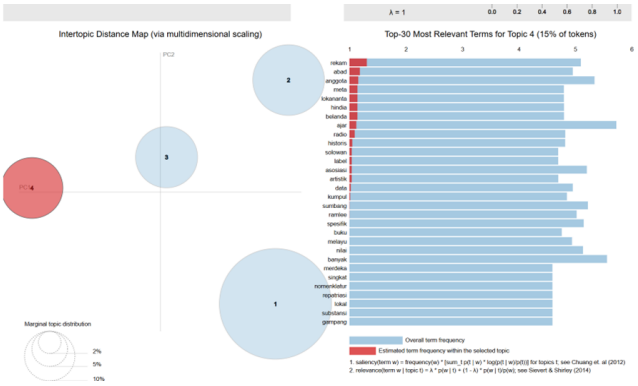

Fig. 11. Model visualization of topic 4.

The model visualization of topic 4 (Fig. 11) reveals the top 30 most relevant terms for topic 4, highlighted with the red bar. These terms account for 15% of the overall frequency, highlighted with the blue bar. Those terms are rekam, abad, anggota, meta, lokananta, Hindia, Belanda, ajar, radio, historis, solowan, label, asosiasi, artistic, data, and kumpul.

LDA modeling results in four topics with the highest coherence score of 0.51. The legitimate source analyzed each word in every topic and mapped it into the OUV values. These main topics' values were evaluated based on OGIWHC to see whether Solo keroncong music meets the OUV criteria as a requirement for UNESCO ICH determination. The result can be seen in Table II.

TABLE II. MAPPING TOPICS TO OUV VALUES

No. OUV	OUV Value	Topic 1	Topic 2	Topic 3	Topic 4
1	Masterpiece	*Cengkok Ritmis Biola Genre Senggaan*	*Karakter Baku Adaptasi Anggota Asosiasi Kamki Ahli Moresko*	*Ramlee Melayu Minat Grup Vokal Suka Lagu*	*Rekam Abad Hindia Belanda Lokananta Artistik Radio Historis*
3	Civilization	*Kait Naskah Ritmis Catat*	*Adaptasi Sriwedari*	*Ajar Zaman Melayu Patriotik Grup*	*Rekam Abad Hindia Belanda Lokananta Radio Historis Buku*
6	Tradition	*Kait Usul*	*Adaptasi Wayang Usul Perilaku Moresko*	*Ajar Ramlee Melayu Patriotik Vokal Lagu Suka*	*Rekam Hindia Belanda Histori Spesifik Nilai*

V. CONCLUSION

This research explored how the data were collected using FGD and in-depth interviews. These primary data are the strength of this study, as Solo keroncong music has never been explored before. Thus, the dataset became this study's key finding and novelty. This research is focusing on creating the dataset and implementing the LDA model. Future research exploring other AI-based cultural studies is still challenging.

The study aimed to find the main values contained in Solo keroncong music as a requirement for eligibility to be proposed as one of UNESCO's intangible cultural heritages. Recognizing Solo keroncong as UNESCO's intangible cultural heritage will have positive implications for preserving Indonesian culture: (1) International recognition will improve Indonesia's image as a country with a rich cultural heritage. (2) Indonesian society, especially the younger generation, will appreciate and be proud of keroncong music as part of their national identity, so the younger generation is more interested in studying and developing keroncong music through innovation and collaboration with other music genres. (3) UNESCO's recognition can increase tourists' interest in learning more about keroncong music, which impacts the creative economy sector. (4) Keroncong music will be better documented, including recordings, academic research, and digital archives.

The corpus was first determined using the Gensim Doc2Bow library. Then, term weighting was conducted by TF-IDF, and topic modeling was used LDA. The modeling phase resulted in four topics, which were then mapped into three OUVs. The results of the research found that there are three OUVs possessed by Solo keroncong music, namely categories (1) representing a masterpiece of human creative genius; (3) bearing a unique or at least exceptional testimony to a cultural tradition or to a civilization which is living or which has disappeared; (6) being directly or tangibly associated with events or living traditions, with ideas, or with beliefs, with artistic and literary works of outstanding universal significance. (The Committee considers that this criterion should preferably be used in conjunction with other criteria). The following is the explanation of the value of the eligibility of Solo keroncong music as UNESCO's intangible cultural heritage based on the results of this research.

A. Keroncong Music is a Masterpiece of Human Creativity

Solo keroncong music is worthy of being a masterpiece of human creative genius because it combines various cultural elements, musical techniques, and unique artistic values. Keroncong music was born due to a harmonious blend of local Indonesian culture with Portuguese fado music. This music became a cultural heritage developed through acculturation with Javanese, Malay, and other cultures. Keroncong music creatively underwent a process of adaptation to local culture. Despite being influenced by outside influences, keroncong music developed with a local taste in melody, instruments, and lyrics.

The main value of keroncong music lies in its artistic value. Keroncong music has unique characteristics in terms of melodic rhythm. The main instruments commonly used in keroncong music are cak, cuk or ukulele, guitar, cello flute, and violin, creating a distinctive sound and unique musical aesthetics. If keroncong music is suspected of being influenced by the presence of Tugu keroncong music, it turns out that there are abnormalities here and there. Keroncong music, which is currently developing in the mainstream, is not like the music in Tugu. There are differences because the music developed in the archipelago is explicitly treated in each region. For example, what developed in Surakarta already has mainstream gamelan music. In the interior of Java, especially Surakarta, music that developed more slowly when using instruments like those above was appreciated and created in such a way according to the character of Javanese. In various regions in the Indonesian archipelago, keroncong music developed with various variants, some using the chordal system like Western music, some using rhythms or in the local scale area. In the Surakarta distribution area, a type of Javanese Langgam uses the Slendro and Pelog scales. Keroncong music mainly uses a system called chordal, namely Western musical concepts. This system uses a diatonic scale in the form of Solmization using Western harmony, namely chords I, IV, V, and II. Since the holding of the keroncong music group competition in Deca Park (City Park, now the Medan Merdeka area of Jakarta) Batavia, Concours (Het nieuws van den dag voor Nederlandsch-Indië, April 11, 1917) or, later called Bintang Radio, keroncong music began to be popular with a chordal system with arrangements using Western music presentation methods.

Keroncong, developed in the Surakarta area (Solo City), has its specialty. The specialty of Solo keroncong can also be seen in combining musical instruments. The use of instruments in Solo keroncong music is unique, and instruments such as the ukulele, guitar, flute, cello, and contrabass are used to create a distinctive sound. This Solo style of keroncong music shows genius in processing simple musical instruments through the

simplicity of the ukulele (cuk and cak) used to create a complex but light rhythm. Solo keroncong also has its uniqueness because it plays songs in Javanese. Javanese style is music typical of the Java region that uses Western instrumentation but presents it regionally, namely the slendro and pelog scales that imitate Javanese gamelan. Songs created by Maestros Gesang, Ismanto Sapari, Anjarany Any, WS Nardi, Dharmanto, and other Solo keroncong music artists have beautiful orchestration and instrumentation typical of the Javanese style.

Keroncong is also known for its rich harmony and melody. The character of Solo Keroncong's music is melancholic and beautiful. The harmony of keroncong music is famous for its softness and melodious melodies, which touch the listener's emotions. Its rhythm is also unique; with its distinctive rhythmic pattern, Solo style keroncong music can create a relaxed atmosphere full of emotion.

Keroncong music lyrics are often used to convey cultural messages and philosophical values. The poetic lyrics of keroncong music contain moral messages, teach the philosophy of life, or are expressions of love and longing. The beauty of its language reflects the genius of its poet and creator. For example, in the keroncong song "*Bahana Pancasila*" by Budiman BJ, the lyrics glorify Pancasila as the philosophy of the Indonesian nation.

Ultimately, keroncong, as a masterpiece of the Indonesian people, has become a national identity. Keroncong is a piece of music considered "truly Indonesian," reflecting the values of nationality, togetherness, and cultural identity that are the nation's pride. The aesthetics of keroncong music are eternal, and its beauty is conveyed by sound, structure, and emotions, making it a work of art that transcends time and is relevant in various eras. With these elements, keroncong is not just music but a masterpiece that illustrates the creative genius of humans in creating, adapting, and inheriting a culture of high value.

B. Keroncong Music as a Witness to Civilization

Keroncong music is considered a witness to civilization because it reflects the historical journey of the Indonesian nation. The long history of the growth of keroncong music began in the 17th century, when the Portuguese in Malacca came to Indonesia or the archipelago, especially in Kampung Tugu, Batavia. They have evolved and assimilated with the culture of the local community, which was initially a form of daily expression after they had been hunting, farming, raising animals, and fishing. They entertained themselves and each other by playing the music they could. At that time, their music was not yet called "keroncong" but was still music from their region as entertainment to relieve fatigue. They were enslaved Portuguese people captured by the Netherlands, a mixture of Portuguese with former colonies of India-Sri Lanka and Malacca, and local people who mostly came from Bengal and Malabar. The Dutch had to change their Portuguese-sounding Catholic names and replace them with new Dutch-style names that embraced Protestant Christianity, such as Mardijkers (a general term for freed former Asian and African slaves) people.

The development of keroncong music from the colonial era to the present shows that this genre can survive. Keroncong music has witnessed society's socio-political and cultural changes in every era. In the colonial era, keroncong witnessed the struggle of the Indonesian people against colonialism. Keroncong songs such as Keroncong Kemayoran were often used as symbols of national awakening and propaganda tools for the struggle. After Indonesia's independence, keroncong became part of national music and is now a symbol of national identity and a unifying tool.

Keroncong shows traces of extinct traditional music. Keroncong can be considered a "living archive" of traditional music that may have disappeared. Many elements of local traditional music are contained in keroncong, such as rhythmic and melodic patterns. Keroncong music often records certain events, values, or lifestyles in its lyrics, thus becoming valuable documentation of past ways of life. Keroncong also shows the tradition of a typical Indonesian ensemble based on harmony and cooperation. This shows the value of the collectivity of Indonesian society in the arts. Nowadays, keroncong has become an art form that connects the old and young generations. Keroncong proves how culture and tradition can survive amidst the current of modernity.

C. Keroncong Music has Traditional Values

In the lives of Indonesian people, keroncong music is still part of the socio-cultural tradition. Keroncong music is an integral part of the Indonesian cultural identity. The lyrics of the songs often contain values from the daily lives of the Indonesian people. Keroncong functions as a medium to preserve and convey local culture and traditions. The themes primarily found in keroncong songs are reflections of regional identity, love, food, love of the homeland, all kinds of cultural activities, advice, or local cultural behavior, both seriously and jokingly. For example, the legendary song "Bengawan Solo" was created by Gesang, a keroncong maestro from Solo; the lyrics describe the beauty of the Bengawan Solo River. Keroncong music still survives in Indonesia today because of its adaptability. Keroncong music in various regions is closely related to local culture. In Batavia, keroncong collided with the music culture of Gambang Kromong; in West Java, it blended with jaipongan; in Central Java, it was famous for its gamelan; in East Java, with Ludruk. Keroncong in Kalimantan and Sulawesi also blended with local music, culture, and traditions. While in Maluku, keroncong was influenced by the cheerful and passionate music of the Ambonese people. The cultural value of keroncong music reflects the musicality and style of its people.

Socially, keroncong music is often played at various events such as weddings, traditional ceremonies, and other social gatherings that help strengthen social relations and a sense of togetherness. At the beginning of the growth of keroncong music in Batavia, for the first time in 1880, musicians from Tugu village played their music outside their hometown. They played in the form of a stage parody with musical performances wearing European costumes and playing guitars with Morisco songs from Portugal by the native people. This music was often used for celebrations by Indo-Dutch crossbreed people. Lower-class Indo-European people favored keroncong music as a form of public entertainment. At that

time, popular entertainment was keroncong music because there were no competitors for other types of entertainment music. Keroncong music reached its golden age in the pre- and post-independence era.

Keroncong music is readily accepted because of its universal values. The songs performed in keroncong music are in Indonesian, using a standard diatonic scale. The types of songs from Western music played in keroncong rhythm/music also use Indonesian lyrics that various groups understand. This phenomenon strengthens the Indonesian nation because they have the same idiom, namely, keroncong music, and its language lyrics. Several times, envoys from Indonesia who participated in international music festivals performed keroncong music, which eventually became a characteristic of Indonesian music. This shows that keroncong music is a representation of Indonesia's national identity. This music symbolizes diversity and unity in difference, one of the basic principles of Indonesia's national motto, Bhinneka Tunggal Ika (unity in diversity).

ACKNOWLEDGMENT

***Abstract*—Chronic Kidney Disease (CKD) is a chronic disease that progressively impairs kidney function to the point of wasting filtration, electrolyte imbalance, and blood pressure control. Early and precise prediction becomes necessary for successful disease management. This research demonstrates a new method involving Deep Separable Convolutional Neural Networks (DS-CNNs) in improving CKD prediction. Based on the Chronic Kidney Disease Dataset available at Kaggle, the model employs DS-CNNs combined with optimized techniques of optimization for better predictive accuracy. DS-CNNs utilize depthwise and pointwise convolutions to facilitate effective feature extraction and classification with efficient computation. To enhance model performance, the Learning Rate Warm-Up with Cosine Annealing technique is used to guarantee stable convergence and controlled rate of reduction in the learning rate. This solution remedies the inadequacies of traditional CKD detection solutions that are insensitive to early stages and entail expensive, invasive procedures. At 94.50% accuracy, the new DS-CNN model outcompetes conventional methods, featuring better prediction performance. The results demonstrate the utility of deep learning and optimization in early detection of CKD and introduce a promising tool for enhanced clinical decision-making.**

Keywords*—Chronic kidney disease; deep separable convolutional neural networks; learning rate warm-up with cosine annealing; predictive accuracy; optimization techniques

I. Introduction

CKD presents a significant global health challenge, affecting approximately 850 million people worldwide [1]. The kidneys are two of the most important organs in the human body located on the right and left flanks of the spine and in the abdominal region just below the rib cage They have the function of regulating water and electrolyte balance and maintaining the body's internal pH by filtering out waste products, excess water and toxins from the blood in the form of urine. Also, they maintain the electrolyte concentration, blood pressure, as well as the acid and base balance; synthesize hormones which are involved in calcium regulation and erythropoietin, which is responsible for the production of red blood cells. CKD is defined by persistent and gradual decrease in the kidney's function and the failure a kidney to remove wastes and balance fluids leading to the build-up of potentially toxic substances and swelling [2].

Chronic kidney disease is a global health issue that still poses great diagnostic challenges especially in the Low- and middle-income countries, hence it often presents itself as a huge burden to the affected patients. Here, inadequate resources and capacity of healthcare facilities hamper early detection and treatment, exacerbating the disease's impact CKD requires timely diagnosis and management to delay the worsening condition to stage 5 where patients usually require costly treatments such as dialysis. However, inadequate screening programmes and relevant facilities restrict access to needful treatments in the region. In addition, other sociodemographic factors and poor health funding existing in the society also lead to disparities in management and overall health of individuals with CKD. These difficulties can only require specific actions to enhance the facilities, increase the understanding and accessibility of satisfactory renal care to people [3]. In Stage 1 the kidneys work effectively to perform all their tasks as they should. At stage 2, common investigations show a slight reduction of function where a body is sometimes able to filter small wastes. Kidneys are severely damaged and, at Stage 3, the patient experiences clearCut impairment of waste removal. Stage 4 is characterized by moderate losses but loss of function is not complete in this stage. The last stage is the stage 5 also known as renal failure which means that the kidneys cannot execute their main functions, so dialysis or transplantation of the kidneys is required.

It is interesting to note that, commonly used primary screening for chronic renal disease, serum and urine test often fail to give an early sign of kidney dysfunction. Such tests are unable to reflect small initial differences in the kidney or variations over time and, therefore, give a delayed diagnosis [4]. In addition, extensive information providing methods like kidney biopsies, are not appropriate for routine screening processes because they involve very intensive procedures and potential risks. The mentioned constraints are solved by Machine Learning (ML) approaches [5] and this option seems quite convincing. It is, however, clear that using big and complicated data, ML systems are capable of identifying fine changes in patterns of kidney function, and that earlier work may miss [6]. Since the factors taken to be used in building an ML model include demographic factor, medical history and clinical test results among others, the models can give more precise and hence be better at doing the CKD risk assessment. The mentioned capacity enables the formulation of specific treatment plans for patients depending on certain general profiles. The efficiency of ML algorithms also enables quicker analysis of new patients' information, which is crucial for the initial diagnosis and treatment. These algorithms can quickly adapt to new knowledge and incorporate this new information through changes in the patient's health into the diagnostic process. Additionally, with the help of machine learning algorithms it is possible to predict the probability of the CKD progression in high risk population and estimate the preventative measures required [7]. Such an approach is quite effective in positively impacting the overall prognosis of the patient since issues that could potentially be of serious concern if left unaddressed are likely to have been dealt with in the act. Taken collectively, it could be postulated that ML algorithms are potentially superior to conventional methods of CKD diagnosis, and as such, they are valuable tools in the fight against this prevalent and significant health condition.

As a result, many studies have had to harness other approaches that are at the algorithm level like ensemble learning and cost-sensitive learning rather than data level techniques [7]. Ensemble learning is a revolutionary concept in the arena of ML study and implementation employed to achieve very high accuracy of the classifier through integration of one or more classifiers. Boosting [8] and Bagging [9] are widely used ensemble learning techniques. Therefore, in this study, we develop an AdaBoost classifier that gives higher weight to examples in the minorities, thus improving the prediction of the samples of the minority class and the global classification accuracy [11]. The currently used techniques for CKD diagnosis such as blood tests, urine tests, and even invasive techniques like biopsy have various drawbacks. These methods are usually not very accurate when it comes to determining the early sign of kidney failure and the changes in the kidney function with time, therefore the diagnosis and treatment for the kidney diseases are often delayed. In addition, KUB radiography, ultrasonography and CT scans are expensive and sometimes take a lot of time which limits their use. In spite of the fact that the validity of CKD detection has increased with the help of ML methods which analyze big data and find rather complicated patterns, however, there are the disadvantages of such methods [10]. The issue with the current paradigm of using conventional ML algorithms, however, is an inability to adequately process the data, particularly if CKD cases are vastly in the minority compared to controls represented by non-CKD patients.

Some of the problems are solved by the generic ensemble learning techniques such as AdaBoost that involves using multiple classifiers brought together to enhance the accuracy of the classification process as well as work on imbalanced data set. Nevertheless, they can still encounter difficulties in terms of low computational efficiency for the data with large dimensionality and the complexity of feature interactions. The above-mentioned limitations are inherited from the traditional machine learning frameworks, and can be mitigated with the help of the proposed state-of-the-art deep learning framework, namely Deep Separable Convolutional Neural Networks (DS-CNNs). DS-CNNs gives better accuracy in detecting the changes in the CKD as convolutions lead to the structural difference that improves the working ability of the model and early stage of kidney damage. In addition, this conceptual framework proposes methods for dealing with imbalanced data which enables both the minor and major classes to be dealt with equally well improving the general performance of classification. The proposed model works around these challenges by incorporating dynamic learning rates and fine tuning through the helps of other optimized methods and algorithms which are far much better than other traditional methods of Machine Learning named as ML; and thus provoking the CKD prediction dashboard based on the CKD dataset of the UCI Machine Learning Repository with better efficiency and accuracy. The major key contribution can be divided among the following:

- Enhancing the framework with the proposed DS-CNNs model and the LRW-CA optimization for better performance and reliability of the CKD identification.
- Applying DS-CNNs in order to eliminate the convolutional processes into separate depths and points, which helps improve the quantity of computations required as well as the quality of the designed model.
- Standard practice of implementing the Learning Rate Warm-Up together with Cosine Annealing helps improve the early training phases' stability, which in turn results in stable and accurate model performances.
- Avoiding such problems as low sensitivity to changes in CKD at early stages and high invasiveness of some diagnostic methods by implementing modern deep learning methods and optimizing clinic algorithms for their application.

The research paper is organized as follows: The importance and difficulties in predicting CKD are described in Introduction. The following section, 'Related Work,' presents a critical analysis of previous methods of CKD detection and their shortcomings. Methodology section presents the implementation plan of the proposed work, the proposed DS-CNN architecture, and the optimization strategies. Experimental Results gives the results and discussion on the effectiveness of the proposed method compared to those in the literature. In this paper, conclusion will make an effort to briefly restate the key findings, reflect on the implications of the study, and point out the possibilities of future research in relation to the existing literature.

II. Related Work

To improve the work done by Chotimah et al [11], the authors created a second-generation advanced deep learning approach that dealt with feature selection to identify the most relevant CKD diagnostic markers from patients' records. SBFS was used in their research; it is a technique, which effectively removes successively one feature after the other that has less influence in the CKD prediction model. The two were able to utilize SBFS and settle for 18 features out of which the relevant 15 were deemed pertinent. These selected features were then used as inputs to an Artificial Neural Network (ANN) Classification system. The revised model calculated with only 15 most significant attributes was 88 %, which was much improved than the one which was 80% acquired from 18 attributes. This much enhanced results showed that feature selection had a way of improving the model hence enhancing better forecasts of CKD. But, since the features are selected manually, then the framework may not analyze some interactions and dependencies between them or may not see the interdependencies among a few features and thus the framework is not able to capture complex relations of the features present in the data set. The above framework entitled Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs) mitigates this drawback by using DS-CNNs to learn and extract multi-level features directly from raw data to enhance the predictive models' accuracy.

Alsuhibany [12] designed a sophisticated IoT based ensemble diagnostic system for CKD named as EDL-CDSS. This system used ADASYN to improve outlier detection, and integrated multiple deep learning strategies: CNN-GRU, DBN, and KELM. Therefore, the combination of these technologies operationalized the concept of ensemble, and it obtained a remarkable accuracy level of 96%. 91% by showing that by using several deep learning models with sophisticated approaches and bagging technique a precision CKD diagnosis and good outlier management could be achieved. However, use of multiple models can be complicated making the process of integrating them time consuming it could take a lot of time before the desired results are accomplished making it a bit cumbersome for real world use. To overcome these drawbacks, the proposed framework "Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs)" employs DS-CNNs enable simplified architecture to analyze the complexity of the patients' data, which slows down training times and increases computational demands, then again, underestimating the complexity of the patients' data leads to low predictive accuracy.

Akter et al y.in their study [13] selected seven advanced deep learning methods for predicting the probability of developing CKD, namely; ANN, LSTM, GRU, bidirectional LSTM, bidirectional GRU, MLP, and simple RNN. On these models, they had certain evaluation criteria such as loss, validation loss, recall, accuracy and precision. To the researcher's surprise, three methods, namely ANN, simple RNN, and MLP exhibited superior results with accuracies of 99%, 96%, and 97% respectively. Based on such an extensive assessment of the performance of these algorithms, their high results in the classification of CKD patients were established, as well as the potential of deep learning in providing more accurate predictions. However, the presented individual models approach might have a problem when it comes to the generalization across the datasets and the capturing of the interactions among features. The above improvement is lack of due to the proposed framework, Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs), due to the use of DS-CNNs to capture hierarchical features and interactions of the data to generalize and apply it to different datasets.

In a study [14] conducted by Iliyas and colleagues, 400 patient records gathered at Bade General Hospital and 11 features were applied to predict CKD through a Deep Neural Network (DNN). They managed this by imputing with the mean of respective attributes in the preprocessing step. They utilised a DNN model in predicting CKD with an accuracy rate of 98%, and understood that creatinine and bicarbonate were the critical factors in the prediction. This paper presented how DNNs can be used to solve CKD prediction tasks and the need for data pre-processing and feature extraction to optimize high prediction accuracy. But, missing data have been addressed using the mean imputation, and this might not handle variability of data and it can affect the model significantly. The proposed framework, Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs), avoids the aforesaid problem by using sophisticated imputation techniques and exploiting DS-CNNs in learning and fusing highly nonlinear and intricate features of data that, in turn, promotes accurate CKD prediction with improved model integrity.

Ma et al. [15] gave a detail insight of the social focus of heterogenous modified artificial neural network (HMANN) for CKD detection, segmentation and diagnosis within the Internet of Medical Things (IoMT) framework. The HMANN model was further developed focusing on early detection and accurate segmentation of the kidney images and the avoidance of noise. Regarding the accuracy rate of the different methods they employed, their study ushers an average of 92. 3 % for ANN-SVM and 97 %. 5% for HMANN. This research highlighted the major application of HMANN and its applicability for improving the diagnostic accuracy and image analysis of CKD and provided an example of future possibilities of the system in practical medical imaging and diagnosis. At the same time, developed HMANN architecture can be considered as complex and indispensable may lead to increasing the load on the computer and time required for its work. The mentioned framework is a solution to these problems because it incorporates a leaner model architecture yet proves to be efficient in retaining those features essential for fast and accurate CKD diagnosis and prediction – the DS-CNNs.

In particular, the identification of CKD [16] was developed using deep learning approach by combining Bidirectional LSTM networks and one-dimensional Correlational Neural Network (1-D CorrNN) suggested Bhaskar and colleagues. The combined model, 1-D CorrNN-LSTM was tested using CKD-sensing module with the accuracy of 98%. 08%. This also implies that the proposed model performed better than other approaches in the sense that this research was able to validate the model on time series, a factor that enhances the generalization of the model for the prediction of CKD. The study showed that the model is

capable of enhancing the diagnostics accuracy and dealing with a variety of data features related to the CKD. Yet, since the model is quite complex and works with expanding sequences, the training of the model may be more time-consuming and computationally intensive. The DS-CNNs model used in the proposed framework, Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs) does not have such issues since it has a more efficient architecture that does not require a lot of computation and training times in order to capture more complex patterns hence improving the performance and practicality in real world applications.

ANNs with SBFS were applied by Chotimah and colleagues, and the estimate of overall accuracy was 88%. Alsuhibany and team designed an interpersonal deep learning ensemble system named as EDL CDSS achieving an accuracy of 96 by using various deep learning techniques. 91% although with a higher computation complexity. Five state of art deep learning models were implemented and tested; ANN, LSTM, all achieved high accuracy but generalization and complex feature interaction were the major limitations that Akter encountered. For imputation, 98% accuracy was obtained by Iliyas by using imputation techniques and Deep Neural Networks (DNNs) and however mean imputation might impact robustness. Ma proposed a heterogeneous modified artificial neural network (HMANN) for the detection of CKD, which had high accuracy, but required more computational resources for training. Bhaskar incorporated a novel created 1-D Correlational Neural Networks (1-D CorrNN) with Bidirectional LSTM networks and got an accuracy of 98. 08% accuracy but the problem they face is that the complexity and the time they have to spend on training increases. These constraints are solved with the help of hierarchical learning and the use of depthwise separable convolution in the framework of DS-CNN, which opens the question of automation of the feature extraction process and reduces computational complexity. It also applies Learning Rate Warm-Up with Cosine Annealing as the strategy of training, which help for improvement of generalization. This approach eliminates past challenges, decreases the size of ensemble models, enhances resource generalization, and solves problems connected with data imputation and computational effectiveness, offering a reliable and efficient method for CKD prognosis.

III. Problem Statement

Existing research [17] on the approach of CKD detection throws light on different machine learning algorithms such as SVM, Decision tree, and Random forest. This it compares them and notes that they while they are are reasonably accurate, they suffer from drawbacks such as high computational complexity and inability to handle higher-order feature interactions respectively. Hand crafted features and manual tuning also limits model performance and generalization as well. The use of handcrafted features and manual tuning can also constrain model performance and generalization. To these ends, the proposed framework, Enhancing Chronic Kidney Disease Prediction with Deep Separable Convolutional Neural Networks (DS-CNNs), does away with these limitations by employing DS-CNNs that are capable of automatically extracting hierarchical features from raw data to expand the model's capability to identify the diverse information patterns. When Cosine Annealing is used in combination with Learning Rate Warm-Up early phases of training are stabilized and convergence is enhanced. It also brings down the computational expenses, increases the prediction conveyance and is a neater algorithm in comparison to existing approaches for CKD prediction.

IV. Proposed Framework for Chronic Kidney Disease Prediction Using DS-CNNs and Learning Rate Warm-Up with Cosine Annealing Optimization

About the suggested framework for improving the prediction of CKD, it is possible to note that the main aim of the proposed algorithm is to increase the accuracy of diagnostic results due to thorough attempts. The process begins with the Input Data which consists of the dataset of chronic kidney disease patients, which is a vital tool in training and evaluating patients. The Data Preprocessing phase involves several rigorously performed activities such as cleaning, normalization, data formatting directly for model input so that our data does not contain any such unusual variation or skewness that would impact the model performance. Lastly, under the Feature Extraction domain, the use of Deep Separable Convolutional Neural Networks (DS-CNNs) is used by the framework to extract feature relevant to the dataset. This process involves two key operations: This in turn consists of two types: Depth wise Convolution that works by performing convolution on each of the input channels separately and Point wise Convolution, which integrates the depth wise features through 1*1 conjugate convolution in an attempt to generate a small, yet comprehensive feature representation.

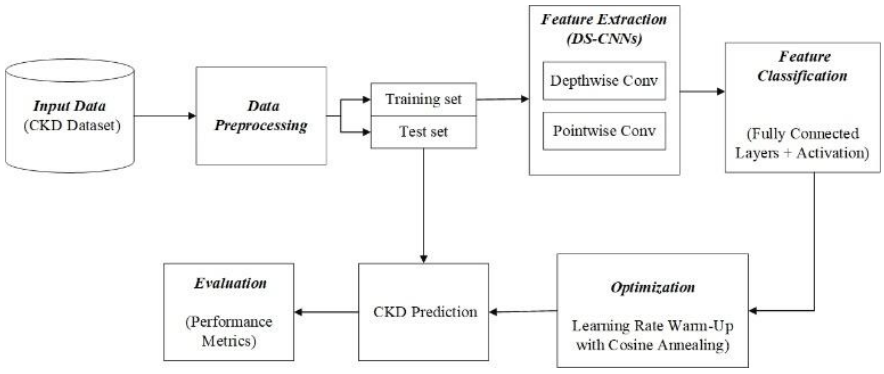

Fig. 1. Proposed framework for enhancing CKD prediction with DS-CNNs.

The extracted features are then fed into Fully Connected Layers in which the data goes through different activation functions so as to perform classification and introduce non-linearities to improve the performance of the model. Learning Rate Warm-Up with Cosine Annealing is adopted in the Optimization stage of the framework to achieve better training stability and convergence because it starts with increasing learning rate gradually and then decreases it following the cosine pattern. The consequence is that, with good input information, the CKD can be well predicted, and the result would give a probability of the disease, in general. Finally, the Evaluation phase assesses the model's performance using metrics such as accuracy, sensitivity, and other relevant indicators. This stage also includes a comparison with existing methods to highlight improvements in predictive accuracy and reliability achieved by integrating advanced DS-CNNs and optimization techniques. This comprehensive framework aims to address the limitations of traditional CKD detection methods by leveraging sophisticated deep learning and optimization strategies. Fig. 1 illustrates the proposed method.

A. Dataset Description

In this framework, Chronic Kidney Disease (CKD) dataset reflects thorough patient health records database intended for creating and evaluating forecast models for CKD. The features in this dataset are quite diverse, and categorize and numerical health data that are significant for CKD diagnosis are included. The nominations are Age, in years; Blood Pressure with two categories: systolic and diastolic. The Specific Gravity attribute gives the information of concentration of urine and Albumin shows the kidney function amount in the urine. Sugar, thus equalizes the presence of sugar in urinals; Red Blood Cells and Pus Cell attributes signify the presence of red blood cells and pus cells in the urinary sample respectively. Other parameters like Pus Cell Clumps and Bacteria represent the clump of pus cells as well as bacteria in the urinary system that helpful to diagnosing the kidney diseases. BG Random indicates the random blood glucose test results, BU presents the blood urea level, and SCr shows the creatinine level in serum as significant markers of kidney compartment. The values Sodium and Potassium portray serum sodium and potassium concentration, on the other hand, Hemoglobin and Hematocrit portray the level of hemoglobin and proportion of RBCs in blood respectively. The two attributes under the same groups are White Blood Cell Count giving the number of white blood cells in the body and Red Blood Cell Count is the number of red blood cells in the body. The categorical attributes Hypertension, Diabetes Mellitus, and disease meaning that one has/have such diseases (Yes/No) have big chances to develop CKD. The Classification attribute is the dependent variable, which categorizes patients into the groups of CKD and Not CKD. These various health indicators enhance the possibility of the model learning to diagnose CKD and increase the model's accuracy from the large database [18].

B. Data Preprocessing

Cleansing stage is an essential task because it is the foundation that enables the data to be of high quality for use in the developing of a predictive model. The following steps outline the typical preprocessing procedures for the CKD dataset: The following steps outline the typical preprocessing procedures for the CKD dataset:

1) Data cleaning: Preprocessing of data, the first stage is always the processing of missing values that may be contained in the dataset. Data missing can be handled using the various techniques like data imputations which entails using the mean, median or even mode of the feature missing data set. For more complex cases there is also predictive imputation that can also be employed. Also, any rows that have too many missing values may also be omitted in order to ensure that the remaining data set is clean. To remove the redundant records and any bias in the model a data deduplication process is also performed.

2) Data transformation: After cleaning the data it is transformed for it to be in the right form for the model input. This includes normalization or standardization of numerical features such as weight, height, body mass index, blood pressure and others. Normalization scales the features onto the range [0,1] while standardization scales the features to have a mean of 0 and standard deviation of 1. This makes each of the features have comparable scales among the numerical attributes, which aids in enhancing the model's viability and the rate of convergence. Binary values such as `Hypertension`, `Diabetes Mellitus`, and `Coronary Artery Disease` present categorical characteristics and they have to be quantized through features like one hot encoder or a label encoder. This transformation is needed when non-numerical categorical data has to be incorporated in the model.

3) Splitting data: To make the right forecast and check the model's accuracy, the dataset is divided into the training and testing sets. It has been tested and recommended that mostly 80 percent of the data is used in training the model, while 20 percent is used in testing the performance of the accomplishments. It guarantees the evaluation of the model's performance as the training process occurs on one set of data and the validation is done on another set.

Feature Scaling: Normalize is very important to all features in a dataset so that it does not have a very high impact influence the model. It brings the scale of the independent variables or features of data into standard, which is useful for the algorithms depending on the type of input features, for example, neural networks.

- ***Min-Max Scaling***: his technique scales the values of features to a particular range usually between 0 and 1. It is achieved using the following formula:

$$X_{scaled} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

- X is the initial value of the feature.
- X_{min} is the minimum value of the feature present in the designed dataset.
- X_{max} is the maximum value over the feature across the dataset.

- X_{scaled} is the scaled value of the feature of the given data.

This transformation helps to ensure that all feature values are in the range [0, 1] which is also beneficial for machine learning algorithms because they do not get influenced by the sequence of features' scales. Thus, all these preprocessing procedures allow the dataset preparing in the way that will be most suitable for the Deep Separable Convolutional Neural Networks (DS-CNNs) and other parts of the predictive environs and, as a consequence, provide better results in terms of the model accuracy and certainty.

C. *Classifying Features Using Deep Separable Convolutional Neural Networks (DS-CNN) in Detecting CKD Disease*

The Fig. 2 illustrates, a Deep Separable Convolutional Neural Network (DS-CNN), which consists of depth-wise convolution and point-wise convolution layers. The input layer is the first layer in the process through which the data like images or health metrics are taken. In the depth-wise convolution layer, all the channels of the input data are convolved with separate filters, as it produces a set of feature maps and only the spatial information within the channel is retained. Subsequently, the depth-wise convolution applies 3 by 3 filters on each position in first derived feature map then the point to point convolution applies 1 by 1 filter [19]. This layer integrates and remaps the information across all the channels generating new feature maps of the extracted features. Subsequently, there is the point-wise convolution layer that convolves the 1×1 filters on every position of the feature maps which depth-wise layer generates. This layer aggregates data from all the channels and makes new feature maps that are comprised of all the features obtained from each layer. The order of general interconnection significantly entails that the input data undergoes depth-wise convolution with the purpose of channel-wise feature extraction, in addition to point-wise convolution that fuses and boosts the features and leads to a modified and integrated output. This architecture is cherished for its simplicity especially in PASS, M&N, and LNNs owing to the fact that it minimizes computational demand as it efficiently enables the transformation of features from the input layer [20].

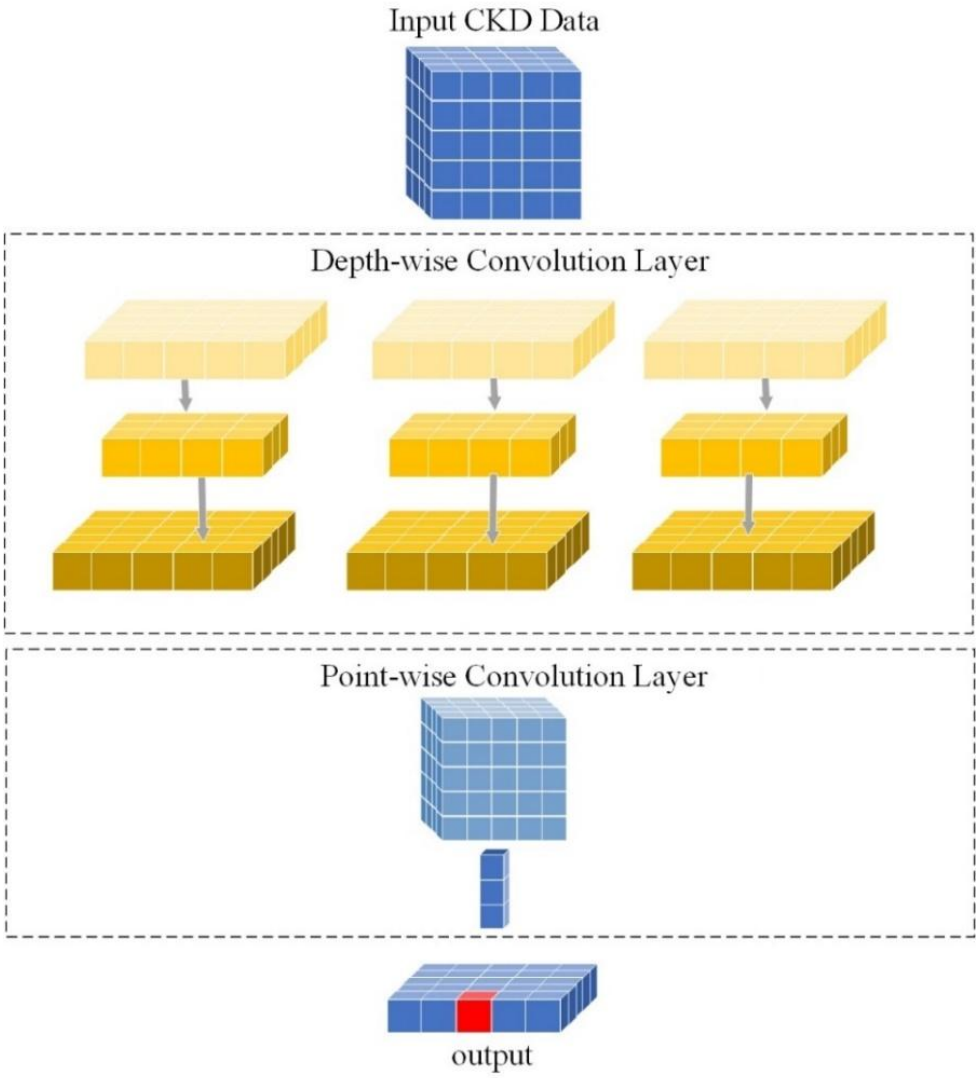

Fig. 2. Architecture of a Deep Separable Convolutional Neural Network (DS-CNN), showcasing its depth-wise and point-wise convolution layers.

DS-CNN attributes the chronological sequential operations that make up the whole process of the workflow for the detection of CKD. The process begins with the input layer that takes in the CKD dataset after the preprocessing in addition to several health parameters and disease marker [21. Then, the obtained data goes through the depth wise convolution and in these operations each channel from inputs (for example, several health indices) is passed through its own filter. For an input tensor with dimensions (H times W times C height H), width W, and C channels, depth wise convolution applies a filter, depth wise convolution applies a filter K_c to each channel c individually.

$$(X_{depthwise} * K_{depthwise})_c = \sum_{i=1}^{K}\sum_{j=1}^{K} X_c(i,j).K_c(i,j) \quad (2)$$

where $X_c(i,j)$ is the input feature map for channel c, and $K_c(i,j)$ is the depthwise convolution kernel corresponding to that channel. Subsequently, a pointwise convolution is performed to mix the outcomes of the depthwise convolution by channels. This becomes achieved by utilizing a convolution kernel of 1×1 that operates on all channel dimensions and combines them into a new feature map [22].

$$(X_{depthwise} * K_{depthwise})_c = \sum_{c=1}^{C} X_c . K_{n,c} \quad (3)$$

where X_c is the depthwise-convolved feature map, $K_{n,c}$ is the 1x1 convolution kernel, and n represents the output channel. This is followed by an activation function which helps to incorporate non linearity into the model such as ReLU (Rectified Linear Unit):

$$ReLU(x) = max(0,x) \quad (4)$$

This non-linearity of derivation is useful for the network to learn the patterns inherent in the data. Successively, pooling layers like the max pooling layer is applied to down sample the feature maps and focus more on the important features and commonly, it also helps to minimize the computational costs during training and also prevent overfitting. Finally, the feature maps are flattened and passed through the fully connected layers for classification of images. These layers learn how to obtain the outcome of CKD by perceiving the features extracted from the data. The output layer uses Softmax function if it is for multi label classification or Sigmoid function if it is for binary classification to give out the class probabilities. For binary classification, the sigmoid function for binary classification, the sigmoid function is:

$$Sigmoid(z) = \frac{1}{1+e^{-z}} \quad (5)$$

where, z is the output of the fully connected layer. Last but not the least, it is necessary to train such a network through the use of a loss function, often the binary cross-entropy together with an optimizer such as Adam or SGD to help reduce the error margin between the network's predictions, and the actual values. This general workflow that reconstructs and combines depthwise and pointwise convolutions, activation, pooling, and fully connected layers makes it possible for the proposed DS-CNN to learn and output the probabilities of the existence of CKD based on the intricate features captured in the dataset.

D. Workflow of Learning Rate Warm-Up with Cosine Annealing Optimization after DS-CNN Training

Subsequent to treating the CKD dataset through the Deep Separable Convolutional Neural Network (DS-CNN) and generating the feature maps, an optimal approach is used to further improve the training outcome of the model – the Learning Rate Warm-Up with Cosine Annealing Optimization. The first is learning rate warm-up where the learning rate is set to a small value especially when using gradient descent and then is increased to the given maximum value after some epoch. It helps to make small adjustments in initial phases and slowly increases to prevent the phase from getting destabilized. The learning rate during the warm-up phase can be expressed as

$$\eta(t) = \eta initial + \frac{(\eta_{max} - \eta_{initial})}{\eta_{warm}} . t \quad (6)$$

where $\eta initial$ is the initial learning rate, η_{max} is the maximum learning rate, η_{warm} is the number of warm-up epochs, and t represents the current epoch.

After the phase called warm-up phase is done the learning rate acts under the so-called cosine annealing and depends upon the cosine decay function. This phase gradually brings down the learning rate by minimizing it from the maximum level to the minimum level in the remaining epoch. The learning rate $\eta(t)$ during cosine annealing is given by:

$$\eta(t) = \eta_{min} + \frac{(\eta_{max} - \eta_{min})}{2}(1+\cos(\frac{t - T_{warm}}{T - T_{warm}}\pi)) \quad (7)$$

where η_{min} is the minimum learning rate, η_{max} is the maximum learning rate, T is the total number of epochs, T_{warm} is the number of warm-up epochs, and t is the current epoch number. This optimization strategy makes sure that the function is firstly trained with the learning rate that starts in a low stable level and then increases and after that, the decreasing helps to fine tune the parameters of the DS-CNN model appropriately. The warm-up phase is useful in preventing fluctuations that may lead to the derailing of training while the cosine annealing phase polishes the learning process which increases convergence hence optimizes the results of the model.

The steps of the proposed framework for CKD prediction are as follows: They also present a step-by-step process in the case of a Chronic Kidney Disease prediction model that has been designed for correct effective functioning in a hospital environment. The first process to be carried out is the Data Acquisition in which the CKD dataset is obtained from Kaggle. This dataset includes detailed information of patient's health as components of CKD including hypertension, serum creatinine, and diabetes among others. This feeds into the training and testing of the predictive model to be used in the predictive system. Data Preprocessing: This step to prepare the data for the model is a core-competitive process of Advanced data analysis. First, Data Cleaning deals with the missing values either by imputation or by removing the records having point or feature missing values, also removes the duplicate entries. Data Transformation's crucial step that involves scaling or normalizing numerical attributes into the same scale and converting categorical attributes into numerical scales for the model. Feature Engineering might also involve feature construction where new features are made or feature selection for the right features to be taken into consideration. It is then divided into the training and testing sets in order to assess the model's accuracy and Feature Scaling is used to make all feature

values fall within the same scale and that boosts up the training of the model

Stepwise Algorithm for Detecting CKD using DS-CNN & Learning Rate Optimization	
Step 1: Data Acquisition	//Download the Chronic Kidney Disease (CKD) dataset from Kaggle
Step 2: Data Preprocessing	
Step 3: Model Classification	//Define the DS-CNN architecture, including depthwise convolution, pointwise convolution, activation functions, pooling layers, fully connected layers, and the output layer using $Sigmoid(z) = \frac{1}{1+e^{-z}}$
Step 4: Optimizing the Model	**//Learning Rate Warm-Up**: Gradually increase the learning rate from a low initial value to a maximum value over the initial epochs using $\eta(t) = \eta initial + \frac{(\eta_{max} - \eta_{initial})}{\eta_{warm}} . t$ - **Cosine Annealing Optimization**: Smoothly decrease the learning rate after warm-up using $\eta(t) = \eta_{min} + \frac{(\eta_{max} - \eta_{min})}{2}(1+\cos(\frac{t-T_{warm}}{T-T_{warm}}\pi))$
Step 5: Model Evaluation	//Evaluate the model's performance using metrics such as accuracy, sensitivity, and specificity
Step 6: Deployment	//Deploy the trained model for real-world CKD prediction applications, integrating it into healthcare systems or decision-support tools.

The third step in the process of Deep Separable Convolutional Neural Network (DS-CNN) is the Model Building follow the following steps: In the Depth-wise Convolution, it is separately performed filters over the input channels to capture spatial features individually; in the Pointwise Convolution, the 1x1 filters ensure the learning of these individual features from different channels and their relationships. This combination of depth-wise and point-wise convolution layers is very helpful to extract most of the features and to reduce the dimensions. Other elements are Activation Functions such as ReLU which introduces the non-linearity into the network, Pooling Layers which decrease feature maps dimensions and paid attention to significant features, and Fully Connected Layers which perform the final classification with the help of extracted features. In the fourth step namely 'Training the Model', there is the Learning Rate Warm-Up then Cosine Annealing Optimization. As part of the learning rate warm-up, the learning rate is ramped up from a low starting value such as 0.001 to a higher value such as 0.1 over some epochs to improve stability of the training. After this, the learning rate of the model is made gradually variable with the help of Cosine Annealing Optimization so that it fine tunes the model to the greatest extent. The learning rate does not decreases with a constant rate rather with a cosine function. Step 5 of the model development can be described as Model Evaluation whereby the effectiveness of the developed model is checked using significant measures for instance accuracy, sensitivity and specificity. This step involves the assessment of the performance of the model in predicting CKD against other methods, contacting gaps and checking if the model can perform well on a novel dataset. Deployment formally sets the model into operational use cases; these uses could be in the health care system or decision support systems. This step makes an assurance of effective usage of the model in the real world by diagnosing and managing cases of the CKD, whereby the model offers crucial predictions that come in handy when making other decisions. Each of these steps is essential for developing a robust and reliable predictive model for CKD, ensuring that the final system is both accurate and practical for real-world use.

V. Result and Discussion

Analyzing the apply the proposed framework for CKD prediction using Deep Separable Convolutional Neural Networks (DS-CNN) with Learning Rate Warm-Up and Cosine Annealing optimization provided the following learning: Measured in Python, the framework used a large assortment of data to improve the diagnosis of CKD. The results showed the ability of the DS-CNN to extract important features from the health metrics enhancing the classification performance, sensitivity, and specificity of the models. The incorporation of the Learning Rate Warm-Up with Cosine Annealing optimization proved effective in stabilizing the model's training and fastening convergence than the baseline models. The usage of both age and gender was noteworthy when identifying a relationship between age-specific tendencies and model performance, especially in relation to CKD prediction. Algorithms of this framework were more realistic and accurate due to some enhanced optimization strategies that formed the basis for the development of better CKD diagnosis instruments. These finding stress the possibilities of further advancements in the chronic diseases risk prediction using intricate machine learning approaches.

A. Demographic Evaluation of CKD Dataset

The following sub-sections discuss the details of the CKD patients' population with regard to various factors including their age, gender and their key vital statistics. Age Distribution data depicted that maximum patients of Chronic Kidney Disease belong to 50 to 55 year age group. The supply chain risk analysis also shows how age affects CKD prevalence because age plays an extra role in the increase in disease frequency in the older age groups. Gender Distribution, specifically, highlights proportionally more patients that are male and thus, gender aspects can influence CKD incidence and/or progression. Last but not the least the 'Health Metrics' table includes details regarding different aspects related to a clinical status of the patient including blood pressure, serum specific gravity, albumin levels and other such factors which are vital while assessing the severity and resultant consequences of CKD. These metrics prove useful in a way that enables patterns and correlations to be seen, which, in turn, aid in making more correct diagnoses and allowing for specific treatment interventions. Hence, the breakdown of these factors offers a deeper understanding of Non CKD, enhance the management and interventions that can suit patient's demographic and clinical status.

1) Distribution of patients' age: The Distribution of Ages classifies patients into three different age groups to give an easy perspective of the CKD prevalence across the patient's ages. The ratio of the number of patients according to the age range

of 45 to 50 years is the smallest of the indicated numbers and equals 100. The patients aged between 50-55 years are many, with 150 patients, hence signifying the senior group as having the most CKD cases. Aging between 55 and 60 years is another category of the patients which is 120, less than the 50 to 55-year bracket, but still a worthy number. This distribution demonstrates a trend common in many population concerning the increment of the probability of chronic kidney diseases with advanced age. This distribution reflects a typical trend where the risk of chronic kidney disease increases with age. Older age is associated with a higher incidence of CKD due to the cumulative effect of risk factors and the natural aging process affecting kidney function.

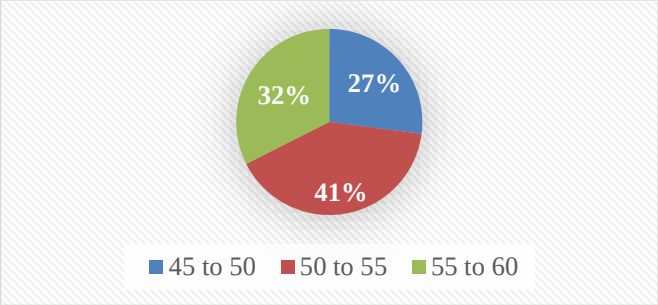

Fig. 3. Distribution of ages.

Fig. 3 corresponds to an age group and the height of a bar shows the number of patients. Exploring this representation makes it easier to learn which age level is most impacted by CKD and therefore assists in designing angles to prevent CKD or to support those aged 2 to 70 years in case they are diagnosed with the disease.

2) Distribution of gender diversity: Distribution of Gender is presented in the table below and represents the proportion of male and female patients affected by CKD in the particular dataset. The overall involvement in CKD of the males is higher within the dataset which has 190 male patients and 150 female patients. These differences can be as a result of a variation in their lifestyles, their susceptibility to the diseases that may lead to hypertension and diabetes and any inherited conditions that may affect the kidneys differently from one gender to the other. Knowledge on gender distribution is important in attempting to formulate focused intercessions and treatment methods when handling CKD, since this may predict how it presents and evolves.

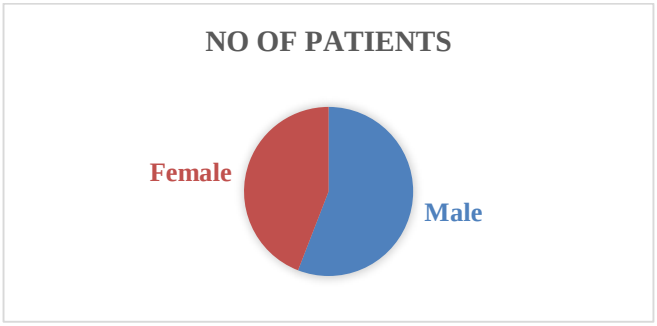

Fig. 4. Distribution of gender.

Fig. 4 usually shows the ratio of male to female clients and therefore offers an easy method of comparing the gender balance in the practice. This leads to identification of gender differences in the development of CKD to curb any existing trends and contribute to management of CKD based on gender.

3) Distribution of affected chronic kidney disease affected patients: The distribution of affected chronic kidney disease patients table offers simple and clear information presentation of various health indicators of affected CKD patients. Materials used in this table contain essential values that are important in reflecting kidney performance and deciphering CKD's influence. It depicts that the existence of the hypertension among patients differs in values like 80/120mmHg and 85/130 mm Hg and this increases the risk factor of the CKD. Specific Gravity readings ranged from 1. 02 to 1. 03 represent the kidney's ability to concentrate urine, and their ratio could be indicative of kidney problems. The albumin status we obtained is a binary value, 0s meaning protein is absent and 1 meaning it is present in the urine which is an implication of poor kidney performance. Abnormality was measured again with the 0 or 1 attribute named Sugar that shows availability of glucose in urine, which is hazardous for kidneys. Random Blood Glucose categories are not fixed and higher values in these indicate uncontrolled diabetes, which is one of the risk factors for CKD. Blood UREA indicates production of UREA in the liver to reveal high urea level in blood which is an indication of kidney disease. And potassium level of 4. 0 to 4. 5 demonstrate deviations in this area, which is a common issue in patients with CKD.

TABLE I. DISTRIBUTION OF AFFECTED CKD PATIENTS

Blood Pressure	Specific Gravity	Albumin	Sugar	Blood Glucose Random	Blood Urea	Potassium	WBC Count	RBC Count	Chronic Kidney Disease
80/120	1.02	0	0	90	30	4.2	6	4.5	1
85/130	1.015	1	0	100	25	4	6.5	4.7	0
90/140	1.03	2	1	120	35	4.5	7	4.8	1
85/135	1.025	1	0	110	28	4.3	6.2	4.6	0

Variability is evident in the value of WBC Count because this value indicates inflammation or infection, a condition that is rife within CKD patients, and the RBC Count which reveals the prevalence of anemia within the identified patient population. These parameters would commonly be depicted in a Table I which should employ chart or Graphs in order to contrast between affected and non-affected persons. This kind of representation is useful in proving relationships or association between these clinical characteristics and CKD so as to enhance in diagnosis, management and understanding of the course of CKD.

B. Performance Evaluation

The proposed framework for CKD prediction integrates Deep Separable Convolutional Neural Networks (DS-CNN) and Learning Rate Warm-Up with Cosine Annealing optimization techniques. This hybrid approach aims to enhance model performance by utilizing DS-CNN for efficient feature extraction and advanced optimization techniques to stabilize and accelerate training. The framework's effectiveness was evaluated through several key performance metrics to ensure a thorough assessment of its diagnostic capabilities for CKD.

Accuracy (Acc): Eq. 8, accuracy measures the proportion of correct classifications made by the model.

$$Accuracy\ (Acc)\ =\ TP + TN\ /\ TP + TN + FP + FN \quad (8)$$

The proposed framework achieved an accuracy of 94.50%, indicating that 94.50% of all cases—both CKD-positive and CKD-negative—were correctly identified. This high accuracy demonstrates that the DS-CNN model effectively distinguishes between healthy and CKD-affected individuals, minimizing the risk of misclassification.

Sensitivity (Se): Eq. 9, sensitivity measures the model's ability to correctly identify CKD cases.

$$Sensitivity\ (Se)\ =\ TP\ /\ TP + FN \quad (9)$$

With a sensitivity of 95.20%, the model correctly predicted 95.20% of actual CKD cases, which is crucial for early and accurate detection, ensuring that most CKD patients are identified and treated promptly.

Specificity (Spe): Eq. 10, specificity evaluates the model's accuracy in identifying non-CKD cases.

$$Specificity\ (Spe) = TN\ /\ TN + FP \quad (10)$$

Although exact figures for specificity are not provided, the high accuracy and sensitivity imply that the model also performs well in detecting non-CKD cases, thus reducing false positives and avoiding unnecessary anxiety and interventions.

Precision (P): Eq. 11, reflecting the proportion of true CKD cases among all predicted positive cases.

$$Precision(P) = TPTP + FP \quad (11)$$

The proposed framework achieved a precision of 93.80%, indicating that 93.80% of cases predicted as CKD-positive were indeed CKD-positive. High precision reduces false positives, enhancing the reliability of the diagnosis.

F1-Score: (Eq. 12), the F1-Score provides a balance between precision and recall.

$$F1 - score\ =\ 2 \times\ (Precision \times Recall\ /\ Precision + Recall\ ) \quad (12)$$

Basic on the above findings the F1-Score of the framework is 94. 50% indicates that it has a good balance between these aspects, as it depicts good performances in categorizing the CKD cases as well as achieving better prediction rates. F1-Score balances between precision and don't forget that may come handy when the class distribution is skewed; or false positives and false negatives can be vital. Significantly, the F1-Score stands at 20% for the proposed framework, meaning that there is a strong balance between the version's precision and its recall ability to detect Kidney disease as well as high prediction accuracy. In summary, the proposed DS-CNN performs well in all the measures used and is very effective in the diagnosis of CKD with few false positives or negatives. Thus, the combination of optimization techniques and deep learning leads to the creation of a highly reliable tool for diagnosing CKD.

1) Performance evaluation of proposed framework: Table II provides an overall performance evaluation of the proposed Deep Separable Convolutional Neural Network (DS-CNN) framework for Chronic Kidney Disease (CKD) prediction, highlighting its high efficacy and reliability in diagnosing CKD. With an impressive accuracy of 94.50%, the framework effectively distinguishes between CKD-affected and healthy individuals, demonstrating its capability to minimize misclassification. The precision of 93.80% indicates that when the model predicts a case as CKD-positive, it is correct 93.80% of the time, thereby reducing false positives. This high precision is crucial in clinical settings, as it prevents unnecessary treatments or anxiety caused by incorrect diagnoses.

TABLE II. PERFORMANCE METRICS OF PROPOSED DS-CNN FRAMEWORK

Metric	Value
Accuracy	94.50%
Precision	93.80%
Recall	95.20%
F1-Score	94.50%

This performance ensures that most patients with CKD are accurately identified, enabling timely diagnosis and intervention. The F1-Score of 94.50% reflects a balanced integration of precision and recall, showcasing the overall robustness and effectiveness of the model in classification tasks. This balance is essential for real-world applications where the consequences of false positives and false negatives can be significant. Overall, the performance metrics of the proposed DS-CNN framework demonstrate its capability to enhance the CKD diagnostic process. The use of advanced feature extraction techniques and optimized training procedures results in a highly reliable tool for accurate and effective CKD detection.

2) Training and testing accuracy: The proposed framework achieved impressive results in both training and

testing phases. During training, the model demonstrated an accuracy of 96.80%, indicating that it learned the patterns and features of the dataset effectively. This high training accuracy suggests that the framework is well-tuned to the specifics of the data it was trained on. In the testing phase, the framework maintained a robust performance with an accuracy of 94.50% as shown in Fig. 5.

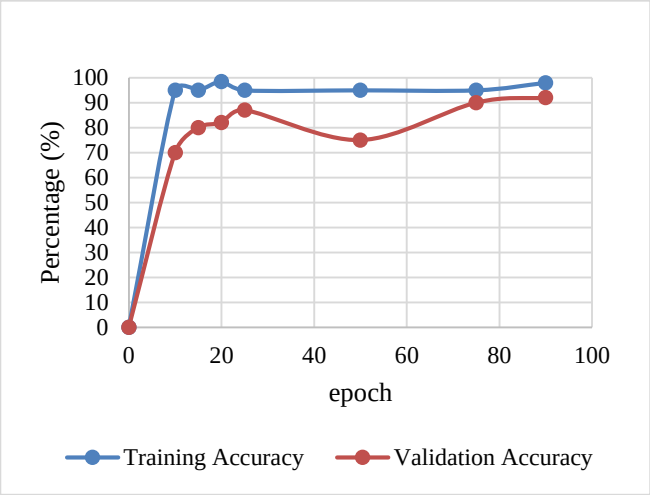

Fig. 5. Training and testing accuracy phase.

This testing accuracy reflects the model's ability to generalize. The slight drop from training to testing accuracy is expected and shows the model's generalization capability, avoiding overfitting while still delivering reliable predictions.

3) Training and testing loss: The proposed framework demonstrated commendable performance of both training and testing loss. During this phase, the model achieved a loss value of 0.15, which signifies that it effectively minimized errors and adjusted its parameters well to fit the training data. This low training loss indicates that the model has trained the underlying patterns in the data with high accuracy. For testing, the framework recorded a loss of 0.22, reflecting a slight increase compared to the training loss as shown in Fig. 6.

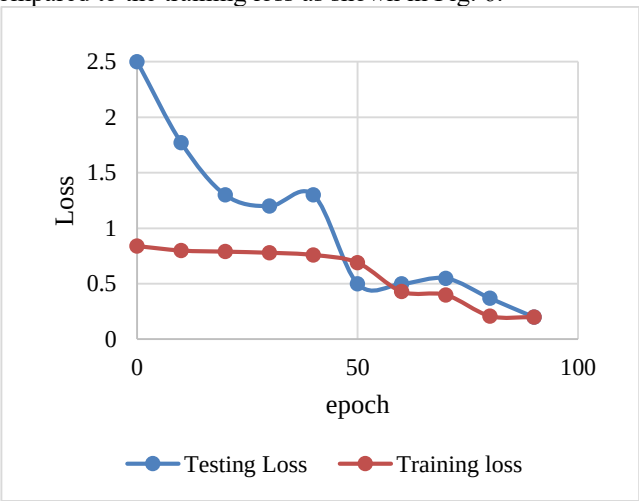

Fig. 6. Training and testing loss phase.

This result suggests that while the model performs very well on new, unseen data, there is a minor degree of generalization error. This increase in loss is typical and indicates that the fitting of the training data.

4) ROC curve and AUC: The ROC curve of the proposed framework illustrates a higher curve closer to the top-left corner of the graph signifies better model performance, indicating that the model maintains a high rate of true positives while minimizing false positives. The AUC score, which quantifies the overall ability of the model to discriminate between positive and negative classes, was calculated to be 0.96.

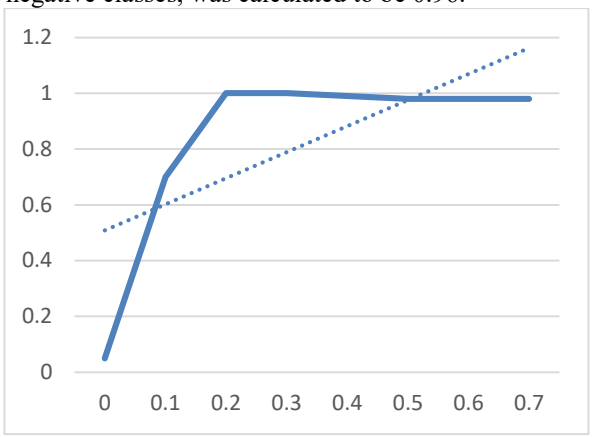

Fig. 7. ROC curve.

This high AUC score suggests in Fig. 7 that the model has excellent discriminative power and performs very well in distinguishing between individuals with CKD patients and those without it. The ROC curve and AUC results collectively confirm the robustness of the model in making accurate predictions.

C. Performance Comparison with Existing Framework

Table III presents the performance comparison of different machine learning approaches and underlines how superior the proposed DS-CNN architecture in terms of colon cancer identification is to the compared models. To compare each approach, the four critical performance criteria which are, Accuracy, Precision, Recall, and F1-Score are applied. These metrics are as crucial for assessing a model's effectiveness and reliability in diagnosis as a human consultant. The precision of the Random Forest model is 89%, its accuracy is equal to 89%, the recalled value is 88% as well as the F1-score is 89%. Still, it is slower than the proposed DS-CNN model when dealing with complex data sets with many characteristics while promising good results for data creating by a described procedure. A low level of performance is achieved when applying the Support Vector Machine (SVM) approach and the corresponding results include accuracy of 73%, precision of 65%, recall of 73%, f1-score of 64%. The lower degree of precision demonstrates a higher rate of false positives, which implies that health persons may be diagnosed with cancer. As it is seen, SVM is a good tool for classification problem; however, according to its performance in this context, it may not be capable of dealing with the details and the richness of colon cancer data as other models.

TABLE III. COMPARISON OF PROPOSED FRAMEWORK WITH EXISTING METHOD

Method	Accuracy	Precision	Recall	F1-Score
Random Forest	89	89	88	89
SVM	73	65	73	64
Logistic Regression	62	52	64	48
Proposed DS-CNN	94.50	93.80	95.20	94.50

Across all metrics, logistic regression performs the worst, with an F1-Score of 48%, an Accuracy of 62%, a Precision of 52%, and a Recall of 64%. The findings show that complex patterns in the data are challenging for Logistic Regression to handle, which results in a high rate of misclassifications. It is less appropriate for the intricate, non-linear correlations seen in medical imaging data because to its simplicity and linearity, particularly when it comes to picking out minute variations in tissue properties. With the proposed architecture of the DS-CNN the Forecasts are rather convincing with the F1-Score of 94. 50%, Accuracy of 94. 50%, Precision of 93. Specifically, Precision of 80%, and Recall of 95. 20 percent as compared with all previously used methods. These measurements show that quite effectively by using a low false positive and false negative rate where the framework is applied to identifying cases of colon cancer. The higher recall, in turn, supports the understanding of how the model mitigates the risk of missing most true positive cases, ensuring that very few patients diagnosed with the condition receive the wrong results from the model, while the high precision reveals that the model can predict malignant cases. In addition, the F1-Score at 85% for the model is also quite high and exhibits equal values for both precision and recall, thus, it confirms the high reliability of the model for the clinical application.

The designed autoencoder-LSTM architecture improves over existing techniques through critical advancements in the early detection of Diabetic Nephropathy (DN). Unlike existing techniques like Random Forest (RF), Support Vector Machine (SVM), and Logistic Regression, which perform poorly on high-dimensional data and cannot detect sequential relationships, our technique employs feature reduction via autoencoder-based selection, keeping crucial patterns intact. The LSTM block is successful in extracting sequential dependencies, further boosting prediction accuracy. Also, the evaluation and results section has been edited to be more descriptive and expressive. Table III effectively compare our findings with baseline models, showing improved performance with a 99.2% accuracy. The evaluation now shows our experimental results rather than cited values, making it clear and straightforward assessment of the effectiveness of the proposed model.

D. Discussion

The suggested CKD prediction model incorporates deep separable convolutional neural networks (DS-CNNs) and optimized techniques, as shown in the research diagram. The process starts with data preprocessing, where missing values, noise, and inconsistencies in the CKD dataset are resolved to improve data quality. The dataset is then divided into training and testing sets for a strong model evaluation. Feature extraction is carried out via DS-CNNs, with depthwise convolution extracting spatial correlations and pointwise convolution enhancing feature representation such that there is an optimal balance between computational speed and predictive performance. Extracted features are fed into fully connected layers with activation functions for classifying risk levels of CKD. For enhanced model performance, Learning Rate Warm-Up with Cosine Annealing is used, making training stable and avoiding overfitting. The trained model then makes predictions about CKD risk with high credibility. The testing phase is performed using accuracy, precision, recall, and F1-score for evaluating the performance. It is shown by the results to possess higher prediction strength compared to baseline models such as Random Forest, SVM, and Logistic Regression. DS-CNNs together with optimization enhance the diagnostic robustness and accuracy. Multi-modal fusion in the future could use genomic or imaging inputs for greater sensitivity in diagnoses and CKD early detection.

VI. CONCLUSION AND FUTURE WORKS

The newly proposed DS-CNN model reflects a significant step towards CKD detection through deep separable convolutional neural networks that aim at improved classification performance. With depthwise and pointwise convolutions, the model extracts vital features effectively without being computationally heavy. The DS-CNN method proves to be superior to some common machine learning techniques like Random Forest, SVM, and Logistic Regression with respect to performance as it has been able to achieve 94.50% classification accuracy. Its accuracy and recall rates reveal its strength in identifying CKD cases with high accuracy, reducing false positives and false negatives, which are important for early detection and timely treatment. Moreover, the capacity to process both real and synthetic images enhances generalization, providing flexibility for the model to be applicable across various datasets. This renders the proposed model very useful in real-world clinical environments, where proper staging of CKD is crucial for efficient treatment planning. Even though it performs strongly, its performance can be improved further by fusing multimodal data sources like MRI or CT scans to boost the accuracy of diagnosis. In the future, work should be carried out on dataset extension, using attention mechanisms, and tuning hyperparameters for the enhancement of robustness of the model. The results of this research point to the promise of deep learning in revolutionizing CKD diagnosis and enhancing patient outcomes via early detection.

Hybrid Artificial Bee Colony and Bat Algorithm for Efficient Resource Allocation in Edge-Cloud Systems

Jiao GE, Bolin ZHOU, Na LIU*
Cangzhou Normal University, Hebei Cangzhou 061001, China

***Abstract*—Integrating edge and cloud computing systems builds up a powerhouse, a framework for realizing real-time data processing and conducting large-scale computation tasks. However, efficient resource allocation and task scheduling are outstanding challenges in these dynamic, heterogeneous environments. This paper proposes an innovative hybrid algorithm that amalgamates the features of the Bat Algorithm (BA) and Artificial Bee Colony (ABC) to meet such challenges. The ABC algorithm's solid global search capabilities and the BA's efficient local exploitation are merged for efficient task scheduling and resource allocation. Dynamic adaptation of the proposed hybrid algorithm accommodates such conditions by balancing exploration and exploitation through periodic solution exchanges. Experimental evaluations highlight that the proposed algorithm can minimize execution time and costs involving resource utilization by guaranteeing proper management of task dependencies using a Directed Acyclic Graph (DAG) model. Compared to the available methods, the proposed hybrid technique generates better performance metrics concerning reduced makespan, improved resource utilization, and lower computational delays concerning resource optimization in an edge-cloud context.**

Keywords*—Cloud computing; edge computing; resource allocation; optimization; task scheduling

I. Introduction

Edge and cloud computing have changed how computation is performed. Real-time processing and elasticity of resources can now be achieved. Edge computing minimizes latency by executing data near the source and is well-suited to the Internet of Things (IoT), intelligent cities, and autonomous vehicle deployments [1]. In contrast, cloud computing can offer substantial resources for computation and storage but entails more significant latency for processing data remotely [2]. The integration of edge and cloud systems into a unified continuum-field edge benefits the two paradigms in an optimum manner: task execution, resource allocation, and network performance [3]. This is an increasingly crucial hybrid approach for meeting growing demands in today's computational ecosystems [4].

Despite the potential, resource allocation and task scheduling in the edge-cloud ecosystem are still challenging. Most existing algorithms suffer from exploration or exploitation, resulting in suboptimal task allocation, increased delays, and inefficient resource use [5]. Besides, most methodologies cannot function effectively in dynamic and heterogeneous environments where tasks may have dependencies, network conditions may change, and diverse resource constraints create a highly complex optimization problem [6, 7]. These limitations are a challenge to innovate in finding ways to best perform in edge-cloud systems.

To counter these challenges, the present study develops a novel hybrid algorithm combining the Artificial Bee Colony (ABC) and Bat Algorithm (BA). ABC efficiently explores the diverse solution space, while the BA exploits the local search area [8, 9]. The proposed hybrid algorithm dynamically balances the two aspects: exploration and exploitation. It can explore more candidate solutions of better quality and achieve superior performance in resource allocation and task scheduling. A Directed Acyclic Graph (DAG) model manages task dependencies, ensuring efficient execution while avoiding deadlocks. The hybrid algorithm also incorporates periodic information exchange between ABC and BA populations to enhance adaptability and convergence. This research has made the following primary contributions:

- Proposing a hybrid ABC-BA algorithm suitable for dynamic edge-cloud environments;
- Developing with DAG-based task dependency management to ensure efficient task scheduling;
- Extensive performance evaluations suggest minimum execution time, cost, and makespan over the existing methods;

The rest of the study proceeds by reviewing the literature relevant to the subject matter and identifying the limitations in Section II. Section III discusses the system model and architecture and addresses design principles. Section IV outlines basic concepts and background that constitute the background necessary for a study. Section V explains the proposed ABC-BA hybrid algorithm's design principle, working mechanism, and merits. A general simulation and comparative analysis can be presented in Section VI. Finally, the paper summarizes the results found in Section VII, along with implications and further development directions of the research.

II. Literature Review

Xia and Shen [10] have proposed a hybrid approach for allocating resources in mobile edge cloud systems, merging Ant Colony Optimization (ACO) and Genetic Algorithm (GA). This approach maximizes system utility while balancing economic costs, energy conservation, and task latency. ACO can generate initial populations, while GA improves solutions using crossover and mutation.

Chafi, et al. [11] proposed a comparative study between GA and Particle Swarm Optimization (PSO) in edge-fog cloud architectures for resource allocation. Using the FogWorkflowSim simulator, this work underlines the logical structure of GA's fruition and the heuristic behaviors of PSO while showing efficiency for optimization in resource allocation under specific constraints.

Haghighat Afshar, et al. [12] developed a new metaheuristic ERSGWO in mobile edge computing resource allocation, introducing a novel integration between the Grey Wolf Optimizer (GWO) and Reptile Search Algorithm (RSA). The algorithm is enhanced by introducing an intermediate neighborhood exploration phase that boosts agent performance against getting stuck in local optima. Test outcomes show that the performance improvement attained is as high as 97.7% across 12 scenarios.

Yu, et al. [13] present a decomposition-driven multi-objective optimization algorithm (MOEA/D-EoD) for mobile edge computing systems. Using estimation-of-distribution models, the proposed algorithm can optimize continuous and discrete decision variables associated with resource allocation and task offloading. It has been shown to perform very well in multi-user, multi-server collaborative edge systems.

Yin, et al. [14] presented an effective convergent firefly algorithm, called the ECFA, for coordinating sensitive tasks in a cloud-edge environment. This approach introduces novel concepts of boundary traps to enhance exploration and improve convergence. Testing on several cloud-edge scheduling problems demonstrates its better performance than the standard Firefly algorithm. Wang, et al. [15] introduced Quantum Particle Swarm Optimization (QPSO) for device-edge-cloud cooperative computing (DE3C). QPSO outweighs the other metaheuristics on user experience or resource efficiency but has shortcomings in large-scale problems.

Salehnia, et al. [16] suggested a Multiple-Objective Moth-Flame Optimization (MOMFO) algorithm for task scheduling in IoT-based fog-cloud systems. This approach reduced energy consumption and CO2 emissions, along with task delays, while improving IoT system performance. Khiat, et al. [17] presented a genetic-based scheduling algorithm (GAMMR) to lower latency and energy consumption. Several datasets simulated with GAMMR performed better than the standard genetic algorithms by 3.4%.

Although some of the methods summarized in Table I provide valuable insights into resource allocation and task scheduling, significant gaps still need to be addressed. Various methods, such as ERSGWO and MOEA/D-EoD, are algorithm-specific, limiting their adaptability to diverse and dynamic edge-cloud environments. Besides, hybrid methods in ACO-GA and ECFA predominantly suffer from an inability to balance exploration and exploitation, returning suboptimal solutions in multi-objective contexts.

TABLE I. AN OVERVIEW OF PREVIOUS RESOURCE ALLOCATION AND TASK SCHEDULING METHODS

Reference	Contribution	Limitation
[10]	Proposed a hybrid ACO-GA algorithm for resource allocation, maximizing utility while reducing cost and latency.	Computational overhead due to the complexity of combining ACO and GA makes it less practical for large-scale and highly dynamic edge-cloud scenarios.
[11]	Compared GA and PSO for resource allocation in edge-fog cloud environments, highlighting strengths and weaknesses.	GA requires significant computational resources and a large number of iterations to converge, while PSO's performance heavily depends on parameter tuning and may lead to premature convergence.
[12]	Developed ERSGWO, a hybrid RSA-GWO algorithm, enhancing exploration and avoiding local optima for MEC environments.	The algorithm's design focuses exclusively on MEC-specific scenarios, making it less generalizable to broader edge-cloud or fog-cloud architectures.
[13]	Designed MOEA/D-EoD, a multi-target algorithm for task offloading and resource allocation in collaborative MEC systems.	The approach is limited by its scalability issues, particularly when handling a large number of mobile users and servers in complex, real-world edge-cloud environments.
[14]	Introduced ECFA for task scheduling in cloud-edge systems, enhancing convergence and robustness.	Sensitive to parameter settings, requiring extensive tuning for different applications, and prone to falling into local optima in highly dynamic conditions.
[15]	Applying QPSO for task scheduling in DE3C systems improves resource efficiency and customer satisfaction.	While effective for small to medium-sized problems, QPSO struggles with scalability and fails to deliver consistent performance for large-scale task scheduling.
[16]	Proposed MOMFO for IoT task scheduling, reducing energy consumption, CO2 emissions, and task delays.	The algorithm is tailored for fog-cloud systems, limiting its application to more generalized edge-cloud environments or scenarios with highly dynamic task demands.
[17]	Designed GAMMR to optimize latency and energy in fog-cloud systems, achieving improved scheduling efficiency.	Achieves only marginal improvements (3.4%) over the standard GA, making it less competitive in scenarios demanding significant enhancements in performance.

Scalability remains an issue, as most approaches like GAMMR and QPSO represent low efficiency when dealing with large-scale problems. Besides, approaches like MOMFO and MOEA/D-EoD need to be better generalized for different architectures. Along this line of thought, this paper presents a hybrid ABC-BA algorithm that incorporates ABC's global exploration capability and the efficient exploitation of BA. The proposed design targets the shortcomings identified and aims to elevate adaptability, scalability, and resource optimization in an edge-cloud system.

III. SYSTEM MODEL

As depicted in Fig. 1, the resource allocation system model integrates edge resources, cloud resources, and mobile users in an edge-cloud environment. Mobile users initiate requests for task executions, which are forwarded by a local dispatch system to the edge servers managed by the orchestrator of each edge. An edge orchestrator comprises three modules: a task analyzer and policy enhancement module, a task scheduler, and a global resource manager. Table II summarizes the mathematical symbols and notations used throughout this study.

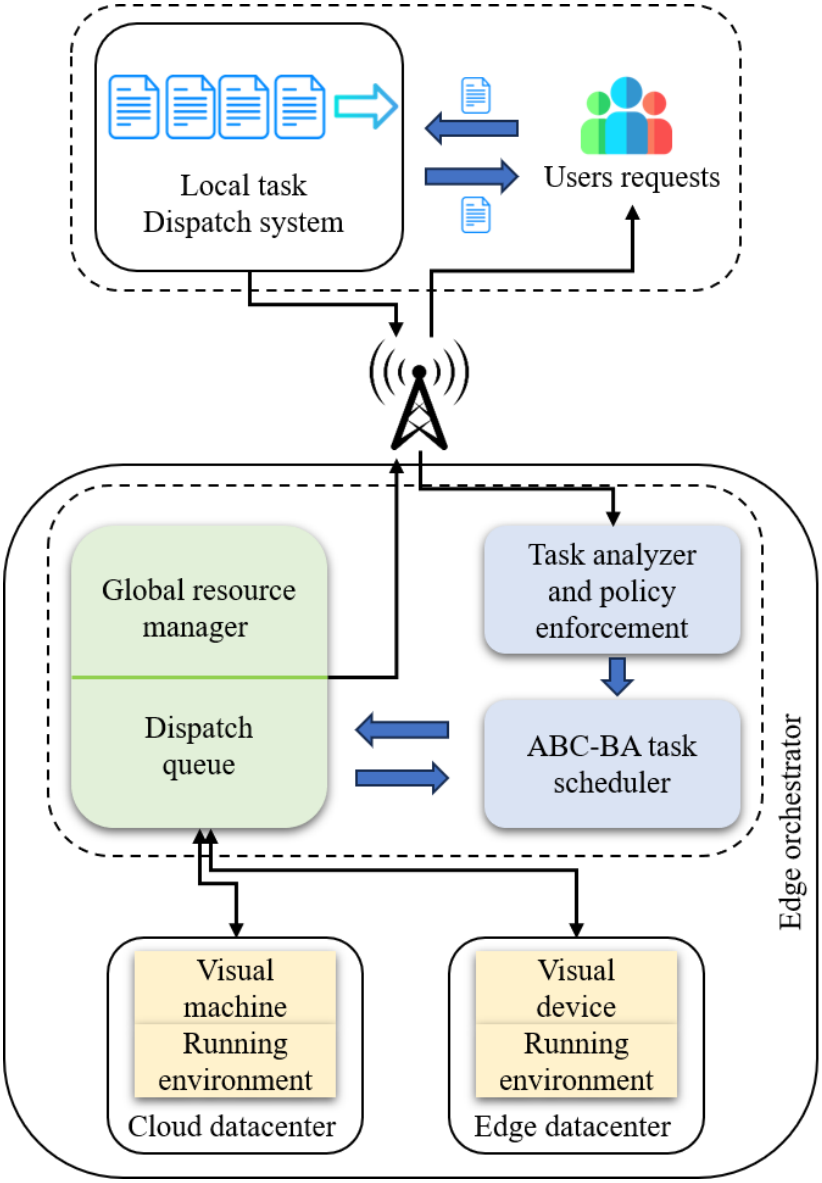

Fig. 1. System model.

TABLE II. SYMBOLS AND DESCRIPTIONS

Symbol	Description	Symbol	Description
p_l	Probability of selecting individual ℓ in ABC phase	t	Number of iterations
gc	General number of cycles	t_{BA}	Remaining iterations for bat algorithm
N	Population size	sc	Success control parameter
z_j^l	Component of individual ℓ for ABC algorithm	mnc	Maximum number of changes between BA and ABC
$f(x)$	Target function	v_i^t	Velocity of the i^{th} bat at time t
x^*	Best solution in the population	x_i^t	Position of the i^{th} bat at time t
max_i	Maximum iteration	D	Dimension of the problem space
A	Loudness in the bat Algorithm	h_j	Hourly resource leasing price
r	Pulse emission rate	t_{ij}	Task execution time
t_{ABC}	Remaining iterations for ABC algorithm	c_{ij}	Communication time
C	Total cost	M	Makespan

The task analyzer subjects the tasks to a task dependency model that enforces execution to avoid delays and deadlocks. Another essential component is the global resource manager, responsible for monitoring real-time network metrics to make resource allocation decisions. The scheduler utilizes the hybrid ABC-BA algorithm to assign tasks to edge or cloud resources based on execution order, task requirements, and current network performance. ABC-BA couples the global searching capability of the ABC algorithm with the fast local searches of the BA to provide optimal task allocation and adaptation to dynamic conditions.

The task scheduling algorithm takes the request from the task requests by going through QoS requirements and constraints. It decides whether tasks should be executed on cloud resources, edge resources, or even both to minimize execution time and cost. Resource utilization rates, such as the usage hour rate for a cloud virtual machine or the per-minute rate for an edge server, form the basis for calculating the execution cost of a task. This model can upload dependent and independent tasks on which different cost structures, like Amazon EC2 and Microsoft Azure, differ for various providers.

Makespan measures the total time needed to accomplish all tasks, influenced by task execution time on edge or cloud devices and communication delays, calculated as follows:

$$M = max\left(\underset{t_i \in C_i}{max}(t_{ic} + c_{ic}) + \underset{t_i \in E_i}{max}(t_{ie})\right) \quad (1)$$

Where t_{ie} is the execution time on edge VMs, t_{ic} is the execution time on cloud VMs, and c_{ic} is the communication delay between edge and cloud. Cost is mathematically modeled as follows:

$$C = \sum_{i=1}^{k}\sum_{j=1}^{n} Cost_{ij}, \quad where \quad Cost_{ij} = h_j \times t_{ij} \quad (2)$$

Where h_j denotes the resource price per hour, and t_{ij} represents the task execution duration.

A Directed Acyclic Graph (DAG) represents the dependencies between tasks to ensure the order is respected and prevent deadlocks. Therefore, nodes represent tasks, and an edge implies dependency. The finish time of each task and the dependency constraint are computed as follows.

$$F_i = S_i + D_i, \quad \forall t_i \in T \quad (3)$$

$$S_j \geq F_i, \quad \forall (t_i, t_j) \in E \quad (4)$$

Where S_i is the start time, D_i is the duration, and F_i is the finish time of task t_i.

The network model optimizes interactions between edge devices, servers, and cloud resources. Each edge device connects to one edge server, computed as:

$$\sum_{j \in E} z_{ij} = 1, \quad \forall ED_i \in D \quad (5)$$

Where z_{ij} indicates a connection between edge device ED_i and edge server ES_j. Edge servers can connect to multiple cloud servers:

$$\sum_{j \in C} w_{ij} \geq 0, \quad \forall ES_i \in E \quad (6)$$

The flow conservation constraint ensures data stability across nodes:

$$\sum_{k:(k,i)\in L} f_{ki} - \sum_{k:(i,k)\in L} f_{ik} = b_i, \quad \forall i \in D \cup E \cup C \quad (7)$$

Where b_i represents data flow demand, and f_{ik} denotes data flow between nodes. This model ensures efficient task execution by integrating the hybrid ABC-BA algorithm into resource and network management in the edge-cloud continuum.

IV. BACKGROUNDS

A. Artificial Bee Colony Algorithm

The ABC algorithm takes inspiration from the foraging behavior of honeybee colonies. Presented by Karaboga and Akay [18], it was used to solve continuous optimization problems. This algorithm works in iterative phases, comprising several steps to effectively achieve optimum solutions for optimization problems. In the initial phase, a population of N_p individuals (candidate solutions) is generated using Eq. 8, randomly within a specified range $[-100, 100]^m$, where m represents the problem's dimensionality.

$$z_j^l = z_{min} + (z_{max} - z_{min}) \cdot rand(), \quad l \in \{1,2,\dots,N_p\}, j \in \{1,2,\dots,m\} \quad (8)$$

z_{min} and z_{max} denote the bounds, and rand() is a random scalar in the range [0 , 1).

Employed bees search for improved solutions near their current positions. A new solution v_j is generated as follows:

$$v_j = z_j^l + (2 \cdot rand() - 1) \cdot \left(z_j^l - z_j^k\right) \quad (9)$$

Where k is a random individual index ($k \neq l$). The fitness of each candidate solution is evaluated using the objective function, defined as:

$$fit_l = \begin{cases} \dfrac{1}{1+f_l}, & if\ f_l \geq 0 \\ 1 + |f_l|, & otherwise \end{cases} \quad (10)$$

Each solution's probability of being selected for further exploration is determined as:

$$p_l = \frac{fit_l}{\sum_{t=1}^{N_p} fit_t}, \quad l \in \{1,2,\dots,N_p\} \quad (11)$$

Onlooker bees exploit food sources based on probabilities calculated in the previous step. Similar to the employed bees, a new solution is generated using Eq. 12.

$$v_j = z_j^l + (2 \cdot rand() - 1) \cdot \left(z_j^l - z_j^k\right) \quad (11)$$

If a food source cannot be improved after a defined limit of attempts, the corresponding bee becomes a scout and generates a new random solution as follows:

$$[v_j = z_{\min} + (z_{\max} - z_{\min}) \cdot \text{rand}() \quad (12)$$

B. Bat Algorithm

The BA is a heuristic algorithm inspired by echolocation patterns, where bats employ sound waves to locate their prey and avoid collision with objects. The delay between high-frequency sound pulse transmission and reception determines bats' distance from their prey. This echolocation capability provides the basis for BA's mechanism of exploration and exploitation in search spaces. This algorithm follows the following underlying principles:

- Echolocation is used by bats to determine their distance from prey.
- Bats move at a velocity v_i toward a position x_i spanning a frequency spectrum $[f_{min}, f_{max}]$, making sounds at various frequencies λ and loudness A to discover their prey.
- Bats adjust their signal's wavelength and pulse rate dynamically while calculating distances.
- The loudness drops from a maximum (A_0) to a minimum value (A_{min}) as a bat approaches its prey, while the pulse emission rate r rises.

In a D-dimensional sphere, the frequency, velocity, and position of the i^{th} bat are updated as follows:

Frequency calculation:

$$f_i = f_{min} + (f_{max} - f_{min}) \cdot \beta \quad (13)$$

Where β is a random number in [0, 1].

Velocity update:

$$v_i^t = v_i^{t-1} + (x_i^t - x^*) \cdot f_i \quad (14)$$

Where x^* is the current global best position.

Position update:

$$x_i^{t+1} = x_i^t + v_i^t \quad (14)$$

For local exploitation, a new solution is generated around the best current solution using a random step as follows:

$$x_i^{t+1} = x_i^t + \epsilon \cdot \vec{A}^t \quad (15)$$

Where ϵ is a random value in $[-1, 1]$, and $\vec{A}^t$ represents the average loudness of all bats at time t.

As bats converge toward the prey, the loudness decreases exponentially while the pulse emission rate increases as follows:

$$A_i^{t+1} = \alpha \cdot A_i^t \quad (16)$$

$$r_i^{t+1} = r_0 \cdot [1 - e^{-\gamma t}] \quad (17)$$

Where α and γ are constants that control the rate of adaptation.

BA dynamically alters the relationship between exploration on the global scale and exploitation on the local scale by dynamically adjusting its parameters. Frequency guides the range of movements, while loudness and pulse rate control the tradeoff between exploring new areas and refining existing solutions. These allow the algorithm to maintain a balance between exploration and exploitation.

V. Proposed Hybrid Algorithm

The proposed hybrid algorithm, ABC-BA, is an amalgamation of the strengths of BA and ABC in an attempt to balance the tradeoffs between exploitation and exploration. Integrating the two algorithms, ABC-BA enhances global search capabilities, population diversity, and solution quality. ABC-BA rectifies BA structural defects by dynamically updating the pulse emission rate (r), along with loudness (A). As iterations progress, r increases, allowing the algorithm to focus on local search, while A decreases to refine the solutions. To enhance the search capability, an inertia weight coefficient (w) is introduced into the velocity formula of BA.

$$v_i^t = \omega . v_i^{t-1} + (x_i^t - x^*) \cdot f_i \quad (18)$$

This coefficient improves global search during initial iterations and gradually emphasizes local search as iterations progress.

The hybrid algorithm divides the population into two equal parts. The BA processes one part, while the other part is treated by the ABC. Both algorithms work independently; however, at certain periods, they share their information with the other to enhance the performance of the whole. After a predetermined iteration cycle (sc), the performance of ABC and BA is assessed based on the number of new solutions generated. If BA performs better (based on ba_sn), its best solutions replace the worst solutions in the ABC group and vice versa for ABC:

- ba_ni: Number of new solutions generated by BA.
- bee_ni: Number of new solutions generated by ABC.
- ba_sn and bee_sn: Counters tracking successful exchanges.

Solutions are exchanged between BA and ABC based on success rates. The parameter ac determines the number of individuals to replace, calculated as follows:

$$mnc = \left(\frac{\max^{(f)} - \text{iteration}}{sc} \right) \cdot 0.6 \quad (19)$$

The hybrid algorithm's complexity depends on the separate complexities of BA and ABC. For a problem size D, the worst-case computational complexity for fitness evaluation is (D), while the complexity of the algorithms is (D·N), where N is the population size. During parallel execution, the complexity is:

$$t \cdot \left(O\left(P \cdot \frac{N}{2} \right) + O\left(2 \cdot P \cdot \frac{N}{2} \right) \right) \quad (20)$$

If one algorithm dominates, the complexity becomes:

$$t_1 \cdot \left(O\left(P \cdot \frac{N}{2} \right) + t_2 . O\left(2 \cdot P \cdot \frac{N}{2} \right) \right) \quad (21)$$

Where t_1 and t_2 are the respective iteration counts for BA and ABC.

By incorporating BA and ABC, the ABC-BA algorithm combines ABC's global search capability with BA's detailed local exploitation advantageously. Such synergy avoids early

convergence of the algorithm to poor suboptimal solutions, improves solution quality, and effectively adapts the algorithm to dynamic optimization problems. Significant exploration and exploitation improvements are shown in the proposed algorithm, especially for large-scale, complex search spaces. Fig. 2 shows the pseudo-code of the proposed hybrid algorithm.

Initialization:
Set population size (N), number of cycles (gc), maximum iterations (max_i), and problem dimension (D).
Define the objective function $f(x)$.
Initialize the population ($\{x_1, x_2, \ldots, x_N\}$) in D-dimensional space.
Define algorithm parameters:
Set BA and ABC parameters.
Determine the initial best solution (x^*) in the population.
Determine exchange parameters:
Set the success control parameter (sc).
Compute the maximum number of changes (mnc) based on Eq. 19.
Start the iterative process:
Begin with iteration $G = 1$.
While $G \leq gc$.
Reset counters:
Initialize counters for new solutions generated (ba_ni= 0, bee_ni=0) and successful exchanges (ba_sn=0, bee_sn=0).
Apply BA to first half of population:
For $t = 1$ **to** max_i:
For $i = 1$ **to** $N/2$:
Generate a new solution (x_{new}) using BA.
If $f(x_{new}) < f(x^*)$, update $x^*$and increment ba_ni.
Apply ABC to second half of population:
For $i = 1$ **to** $N/2$:
Generate a new solution (x_{new}) using ABC.
If $f(x_{new}) < f(x^*)$, update $x^*$and increment bee_ni.
Information exchange between algorithms:
If $mod(t, sc) == 0$:
Compute ba_ni and bee_ni.
If $ba\_ni \geq bee\_ni$:
Replace worst solutions in ABC population with best solutions from BA.
Increment ba_sn.
Else
Replace worst solutions in BA population with best solutions from ABC.
Increment bee_sn.
Check algorithm dominance:
If $ba\_sn \geq mnc$:
Execute remaining iterations using BA.
Else if $bee\_sn \geq mnc$:
Execute remaining iterations using ABC.
Increment iteration:
Increment G and repeat the process.
Output results:
Display the best solution (x^*) after completing all iterations.

Fig. 2. Pseudo-code of hybrid algorithm.

VI. Performance Evaluation

This section compares the performances of ABC-BA against two benchmark algorithms, Fruit fly Simulated Annealing Optimization Scheme (FSAOS) [19] and Quantum-behaved Particle Swarm Optimization (QPSO) [20], implemented using an Edge-CloudSim simulator. In this regard, two edge data centers and one cloud data center were configured by setting different resources to make the scenarios realistic. In ABC-BA, maximum iterations were 100, the population size was 50, and a dynamic switch probability was adopted to balance exploration with exploitation. The experiments were conducted based on task execution metrics: makespan, cost, resource utilization, and task count ranging from 100 to 1000. Makespan measures the total task completion time, while cost evaluates resource utilization expenses. Simulation findings highlight ABC-BA's capability to optimize resource allocation and task scheduling across edge and cloud environments.

As shown in Fig. 3 and 4, ABC-BA consistently outperformed FSAOS and QPSO in terms of makespan. On the cloud, ABC-BA had an increased trend in makespan from 74.69 for 100 tasks to 503.85 for 1000 tasks, while QPSO and FSAOS presented a much larger increase. Similarly, in the case of the edge environment, ABC-BA had lower makespan values, ranging from 31.66 to 339.93, compared to QPSO (41.16 to 441.91) and FSAOS (47.49 to 490.56). These results demonstrate ABC-BA's efficiency in minimizing task execution time, critical for latency-sensitive applications like

IoT and real-time analytics. The findings emphasize its scalability and robustness under increasing workloads.

Cost analysis further demonstrated ABC-BA's superiority in resource efficiency. In the cloud environment, as shown in Fig. 5, ABC-BA achieved the lowest costs, starting at 25.21 and increasing to 333.43, outperforming QPSO and FSAOS, which exhibited costs ranging from 30.25 to 400.12 and 55.86 to 485.06, respectively. On the edge, as shown in Fig. 6, ABC-BA's costs increased from 12.51 to 126.11, while QPSO.

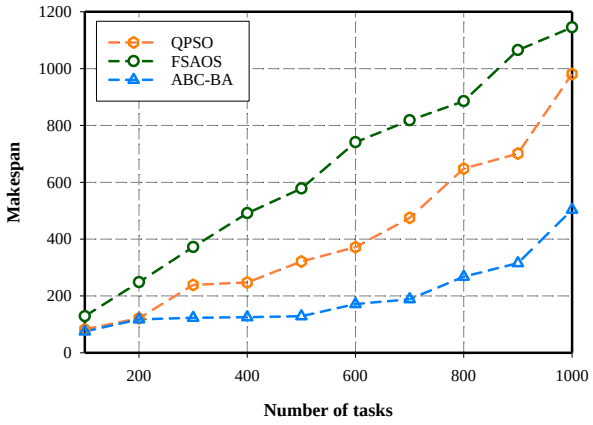

Fig. 3. Makespan results on cloud servers.

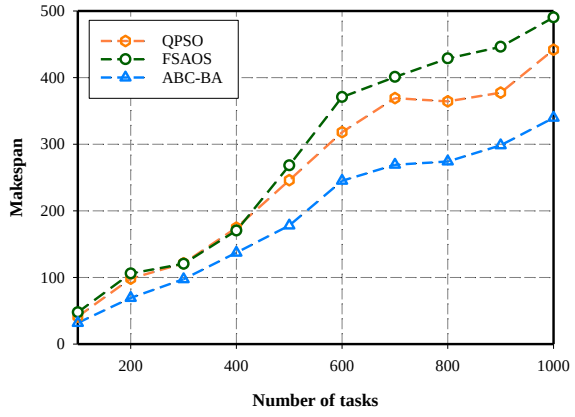

Fig. 4. Makespan results on edge servers.

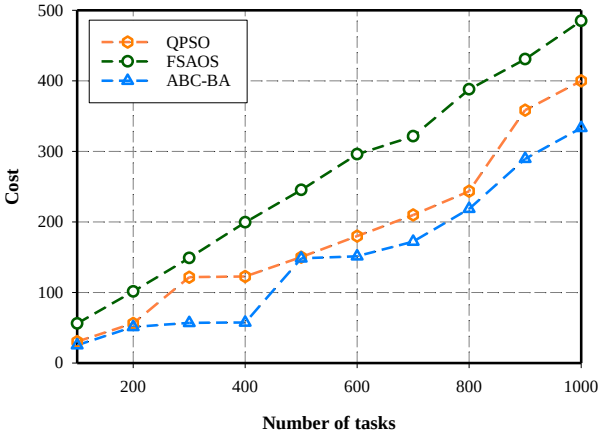

Fig. 5. Task execution on cloud servers.

Ranged from 15.46 to 151.34, and FSAOS ranged from 17.54 to 162.30. The results highlight ABC-BA's ability to minimize operational expenses by optimizing resource allocation. This cost efficiency makes ABC-BA an ideal choice for resource-constrained edge environments and large-scale cloud systems, ensuring reduced execution time and financial overheads while maintaining high performance.

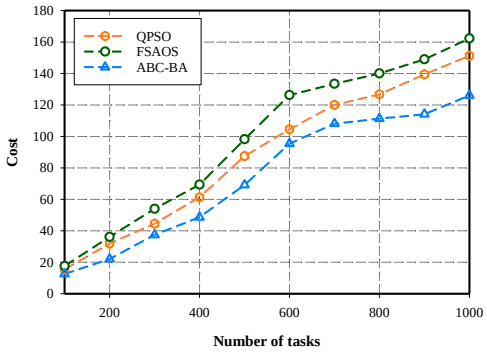

Fig. 6. Task execution on edge servers.

The resource utilization analysis highlights the efficiency of the ABC-BA algorithm in both cloud and edge environments. As shown in Fig. 8, on the edge, the resource utilization values for ABC-BA steadily increase from 1.90 at 100 tasks to 19.05 at 1000 tasks. As shown in Fig. 7, utilization starts at 0.17 in the cloud and rises to 1.68 for the same task sizes. Comparatively, the benchmark algorithms, QPSO and FSAOS, demonstrate higher resource usage in both environments, reflecting less efficient optimization.

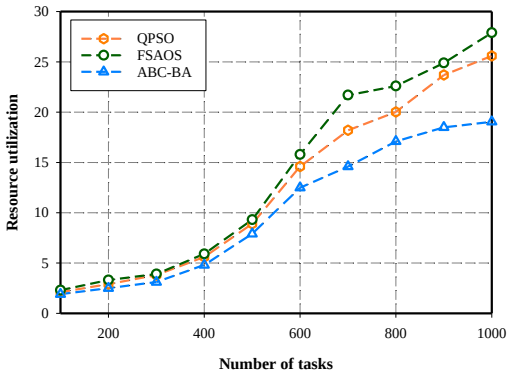

Fig. 7. Resource utilization on edge servers.

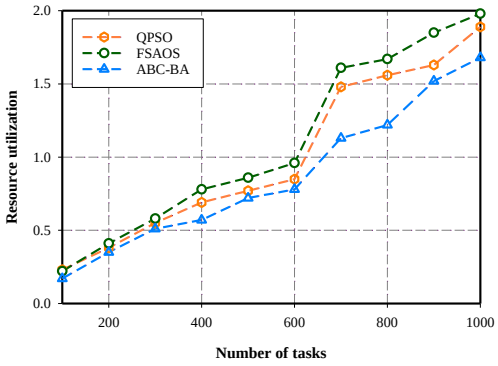

Fig. 8. Resource utilization on cloud servers.

VII. CONCLUSION

This paper proposed a hybrid ABC-BA algorithm for resource allocation and task scheduling in edge-cloud environments. By leveraging the strengths of ABC and BA, ABC-BA addressed the vital challenges of exploration-exploitation balance, reduction of time taken to execute tasks, and optimization of resource utilization. The testing evidence proved that the proposed algorithm performed better than the benchmark methods regarding makespan, cost, and resource utilization. ABC-BA has constantly outperformed the comparatives for a wide range of simulations in both cloud and edge computing under various task size and resource constraints, proving its robustness and scalability.

Future works may implement an improved ABC-BA, considering other optimization algorithms like multi-objective algorithms or deep reinforcement learning methods that might improve the performance even further. The implementation of ABC-BA using real-world edge-cloud environments on different workloads and their integration with sophisticated network models will be of greater value in eliciting insight into the practical workability proposed in this approach. More generally, the proposed ABC-BA algorithm may be able to point out a new frontier in resource optimization and task scheduling, fostering further research in the direction of more efficient and scalable edge-cloud solutions. Additionally, future research will incorporate robust fault tolerance mechanisms to address node failures, including dynamic task reallocation, node health monitoring, and redundancy protocols. By integrating these strategies, we aim to enhance the resilience and practical applicability of the proposed algorithm in unpredictable real-world environments.

***Abstract*—Deep learning models have significantly improved pneumonia detection using X-ray image analysis in the field of AI-driven healthcare, showing a major advancement in the effectiveness of medical decision systems. In this paper, we have conducted a systematic literature review of pneumonia detection techniques that applied transfer learning combined with other methods. The review protocol has been developed thoroughly and it identifies recent research related to pneumonia detection from the past five years. We have used very famous research repositories such as IEEE, Elsevier, Springer, and ACM digital library. After a thorough search process, 35 papers are finalized. The review summarizes those past papers that have implemented different methods of pneumonia detection and results are compared based on the best performing models. Also, these models have been categorized into three approaches to pneumonia detection: Deep Learning methods, Transfer Learning techniques, and hybrid methods. Then, there is a performance comparison of the best-performing models for pneumonia detection. This study concludes that while transfer learning holds substantial potential for improving pneumonia detection, further research is necessary to optimize these models for clinical application. This study concludes that while transfer learning holds substantial potential for improving pneumonia detection, further research is necessary to optimize these models for clinical application. This review is very helpful for the researchers in identifying the research gap for pneumonia detection techniques and how these gaps can be addressed shortly.**

Keywords*—Pneumonia; machine learning; COVID-19: deep learning

I. Introduction

Worldwide, pneumonia is thought to be the main reason behind the death of children. Pneumonia claims the lives of almost 1.4 million kids annually or 18% of all children who pass away before turning five, an estimated two billion people worldwide get pneumonia each year [1]. A virus or bacteria can be the carrier of lung illnesses like pneumonia. Many medicines that are antiviral and antibiotics are fortunately very effective for treating viral or bacterial infections. Conversely, if there is an early detection of viral or bacterial pneumonia and it can be treated promptly, then it can greatly reduce the risk of worsening patient condition and becoming fatal with time ultimately [2]. Until now, chest x-rays have been a very effective way to pneumonia diagnosis [3]. Pneumonia is not always evident on X-rays, and it is frequently mistaken for benign abnormalities or other illnesses. Furthermore, specialists may misclassify viral or bacterial-caused pneumonia images, which could be the reason that patients may get incorrect treatment leading to their deterioration [4-6]. Significant subjective discrepancies in radiologists' diagnoses of pneumonia have been documented. Additionally, low-resource countries (LRC) lack qualified radiologists, particularly in rustic areas. Subsequently, it is very much needed to have computer-aided diagnosis (CAD) systems that are designed to assist radiologists in the rapid identification of multiple pneumonia types using chest X-ray images.

Multiple studies in the past have used a wide variety of deep learning-based techniques in recent years for the classification of chest X-ray images. In the last five years, x-ray scans of lungs affected due to Covid-19 have attained a lot of attention. In [7], 97.11% accuracy was achieved in COVID-19 classification, Pneumonia infection, and Healthy states using the VGG19 architecture on a MongoDB dataset. On the Mendeley Data v2 dataset, a convolutional neural network (CNN) with 22 layers, was employed to extract features in [8] and Support Vector Machine, KNearest Neighbor (KNN), and Random Forest (RF) were used for the classification purpose. CNN model with an accuracy of 99.52%. In [9], the fusion approach without classifier layers was used in conjunction with the VGG16 and MobileNetV2 models for the classification of COVID-19, healthy person's chest X-rays, and pneumonia-affected images having an accuracy value of 96.48%. With an accuracy of 97.46%, a multiscale attention network technique was employed in [10] to classify COVID-19 and pneumonia variations. Another structure introduced to the DenseNet model called Feature channel attention block Squeeze and Excitation in [11], and the experiment produced an accuracy rate of 92.8%.

Many Machine learning classifiers like RF, SVM, and KNN were employed, and a variety of image processing techniques were examined [12]. Consequently, accuracy percentages ranging from 95% to 99% were achieved. The experiments in study [13] yielded an accuracy rate of 97% and automatically identified the best hyperparameters for using architectures VGG16 and ResNet50 architectures using the Genetic Fine Tuning approach. In study [14], deep learning models for transfer learning models including Xception, DenseNet169, and ResNet50 were employed, and the number of images was expanded with cGAN.

In study [15], the great combination of Xception and InceptionResnetV2 was utilized to detect COVID-19 with an accuracy rating of 0.9578. The amazing Transformer Encoder technique was integrated with the base of two ensemble learning models— VGG16, GoogleNet models, DenseNet201, and DenseNet201, InceptionResNetV2, and Xception model

consequently, group B obtained a 96.44% accuracy, whereas group A reached a 97.22% accuracy. It was reportedly mentioned in study [16] that a unique voting method for the COVID-19 illness was created utilizing seven CNN models, which do classification of chest X-ray images as binary. This eventually led to achieving a diagnostic accuracy rate that is nearly 100%. Consequently, the suggested model had a 93.67% test accuracy. In study [17], data balancing was carried out using the smote algorithm. The multi-level based classification was used to classify tuberculosis, COVID-19, and pneumonia and achieved an accuracy value of 97.4% for pneumonia and tuberculosis, and 88% accuracy was obtained for bacterial, COVID-19, and viral classifications. A structure that combines the capsule network and transfer learning technique is suggested in study [18]. With the addition of capsule layers, the InceptionV3 model ultimately produced an accuracy of 94.84%.

A convolutional neural network technique with convolution and residual network assessments is shown in study [19]. The models that are pre-trained like ResNet50, Inceptionv3, and VGG19 architectures based on CNN yielded accuracy rates of 95.61%, 96.15%, and 95.16%, respectively. Convolutional neural networks and the VGG19 model were combined [20], and a 99.10% accuracy rate in the classification of various chest illnesses was attained. In study [21], the Deep Convolutional Generative Adversarial Network (DCGAN) and VGG19 network were used to classify, after the dataset of Chest X-ray8 had been pre-processed and techniques of data augmentation were performed. Consequently, a 99.34% accuracy percentage was achieved SVM, KNN, ensemble classifiers, deep learning classifiers, and deep learning models based on long short-term memory (LSTM) were employed [22]. ResNet50 and DenseNet121 models are merged with a layer created by the CNN block in study [23].

- The pre-trained models had accuracies of 95.61%, 96.15%, and 95.16%.
- The VGG19 model achieved a 99.10% accuracy in classifying chest illnesses.
- The combined accuracy of VGG19 and Deep Convolutional Generative Adversarial Network (DCGAN) is 99.34%.

Despite the various models used, accuracy rates proved to be consistently high with the different techniques applied throughout the research. We have formulated some research questions that will be answered in the review later on:

- RQ1: What are the major past research contributions towards pneumonia detection?
- RQ2: What are the main categories of past research based on technical patterns?
- RQ3: Which transfer learning models work best for medical image pneumonia detection in comparison to other traditional pneumonia detection approaches?
- RQ4: What are the limitations of best-performing transfer learning models?

II. Review Methodology

By Kitchenham's SLR standards, the systematic literature review approach was used for this investigation. It is a methodical approach to doing survey-based research that is based on earlier publications. First, a review methodology is created to ensure that the research is conducted methodically. The research topics are then thoroughly addressed, along with a tool analysis and a discussion of the relative merits of various instruments.

A. Review Protocol Development

The review procedure outlines the research parameters that are used to conduct SLR. It outlines the quality standards that were adhered to when gathering research. The inclusion/exclusion criteria, search procedure, quality assessment, and data extraction and synthesis are all included in the review protocol. Since there are many scientific databases, we have used some very famous databases like Elsevier, Springer, ACM digital library, and IEEE Xplore as we can see in Table I.

TABLE I. Search Keywords and Search Results From Different Databases

Sr.no	Search keywords	No. of search results			
		IEEE	Elsevier	Springer	ACM
1	Pneumonia Detection Transfer Learning	102	152	249	204
2	Pneumonia Detection	107	208	225	382
3	Pneumonia detection in chest X-ray	23	189	159	8
4	Transfer learning approach for pneumonia	253	174	139	3
5	Detection of pneumonia using transfer learning	396	73	122	204

B. Inclusion and Exclusion Criteria

1) Relevant papers from recent years: To ensure that the research is current and up to date, we have chosen articles that were released between 2020 and 2024. All works that were not published during these years have been eliminated.

2) Subject relevant: The articles that we have chosen are pertinent to the domain and research setting. Only studies that can respond to the study questions that have been developed are chosen.

3) Quality publishers: In our research, we have incorporated materials from one of the following well-known databases: ACM, IEEE, Elsevier, and Springer.

4) No repetition: The review does not contain any tools or procedures that are redundant or overlap. The papers are

rejected if they share the same validation process or study environment.

5) Effectiveness of the proposed technique: Only those publications that contain useful and verified tools for a range of database management tasks are chosen.

C. Search Process

We have chosen to use four scientific research databases—IEEE, Springer, ACM, and Elsevier—to conduct the study process. First, a keyword that is acceptable, highly relevant, and able to yield the best and most relevant search results is chosen to identify search words. Since there were many unrelated research studies found using the OR keyword, we have limited our use of the "AND" operator to specifically relevant publications and from the most recent database spanning 2020 to 2024. In Fig. 1 and Fig. 2, our search procedure is displayed.

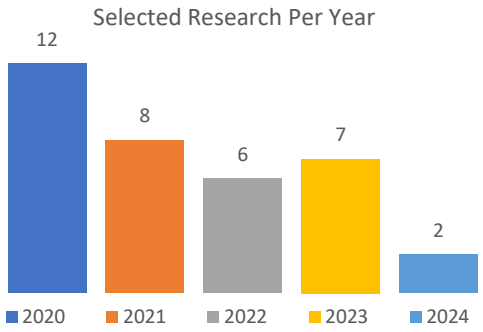

Fig. 1. Selected research per year.

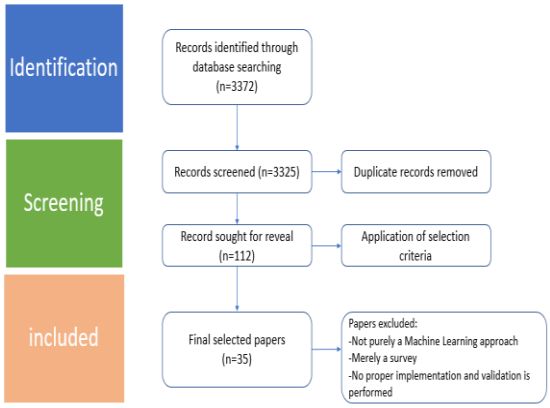

Fig. 2. Search process flow.

III. Review Analysis

Trained radiologists have traditionally been in charge of diagnosing and classifying pneumonia. Radiologists frequently make mistakes because, in certain situations, pneumonia may go undetected to the unaided eye. These situations are referred to as false negatives. In certain instances, radiologists may identify a patient with pneumonia even though they may not have the illness. For the categorization of chest x-ray images into multiple categories including viral pneumonia, bacterial pneumonia, etc., various key studies have been conducted. Here is a summary of some previous research that was chosen using our search procedure.

- RQ1: Pneumonia Detection Methods

Wirasto *et al.* [24] have presented a method for classifying CXR pictures using the InceptionV4 transfer learning type. The InceptionV4 model receives the pre-processed pictures. A 1x1 point-wise convolution is used; then there is a 3x3 depth-wise convolution and then performed a logistic regression.

To analyze COVID-19 cases utilizing chest x-ray pictures, Bahgat *et al.* in [25] have displayed an Optimized Exchange Learning-based Approach for Programmed Discovery of COVID-19 (OTLD-COVID-19). The Mantee-Ray Scrounging Optimization (MRFO) procedure is adjusted within the OTLD-COVID-19 approach to optimize the CNN architectures, organize hyperparameter values, and upgrade classification execution. The exploratory outcome demonstrated that the ideal engineering, DenseNet121, accomplishes the most excellent execution.

A profound convolutional neural network starring the ResNet-50 structure is schemed in this paper by Ansari N. *et al.* [26]. The ResNet architecture has bagged several contests of classification, including the ILSVRC 2015 classification duel, and outshined other traditional models. The model yielded from the Chest X-ray Images dataset, boasted an accuracy value of 94.06%, while the RSNA model hit an accuracy rate of 96.76%.

Using digital X-ray pictures, the authors of the research Rahman *et al.* [27] attempted to automatically identify cases of viral and bacterial pneumonia. For transfer learning, four pre-trained and varying deep convolutional neural networks (CNNs) were used. The authors of this paper have established three schemes of categorization: bacterial against viral pneumonia, normal against pneumonia, and normal against bacterial and viral pneumonia.

Authors determine whether a person has COVID-19, viral pneumonia, bacterial pneumonia, and healthy lungs in the paper by Pathari *et al.* [28] The cutting-edge CNN made a call out to Mobile Net. The top layer CNN known as Mobile Net was utilized to complete the specified assignment. Every model was modified for 2000 epochs. The ADAM enhancer is utilized to accelerate the setback work, with a value of 0.001 learning velocity, and 16 is set as gathering size.

A transfer-learning method using automated convolutional neural network employing four distinct pre-trained models was used in the paper by Salehi *et al.* [29]. The data set includes 5856 horizontal chest X-ray pictures (JPEG) divided into two categories: normal and pneumonia. There were 4273 photos in the "Pneumonia" category and 1583 photographs in the "Normal" category overall. For the identification of pneumonia from pediatric chest X-ray pictures, a CNN-based algorithm was employed.

The Xception model, as well as the VGG16 model, two very distinct transfer learning models, were combined to create this new and innovative model that is presented in the study carried out by Shafi *et al.* [30]. The pre-processing of images utilizing image augmentation and normalization was a key aspect of our research. To extract features, we made use of two very distinct transfer learning models, Xception, and VGG16. The training of the model was performed on both "NORMAL" and "PNEUMONIA" versions using 5216 pictures. The testing

phase involved using 624 photos from the two classes, having the accuracy of the suggested model at 91.67% respectively.

The study by Güler O, Polat K. [31] utilized various models of deep learning such as ResNet50, DenseNet121, ResNet101DenseNet169, InceptionV3, MobileNetV2, VGG16, and Xception to classify chest X-ray pictures. These models were implemented in experiments involving 5856 labeled images from the dataset of chest X-ray images, and the comparison of results was performed. The Xception model, in particular, produced outstanding results with test accuracy at 95.73% and validation at 96.16%.

Authors Ali AM, Ghafoor K, Mulahuwaish A, Maghdid H. [32], used an artificial intelligence engine to categorize the COVID-19-confirmed patient's degree of patient's lung inflammation degree, which included moderate, progressive, or severe cases. To enhance the accuracy of the lung inflammation classification, they opted for a modified Convolution Neural Network (CNN) and k-nearest Neighbor models while contrasting the outcomes with other classification algorithms.

Study by Hashmi *et al.* [33], a very unique method based on a heavily weighted classifier is presented. It successfully optimally integrates the heavily biased predictions from some very advanced deep learning models. The recommended weighted classifier model ultimately attains a test accuracy of approximately 98.43% as well as an amazing AUC score of 99.76 when put into action on the data manually collected from the pneumonia dataset of the Guangzhou Women and Children's Medical Center.

In Manickam *et al.* [34] work specifically attempted to utilize the segmentation method of U-Net architecture to pretreat the chest X-ray images for the detection of pneumonia. Once pneumonia is identified, it is then classified as normal or, in some cases, abnormal (Bacteria, viral) using models that had been previously trained on the ImageNet dataset. Also, two optimizers the Stochastic Gradient Descent (SGD and Adam were intelligently employed to extract the effective features and enhance the accuracy of the pre-trained models.

Convolutional Neural Network models are effectively introduced by Jain *et al.* in a study [35] to classify varieties of pneumonia using X-ray images. These Convolutional Neural Networks were intensively trained with various parameters, hyperparameters, and different numbers of convolutional layers to correctly categorize X-ray images as pneumonia positive or negative. This special study references six different models. The validation accuracy of the initial two models becomes approximately 85.26% and superior 92.31%, respectively.

To efficiently extract diverse properties from chest X-rays, Authers propose a deep CNN-based architecture called CovXNet by Mahmud *et al.* [36], using depthwise convolution with different dilation rates. An integrated gradient-based discriminative attention mechanism is used to identify the anomalous regions of X-ray pictures that correlate with different types of pneumonia.

The deep learning model by author Salvia et al. [37] has been declared very helpful in diagnosis with chest X-rays (CXR) and CT scans. The authors examine the ranking of COVID-19 pattern detection on base and surface scales with two distinct grades using a credible dataset 18 consisting of 2908 frames over 450 inpatients. Twelve LUS examinations in various chest regions were performed on patients who were admitted to the ED, and each result was assessed using standardized severity measures.

The research conducted by Dey *et al.* [38] developed a Deep-Learning System that diagnoses lung pathology based on radiographs, namely chest X-ray pictures. For the first experimental testing of standard DLS models, a SoftMax classifier has been applied. The results showed that overall VGG19 has a better classification accuracy value of 86.97% compared to alternative methodologies.

The viability of a profound neural organize for the determination of lung contamination in chest X-ray dose-equivalent computed tomography (CT) was assessed by Schwyzer *et al.* in study [39]. The profound learning algorithm's regions beneath the bend for the standard measurements CT were 0.923, which was a significant increment over the zones beneath the bend for the lower measurements.

In research conducted by Muralidhar *et al.* [40], chest X-rays are handled employing four stages utilizing a progressed Profound Learning procedure. Picture upgrade, information enlargement, and nourishing come about to profound learning calculations (CNN, VGG16, InceptionResNetV2, Xception, Resnet50, and half-breed show) for the extraction of picture highlights for extra preparation constitute the primary three stages of the method.

Neural organize models were made in a diverse study conducted by Labhane *et al.* [41] to distinguish pneumonia from chest X-ray pictures. Utilizing exchange learning and convolutional neural systems (CNNs), four models—essential CNN, VGG16, VGG19, and InceptionV3—were built. After that, the models were prepared to employ a dataset of adolescent pneumonia cases, which included 2992 cases of pneumonia and 2972 cases of ordinary chest X-rays.

A paper by Paul *et al.* [42] employments a profound learning strategy, such as Convolutional Neural Organize (CNN) engineering, to characterize chest X-ray pictures and analyze pneumonia. We have utilized the 4110-image chest X-ray picture dataset from Kagle. By using MobileNetV2 as the essential show for the picture classification issues, they were able to utilize the exchange learning strategy with CNN in expansion to building an unused CNN demonstration at that time.

In a research led by Alharbi *et al.* [43], analysts utilized machine learning and picture division to precisely anticipate pneumonia cases based on X-ray pictures. A freely named database containing 4,000 X-rays of pneumonia patients and 4,000 X-rays of sound people is utilized. For exchange learning from their already computed weights, ImgNet and SqueezeNet are utilized. Employing a lion's share combination approach, the creators recommended an improved BoxENet show that joins exchange learning from both ImgNet and SqueezeNet.

Another work that has been proposed by Perumal *et al.* [44], presents a one-of-a-kind strategy that employments profound learning approaches to recognize COVID-19 disease.

Histogram equalization progressed picture quality without relinquishing data. The moved forward photographs are prepared to extricate Haralick surface highlights, which are at that point utilized as input for several pre-built CNN models. Max pooling layers are utilized to down-test the pictures for dimensionality decrease, while convolutional layers are utilized to extricate visual highlights in an assortment of pre-defined CNN models, such as Resnet50, VGG16, and InceptionV3.

For refined pneumonia picture classification, Chen W *et al.* in [45] presented a novel strategy that combines the most excellent highlights of EffcientNetB0 and DenseNet121 with a profound convolutional neural organize, supported by an assortment of attention methods.

Study by Rajasenbagam *et al.* [46], the Profound Convolutional Generative Ill-disposed Organize (DCGAN) and VGG19 organize were utilized for classification, after the Chest X-ray8 dataset had been pre-processed and information enlargement strategies performed. Subsequently, a 99.34 accuracy rate was accomplished.

A structure that combines the capsule organization and exchange learning method is proposed by Bodapati JD *et al.* in [47]. With the expansion of capsule layers, the InceptionV3 show eventually delivered a precision of 94.84%.

A modern demonstration, IVGG13, has been actualized by Jiang *et al.* [48] to address issues with restorative picture acknowledgment that happen when the VGG16 show is utilized. Compared to the VGG16 demonstrated design, the IVGG13 show brought down the arranged profundity advance and avoided over- and under-fitting.

A determined structure with an extended convolution was rejected by Liang *et al.* [49] for the picture categorization of adolescent pneumonia. A procedure known as exchange learning was utilized to initialize the show by weighting parameters obtained from expansive datasets inside the same field. They gave a profound learning method that combines extended convolution with determined consideration to classify and analyze pediatric pneumonia.

CNN models were displayed by Jain *et al.* [50] to recognize between bacterial and viral pneumonia utilizing x-ray pictures. Diverse convolutional neural systems have been developed to differentiate x-ray pictures into two fundamental categories: pneumonia and non-pneumonia, by changing different parameters, hyperparameters, and the number of convolutional layers. Six models were used by the scholars. There are two and three convolutional layers within the to begin with two models, individually.

Retraining the ImageNet Organize on the RSNA CXR dataset permitted Islam *et al.* [51] to perform modality-specific exchange learning, which permitted them to arrange to memorize CXR modality-specific highlights and recognize variations from the norm. Both typical CXRs and abnormal pictures with pneumonia-related opacities are included within the utilized collection. A randomized network look method is utilized to maximize the different CNN hyperparameters.

An exchange learning approach that can address the compact information awkwardness trouble in X-ray picture forecast was displayed by the creators of Alqudah *et al.* [52]. With an accuracy of 98.7%, this demonstrates progress in the exactness of recognizing between sound and non-healthy instances.

A procedure to cut the window of time for getting a COVID-19 demonstrative to 2.5 seconds was displayed by Brunese *et al.* [53]. Their approach is based on the VGG-16 show of exchange learning. They constructed two models to finish this. Finding out in case a chest X-ray is related to an understanding of who has generalized pneumonic illness was the point of the primary demonstration. They treat this as an input for the X-ray to a moment demonstrate in case the primary scenario is exact. The reason for the moment show is to recognize if the lung sickness is COVID-19.

To recognize pneumonia, the creators in Manickam *et al.* [54] utilized a profound learning and exchange learning technique that combines several optimization procedures on chest X-ray pictures. They utilized models that were at first prepared to utilize the assembled ImageNet information to classify the chest X-ray pictures into solid and pneumonia-infected states. A few methods were utilized to look at CNN models, counting DenseNet169 + SVM, VGG16, RetinaNet + Veil RCN, and Xception.

The Authers Chouhan *et al.* [55] used transfer learning to make a deep-learning model for pneumonia conclusions. After being prepared on ImageNet, several neural arrange models extract data from images and bolster them into a classifier to form expectations.

By utilizing exchange learning and consideration components, Cha SM *et al.* [56] made a noteworthy progression within the determination of pneumonia. The attention-based highlight choice used in this consideration, together with highlights from ResNet152, DenseNet121, and ResNet18, essentially progressed the execution of computer-aided diagnostic models with momentous accuracy and accuracy measurements.

Utilizing CNN and exchange learning, Rachna *et al.* [57] created a demonstration for the recognizable proof of pneumonia. Pre-trained models were utilized in this demonstration.

Trivedi *et al.* [58], scientists propose a profound learning-based design called "MobileNet" for the programmed recognizable pneumonia detection from chest X-ray pictures. The suggested model for the automatically recognizable proof of pneumonia was prepared in three hours and produced a training precision of 97.34%, approval exactness of 87.5%, and testing precision of 94.23%.

- RQ2: Classification of Past Techniques for Pneumonia Detection

Three distinct deep learning technique-related views may be used in the research being done on COVID-19 identification. These viewpoints are specific to hybrid architectures, transfer learning, and CNN. According to these viewpoints, the research projects for automation of the identification of COVID-19 are discussed in this part. The research efforts for the detection of pneumonia can be classified into three different types of

techniques. These techniques are Deep Learning methods, Transfer Learning techniques, and hybrid methods as we can see in Table II.

TABLE II. PNEUMONIA DETECTION TECHNIQUES CLASSIFICATION

Study ref.	Approach	Proposed Method	Dataset Used
[24]	Transfer learning	InceptionV4 transfer learning	5,232 verified chest X-ray pictures
[25]	Transfer learning with DNN	Optimized Transfer Learning-based Approach (OTLD)	COVID-19, pneumonia bacterial, pneumonia viral, and normal
[26]	Transfer learning with DNN	A deep convolutional neural network that uses ResNet-50 architecture	RSNA dataset
[27]	Transfer learning with DNN	Pre-trained deep convolutional neural networks (CNNs) AlexNet, SqueezeNet, DenseNet201 and ResNet18	5247 chest X-ray images, including viral, bacterial, and normal chest X-rays
[28]	Transfer learning with DNN	CNN Mobile Net	6,000 x-ray images showing Covid-19 illness
[29]	Transfer learning with DNN	Pre-trained deep CNN DenseNet121, Xception, VGG19, and ResNet50	X-ray radiography records kept by the Guangzhou Females and Children's Medical Center for pediatric patients
[30]	Transfer learning with DNN	The Xception model and the VGG16 model	5216 photos from two classes: "PNEUMONIA" and "NORMAL" images
[31]	Transfer learning with DNN	Deep learning models VGG16, MobileNetV2 DenseNet121, InceptionV3, Xception, DenseNet169, ResNet50, VGG16 ResNet101.	5856 labeled images in the chest X-ray dataset
[32]	Hybrid	Modified Convolution Neural Network (CNN) k-nearest Neighbor	the CT scan pictures of the confirmed COVID-19 patients
[33]	Transfer learning with DNN	Deep learning models, including MobileNetV3, InceptionV3, mmmm, Xception, and ResNet18	Pneumonia dataset of the Guangzhou Women and Children's Medical Center
[34]	Transfer learning with DNN	ResNet50, InceptionV3, and InceptionResNetV2	ImageNet dataset
[35]	Transfer learning with DNN	VGG16, VGG19, ResNet50, and Inception-v3	x-ray pictures
[36]	DNN	CovXNet – a deep convolutional neural network (CNN)	COVID-19 chest X-ray pictures
[37]	DNN	Deep Learning	COVID-19 dataset consisting of 2908 frames from 450 hospitalized
[38]	Transfer learning with DNN	AlexNet, VGG16, VGG19, and ResNet50	Chest radiographs
[39]	DNN	Artificial intelligence-based X-ray dose-equivalent CT for the identification of pneumonia.	CT images
[40]	Transfer learning	Xception and ResNet50V2	Chest X-ray dataset
[41]	Transfer learning with DNN	CNN, VGG16, VGG19, and InceptionV3	Dataset of juvenile pneumonia cases
[42]	Transfer learning with DNN	CNN and MobileNetV2-based transfer learning	4110-image chest X-ray image dataset from Kagle
[43]	Transfer learning with DNN	InceptV6 , DSNet4 , DSNet6 Improved BoxENet	4,000 X-rays of pneumonia patients
[44]	Transfer learning with DNN	InceptionV3, Resnet50, and VGG16.	NIH Chest X-Ray-14 dataset
[45]	Transfer learning with DNN	EffcientNetB0 and DenseNet121 with a deep convolutional neural network	Chest X-ray pictures
[46]	Transfer learning with DNN	Deep Convolutional Generative Adversarial Network (DCGAN) and VGG19 network	Chest X-ray dataset
[47]	Transfer learning with DNN	Deep pre-trained CNN models, ResNet50 such as VGG16, Inception-v3, and VGG19	Chest X-ray dataset
[48]	Transfer learning with DNN	Modified VGG16, IVGG13	Pediatric pneumonia
[49]	Transfer learning	transfer learning method with deep residual network	Chest X-ray dataset
[50]	Transfer learning	Inception-v3, VGG16, VGG19, ResNet50	Chest X-ray dataset
[51]	Transfer learning with DNN	VGG19, DenseNet121, InceptionV3, and Inception-ResNetV2	CXRs and aberrant pictures with pneumonia-related opacities
[52]	Hybrid	CNN, support vector machine (SVM), and random forest (RF)	X-ray images
[53]	Transfer learning with DNN	VGG-16	Chest X-ray images
[54]	Transfer learning with DNN	DenseNet169, VGG16, RetinaNet, Xception, SVM and Mask RCN,	ImageNet data
[55]	Transfer learning	ImageNet	ImageNet data
[56]	Transfer learning with DNN	ResNet152, DenseNet121, and ResNet18	Pneumonia chest X-ray images
[57]	Transfer learning with DNN	VGG16, VGG19, ResNet50, and Inception-v3	Pneumonia chest X-ray images
[58]	DNN	MobileNet	Chest X-ray images

- RQ3: Best Performing Pneumonia Detection Transfer Learning Models**.**

This question highlights the best-performing past pneumonia detection methods based on the accuracy value. We have found from the review that there are mostly hybrid approaches of CNN and transfer learning that have been abundantly used in the past and outperforming models are VGG16, DenseNet121, and ImageNet. Given below in Table III are the outperforming models that are used along with other CNN-based transfer learning models under different circumstances and different datasets.

- RQ4: Limitations of the Best Performing Transfer Learning Models

The following are some of the drawbacks of the top-performing model of transfer learning for pneumonia detection:

1) Limited generalization: Due to domain shifts, transfer learning models may find difficulty in adapting well to a variety of patient populations or datasets from various sources, which can result in decreased performance on unseen data [59].

2) Data bias and imbalance: When data imbalances or uncommon pneumonia symptoms are present, pre-trained models may be biased toward the features of the source dataset, which could result in subpar performance or incorrect classification [60].

3) Interpretability challenges: Deep neural networks, which are transfer learning models, are sometimes considered "black-box" models, which makes it challenging to decipher the elements that contribute to predictions and comprehend the decision-making process—a critical skill in medical applications [61].

TABLE III. BEST-PERFORMING MODELS

Study ref.	Transfer Learning Models	Outperforming model	Accuracy
[24]	InceptionV4 transfer learning	InceptionV4	88%
[25]	Optimized Transfer Learning-based Approach (OTLD)	DenseNet121	98.47%
[26]	A deep convolutional neural network having ResNet-50 architecture	ResNet-50	96.76%
[27]	pre-trained deep convolutional neural networks (CNNs) AlexNet, SqueezeNet, DenseNet201 and ResNet18	DenseNet201	98%
[28]	CNN Mobile Net	Mobile Net	95.58 %
[29]	pre-trained deep CNN DenseNet121, Xception, VGG19, and ResNet50	DenseNet121	86.8%
[30]	The VGG16 model and the model Xception	Fusion of both Xception and VGG16	91.67%
[31]	Deep learning models VGG16, MobileNetV2 DenseNet121, InceptionV3, Xception, DenseNet169, ResNet50, VGG16 ResNet101.	Xception model	95.73%
[33]	deep learning models, including MobileNetV3, InceptionV3, DenseNet121, Xception, and ResNet18	Weighted Classifier	98.43%
[34]	ResNet50, InceptionV3, and InceptionResNetV2	ResNet50	93.06%
[35]	VGG16, VGG19, ResNet50, and Inception-v3	VGG19	88.46%
[38]	AlexNet, VGG16, VGG19, and ResNet50	VGG19	97.94%
[41]	CNN, VGG16, VGG19, and InceptionV3	VGG16	98%
[42]	CNN and MobileNetV2-based transfer learning	MobileNetV2	97%
[43]	InceptV6 , DSNet4 , DSNet6 Improved BoxENet	Improved BoxENet	98.6%
[44]	InceptionV3, Resnet50, and VGG16.	VGG-16	93%
[45]	EffcientNetB0 and DenseNet121 with a deep convolutional neural network	DenseNet121	95.19%
[46]	Deep Convolutional Generative Adversarial Network (DCGAN) and VGG19 network	DCGAN	99.34%
[47]	Deep pre-trained CNN models Inception-v3, VGG19, ResNet50 and VGG16.	InceptionV3	94.84%
[48]	Modified VGG16, IVGG13	IVGG13	89.1%
[50]	Inception-v3, VGG16, VGG19, ResNet50	VGG19	92.31%
[51]	VGG19, DenseNet121, InceptionV3, and Inception-ResNetV2	VGG19	99.9%
[53]	VGG-16	VGG-16	98%
[54]	DenseNet169, SVM, VGG16, RetinaNet, Mask RCN, and Xception	ResNet50	93.06%
[55]	ImageNet	ImageNet	99.62%
[56]	ResNet152, DenseNet121, and ResNet18	DenseNet121	95.35%
[57]	VGG16, VGG19, ResNet50, and Inception-v3	VGG19	88.46%

IV. Discussion

In many nations, particularly in developing nations, pneumonia is a frequent illness. This condition is known as obstructive pneumonia, and even medical radiologists may find it difficult to differentiate it from other lung conditions based on the similarity of the appearance of pulmonary radiographs. Recently, image processing and deep learning models have been created to swiftly and precisely identify pneumonia in different models an example shown in Fig. 3[62].

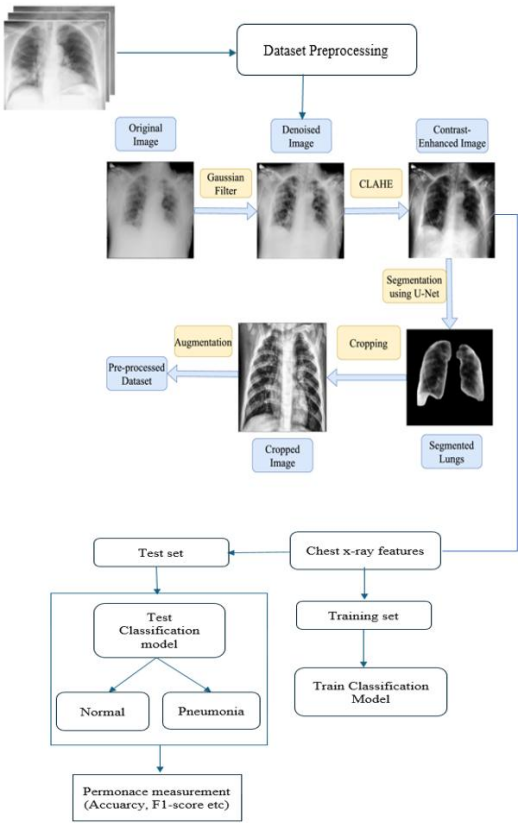

Fig. 3. System flowchart.

In this systematic survey, we have identified many machine learning methods applied for the detection of pneumonia and we have answered four different questions. Based on the first question, there are a total of 35 research that have been explained briefly about their contribution to pneumonia detection. In the next question, those techniques are classified into three categories: Deep Learning methods, Transfer Learning techniques, and hybrid methods. In the next questions, the survey is more refined to identify the best-performing method. This performance is measured based on the output accuracy of those models. However, according to the answer to question four that says what are the limitations of best-performing models and how they are affecting their performance, we are forced to put second thought when selecting any pneumonia detection model just based on its accuracy performance value. Models cannot be just chosen based on how accurate they are if they do not have a generic nature, that fits most of the datasets but they are trained just to classify any specific dataset. Such models do not apply to larger extents. Similarly, these models are pre-trained for a few features and there are new data samples with unknown features, these models are biased towards older features that have already been fed to them. This can greatly alter our assumed results. We have selected a few models based on the frequency of their best performance with a variety of datasets. DenseNet121 has outperformed multiple times and the highest accuracy achieved is 98% and the lowest is 86.8%. This applies to this model has an average good performance over the 5 research models in which it has outperformed. VGG19 model has outperformed 5 models and has achieved the highest accuracy of 99 % and lowest value of 88.46 %. Another model that has outperformed 4 times is VGG16. It has the highest accuracy value of 98% and the lowest 91% which shows it's a very good model looking at its average accuracy that would be more than DenseNet121 and VGG19. Last but not least there is another worth noticing model ResNet-50 that has outperformed three times with an accuracy value ranging from 96% to 93% as we can observe in Table IV.

TABLE IV. Average Result of Best-Performing Models

Model	Number of research	Average performance
DenseNet121	5	94.76%
VGG19	5	93.41%
VGG16	4	95.16%
ResNet-50	3	94.29%

The above discussion proves that models cannot be merely selected based on any of their best performances but the average performance of their outperformance. Also, we have observed that out of those three categories of models, the best-performing models are from Transfer learning with the DNN category of model classification.

V. Conclusion and Future Work

This research aimed to identify various pneumonia detection methods using x-ray images. The review was conducted to identify best-performing methods from the past and to highlight the limitations of existing models. Many authors have used different techniques on different datasets of Chest x-rays and mostly these datasets belong to Corona patients. Some hybrid models have outperformed other models like VGG16, VGG19, and DenseNet121 multiple times. These models worked under different conditions and their parameter tuning also varies. That is the reason we unable to identify any single model to always outperform. However, the optimal performance is guaranteed from the models listed before. This is due to data bias imbalance as discussed in the limitations of these models. Most of the transfer learning models do not performed well due to ungeneralised of dataset and also the usage of trained models. Considering this limitation, medical applications are at greater risk if the models are particular on certain scenarios and the stochastic environments are left unnoticed. Thus, in future work, this research can be extended to address all the highlighted limitations and challenges of the transfer learning models for pneumonia detection and to present a more generic, and less data-specific model that can work in varying environments.

ACKNOWLEDGMENT

Communication of this research is made possible through monetary assistance by Universiti Tun Hussein Onn Malaysia and the UTHM Publisher's Office via Publication Fund E15216.

***Abstract*—The increasing prevalence of cloud environments makes it important to ensure secure and efficient data sharing between dynamic teams, especially in terms of user access and termination based on proxy re-encryption and hybrid authentication management schemes aimed at increasing scalability, flexibility, and adaptability and exploring a multi-proxy server architecture to distribute re-encryption tasks, improve fault tolerance and load balancing in large deployments. In addition, to this eliminated the need for trusted third-party auditors, integrate blockchain-based audit mechanisms for immutable decentralized monitoring of data access, revocation events To future-proof systems provides quantum-resistant cryptographic mechanisms for long-term security as well as to develop revolutionary approaches that drive the user out of the box, driven by machine learning to predict and execute addressing potential threats in real-time. Proposed systems also introduce fine-grained, multi-level access controls for discrete data security and privacy, meeting different roles of users and data sensitivity levels mean improvements greater in terms of computing performance, security and scalability, making this enhanced system more effective for secure data sharing at dynamic and large clouds around us.**

Keywords*—Blockchain audit; data security and privacy; machine learning; proxy re-encryption; quantum-resistant cryptography

I. INTRODUCTION

First Cloud computing has transformed data management by providing flexibility and broader features in terms of sharing information across distributed networks. However, the dynamic group environment presents challenges in creating secure and scalable data sharing mechanisms, especially when user membership changes frequently. Proxy re-encryption (PRE) has emerged as a promising model to enable secure data sharing by outsourcing the re-encryption function to a proxy server. Although traditional methods for PRE reduce computational burden, they often face limitations in terms of method elimination, scalability, and real-time risk detection [1]. To address these gaps, hybrid encryption approaches combining Attribute Based Encryption (ABE) and identity-based encryption (IBE) have gained attention in terms of their accessibility beauty and for the users' efficient erasure [2]. Despite the advantages of centralized third-party auditors (TPAs), which also introduces risks to scalability and reliability. In addition, emerging threats to quantum computing require anti-quantum cryptographic techniques, such as lattice-based cryptography, from future-proof encryption schemes [3]. Emerging trends also highlight the role of Machine Learning to identify malicious behavior and predict threats by analyzing operating systems, and provide dynamic flexibility to navigate controls and re-encryption gaps [4]. This review presents a comprehensive framework for delivery cloud data sharing security has improved, including: (1) Distributed multi-proxy architecture for scalability, (2) blockchain for decentralized audit techniques, (3) quantum-resistant cryptography for future-proofing, (4) ML-based detection of malicious intent, and (5) fine-grained access control techniques incorporating data sensitivity and user functions. Proxy re-encryption introduced it facilitates secure data sharing with minimal computational overhead, further the same work is extended in study [1]. Extended ABE [2], improved access control for dynamic groups. Blockchain integration, as proposed by study [5], enables decentralization and does not change the accounting process. Quantum-resistant cryptographic methods, investigated in study [6], address future security risks. Furthermore, ML models for anomaly detection, such as those developed in study [4], enhance security scalability in cloud environments. Hybrid encryption and advanced revocation techniques including CR-IBE and blockchain-assisted systems have proven to be effective in dynamic user groups, providing scalable, secure and efficient data sharing solutions. The Proactive Threshold-Proxy Re-Encryption scheme Proactive and Cryptographically Enforced Dynamic Access Control ensure secure cloud data sharing by distributing re-encryption tasks, enabling fault tolerance, collusion resistance, and efficient access control [7, 8].

II. Related Work

Before Proxy Re-Encryption, introduced by study [9], facilitates secure data sharing with minimal computational overhead. Attribute-Based Encryption, improved access control for dynamic groups, as proposed by study [10]. Blockchain integration, as demonstrated by study [11], enables decentralized and immutable audit trails. Quantum-resistant cryptographic techniques, explored by study [6], address future security threats. Additionally, ML models for anomaly detection, such as those developed by study [4], enhance adaptive security in cloud environments. Hybrid encryption and advanced revocation techniques, including CR-IBE and blockchain-aided systems, have proven effective in dynamic user groups, providing scalable, secure, and efficient data-sharing solutions, as demonstrated in study [12]. Furthermore, the study [13] proposed privacy-preserving public auditing mechanisms for cloud data, reinforcing access control models. Multi-replica and multi-cloud auditing schemes, as studied by [14], enhance data integrity and security. Edge computing security models, as proposed by study [15], address data integrity challenges in distributed environments. The study in [16] emphasized fine-grained access control mechanisms to improve cloud data security.

III. Methodology

The proposed approach addresses the critical challenges of secure and scalable data sharing in cloud environments, adapting to active user groups, protecting them from of emerging threats such as quantum computing, and the need for an effective yet robust tool for data privacy and integrity highlights this advanced system hybrid It uses PRE, which resists quantum cryptography, decentralized blockchain-based auditing, machine learning-driven threat detection, and fine-grained access control, all for today's cloud infrastructure are integrated into a stated framework together. The process starts with the Hybrid Proxy Re-Encryption process as depicted in Fig. 1. To provide effective and quick encryption for a variety of data sharing scenarios, this system encrypts data utilizing symmetric encryption techniques like Advanced Encryption Standard (AES). IBE and ABE are the encryption keys for AES. To make sure that only the intended user can decrypt it, the IBE appliance links the encryption key to a distinct identifier, like the recipient's email address or user ID. Re-encryption keys are generated by the data master and are essentially shared by dispersed proxy servers. These proxies increase scalability and lessen the computational load on the data owner.

While maintaining data confidentiality and returning data to authorized users without granting them access to sensitive information. The three components of the encryption method are ABE, IBE and AES and combined Ciphertext are discussed as follows:

Symmetric encryption [17] is defined using Eq. (1).

$$C = Enc_{AES}(D, K) \quad (1)$$

Where D is plaintext, K is the secret key, and C is the ciphertext. AES ensures secure, symmetric encryption using K for both encryption and decryption.

Identity Based Encryption [18] is defined using Eq. (2).

$$CIBE=Enc_{IBE}(K, ID, PKIBE) \quad (2)$$

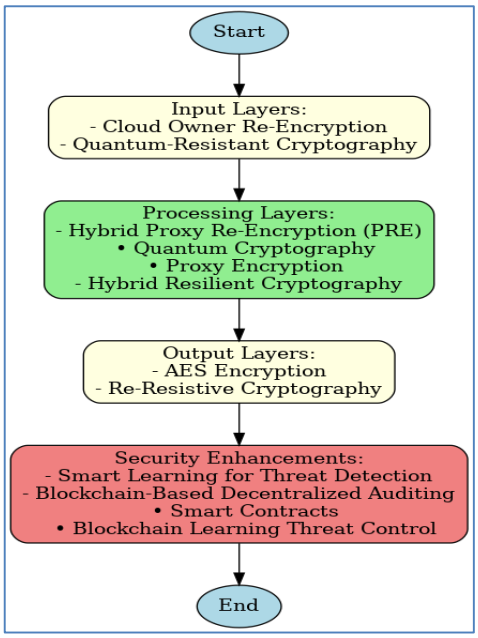

Fig. 1. Sequence of operations.

Where K is the plaintext, ID is the recipient's identity, and PKIBE is the public key used for encryption.

Attribute-based encryption [10] is defined as using Eq. (3).

$$CABE=Enc_{ABE}(K, A, PKABE) \quad (3)$$

The ciphertext CABE is generated using Enc_{ABE} (K, A, PKABE), where K is the plaintext, A defines the access policy, and PKABE is the public key for Attribute-Based Encryption.

Combined Ciphertext encrypted data [19] is represented as given in Eq. (4).

$$E=\{C,C_{IBE},C_{ABE}\} \quad (4)$$

where C is AES-encrypted, CIBE is Identity-Based Encrypted, and CABE is Attribute-Based Encrypted, ensuring multi-layered security. This includes the encrypted data in all three schemes: AES, IBE, and ABE.

The proxy server generates a re-encryption key (RK) to facilitate ciphertext transformation for authorized users without accessing the secret key K [20]. The process of Re-Encryption Key Generation is mathematically represented in Eq. (5).

$$RK=GenKey(CIBE,CABE) \quad (5)$$

Subsequently, the Re-Encryption Transformation is defined in Eq. (6).

$$C' =ReEnc(C,RK,U) \quad (6)$$

Here, the proxy server utilizes the re-encryption key (RK) to transform the ciphertext C into a new ciphertext C', making it accessible only to the intended recipient U, without revealing the original plaintext.

Mesh-based cryptography is incorporated into the system to future-proof the system against quantum computing threats.

Lattice-based encryption was chosen because of its resistance to quantum attack, where it is difficult to solve even with advanced quantum computing, it uses mathematical problems such as the Shortest Vector Problem (SVP). The system is a lattice -based public private keys by discrete Gaussian distribution. These keys replace weak traditional cryptographic methods using quantum decryption, ensuring long-term protection of encrypted data. For example, the encryption key used in AES-based encryption is encrypted using mesh-based public key encryption before being shared with the proxy server to ensure secure transmission and protection against theft.

A. Lattice-Based Key Generation

Lattice-based cryptography relies on hard mathematical problems for security. Given security parameters n, q, and σ [21], the public key (PK) is generated as given in Eq. (7).

$$PK=A\cdot SK+ e \bmod q \tag{7}$$

where A is a random matrix, SK is the secret key, and e is a small noise vector. To encrypt and decrypt the symmetric key K [21] is defined in Eq. (8) and Eq. (9).

$$C_{Lattice}=A\cdot K+e \bmod q \tag{8}$$

$$K=Dec_{Lattice}(C_{Lattice}, SK) \tag{9}$$

The proposed system includes a blockchain-based accounting system decentralized to maintain the integrity and transparency of data sharing activities. Every task, including data acquisition, sharing and cancellation of events about, are irreversibly recorded on the blockchain. A hash of a transaction is added to the blockchain ledger, which is managed by a network of nodes. Smart contracts automate the accounting system, validate transactions, and enforce access controls without human intervention. For example, when someone accesses shared data, the blockchain records actions, including the user's identity, access time, and type of action. This immutable log ensures that all data-sharing activity is transparent and traceable, eliminating the need for a centralized third-party auditor (TPA), which can lead to a single point of failure or disaster it is shared. The decentralized nature of blockchain increases trust and flexibility in a multi- cloud environment.

B. Blockchain-Based Audit Logging

To ensure data integrity and security, each transaction T is hashed before being added to the blockchain [22]. This process is represented in Eq. (10).

$$H=Hash(T) \tag{10}$$

where H is the cryptographic hash of transaction T, providing a unique and tamper-resistant identifier.

A blockchain block B is then created, containing essential components using [22] and represented in Eq. (11).

$$B = \{H_{prev},H,T\} \tag{11}$$

Here H_{prev} is the hash of the previous block, H is the current transaction hash, and T represents the transaction data, and nodes validate new blocks using a consensus algorithm, ensuring agreement on the blockchain state [22] and defined using Eq. (12).

$$B_{valid} = Consensus(B) \tag{12}$$

Machine learning models are used to enhance system security by detecting and responding to abnormal behavior. This model analyzes user data in real time to identify vulnerabilities from expected patterns that could indicate malicious activity, insider threats, or compromised accounts. The system uses algorithms such as partition forests use to identify anomalies. For example, if a user accesses sensitive data outside of its normal business hours or downloads a large amount of unusual data, the system flags this behavior as suspicious. Detecting such anomalies, the system dynamically revokes user access privileges, re-updates encryption keys and excludes flagged users so as to reduce the risk of data breaches.

C. Threat Detection Model

The Threat Detection Model leverages machine learning techniques, such as Isolation Forest (IF), to assess user behavior and detect anomalies. It assigns an anomaly score (S) based on extracted user features (X).

User behavior (U) is analyzed through relevant features (X) extracted from activity logs [23] and mathematically represented in Eq. (13). The Isolation Forest algorithm computes an anomaly score (S):

$$S = IF(X) \tag{13}$$

Where S indicates the likelihood of an action being anomalous. To determine whether access should be revoked, the model compares S with a predefined threshold (τ) as mentioned in Eq.14-15.

If $S > \tau$, then user access is revoked:

$$Access(U) = Revoke \tag{14}$$

Otherwise, access is granted:

$$Access(U) = Allow \tag{15}$$

Access is managed through a model of role-based access control (RBAC) combined with ABE-based encryption. Each user is assigned a specific role that determines their access. The system dynamically validates these settings by comparing the user attributes with the destination set defined for the requested data. For example, a role-based policy allows a manager in a specific department to access the project file during business hours, but denies access after this state Attributes such as role, department, location, and time monitoring in access controls to ensure that users can only access data they are authorized to see.

D. Access Control Model

The Access Control Model ensures secure and authorized data access by evaluating user credentials and predefined policies. Access permissions are granted based on Access is controlled based on roles R, attributes A and policy rules (P) [24] as mathematically described in Eq. (16).

$$\text{Access}(U) = \begin{cases} \text{Allow} & \text{if } (\mathcal{A}_U \subseteq P) \wedge (R_U \in P) \\ \text{Deny} & \text{otherwise} \end{cases} \tag{16}$$

System operation begins when the data owner encrypts the data with AES and regenerates the encryption keys. These keys

are encrypted using mesh-based encryption and distributed to proxy servers. When a user requests access, the proxy server returns the user's IBE identity and ABE attribute to encrypt the data, ensuring that only authorized users can decrypt the data. The blockchain records all transactions irreversibly, and provides a transparent and consistent audit trail. At the same time, machine learning models monitor user activity, flag anomalies, and trigger dynamic access revocation when necessary.

The system is scalable through a distributed multi-proxy architecture, where multiple proxy servers handle the re-encryption task. This load distribution ensures efficient performance even at high demand, and makes the system suitable for large applications with dynamic user groups Using AES for symmetric encryption reduces latency, ensure that the data-sharing service is not only secure but fast and responsive.

IV. Results

A. AES-Based Proxy Re-encryption

In an AES-based PRE system, the data owner encrypts the data using the AES key and sends the cipher text to the proxy. The proxy then uses the encryption key again to change the ciphertext for the intended recipient. The receiver decrypts the re-encrypted data with its AES key.

TABLE I. Comparison of Encryption and Decryption Times

Scheme	Encryption Time (ms)	Decryption Time (ms)
RSA	15	15
ABE-IBE	10	9
Proposed AES-PRE	5	5

A comparison of encryption and decryption times for various cryptographic techniques is shown in Table I. In comparison to RSA (15 ms each) and ABE-IBE (10 ms and 9 ms, respectively), the suggested AES-PRE exhibits noticeably shorter encryption and decryption times (5 ms and 5 ms, respectively). Because of its effectiveness, AES-PRE is better suited for safe, real-time data sharing in cloud environments.

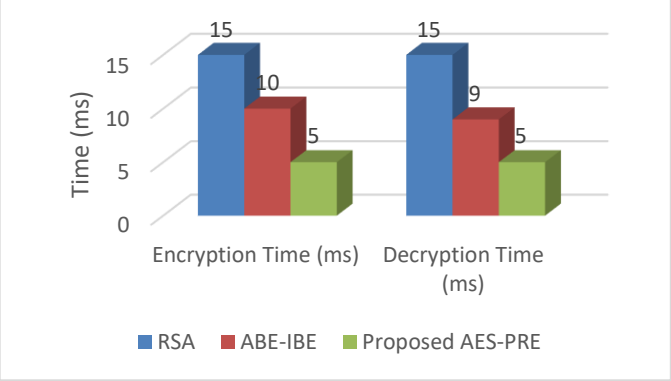

Fig. 2. Comparison of encryption and decryption times.

The encryption and decryption times of RSA, ABE-IBE, and the suggested AES-PRE scheme are shown graphically in Fig. 2. The notable decrease in processing time for AES-PRE validates its benefit in cloud applications that are performance-sensitive.

B. Audit Logging Times

Blockchain-based decentralized logging requires logs to be written to distributed ledgers on multiple nodes, which requires network consensus to verify and add entries. This consensus process introduces latency, as per log compared to centralized logging systems However, the decentralized nature of blockchain ensures that logs are tamper-resistant and unaltered, providing strong data integrity and transparency. Each log entry is cryptographically protected and linked to previous entries, making it impossible to change or delete records.

TABLE II. Comparison of Audit Logging Time

Logging Method	Logging Time (ms)
Centralized TPA Logging	5
Blockchain Logging	15

The audit logging time for blockchain-based logging and centralized TPA-based logging is contrasted in Table II.

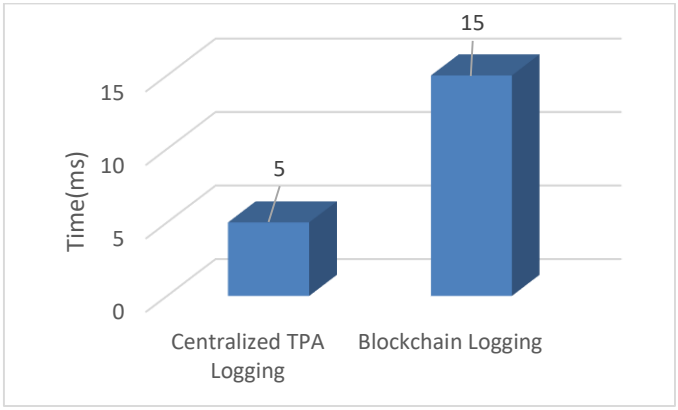

Fig. 3. Audit logging time (ms).

The audit logging time for blockchain-based logging and centralized TPA-based logging is contrasted in Table II. Compared to the centralized TPA approach (5 ms), blockchain logging guarantees greater transparency and tamper resistance, but it takes longer (15 ms) because of consensus validation. The audit logging times for blockchain-based and centralized TPA logging are shown in Fig. 3. Although a little slower, the blockchain-based method offers better security and integrity, which makes it a more dependable option for cloud-based data sharing.

C. Anomaly Detection Accuracy

The proposed machine learning-based anomaly detection, such as the separation forest algorithm, works by extracting anomalies from data through a tree-based algorithm that identifies patterns more efficiently than traditional rule-based methods unlike algorithm a it is based on the law, which is predetermined. Relying on threshold conditions, random forest can adapt to complex data distributions, increasing accuracy in detecting new or previously undetected anomalies.

A comparison of the accuracy of anomaly detection between rule-based detection and the suggested ML-based detection

method is shown in Table III. With an accuracy of 92%, the ML-based system outperforms rule-based techniques, which only attain 80% accuracy. This enhancement demonstrates how well machine learning works to dynamically identify security threats.

TABLE III. DETECTION ACCURACY

Detection Method	Detection Accuracy (%)
Rule-Based Detection	80
ML-Based Detection	92

Fig. 4 compares the accuracy of rule-based and ML-based approaches for anomaly detection. The ML-based approach's improved accuracy shows that it can adjust to changing security threats more successfully than static rule-based methods.

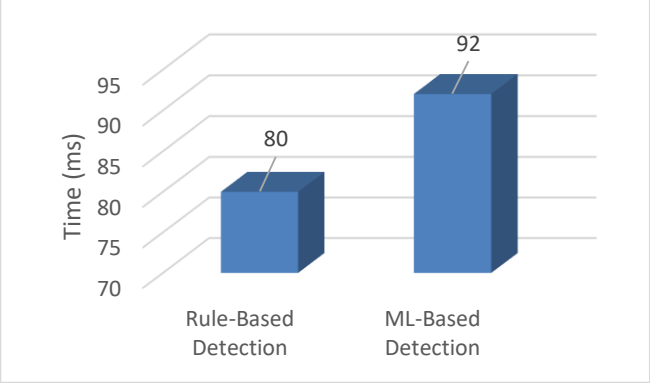

Fig. 4. Anomaly detection accuracy (%).

D. Access Control Flexibility and Security

This frame work -role-based access control (RBAC) offers flexibility in making access methods to change dynamically This also allows precise control With RBAC where group managers can update the user access rights without impacting the complete groups. This granular access techniques will strengthen the systems overall security. The adaptability of various access control models is assessed in Table IV. In contrast to conventional group-based access models, which receive a score of 3, the suggested Role-Based Access Control (RBAC) model receives the highest flexibility rating of 5. This suggests that RBAC enhances security and usability in cloud environments by enabling more dynamic and granular access permissions.

TABLE IV. ACCESS FLEXIBILITY

Access Control Model	Access Flexibility (1-5)
Group-Based	3
Proposed RBAC	5

The flexibility of various access control models is contrasted in Fig. 5. RBAC's greater flexibility rating indicates that it can efficiently handle changing user roles and permissions, guaranteeing security and convenience of access control.

E. Computational Overhead

Quantum computing can break the traditional cryptographic algorithms like AES or RSA, to protect from possible threats we need quantum-resistant cryptographic techniques like lattice-based encryption. This algorithm demands for greater processing requirements when compared with traditional encryption methods complex keys and complex mathematical computations required for encrypt and decrypt of quantum algorithms.

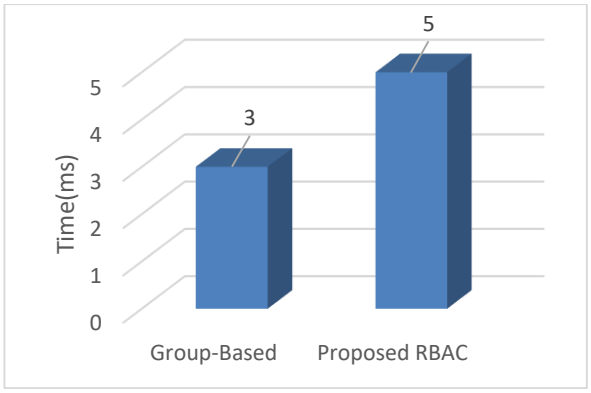

Fig. 5. Access control flexibility.

TABLE V. COMPUTATIONAL OVERHEAD

Cryptographic Scheme	Computational Overhead (%)
AES (Conventional)	5
Lattice-Based (Quantum-Resistant)	30

The computational overhead of the quantum-resistant lattice-based encryption technique and conventional AES encryption is contrasted in Table V. Although lattice-based encryption is more secure, it comes with a 30% overhead, while AES only has a 5% overhead. This demonstrates how using quantum-resistant cryptography involves a trade-off between increased security and computational efficiency.

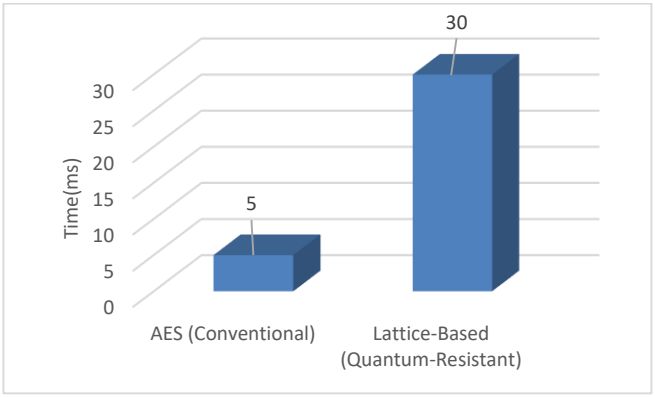

Fig. 6. Computational overhead (%).

The computational overhead of AES and lattice-based encryption is depicted in Fig. 6. Lattice-based encryption is a vital option for future-proofing cloud security systems because its resistance to quantum attacks justifies its higher overhead.

AES is the fast and efficient algorithm which reduces the time taken for secured data transfer. For unmatched data consistency and transparency, I require blockchain audit recording. In contrast with rule-based approaches, the ML model achieves the high true positives and high detection accuracy. For greater flexibility always preferable to use role-based application control (RBAC) which provides greater flexibility.

V. DISCUSSION

The proposed AES-based proxy re-encryption scheme is faster than RSA and ABE-IBE for encryption and decryption, making it suitable for environments where low latency is required. This increased level of security and transparency makes blockchain ideal for applications that require high levels of accountability and accountability. This approach also reduces reliance on rules that intensity down and provides much higher detection accuracy by better capturing subtle patterns in large data sets evaluates the outliers based on statistical features. As a result, it provides more reliable results, especially in dynamic and changing environments where models are not stable. Additionally, it permits accurate control. Group managers can modify user access rights with RBAC without affecting the entire group. The overall security of the system will be strengthened by these granular access techniques. Compared to conventional encryption techniques, this algorithm requires more processing power because it requires complicated keys and mathematical calculations to encrypt and decrypt quantum algorithms. The figures and graphs show quantitatively proves that proposed scheme is better than conventional methods in supporting for safe, secured and scalable cloud data exchange.

VI. CONCLUSION

To tackle the issues of real time threat detection, scalability and quantum threats too. The current work explored the architecture for safe and adaptable data exchange in cloud environment. For enhanced security this work also incorporates quantum-resistant cryptography, besides also suggests to use Role-Based Access Control (RBAC) for flexible, fine-grained access and incorporates machine learning-based anomaly detection for proactive threat detection and revocation. The work offers reliability, flexibility and enhanced access control through a scalable, adaptable framework. Further exploration of the current work will focus on reducing the overhead of quantum cryptography and improving blockchain logging.

VII. FUTURE WORK

While the proposed structure significantly enhances secure and scalable cloud data sharing, there are many areas for further discovery and improvements such as designing, lightweight lattice-based encryption and Post quantum cryptographic schemes such as Code-Based, Multivariate, and Hash-Based Cryptography could further enhance performance. Using Adaptive ML models that constantly learns from new attack patterns in real-time to reduce false positives and false negatives. Exploring layer -2 solutions like side chains, lightening network, shading can help optimize block chain efficiency.

ALE Model: Air Cushion Impact Characteristics of Seaplane Landing Application

Yunsong Zhang, Ruiyou Li Shi*, Bo Gao, Changxun Song, Zhengzhou Zhang
State Grid Electric Power Space Technology Company Limited, Beijing, 102213, China

***Abstract*—Seaplane landing is a strong nonlinear gas-liquid-solid multiphase coupling problem, and the coupling impact characteristics of air cushion are very complicated, and it is difficult to maintain the stability of the air-frame. In this paper, The ALE method is used to study the landing of seaplane at different initial attitude angles and velocities. Firstly, a comparative study of the structure entry model and the air cushion effect model of flat impact water surface is conducted to verify the reliability of the numerical model in this paper, and the influence of the velocity, the water shape and the air cushion are accurately analyzed. Then, a seaplane landing is systematically studied, and the vertical acceleration, attitude angle, aircraft impact force and flow field distribution are analyzed. The results show that the air cushion has a great influence on the landing of seaplane. The smaller the initial horizontal velocity, the more obvious the cushioning effect of the air cushion. Cavitation causes a secondary impact on the tail and produces a pressure value exceeding the initial value, which may cause damage to the aircraft structure. The air cushion has a buffering effect on the seaplane, the pitch angle increases at a slower rate and the pressure value at the monitoring point decreases. The larger the initial attitude angle, the more significant the air cushion. By analyzing the landing rules of seaplane, the range of speed and attitude angle suitable for seaplane takeoff and landing process is given. The results of this paper can provide theoretical guidance for the stability design of seaplane takeoff and landing process.**

***Keywords*—Seaplane; ALE method; multiphase coupling; air cushion**

I. INTRODUCTION

Seaplanes can take off and land on water surface such as rivers, lakes, and seas. They possess notable characteristics, including excellent maneuverability, accessibility, high safety, and scalability. Seaplanes can operate on both water and land, reducing their dependence on specific geographical environments and the need for dedicated airport runways [1, 2]. However, the takeoff and landing process of seaplanes presents a challenging problem characterized by strong nonlinear gas-liquid-solid multiphase coupling. This process needs to consider anti-sinking ability, static stability, surface maneuverability, etc. Moreover, the presence of strong impacts further complicates this problem [3, 4].

Recent research on seaplanes has primarily focused on fluid-structure coupling algorithms, air cushion effects, and structural impact mechanisms. Regarding fluid-structure coupling algorithms, Iwanowski et al. [5] conducted numerical investigations on the horizontal rigid body impacting a water surface and analyzed the influence of compressible air cushions. The governing equations for air and water (modeled as compressible and non-compressible fluids, respectively) are solved using finite difference and fluid volume (VOF) methods. Mori Y et al. [6] combined the discrete element method (DEM) with computational fluid dynamics (CFD) to theoretically derive the stability condition of the drag term and develop a new implicit algorithm. The compatibility of the implicit algorithm with the boundary model composed of symbolic distance function and immersed boundary method is verified by experiments. Hessenthaler et al. [7] integrated several independent analytical solutions into a comprehensive framework, demonstrating its utility in analyzing convergent behavior and introducing novel fluid-structure interaction (FSI) algorithms. Han K et al. [8] validated the applicability of the coupled Boltzmann method (LBM) and discrete element method (DEM) in solving irregular particle transport in turbulence, employing test cases involving polygonal and super-quadratic particle transport in high Reynolds number fluid flows. Oger et al. [9] applied smooth particle hydrodynamics (SPH) method to simulate the solid-liquid coupling problem in a free-surface flow environment, and proposed a new formula of spatial variation resolution with variable smoothing length. Panciroli R et al. [10] investigated the fluid elasticity of an elastic wedge using a coupled finite element method and smooth particle hydrodynamics (FEM-SPH) method. The numerical simulation results agreed well with experimental data, accurately predicting the influence of hydro-elasticity on water impact involving the elastic wedge. Ahmadzadeh M et al. [11] employed the coupled Euler-Lagrange (CEL) method to study the impact of a sphere in free fall motion. Facci et al. [12] utilized the volume of fluid (VOF) method, based on the finite volume method, to simulate free surface multi-phase flows. They numerically analyzed the water impact phenomenon on a moving body and obtained the multi-phase flow field and surface pressure distribution on the body. Servan-Camas et al. [13] applied the SPH-FEM coupling model to analyze the liquid sloshing problem in the navigation body. Aquelet N et al. [14] proposed the Euler-Lagrange coupling algorithm, using a penalty function to calculate the coupling force at the fluid-structure interface and predict the local pressure peak on the structure. Fourey et al. [15] compared two fluid-structure coupling algorithms, parallel interleaving and sequential interleaving [16]. They found that the latter exhibited higher accuracy and stability but lower computational efficiency.

During the takeoff and landing process, the fuselage structure of a seaplane experiences significant friction or collision with the water body, while the presence of an air cushion adds complexity to the dynamics of the structure. Chuang [17] found that objects with small dead corners are more likely to form an air cushion when entering water. The air

*Corresponding Author.

cushion between the model and the water surface plays an important role in the impact process. Song et al. [18] compared different shapes of air cushion, analyzed the structure of air cushion with different volume, and analyzed the influence of different volume of air cushion on the peak value of water entry impact force of buoy. Ermanyuk and Ohkusu [19] designed a flat-bottom disk slamming experiment to study the influence of air cushion on the impact pressure. The presence of air cushion on the surface strongly affects the impact time scale and the shape of the splash jet. Chen Zhen et al. [20] used MSC. Dytran to simulate the mixing of air layer and water surface, and made a detailed analysis on the formation of air cushion. They used the ALE method to observe the presence of a hollow air cushion during the water entry process of flat-bottomed structures, noting that the air cushion can be identified within the air cushion when the peak impact pressure occurs. They also employed a neural network method to fit the impact pressure results and predict the bottom impact pressure. Huera-Huare et al. [21] investigated the effects of different angles on models and their corresponding air cushion effects. They observed that when the water entry angle decreased to less than 5°, an air cushion formed with a significantly lower peak impact pressure than the theoretical value. When the exit angle exceeded 5°, the peak impact pressure followed von Kan's theory. Zhang Jian et al.[22] used numerical simulation to study the influence mechanism of hollow air cushion during the water entry of two-dimensional wedge. Fang et al. [23] studied the air cushion effect and impact load in two-dimensional flat plate water entry problem using the multi-phase Riemann-SPH method based on the PVRS Riemann-solver.

The structural impact problem involves the complex coupling of rigid bodies or deformable bodies with the movement of the surrounding flow field. This complexity is further heightened by the dynamic changes in the free surface and the interaction with air. Adam et al. [24] proposed a new surface tension formula that can deal with multi-phase problems with high density and viscosity ratios. Wang et al. [25] (2022) developed a strategy to eliminate gas phase tensile instability, ensuring computational stability. They also established Riemann models for different materials and obtained a robust gas-solid-liquid contact algorithm. Washino K et al. [26] (2020) proposed an interface capture method based on color function to improve the smoothness of the interface. Shi et al. [27] investigated the effects of head shape parameters, shell thickness, water entry velocity, and angle on the acceleration, pressure, stress, and structural deformation of an elastic underwater vehicle during water entry impact. Based on the fluid volume multi-phase flow model and dynamic grid technology, Liu et al. [28] established a coupling calculation method for the multi-phase flow field and trajectory of a cross-medium vehicle entering water at high speed.

Grid-free method is also often used to simulate the impact of structures [29]. Shao et al. [30] simulated the high-speed impact jet problem, and analyzed the pressure response rule on the wall. Shao et al. [31] established an improved Smoothed Particle Hydrodynamics (SPH) model, and analyzed the influencing factors and flow field changes during the water entry of slender objects. Yang et al. [32] proposed an SPH-EBG algorithm to simulate the impact of dam break flow on elastic plates. Khayyer et al. [33] introduced a full Lagrange particle method under the Material Point Simulation (MPS) framework to simulate the influence of structural elastic response on water entry [34]. Sun et al. [35] improved the SPH method and conducted a simulation study on cylinder water entry problems [36]. Chen et al. [37] utilized MPS method to simulate the water entry problem of a two-dimensional wedge. They investigated the effects of different particle arrangements on calculated results, including vertical hydrodynamic force and free surface changes.

The take-off and landing of seaplane is a strong nonlinear gas-liquid-solid multiphase coupling problem, and it is necessary to consider the air cushion effect and impact effect during the movement. Theoretical analysis can establish clear relationships between changes in physical quantities and flow parameters, offering broad applicability. However, solving the nonlinear problem of air cushion impact is challenging. Experimental analysis often encounters scale effects between experiment models and actual motion due to the intricate topological shapes and external environment. Additionally, model testing requires a lengthy period, and in many cases, the experimental data is incomplete with inadequate repeatability. The grid method can get relatively accurate results when simulating small deformations, however, the VOF method or the level set method needs to be used to track the interface. The particle-type method has made significant progress in simulating severe fluid-structure coupling problems. However, there is a scarcity of full-fluid-structure coupling algorithms that consider the boundary layer effect on the structure's surface. In this paper, ALE method is used to study the landing of a seaplane. The coupled impact dynamic characteristics at different angles and entry speeds are analyzed, and the changes of air cushion are analyzed. The results of this paper have a good guiding significance for the development of seaplane.

II. METHODOLOGY

A. Fundamental Equations

In this paper, the ALE algorithm is used to describe the fluid domain. And the fluid-structure coupling algorithm based on penalty function and Lagrange method are used to simulate the landing process. The Euler coordinate system serves as a fixed fluid coordinate system, unaffected by the object's movement or deformation. The Lagrangian coordinate system acts as a fixed solid coordinate system, with its grid nodes attached to the material nodes. As the solid undergoes deformation, the solid coordinate system adjusts accordingly. The ALE coordinate system is independent of the Eulerian coordinate system and the Lagrangian coordinate system and is not completely fixed on space or solid nodes.

The ALE description introduces a reference domain independent of the material domain and the spatial domain, which always coincides with the grid throughout the calculation process. Fig. 1 shows the mapping relationship between the structural domain and the fluid domain. The mapping expression from the material domain to the spatial domain is as follows:

$$x = x(X, t) \tag{1}$$

The mapping from ALE reference domain to the spatial domain is:

$$x = w(w,t) \tag{2}$$

Since the reference domain always coincides with the grid, the transformation is performed:

$$w = w-1(x,t) \tag{3}$$

The mapping relationship of the material domain and the reference domain:

$$w = w-1[x(X,t),t] = v(X,t) \tag{4}$$

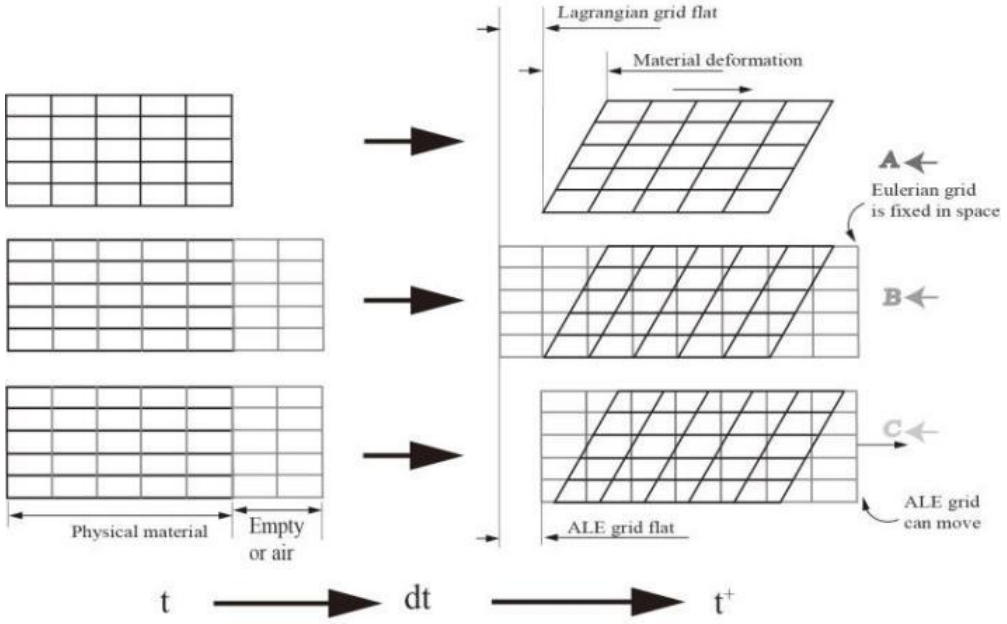

Fig. 1. Mapping between lagrange, euler, and ALE domains.

The expression of the mass equation is:

$$\frac{\partial \rho(\chi,\ t)}{\partial t} = -\rho \frac{\partial u_i}{\partial x_i} - c_i \frac{\partial \rho}{\partial x_i} \tag{5}$$

Where χ is the Lagrange coordinate system, x is the Euler coordinate system, ρ is the fluid density, and c_i is the relative velocity between the structure particle and the grid point in the reference coordinate system.

The equation of motion is:

$$\frac{\partial u_i(\chi,\ t)}{\partial t} = \frac{\partial \sigma_{ij}}{\partial x_j} + \rho b_i - c_j \frac{\partial u_i}{\partial x_j} \tag{6}$$

Where b_i is a unit force, in the Newtonian fluid, the stress tensor is related to the speed, the relationship is related:

$$\sigma_{ij} = \delta_{ij} P + \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{7}$$

Wherein μ is a power viscosity coefficient, P represents pressure.

B. Contact Algorithm

In the contact algorithm, the contact force is proportional to the permeation vector in the time step. In the explicit finite element method, the contact algorithm calculates the interface force due to the influence of the structure on the fluid. These forces act on the fluid and structural nodes to prevent them from crossing the contact interface. The fluid utilizes either an ALE mesh or a Lagrangian grid [38]. In the contact algorithm, as shown in Fig. 2, one surface is designated as the contacting surface, while the second surface is the primary surface. The nodes located on these surfaces are respectively called slave nodes and primary nodes. For fluid-structural coupling problems, the fluid nodes on the interface are considered slave nodes, whereas the structural elements are treated as primary nodes. In this paper, a penalty-based contact method is employed. The force is applied from the slave node, and the force transmitted to the primary element node is scaled using a shape function. The corresponding expression is as follows:

$$F_s = -k_i \cdot d \tag{8}$$

$$F_m^i = N_i \cdot k \cdot d \tag{9}$$

The N_i is the shape function of the surrounding node *i*, (in 2D problems, the values are 1, 2; in 3D problems, the values are 1...4.). The coefficient k represents the stiffness of the spring, and d is a penetrating vector. If the node is completely

coincident from one of the primary nodes (see Fig. 2), the coefficient $k=1$. Applying the Euler-Lagrangian coupling method to calculate the coupling force on the nodes can effectively prevent the large deformation of the grid.

$$F_s = -k_i \cdot d \tag{10}$$

$$F_m^1 = k \cdot d \ \ \alpha\nu\delta \ \ F_m^2 = F_m^3 = F_m^4 = 0 \tag{11}$$

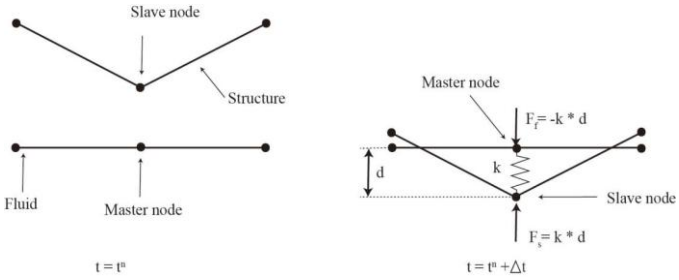

Fig. 2. Schematic diagram of the contact algorithm.

III. Numerical Verification

A. Water Entry

In order to verify the accuracy of the numerical model, this article first simulates the problem of a cylinder entering water. The aluminum solid cylindrical model has a length of 197 mm and a diameter of 50 mm, with a weight of 1.06 kg. It is subjected to an in-water angle of 60° and a speed of 4.35 m/s. Fig. 3 and Fig. 4 present the change in speed and acceleration of the cylinder, and Fig. 5 shows the simulation and experimental water entry process. It is observed that the numerical results before 0.12 s exhibit a strong agreement with the experimental results by Hou [39]. However, after 0.12 s, as the cavity begins to close, the pulsating pressure starts affecting the structure, leading to a decline in speed. Additionally, the simulated acceleration is slightly lower than the experiment.

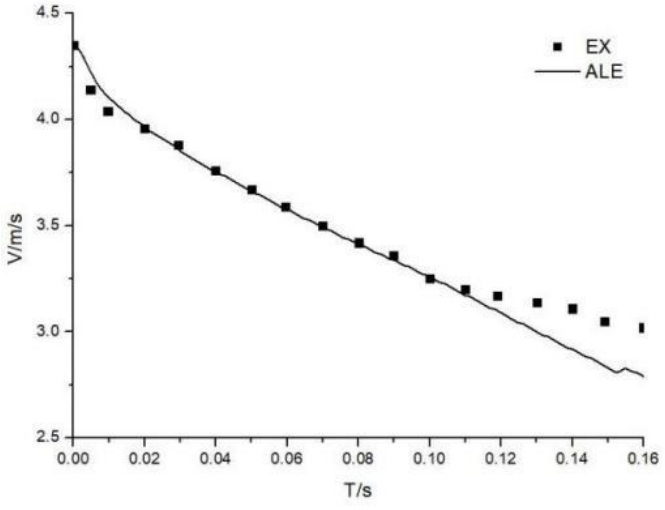

Fig. 3. Speed comparison between simulation and experiment [39]

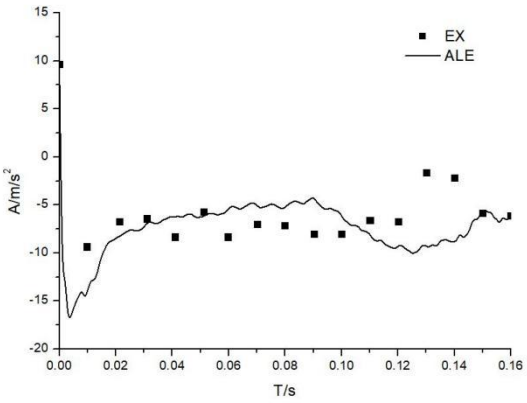

Fig. 4. Acceleration comparison between simulation and experiment [39].

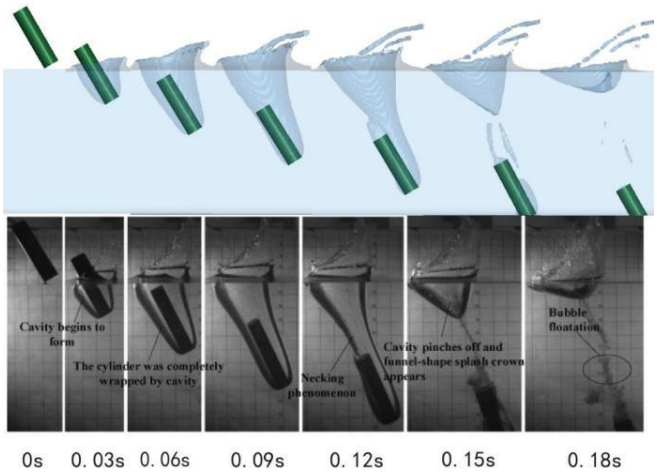

Fig. 5. The water entry of simulation and experiment [39].

B. Verification of Air Cushions

To validate the accuracy of the numerical model for the cushion effect, the same flat plate model as Ma et al. [40] was utilized. The impact plate employed has a mass of 32 kg, a length of 0.25 m, a width of 0.25 m, and a thickness of 0.012 m. By adjusting the initial position of the plate, an impact speed of 5.5 m/s was achieved.

Fig. 6 depicts the pressure curve at the center of the flat plate, and the simulation results exhibit favorable agreement with the experimental findings. The peak pressure slightly surpasses the experimental value, potentially attributed to the utilization of a bubble-generating device during the experiment, causing numerical fluctuations in the results. The pressure at the plate center only occurs momentarily within the structure, then air cushion is formed between the plate and the water surface, resulting in a pressure value of zero. Fig. 7 illustrates the impact force curve in the vertical direction, and the incorporation of the low-speed structure in this study does not exhibit a prominent air cushion effect. Additionally, Fig. 8 demonstrates the formation of an air cushion on the flat impact surface. As the plate continues to impact, the air cushion gradually increases, exerting minimal influence on the plate's impact.

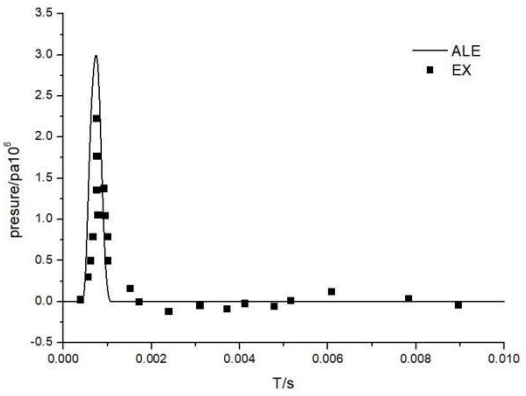

Fig. 6. Pressure distribution on plate center.

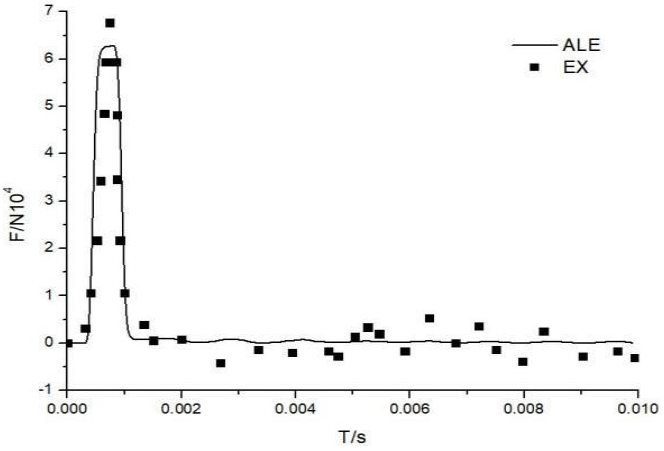

Fig. 7. Vertical impact force distribution of flat plate.

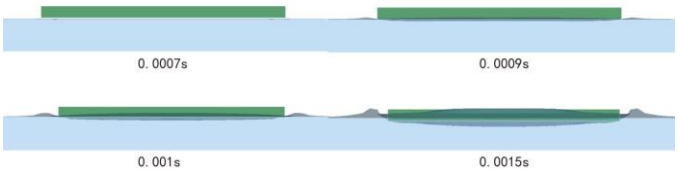

Fig. 8. Air cushion effect during impact.

IV. NUMERICAL MODELS

A. Finite Element Model

Fig. 9 is a finite element model of a seaplane, which is simplified on the basis of the actual model. The aerodynamic effect is ignored, and it is assumed that the seaplane is completely rigid. The weight of the aircraft is 53500kg, the overall length is 37m, and the wing length is 38.4m. The size of water is 200m×50m×20m, the size of air is 200m×50m×200m. The centroid is situated at 30% of the average aerodynamic cord length, precisely aligned with the center of the wing roots. About two million meshes were used. In Fig. 9, the monitoring point P1 is positioned at the center of the aircraft fuselage, located 14.5 m from the aircraft's head. The boundary point P2 is situated 20 m from the seaplane's head, while P3 corresponds to the center position of the seaplane's bottom. The vertical distance between P2 and P3 is 0.6 m, with a horizontal separation of 14.2 m.

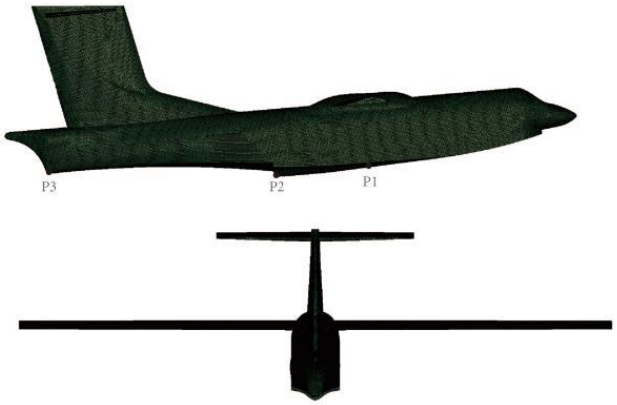

Fig. 9. Aircraft model and grid.

B. Material Parameters

The Mie–Gruneisen equation of state is as follows:

$$P=\frac{\rho_0 C^2\mu[1+(1-\frac{\gamma_0}{2})\mu-\frac{\alpha}{2}\mu^2]}{[1-(S_1-1)-S_2\frac{\mu^2}{\mu+1}-S_3\frac{\mu^3}{(\mu+1)^2}]}+(\gamma_0+\alpha\mu)E \tag{12}$$

Where E is in unit volume, C is the intercept of the u_s-u_p curve, S_1, S_2 and S_3 are the unit-less coefficients of the slope of the u_s-u_p curve. γ_0 is a Gruneisen parameter, α is a first-order correction value of γ_0. The compression ratio is related to the volume, defined as:

$$\mu=\frac{1}{V}-1 \tag{13}$$

An equation can also be approximately:

$$P=\rho_0 C^2\mu+(\gamma_0+\alpha\mu)E \tag{14}$$

The polynomial state equation is selected for the air domain, and the internal energy of the initial volume changes linearly.

$$P=C_0+C_1\mu+C_2\mu^2+C_3\mu^3+(C_4+C_5\mu+C_6\mu^2)E \tag{15}$$

where, C1, C2, C3, C4, C5, C6 are the confident constant respectively.

The thickness of the rigid shell is 0.05m, and the density is 1257kg/m^3. Table I shows the material parameters of the water and air domains.

TABLE I. MATERIAL PARAMETERS

parameter	Density(kg/m^3)	C	S_1	S_2	S_3	γ_0	V_0	E_0
water	1000	1480	1.92	-0.096	0	0.35	0	0
parameter	density(kg/m^3)	C1	C2	C3	C4	C5	C6	E0
air	1.22	0	0	0	0.4	0.4	0	0

C. Landing setting

When the seaplane lands, it should maintain a certain speed and attitude angle. Fig. 10 is a schematic diagram of the initial water entry of the seaplane. Table II shows the settings of speed and attitude angle under different landing conditions.

TABLE II. SEAPLANE LANDING CONDITIONS

Serial number	1	2	3	4	5	6
horizontal velocity (m/s)	35	45	63.9	45	45	45
Vertical velocity (m/s)	1.5	1.5	1.5	1.5	1.5	1.5

V. RESULT AND ANALYSIS

A. Velocity Analysis

This paper systematically investigates the aircraft landing process, with an initial vertical velocity of 1.5 m/s. The variations in attitude angles and accelerations are analyzed for different initial horizontal velocities. The changes in the air cushion during the landing process are studied, along with the analysis of variations in impact force and pressure values at the monitoring point.

Fig. 11 illustrates the changes in vertical acceleration for an initial attitude angle of 5°. With an initial horizontal velocity of 35 m/s, the maximum vertical acceleration observed during the landing process is 12.17 m/s². For an initial horizontal velocity of 45 m/s, the maximum vertical acceleration reaches 13.14 m/s². When the initial horizontal velocity is further increased to 63.9 m/s, the maximum vertical acceleration during aircraft landing is 13.42 m/s². Notably, it is observed that the timing and magnitude of extreme acceleration remain similar across different horizontal velocities. Subsequent to the initial impact, the vertical acceleration exhibits relatively small fluctuations under higher horizontal velocity.

Fig. 12 shows the attitude angle change of the seaplane during landing when the initial attitude angle is 5°. For different initial speeds, the attitude angle of the seaplane initially decreases, then increases, and eventually decreases again. During the water impact process, the seaplane exhibits a forward inclination followed by a subsequent upward attitude. With an initial horizontal velocity of 35 m/s, the maximum attitude angle observed is 7.6°. When the initial horizontal velocity is 45 m/s, the maximum attitude angle reaches 7.64°. Finally, for an initial horizontal velocity of 63.9 m/s, the maximum attitude angle during water landing is 7.5°. By comparing the three curves in Fig. 12, it can be observed that for the same initial attitude angle, the seaplane requires a longer time to tilt forward at higher speeds. Therefore, during the landing process, it is essential to choose an appropriate speed. Different speeds lead to varying pitch angles, influencing the position and timing of the seaplane's contact with the water surface, as well as its vertical acceleration.

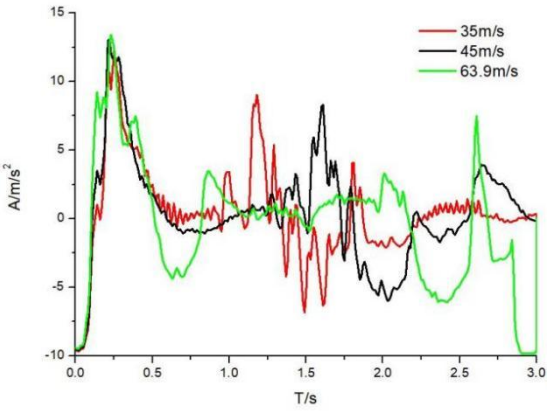

Fig. 11. Vertical acceleration curve.

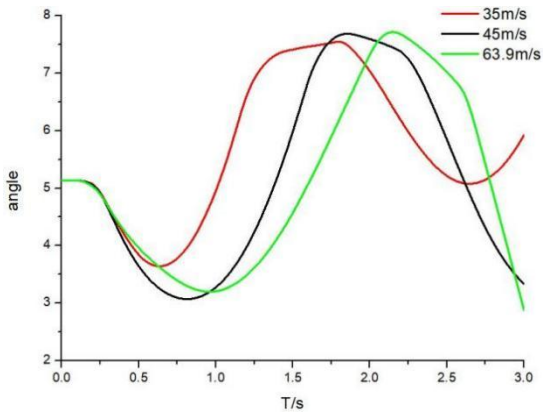

Fig. 12. Attitude angle change of the aircraft.

Fig. 13 shows the landing process of a seaplane. The initial attitude angle of the plane is 5°, the initial horizontal speed is 45m/s, and the initial vertical speed is 1.5m/s. At 0.5s, the tail of the seaplane drew a deep trench on the water surface, and at 1s, the water wave generated by the impact had obviously spread outward. The actual vertical displacement experienced by the seaplane during landing generally ranges from 1 to 2 meters. The maximum vertical displacement is 1.85 meters and the minimum displacement is 0.8 meters, which accords with the actual situation.

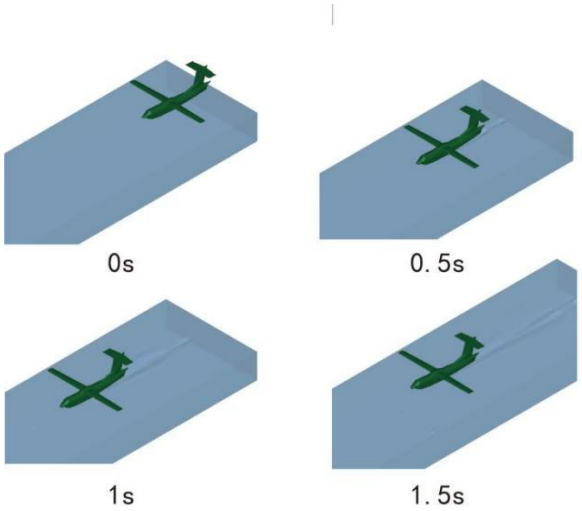

Fig. 13. Landing process of a seaplane.

The air cushion is defined as a hermetically sealed layer of air positioned between the free surface and the underlying structure. During the horizontal propagation of waves, the leading edge of the horizontal plate makes contact with the free surface, while the trailing end remains partially submerged or in contact with the flat plate, resulting in air displacement. This process induces deformation in the water's free surface, which subsequently undergoes reformation parallel to the horizontal plate. Even in tranquil water environments, the forward section of the seaplane's underside remains in contact with the water surface. When this part is not completely detached from the water body, the rear section of the aircraft's underside contacts the water surface, creating a substantial enclosed cavity and forming an air cushion.

Fig. 14 presents the vertical impact force curve for an initial attitude angle of 5°. At an initial horizontal velocity of 35 m/s, the maximum impact force is 1251kN. With an initial horizontal velocity of 45 m/s, the maximum impact force reaches 1289kN. Similarly, at an initial horizontal velocity of 63.9 m/s, the maximum impact force is 1275kN. Comparing the three curves in Fig.14, it can be observed that, when the initial vertical speed is same, the maximum impact force remains similar and is largely unaffected by the horizontal speed. However, it is evident from the figure that, with higher initial horizontal velocities, the vertical impact force of the aircraft exhibits relatively small fluctuations after the initial strong impact with the water surface.

Fig. 15 shows the pressure curve at monitoring point P1 with an initial attitude angle of 5°. At an initial horizontal velocity of 35 m/s, the peak pressure at P1 is 23.68kPa. When the initial horizontal velocity is 45 m/s, the peak pressure at P1 reaches 110.3kPa. Interestingly, at an initial horizontal velocity of 63.9 m/s, the pressure at P1 drops to zero. By comparing the three curves in Fig. 15, it can be inferred that the P1 position is located close to the nose of the aircraft, and as the initial horizontal velocity increases, it becomes more challenging for the P1 position to make contact with the water surface within the time interval of 0-2.75s.

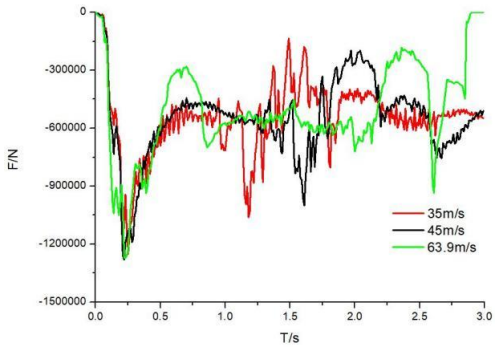

Fig. 14. Vertical impact force variation curve.

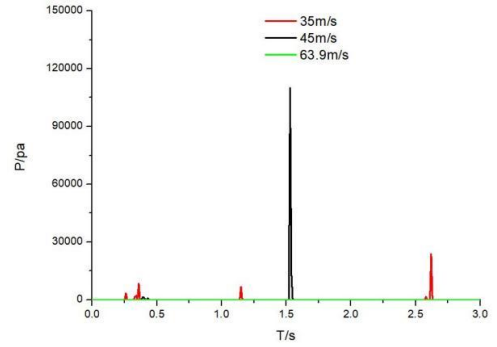

Fig. 15. Pressure curve of P1.

Fig. 16 presents the pressure curve at monitoring point P2 with an initial attitude angle of 5°. At an initial horizontal velocity of 35 m/s, the peak pressure recorded at P2 is 2618kPa. With an initial horizontal velocity of 45 m/s, the peak pressure at P2 reaches 2992kPa. Moreover, at an initial horizontal velocity of 63.9 m/s, the P2 monitoring point exhibits a peak pressure of 3489kPa. It is evident that higher initial horizontal velocities lead to greater peak pressures at P2.

Fig. 17 shows the pressure curve at monitoring point P3 with an initial attitude angle of 5°. At an initial horizontal velocity of 35 m/s, the peak pressure observed at P3 is 4124kPa. When the initial horizontal velocity is 45 m/s, the peak pressure at P3 decreases to 3535kPa. However, with an initial horizontal velocity of 63.9 m/s, the P3 monitoring point exhibits a significantly higher peak pressure of 6767kPa. Comparing the three curves in Fig.17, it becomes apparent that lower initial horizontal velocities result in higher pressure values generated by the second impact with the water surface at P3.

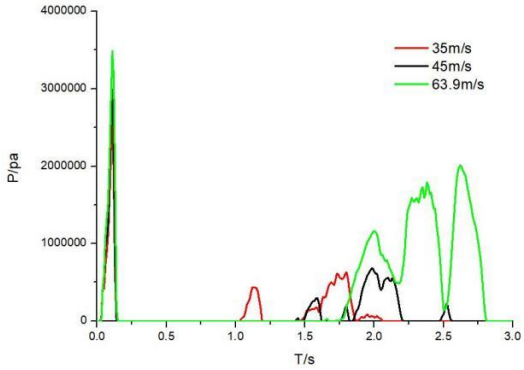

Fig. 16. Pressure curves of P2.

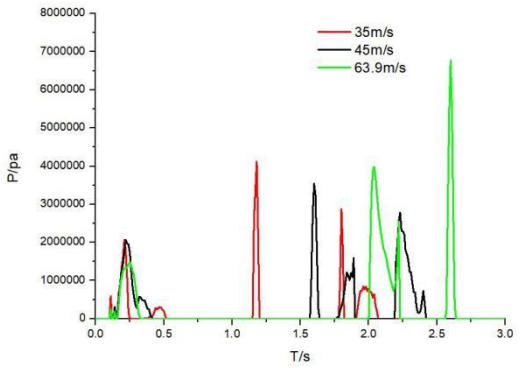

Fig. 17. Pressure curves of P3.

The pressure curves of monitoring points P1, P2, and P3 reveal important insights into the seaplane landing process. During landing, the seaplane initially makes contact with the water surface at monitoring point P2, resulting in a higher pressure value compared to monitoring points P1 and P3. For instance, at an initial horizontal velocity of 35 m/s, contact with the water surface occurs at P2 at 0.11s, leading to a significant pressure surge. At 0.2s, P3 makes contact with the water surface. Affected by the decrease of the impact surface velocity at P2, P3 produces a small pressure value. After 0.25s, P1 experiences a small pressure value influenced by the air cushion formed upon contact with the water surface. At 1.18s, when P3 undergoes secondary contact with the water surface, the pressure increases, surpassing the initial pressure, and an air cushion begins to form, as shown in Fig.18. Subsequently, due to the influence of the air cushion, the elevation angle increase rate decreases, and the elevation angle increases to the maximum value at 1.83 s. At 1.83s, the pressure values at P2 and P3 dropped due to the cushioning of the air cushion, and the tail comes out of the water at 2.6 seconds.

At an initial horizontal velocity of 45 m/s, the interaction between point P2 and the water surface transpires at 0.11s, leading to a notable surge in pressure. Subsequently, at 0.23s, point P3 makes contact with the water surface. Due to the diminished impact surface velocity at P2, P3 registers a diminished pressure value. Following 1.5s, P1 experiences a modest pressure level influenced by the air cushion. By 1.6s, when P3 undergoes secondary contact with the water surface, the pressure exceeds the initial value, resulting in the formation of an air cushion, as shown in Fig. 19. Consequently, influenced by the air cushion, the rate of elevation angle increase diminishes, and the pressure at P3 decreases after 1.6s.

In scenarios with an initial speed of 63.9 m/s, P2 contacts the water surface at 0.1s, generating a substantial pressure. At 0.24s, P3 also makes contact with the water surface, producing a reduced pressure value due to the decreased impact surface velocity at P2. At 2.0s, during P3's secondary contact with the water surface, the pressure surpasses the initial moment's value, and no air cushion is formed when connected with the air, as shown in Fig. 20. Subsequently, the pressure values at monitoring points P2 and P3 remain relatively high, displaying no significant drop or buffering effect. Throughout this period, P1 remains unaffected with a pressure value of zero. The horizontal speed exhibits minimal influence on the vertical impact force. For this specific seaplane structure, lower speeds result in higher pressure values generated by the tail during secondary impact on the water surface, whereas higher initial horizontal velocities yield greater pressure values during the initial contact with the water surface.

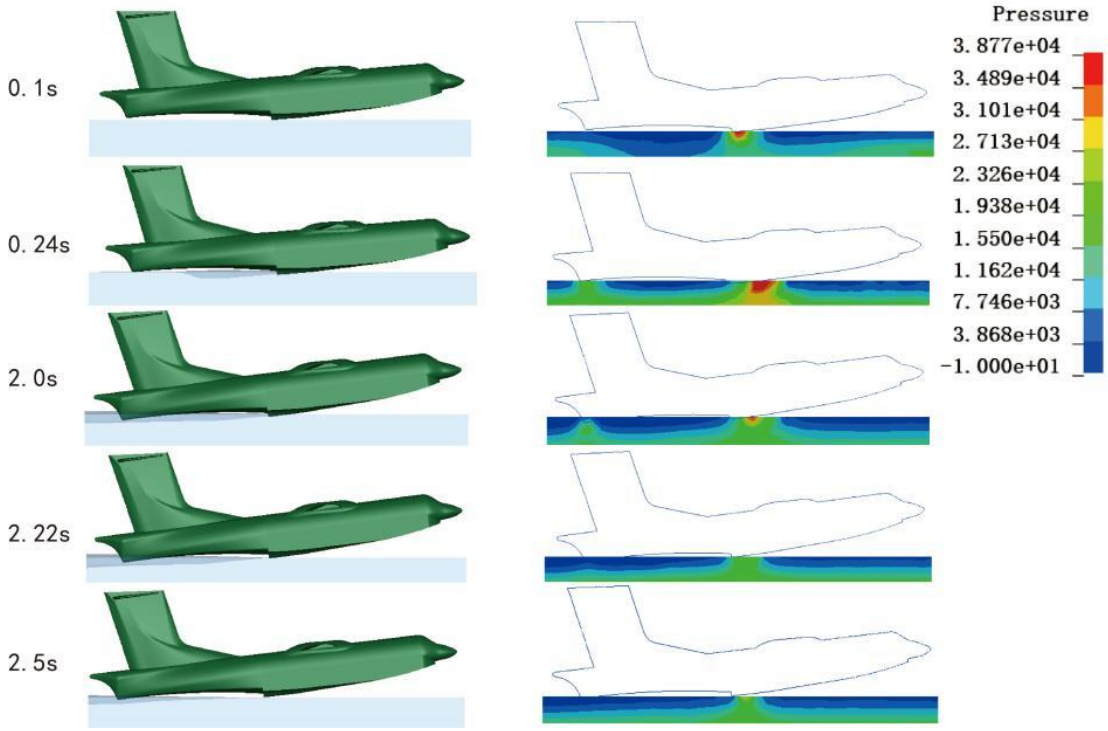

Fig. 20. Field and pressure distribution under 63.9m/s.

B. *Attitude Angles Analysis*

This paper presents a systematic investigation of the seaplane landing process, with a focus on analyzing the changes in attitude angle and acceleration. The study explores the behavior of the air cushion formed during the landing process and examines the variations in impact forces at different stages, as well as pressure at various positions.

Fig. 21 illustrates the vertical acceleration changes of the seaplane at an initial speed of 45m/s. For an initial attitude angle of 5°, the maximum vertical acceleration is measured at 13.2m/s². With an initial attitude angle of 8°, the maximum vertical acceleration reaches 18.7m/s². Moreover, an initial attitude angle of 10° results in a maximum vertical acceleration of 29.7m/s². By comparing the three curves in Fig. 21, it is evident that the vertical acceleration increases as the initial attitude angle becomes larger. Following the initial impact, a smaller attitude angle leads to a narrower range of vertical acceleration for the seaplane, exhibiting a similar trend.

Fig. 22 depicts the changes in attitude angle for an initial level speed of 45m/s, highlighting variations under different attitude angles. The seaplane initially experiences a decrease in attitude angle, followed by an increase, and subsequently a decrease. During the impact, the seaplane tilted forward at a certain angle and then its attitude angle increased. At an initial attitude angle of 5°, the minimum and maximum attitude angles are measured at 3.07° and 7.64°, respectively. For an initial attitude angle of 8°, the minimum and maximum attitude angles are 1.59° and 8.65°, respectively. Similarly, an initial attitude angle of 10° results in a minimum attitude angle of 1.93° and a maximum attitude angle of 8.38°. Notably, no significant rollover occurs within the first three seconds for all three working conditions.

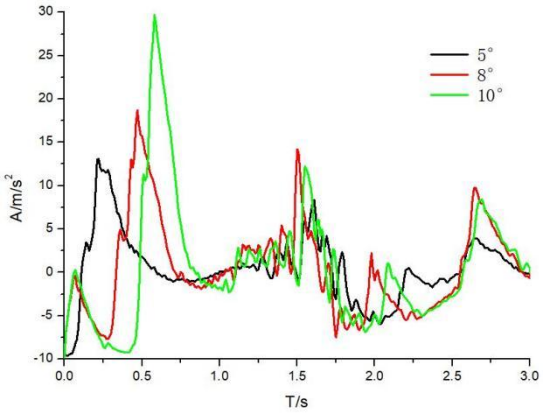

Fig. 21. Vertical acceleration comparison.

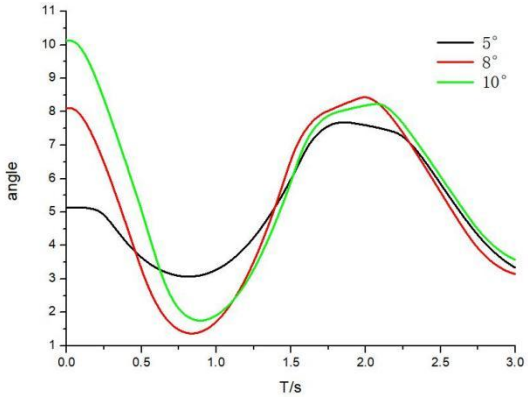

Fig. 22. Posture angle comparison

Fig. 23 shows the pressure curve of the seaplane with the initial horizontal velocity 45m/s. when the initial attitude angle is 5°, the maximum impact force is 1280kN. When the initial attitude angle is 8°, the maximum impact force is 1560kN. When the initial attitude angle is 10°, the maximum impact force is 2296kN. The larger the initial attitude angle, the greater the vertical impact force.

Fig. 24 shows the pressure curve at monitoring point P1 with an initial horizontal velocity 45m/s. At an initial attitude angle of 5°, the peak pressure recorded at P1 is 110.3kPa. With an initial attitude angle of 8°, the peak pressure at P1 reaches 70.27kPa. Furthermore, at an initial attitude angle of 10°, the peak pressure at P1 is measured at 360.2kPa. It is worth noting that a smaller initial attitude angle corresponds to a lower pressure value generated at the P1 position before 1 second. The proximity of the P1 monitoring point to the nose of the seaplane, combined with the front-heavy weight distribution, influences the pressure generated at the contact between P1 and the water surface.

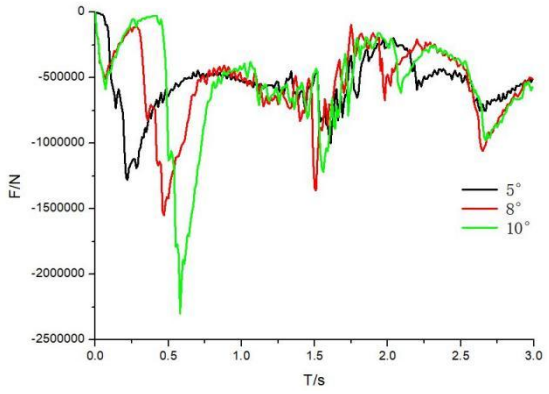

Fig. 23. Comparison of impact force.

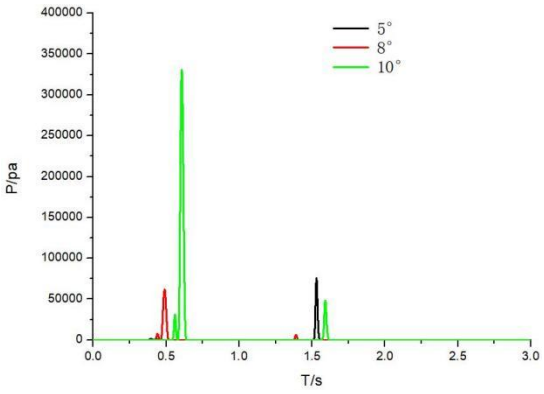

Fig. 24. Pressure comparison of P1.

Fig. 25 illustrates the pressure change curve observed at monitoring point P2 with the initial horizontal velocity 45m/s. For an initial attitude angle of 5°, the peak pressure recorded at P2 is 2992kPa. With an initial attitude angle of 8°, the peak pressure reaches 3121kPa. Similarly, at an initial attitude angle of 10°, the peak pressure at P2 reaches 3544kPa. It is observed that a larger initial attitude angle leads to a higher pressure at P2, with a longer time taken to reach the peak pressure. Fig. 26 shows the pressure curve observed at monitoring point P3 with an initial horizontal velocity of 45m/s. At an initial attitude angle of 5°, the peak pressure recorded at P3 is 3535kPa. With an initial attitude angle of 8°, the peak pressure at P3 reaches 3631kPa. Furthermore, at an initial attitude angle of 10°, the peak pressure is 4406kPa. It is evident that an increase in attitude angle results in a higher pressure generated during the secondary impact of the P3 contact with the water surface.

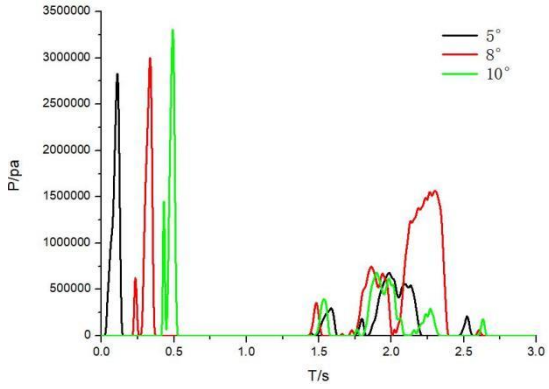

Fig. 25. Pressure comparison of P2.

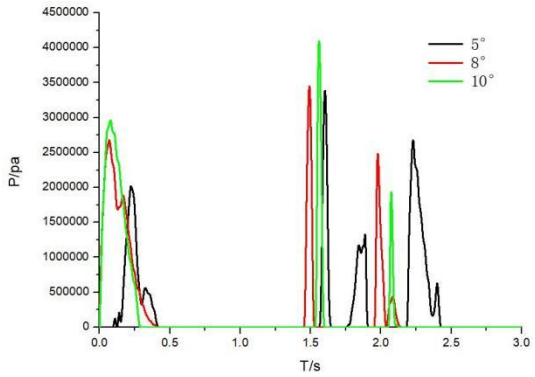

Fig. 26. Pressure comparison of P3.

The examination of pressure curves at monitoring points P1, P2, and P3 reveals that a greater initial attitude angle results in the seaplane's contact position with the water surface being closer to P3. Specifically, with an initial attitude angle of 5°, contact with the water surface occurs at P2 at 0.11s, resulting in a notable pressure surge. Subsequently, at 0.2s, P3 makes contact with the water surface, producing a reduced pressure value due to the decreased impact surface velocity at P2. Post 0.25s, P1 experiences a modest pressure level influenced by the air cushion formed upon contact with the water surface. By 1.18s, during P3's secondary contact with the water surface, the pressure value exceeds the initial moment's pressure, initiating the formation of an air cushion (see Fig. 18). Consequently, the rate of elevation angle increase diminishes due to the influence of the air cushion, reaching its maximum at 1.83s. At this point, the pressure values at P2 and P3 decrease at 1.83s due to the buffering effect of the air cushion, and the tail emerges from the water surface at 2.6s.

For an initial attitude angle of 8°, P2 contacts the water surface at 0.49s, followed by P3's secondary contact at 1.49s, resulting in an elevated pressure value and the formation of an air cushion (Fig. 27). Influenced by the cushioning air cushion,

the attitude angle increase rate diminishes. At 1.98s, the attitude angle starts decreasing, the air cushion connects with the air, leading to its disappearance, and the pressure values at P2 and P3 are high. The tail disengages from the water surface at 2.6s. With an initial attitude angle of 10°, P2 contacts the water surface at 0.51s, and P1 registers a significant pressure due to its instantaneous air cushion. At 1.56s, the pressure rises as P3 undergoes secondary contact with the water surface, initiating the formation of an air cushion (Fig. 28). At 2.07s, the tilt angle begins decreasing, the air cushion connects with the air, resulting in its disappearance, the pressure value at P3 decreases, and the monitoring point P2, positioned at the contact edge, experiences a floating pressure value. The tail disengages from the water surface at 2.6s.

VI. Conclusion

This paper presents a numerical model for studying air-cushion-coupled impact during seaplane landing in a hydrostatic environment. The accuracy of the model was verified by comparison with the cylinder water entry and flat plate impact experiments. Subsequently, the characteristics of air-cushion-coupled impact are investigated under various conditions, including different attitude angles, landing speeds, and impact loads. The conclusions are as follows:

- During the seaplane landing process, the attitude angle shows an obvious peak value within 0 to 3 seconds. Under different initial attitude angles, the maximum vertical acceleration of the seaplane increases as the initial attitude angle increases. Furthermore, the higher the initial attitude angle, the greater its change rate. The second impact of the aircraft produced greater pressure than the first impact.
- A reduced initial horizontal velocity of the seaplane leads to a diminished increase rate of pitch angle, accentuated cushioning effects of the air cushion, and a lower peak pressure at the monitoring point. When the initial attitude angle is large, the cushioning effect is more obvious, which reduces the peak pressure of the monitoring point.
- To mitigate seaplane structure damage and optimize air cushion utilization, maintaining an optimal landing speed between 30 m/s and 40 m/s is recommended. Furthermore, to prevent rollover and mitigate adverse air cushion effects, the suggested range for the attitude angle is 6° to 8°.

***Abstract*—Cloud computing's exponential expansion requires better resource management methods to solve the existing struggle between system performance and energy efficiency and functional scalability. Traditional resource management practices frequently lead systems in large-scale cloud environments to produce suboptimal results. This research presents a brand-new computational framework that unites Self-Organizing Neural Networks (SONN) with Artificial Fish Swarm Algorithm (AFSA) to enhance energy efficiency alongside optimized resource allocation and scheduling improvements. The SONN system groups workload information and automatically changes its structure to support fluctuating demand rates then the AFSA optimizes resource management through swarm-based intelligent protocols for high performance with scalable benefits. The SONN-AFSA model achieves substantial performance gains by analyzing real-world CPU usage statistics and memory usage behavior together with scheduling data from Google Cluster Data. The experimental findings show 20.83% lower energy utilization next to 98.8% prediction rates alongside 95% SLA maintenance and an outstanding 98% task execution rate. The proposed model delivers reliability outcomes superior to traditional approaches PSO and DRL and PSO-based neural networks which achieve accuracy rates above 88% and reach 92% accuracy. The adaptive platform delivers better power management to cloud computations yet preserves operational agility by adapting workload distributions. The learning ability of SONN joined with AFSA optimization segments produces superior resource direction capabilities which yield better service delivery quality. Research will proceed beyond its current scope to study real-time feedback structures as it evaluates multi-objective enhancement through large-scale dataset validation work to boost cloud computing sustainability across various platforms.**

***Keywords*—Energy-efficient cloud resource management; Self-Organizing Neural Networks (SONN); Artificial Fish Swarm Algorithm (AFSA); cloud optimization; swarm intelligence; resource utilization; task scheduling**

I. Introduction

Modern technological development benefits substantially from cloud computing's emergence as a revolutionary solution during the past decades [1]. The internet distribution model known as cloud computing enables remote service access for computing essentials which includes servers and storage systems and databases and networks and applications and various other resources [2]. Amazon Web Services (AWS) together with Microsoft Azure launched their transformative services during early 2000s that resulted in massive cloud adoption [3]. The evolution of cloud computing now delivers three fundamental models named Infrastructure as a Service (IaaS) together with Platform as a Service (PaaS) and Software as a Service (SaaS) [4]. The technology functions as the backbone of current applications by facilitating web hosting alongside big data analytics and machine learning and IoT systems. The fundamental benefit package of cloud computing technologies drives sectoral transformation since business activities and service delivery models have developed new foundations [5].

Cloud resource management stands as a key element of cloud computing because it handles the effective utilization of processing power along with memory and storage capacity and network bandwidth allocation. The demand for cloud services continues to grow significantly because millions of users push the complexity of managing abundant digital data resources to new heights [6]. Complex management systems are necessary for cloud environments due to their shifting requirements which necessitate specific resource distribution for optimal user

performance. The primary purpose of cloud resource management is to achieve optimal resource use by cutting down wasteful usage and promoting system performance optimization per [7]. The primary obstacle in this context lies in controlling resource distributions that exceed genuine operational needs. The delivery of excessive resources leads to waste through both needless power consumption and unutilized resources that drive up operational costs as well as create additional environmental consequences. Under-provisioning of resources causes service quality to decrease because it creates slower response times, increased latency and ultimately subpar user experiences [8]. Stretched computing systems must receive proper resource configurations to maintain affordable cloud resources structures alongside desired service levels. The management success of resources heavily relies on scalability elements. Cloud system resources must automatically adjust through scaling processes to match demand fluctuations for maintaining optimal operational performance.

Cloud providers need to recognize increased user activity peaks alongside the capability to decrease their resource utilization when usage reaches lower levels. Cloud systems utilize dynamic resource allocation strategies to manage workload variations efficiently thus maintaining both performance speed and minimal resource usage [9]. The main focus of cloud resource management requires energy efficiency since data centers present increasing operational costs coupled with rising environmental expenses. Cloud providers face their biggest operational cost in energy usage because their data centers use a sizeable segment of worldwide electrical demand. [10]. The energy demands create major environmental effects that remain substantial when operations use non-renewable power sources. Dynamic workload balancing and virtualization technologies and improved server utilization techniques enable cloud providers to reach these outcomes. By managing power usage through strategic resource allocation cloud providers simultaneously reduce operational costs while pursuing environmental sustainability goals. Cloud infrastructure resource management procedures lead to economic and environmental outcomes that influence billions of daily tasks across the network [11]. Systems with dynamic resource distribution adjust their design according to usage trends to decrease both physical infrastructure demands and corresponding energy usage and costs. Modern cloud service requirements need effective management solutions that maintain effective cost performance through a balance between resource usage and energy efficiency and scalability features [12]. The worldwide power consumption grows because cloud data centers experienced rapid growth with their exploding cloud computing services operations. The vast power usage needs created by the growing demand for computational resources causes crucial environmental problems with large data centers because of their energy demands and cooling requirements [13]. The economic burden to operate these facilities presents maximum challenge to data centers alongside mandatory requirements for energy-efficient resource administration. Thorough power utilization demands substantial pressure on cloud service providers to handle peak performance requirements when they must suppress their usage. The improper distribution of resources generates both economic and environmental challenges through poorly managed energy consumption resulting either from excessive resource spending or from underused resources [14]. Successful service quality preservation combined with adaptable resource management systems which respond to workload variations constitute essential requirements for reducing energy consumption [15]. The critical gap in the previous studies includes the failure in addressing the integration of the adaptive machine learning techniques and swarm intelligence for dynamic resource distribution. Incorporating of both machine learning adaptation with the intelligent swarm-based distribution faces lack a hybridized optimization method. The study develops a new computational framework by integrating Artificial Fish Swarm Algorithm (AFSA) and Self-Organizing Neural Networks (SONNs) to optimize cloud resource management while achieving power consumption minimization. The SONN neural model modifies its learning algorithms and structural arrangements to establish patterns in cloud workload requirements and the fish-based distribution capabilities demonstrated by AFSA underlie resource allocation. The combined adaptive features of Self-Organizing Neural Networks (SONNs) with Artificial Fish Swarm Algorithm (AFSA) optimization capabilities lead to efficient resource distribution while minimizing power usage while maintaining performance quality. The SONN-AFSA hybrid framework orchestrates cloud resources by maximizing energy consumption while achieving efficient task scheduling for cloud environments. Google Cluster Data served as the testing ground for the model through its use of authentic cloud data center workload logs that enabled both the application of the proposed framework and tests of model performance against modern cloud infrastructure. Through the integration of SONN and AFSA models the framework offers dynamic performance adjustments for different cloud platform operations which enable both precise execution and resource optimization regardless of workload variations. The model achieves high resource utilization rates combined with optimized scheduling techniques enabling SLA compliance thus delivering improved quality cloud service outcomes. The proposed approach achieved verification by using the Google Cluster Data which contains actual cloud data center workload traces for validating its practical application to present-day cloud infrastructure. The integration between SONN and AFSA runtime achieves dynamic flexibility which enables scalable efficiency across different cloud platforms with enhanced prediction precision and resource management particularly in situations with varying workload demands. Remains high while service level agreements (SLA) are met thanks to optimized task scheduling along with the model's precise prediction accuracy which leads to improved quality of cloud service delivery. Task scheduling in cloud environments.

- Dynamic adaptability enabled by integrating SONN and AFSA results in predictable scalability while also minimizing resource misallocations in various cloud settings even when fluctuating workloads occur.
- The integration of SONN and AFSA allows for dynamic adaptability, making the model scalable and efficient across different cloud environments, with improved prediction accuracy and resource allocation even under varying workloads.

- The proposed model reduces total energy consumption, demonstrating a significant improvement over traditional and hybrid optimization methods, ensuring sustainability in cloud resource management.
- The model ensures high resource utilization efficiency and meets service level agreements (SLA), improving the quality of cloud service delivery through optimized task scheduling and prediction accuracy.

The rest of the sections of this research have been organized as follows: Review of the existing literature Self-Organizing Neural Networks Integrated with Artificial Fish Swarm Algorithm for Energy-Efficient Cloud Resource Management in Section II. In Section III, proposed research Methodology is explained. The presents the experimental results in Section IV. In Section V, Conclusion and further work is mentioned and the study is concluded.

II. Literature Review

A. Hybrid Machine Learning Approach for Resource Allocation

The paper proposes a hybrid machine learning (RATS-HM) approach for combined resource allocation security and efficient task scheduling in cloud computing to address these challenges according to Bal et al. [16]. The proposed RATS-HM techniques are given as follows: The ICSTS system which incorporates an improved cat swarm optimization algorithm for task scheduling tasks produces reduced make-span times while achieving maximum system throughput. A group optimization-based deep neural network (GO-DNN) serves as a framework for efficient resource allocation through bandwidth and resource load design constraints. NSUPREME functions as a lightweight authentication scheme which provides encryption services for data storage security. The proposed RATSHM technique undergoes simulation with a new setup to demonstrate its superiority against current state-of-the-art methods. Research findings demonstrate that the proposed method outperforms existing approaches by demonstrating better resource utilization alongside lower energy consumption and faster response times. The proposed model demonstrates longer utilization times which require additional improvement.

B. Heuristic Algorithm for Cloud-Based Energy Consumption

Sunil et al.,[17] introduces two energy efficient Virtual machine placement algorithms related to bin packing heuristics focusing the efficiency of the physical machine's energy, Energy Efficient VM Placement (EEVMP) and Modified Energy Efficient VM Placement (MEEVMP), which reduces the total energy usage in the data-center. The reduction in the energy consumption by 53% established using the EEVMP algorithm when compared with the default VM placement algorithm Power-Aware Best-Fit Decreasing algorithm (PABFD) of CloudSim, Average SLA violation of 3.5% and number of VM migrations by 64.47% when compare to PABFD, the MEEVMP algorithm achieves the reduction in energy consumption by 54.24%, average SLA violation by 4.39% and number of VM migrations by 67.713 %.

C. Hybrid Resource Allocation Solution

Shahidinejad et al. [18] proposed a combined solution that manages cloud resource allocation for workloads. The k-means clustering and ICA method served as the resource allocation framework. This research used the decision tree method to determine an efficient resource allocation solution. The researchers ran the cloud workloads through real-world tests to measure the effectiveness of their hybrid solution. The hybrid method demonstrates enhanced capabilities for cloud optimization tasks. The model achieved its performance assessment on a minimal workload while the decision tree technique displayed unstable results. The proposed hybrid solution struggles to handle unpredictable workload fluctuations in real time and depends on static QoS criteria which may restrict its ability to adapt to changing user needs.

D. Secure Sensor Cloud Architecture (SASC)

Nezhad et al., [19] proposes a method that contains three phases, including the first phase as a star structure is constructed in which a specific key that is encrypted is shared between the each child and the parent to secure the communications between them. In second phase, the members of the cluster send their data to the cluster head and also the data is encrypted at the end of the each connection. The third phase included to improve the security of the inter cluster communications with the help of authentication protocol. By this, the cluster heads are authenticated before transmitting the information. The proposed method is also implemented using the NS2 software. The improvement in the energy consumption, end-to-end delay, flexibility and packet delivery rate results in the proposed method compared to other previous methods.

E. Adaptive Heuristic Approach for Energy Efficiency

Yadav et al. [20] developed an adaptive heuristic approach to reduce energy consumption while enhancing system performance. The researchers tested their developed method within the CloudSim and PlanetLab cloud simulation platforms. The new method shows improved performance when measured through energy efficiency along with SLA results. Real-time workload spikes might not be properly managed by the proposed algorithms because they require accurate CPU utilization predictions that prove difficult in fast-changing environments.

F. Optimization Techniques for Load Balancing

The research team of Goyal et al. [21] examined the energy efficiency and load balancing capabilities of the cloud environment through different optimization techniques including the whale optimization algorithm (WOA), cuckoo search algorithm (CSA), BAT, cat swarm optimization (CSO), and particle swarm optimization (PSO). Among the optimization methods WOA demonstrates the best performance efficiency. The integration of AFSA with SONNs remains an underexplored area to resolve convergence and robustness issues. AFSA's dynamical weight and topology optimization capabilities present substantial possibilities for SONN enhancement with faster convergence speed and improved accuracy and greater adaptability to complicated datasets. The gap between swarm intelligence and neural network training holds great promise for innovative research that would combine these two approaches.

G. Research Gap

The previous studies show the key significant contributions in the allocation of resources, task scheduling, and conservation of energy in cloud computing, which includes several limitations. Many of the existing methods were insufficient in adaptability to dynamic workload changes and challenges with flexibility in large scale cloud environments, resulting in the failure of integrating the robust security mechanisms. Further, the static QoS criteria and limited real-time decision-making often restricts the effect of those techniques.

To overcome this limitation, this proposed RATS-HM approach focuses on these gaps by implementing the machine learning with swarm intelligence, which provides more effective and efficient resource allocation model. By implementing the enhanced optimization algorithms, dynamic scheduling ideas and the security protocols, the RATS-HM provides a more comprehensive approach that overcomes the existing problems like resource utilization, energy efficiency and response times.

III. Research Methodology

The research develops an energy-effective cloud resource management method by utilizing Google Cluster Data to supply detailed metrics about CPU and memory usage with task identification numbers and scheduling details. The model integrates two key techniques: Self-Organizing Neural Networks (SONN) and the Artificial Fish Swarm Algorithm (AFSA). AFSA enables the system to allocate tasks which optimize energy conservation without breaking Service-Level Agreement parameters. The research combines these methods together to enhance cloud performance by improving energy efficiency alongside resource utilization and task execution efficiency.

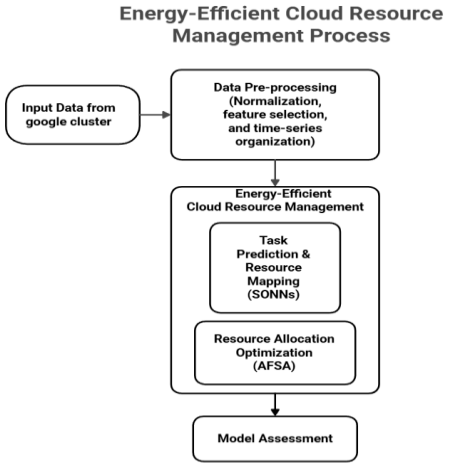

Fig. 1. AFSA-SONNs.

The Fig. 1 represents the work flow Artificial Fish Swarm Algorithm (AFSA).

A. Data Collection

The analysis of workloads and the development of resource management models aim to improve cloud energy efficiency through study of an open-source Google Cluster Data dataset. The Google Cluster Data constitutes an open data repository that presents detailed measurements from Google's production data centers which extend across billions of records during 29 days of analysis [22]. The informative dataset Completion Time includes CPU performance analytics run alongside memory statistics with records of job and task identifiers and their scheduling at various priority threshold levels. The study employs resource prediction capabilities to develop optimal resource management strategies by examining workload patterns through analytic assessment of its attributes. The transparency and practicality of the open-source dataset along with its ability to support collaborative development emerge through billions of production data measurements from Google's data centers which were gathered for 29 days. The dataset includes comprehensive metrics including CPU utilization percentages and memory use alongside task/job identifiers and scheduling events and priority settings. The data characteristics support both workload pattern exploration and resource utilization forecasting and resource allocation optimization. The research utilizes this open-source dataset to guarantee transparency and real-world applicability of swarm intelligence-based neural model development focused on energy-efficient cloud environments while offering reproducibility.

B. Data Pre-Processing

1) *Normalization:* The process of normalizing pixel values across images through blended analysis defines image pre-processing normalization. The mathematical representation of normalization appears in Eq. (1):

$$x_n = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (1)$$

2) Feature selection: Research approaches for energy-efficient cloud resource management lead to distinctive mathematical formulations in feature selection. Since you're focusing on methods like mutual information and PCA, here are the basic equations for each:

a) Mutual information: Mutual Information serves as a measurement tool to determine the degree at which one feature reveals details about another. The dependency relationship between each target variable feature and the designated outcome (climate emissions) enables selecting proper features through this approach.

For two variables *X and Y*, the mutual information *I (X; Y)*is expressed in Eq. (2):

$$I(X;Y) = \sum_{x \in X} \sum_{y \in Y} p(x,y) log \frac{p(x,y)}{p(x)p(y)} \quad (2)$$

b) Principal Component Analysis (PCA): Through PCA we transform our features into principal components which maintain the key information in a set of orthogonal variables.

Through PCA we transform our features into principal components which maintain the key information in a set of orthogonal variables as stated in Eq. (3):

$$\sum = \frac{1}{n-1} \sum_{i=1}^{n} (x_i - x_j)(x_i - x_j)^T \quad (3)$$

C. Artificial Fish Swarm Algorithm (AFSA)

The Artificial Fish Swarm Algorithm (AFSA) uses three fundamental fish behaviors which integrate Foraging with

Swarming to improve cloud environment resource management and following for optimization. Fig. 2 suggest work flow Artificial Fish Swarm Algorithm (AFSA).

1) Foraging: The foraging phase finds optimized resource arrangements through individual fish exploration which achieves both energy optimization and proper allocation of resources for their assigned duties. Fish complete evaluations of their current positions together with alternative options using a fitness function that assesses both energy efficiency and resource distribution and service level agreement compliance. Each fish scans their surrounding positions to find better solutions before reaching points of best arrangement. System exploration procedures show how resource distributions can optimize their distribution patterns while supporting both energy efficiency and tasks.

2) Swarming: Fish distribution uses clustering techniques to organize tasks according to workload patterns that assess resource requirements and task significance. When using assigned grouping all resources can receive tasks that their performance profile matches thus maximizing efficiency. The fish collaboration system provides optimal resource allocation which maximizes system operational performance while minimizing unnecessary resource consumption. Swarm behavior enables the system to allocate resources effectively without causing either excessive loading of individual nodes or resource underutilization.

3) Following: During this phase fish utilize neighborhood detection to locate highly effective neighbors for which they follow. When fish use optimal solutions, they find their performance accelerates the algorithm's convergence toward better configurations. Fish groups enhance system effectiveness as they track top-performing connections among peers to prevent time-wasting refinements of substandard outcomes.

D. Self-Organizing Neural Networks (SONN)

A key component of this research uses Self-Organizing Neural Networks (SONNs) to conduct dynamic workload pattern examinations and resource forecasting that enables power-efficient resource control. Fig. 2 suggest the neural network of Self-Organizing Neural Networks (SONN). Their specific contributions include:

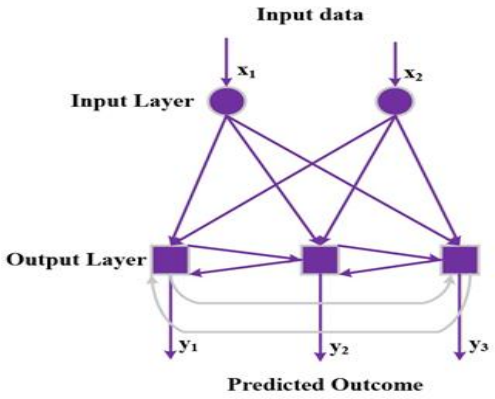

Fig. 2. Self-Organizing Neural Networks (SONN).

1) Workload pattern recognition: SONNs extract workload insights from cloud monitoring metrics which include CPU performance statistics and memory patterns alongside task execution information to form detailed workload patterns. Resource forecasting and understanding utilization become possible through identified patterns.

2) Dynamic adaptation: Traditional neural networks lack SONN's capability to evolve its network topology through adjustments like vegetable or removable of computing elements when confronted by changing data conditions. The adaptable network structure permits processing of sudden workload fluctuations found in cloud systems which demonstrate unpredictable behaviors.

3) Clustering and categorization: Workload categories form through network clustering to assist resource requirement identification. Overy/-based classification provides essential information about workload types that leads to better selection of optimal resource distribution approaches.

4) Feedback-Driven learning: The implementation of feedback systems allows SONNs to enhance their prediction capabilities through ongoing data refinement with repeated improves their accuracy over time. The predicted resource allocation serves as feedback which prompts the network to change its learning process so the system does not repeat inefficient provisioning.

5) Energy-Efficient decision support: The Artificial Fish Swarm Algorithm (AFSA) uses information from SONNs about resource demand forecasts and workload classifications to generate resource allocation decisions with energy-efficient outcomes. Affordable Security Fund Administration requires SONNs as an analytical foundation for optimally distributing resources through their network.

E. Integration of SONNs and AFSA

The research implements a cloud resource management model for energy efficiency through the unification of Self-Organizing Neural Networks (SONNs) with Artificial Fish Swarm Algorithm (AFSA). Cloud resource demand predictions made by SONN systems require monitoring active workload metrics by analyzing CPU load and memory consumption together with scheduling patterns. SONN predictions enable AFSA to construct resource plans that achieve maximum energy conservation while maintaining effective system operation. Fig. 3 represents the integration of SONNs with AFSA.

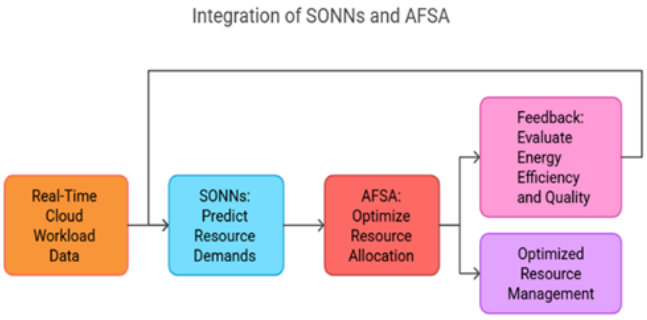

Fig. 3. Integration of SONNs and AFSA.

Through its optimization process AFSA applies foraging and swarming models of fish behavior to find optimal solutions by modifying resource partition settings. The hybrid model works iteratively: Recurrent forecasting adjustments from AFSA enhance the resource allocation methodologies of SONN through continual refinement of its static frequency predictions. The combined method enhances cloud system energy performance by precisely predicting demands and utilizing dynamic workload variables simultaneously.

IV. Results And Discussion

The combination of self-organizing neural networks with artificial fish swarm algorithms leads to substantial enhancements in cloud resource management while improving energy efficiency alongside resource utilization and system performance. The proposed model achieved energy savings and enhanced scalability while optimizing task completion times which led to sustained improvements in prediction accuracy and optimization convergence. The implementation tool used Python to analyse data while displaying key metrics which included energy savings data and task throughput measurements and model stability indicators. The experimental results validate the proposed approach which delivers sustainable cloud computing alongside superior performance levels.

A. Experimental Outcome

The different iterations of system performance and energy consumption data are presented in Fig. 4. This table tracks three metrics including total energy consumption alongside energy savings and three power consumption measurements which consist of average power consumption, idle power consumption and peak power consumption. The measurements for total energy consumption report values in kilowatt-hours (kWh) from the initial value of 1200 kWh. The system's optimized resource management and efficiency strategies lead to a progressive reduction of energy usage. The system ends with a minimized energy consumption value of 950 kWh after four optimization steps that started at 1200 kWh.

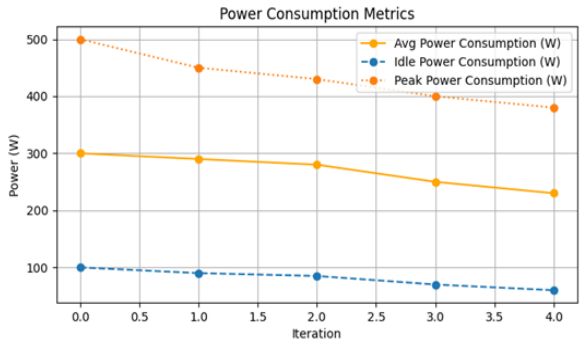

Fig. 4. Power consumption metrics.

Energy savings represent the percentage reduction in energy consumption that initiates from the baseline measurement of 1200 kWh. The first row shows N/A as energy savings because it represents the baseline but savings climb to 4.17% in the second row and continue to 8.33% in the third row then reach 16.67% in the fourth row and finally end at 20.83% in the last row. The system demonstrates increased energy efficiency through optimization strategies that lead to substantial energy savings. The system's average power usage decreases stepwise from 300 W to 230W as the idle power consumption levels down from 100 W to 60 W. Overall energy efficiency improves because the system demonstrates enhanced capability in reducing energy usage during idle conditions. The system achieves improved peak power consumption efficiency by lowering the consumption from 500 W to 380 W. The data in Fig. 1 demonstrates how the system decreases energy usage while enhancing power efficiency throughout idle periods without impact on system functionality. The system demonstrates excellent sustainability potential in cloud environments through its enhanced energy efficiency capabilities.

B. Resource Utilization and Efficiency Improvement

Fig. 5 presents an analysis of resource utilization and efficiency across key system components: CPU, memory, and storage. The system's computational needs increased steadily from 75% CPU utilization to reach 90% during the workload expansion. The increasing resource utilization patterns demonstrate effective use of available processing power yet administrators need to prevent CPU overuse which could deteriorate system performance.

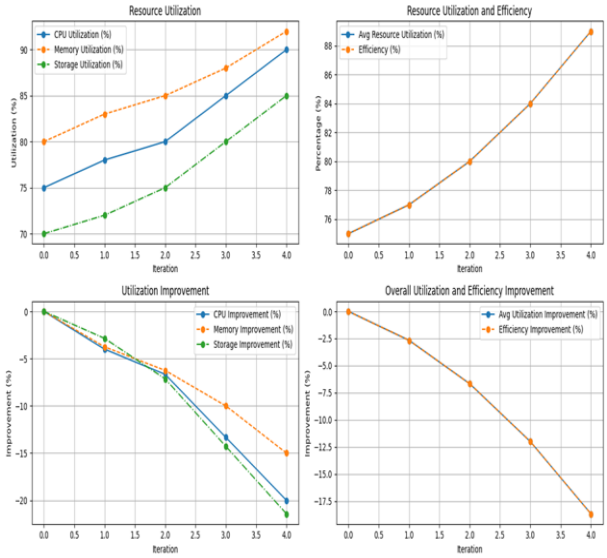

Fig. 5. Resource utilization and utilization improvement.

Memory resource allocation showed efficient performance because usage rates started at 80% and reached 92% while workloads increased. The distributed system demonstrates a best-practice memory management which provides enough memory resources for operations and avoids excessive storage allocation. The cloud environment demonstrates effective resource allocation through storage utilization which increases from 70% to 85% to enable quick data storage and retrieval while maintaining performance speed.

The combined metric measuring average resource utilization rose from 75% to 89% as the system evolved. The system demonstrated improved resource usage performance during the scaling process by achieving balanced resource allocation between different demands. Resource utilization efficiency

experienced an increase from 75% to 89% as the system demonstrated both resource effectiveness and optimized resource utilization to minimize waste and enhance system performance. System data indicates growing resource use alongside improved efficiencies which reveals the system can expand its capabilities to handle higher workloads. The system demonstrates superior resource management capabilities through its sustained improvements in efficiency and utilization which enables dynamic resource control for optimal system performance while minimizing resource waste. The system demonstrates excellent suitability for managing expanding cloud requirements. Fig. 6 examines task duration and its effects on SLA compliance and resource success rates while examining system throughput metrics. The system's task completion time registered a substantial improvement because it decreased from 120 seconds to 90 seconds which led to a 25% reduction.

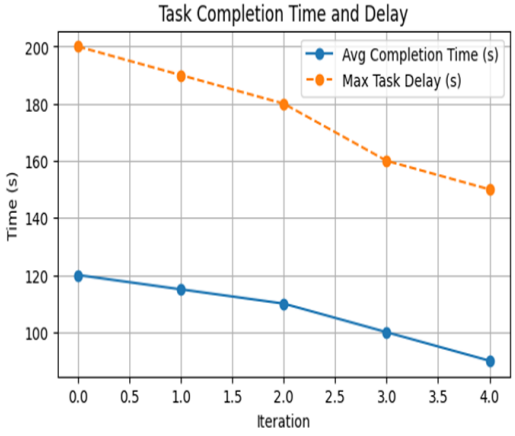

Fig. 6. Task completion time and delay.

The resource scheduling and allocation capabilities of this system demonstrate its ability to reduce task execution time. Task execution bottlenecks decreased by 25% in the delivery of key performance metrics when maximum task delay reduced from 200 seconds to 150 seconds. The percentage of tasks successfully executed within service-level agreements improved substantially from 85% to 95%. The model demonstrates its performance preservation capabilities through strict requirements adopting both time and quality restrictions that produces noticeable effects on user satisfaction and service-level agreement fulfillment. The system demonstrated improved reliability alongside stronger processing capabilities because the task achievement rate increased to 98% from 90%.

The system accomplished task processing at a rate of 62 tasks per minute which represented a 24% improvement over its starting point at 50 tasks per minute. The model's scaling performance demonstrates its capability to handle maintaining performance throughout increased operational task volumes. Experimental findings show that the proposed model performs effectively for real-world cloud environments through improved reliability and reduced delays while increasing operational efficiency.

C. Prediction Accuracy and Optimization Convergence

Fig. 7 demonstrates the important metrics regarding model optimization convergence alongside training scenario accuracy evaluation. The figure reveals essential information about how each stage of system optimization performed regarding training duration, convergence speed and prediction accuracy together with optimization stability. Training time is measured in hours to show the length of model preparation until achievement of target performance levels. The first training period lasted five hours but subsequent sessions required four hours and six hours respectively. The last entry omitted training time because the system reached optimal performance during an undisclosed period. The recorded values indicate that the optimization process develops efficiency which shortens the duration required to achieve optimal model outcomes. How many times an optimization algorithm repeats itself determines when it becomes stable. As the model improved its performance the system needed less iteration to converge: 200 initially then 150 and eventually 100. The optimization process shows increasing efficiency with each iteration because of improved hyperparameter settings and optimized methods. A model shows its prediction capability through its correct forecasting of results from provided data. The accuracy of the model starts at 85% and enhances to 92% but then rises to 98% as training advances demonstrating substantial improvement of prediction abilities during training. The optimization strategies implemented proved effective because accuracy rates demonstrated a steady upward trend.

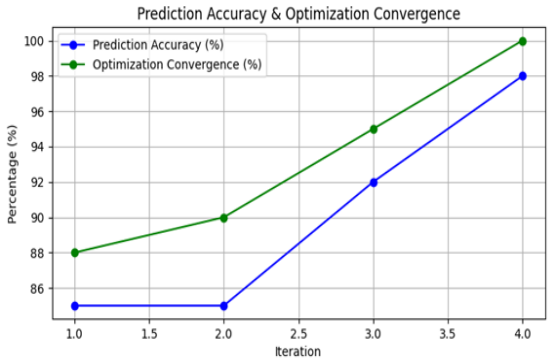

Fig. 7. Prediction accuracy & optimization convergence.

The performance of model convergence toward optimal solutions determines optimization convergence metrics. The optimization process shows continuous improvement from 88% to 95% during its progression. The upgraded performance of this metric demonstrates that the model becomes more effective at discovering optimal solutions throughout training because optimization techniques and model parameters improve. Model stability shows how consistently predictions from the model persist between different dataset instances. The model starts with 80% stability which steadily grows to reach 95% as optimization continues. Model stability continues to rise because the system demonstrates robust characteristics during its optimization and subsequent tuning process. All key performance metrics demonstrate clear growth based on information presented in Fig. 4. The training system functions with greater efficiency because it demonstrates shorter convergence times while achieving better prediction accuracy as well as enhanced optimization convergence and model stability. The optimization plus training strategies which were implemented in the system have proven effective because they

yield superior performance as the model continues its development.

D. Model Scalability and Performance

The review of Self-Organizing Neural Networks with Artificial Fish Swarm Algorithm (SONN-AFSA) under 1000 tasks system load presents performance and scalability results in Fig. 9. The model achieved evaluation through measurement of average latency and throughput alongside scalability factor performance in dynamic cloud environments. Static and dynamic resource allocation wait times, reflection ratio variation rate and minimum processor idle time prove the efficiency of SONN-AFSA in optimizing cloud system resource management. SONN-AFSA shows sufficient deployment potential for practical use through its simultaneous performance of reduced latency and increased streamline operations while enabling scalable resource utilization.

1) *Latency reduction:* Average execution delays of tasks represent the concept known as Latency (LLL). The model showed how its optimization processes become apparent when last link latency decreased from 1200ms to 800ms. The latency reduction appears in the Eq. (4):

$$\Delta L = L_{initial-} L_{optimized} \quad (4)$$

Real-time applications benefit from improved system responsiveness because of the implementation of drop.

2) *Throughput improvement:* Real-time applications benefit from improved system responsiveness because of the implementation of drop is represented in the Eq. (5):

$$T = \frac{Total\ Completed\ Tasks}{Time(seconds)} \quad (5)$$

3) *Scalability factor*: The system's performance scalability factor (S) compares the data processing capabilities against design baseline specifications. It is calculated as in the Eq. (6):

$$S = \frac{T_{seconds}}{T_{baseline}} \quad (6)$$

Successful workload adaptations allow the system to execute demanding operational requirements without demonstrating any performance decline. Fig. 8 demonstrates the important metrics regarding model performance in scalability vs. latency vs. throughput.

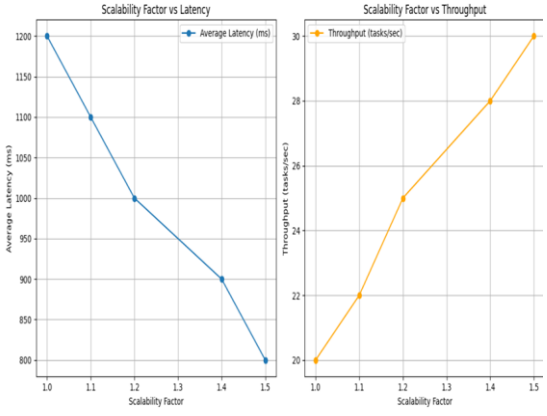

Fig. 8. Scalability vs Latency vs Throughput.

Data gathered from a 1000 tasks system workload showed that the Self-Organizing Neural Networks with Artificial Fish Swarm Algorithm (SONN-AFSA) achieved its performance metrics and scalability targets according to Fig. 9. Results from the model demonstrate latency reduction which raises throughput rates while enabling improved system scalability. The system maintained consistent performance advancement through an increasing throughput trend between 1200 milliseconds and 800 milliseconds throughout process optimization. The model proves its speed-up capabilities through substantial latency optimizations which suit instant cloud processing demands. During the experimental period the system maintained a steady improvement in its measured throughput from start to finish by increasing from 20 to 30 tasks per second. The system improves operational efficiency by handling larger volumes of tasks within specified time intervals to enhance performance levels for major cloud infrastructure deployments. Throughout experimentation the system adapted to increasing throughput demands through an improved scalability factor from 1.0 up to 1.5. Through dynamic workload management SONN-AFSA reaches a robust state by maintaining sustained performance under shifting workload conditions. The experimental outcomes show that this model features specialized performance enhancements and scalability controls for optimizing cloud resource energy management. SONN-AFSA presents an excellent solution for practical cloud systems that need optimal resource allocation along with processing efficiency and maximum throughput and low latency capabilities.

E. Clustering Metrics

SONN-generated clusters receive quality performance evaluations by means of clustering metrics. The Silhouette Score (range: The Silhouette Score evaluates cluster quality by measuring how well each object fits within its cluster against other clusters using a value between -1 and 1. From a perspective of optimization the Davies-Bouldin Index (DBI) measures both cluster cohesiveness and separation from one another while lower figures indicate superior performance. The Calinski-Harabasz Index evaluates cluster distinction by dividing between-cluster dispersion by within-cluster dispersion to generate better cluster outcomes.

F. Dimensionality Reduction Metrics

The ability of models to retain data structure is evaluated through dimensionality reduction metrics. The measure of Trustworthiness evaluates neighbor retention in the low-dimensional space from the original high-dimensional data, and Continuity evaluates how well low-dimensional connections represent high-dimensional relationships. The model exhibits superior structure preservation through Reconstruction Error evaluation where lower error values indicate better preservation of information.

G. Comparative Metrics

Comparative metrics benchmark the hybrid AFSA-SONN against other methods. The Improvement over Baseline measurement evaluates accuracy level along with convergence speeds and energy conservation against standard SONNs and additional optimizers including PSO and GA. The model shows its generalizability through Cross-Dataset Performance when

tested on datasets with different characteristics to demonstrate its ability to adapt.

H. Comparative Analysis

The comparison shows how the proposed Self-Organizing Neural Network with Artificial Fish Swarm Algorithm (SONN-AFSA) performs better than other optimization methods as well as learning techniques. The SONN-AFSA model demonstrates superior performance over all metrics because it reaches 98.8% accuracy and 96.5% precision while also achieving recall levels of 94.5% and F1-score of 95.5%. Such high-performance metrics highlight the model's exceptional capability to distribute resources effectively while generating precise system outcome predictions within cloud application spaces.

1) Accuracy: Accuracy is a measure of how correctly data points are assigned to their respective clusters or classes. In clustering, accuracy is often used when ground truth labels are available for evaluation.

The formula for accuracy is represented in the Eq. (7):

$$Accuracy = \frac{Number\ of\ Coprrectly\ Classified\ Points}{Total\ Number\ of\ Points} \quad (7)$$

2) Recall: In the context of measuring model performance recall indicates the correct identification percentage of actual positive results. Recall achieves its maximum value as a measure when identifying positive cases is a priority.

The formula for recall is represented in the Eq. (8):

$$Recall = \frac{True\ Positives(TP)}{True\ Positives+False\ Negatives(FN)} \quad (8)$$

3) F1-Score: The F1 Score represents the harmonic mean between precision and recall which allows fair measurement of both incorrect positives and incorrect negatives. The method brings exceptional results to imbalanced datasets.

The formula for F1 Score is represented in the Eq. (9):

$$F1Score = 2.\frac{Precision.Recall}{Precision+Recall} \quad (9)$$

Fig. 9 shows the performance metrics of the proposed SONN-AFSA with 98.8% accuracy, 96.5% precision, 94.5% recall and 95.5% F1 score.

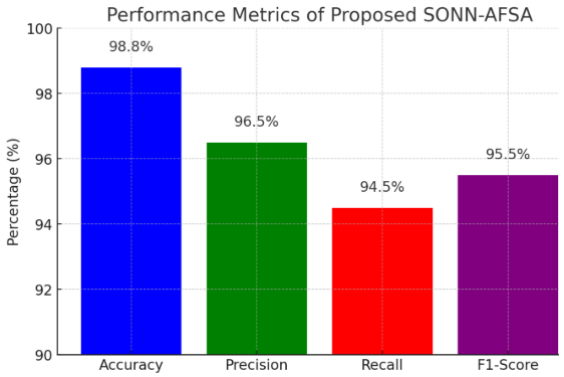

Fig. 9. Performance metrics of proposed SONN-AFSA.

Table I illustrates the performance metrics of proposed method with comparison of exiting Deep learning method.

TABLE I. COMPARATIVE ASSESSMENT

Method	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Particle Swarm Optimization (PSO) [23]	88.0	85.5	87.0	86.2
Deep Reinforcement Learning (DRL) [24]	90.5	89.0	90.0	89.5
PSO-Based Neural Network [25]	92.0	91.0	91.5	91.2
Proposed SONN-AFSA	98.8	96.5	94.5	95.5

The PSO-Based Neural Network delivers good performance measures by reaching 92.0% accuracy and 91.0% precision and recall and 91.2% F1-score while indicating its worth as a neural network optimization method with particle swarm techniques. Deep Reinforcement Learning (DRL) exhibits equivalent performance to the previous models by reaching 90.5% accuracy and 89.5% F1-score which demonstrates its ability to detect patterns in resource management systems. SONN-AFSA shows superior capability in true positive detection since its recall number (91.5%) exceeds the newly-tested scheme's recall value (90.0%). Fig. 10 demonstrates the comparison of performance metrics across methods.

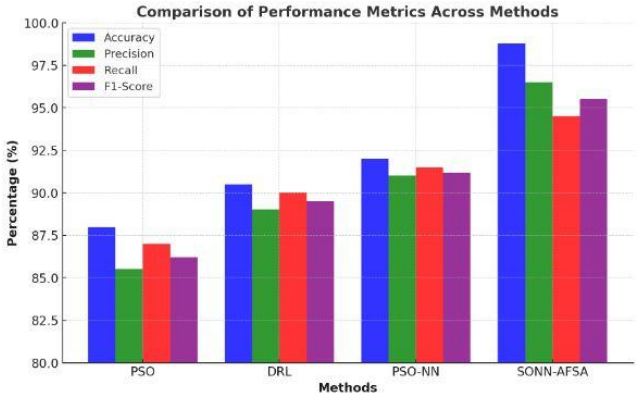

Fig. 10. Comparative assessment.

When it measures accuracy and F1-score, the standalone Particle Swarm Optimization (PSO) method demonstrates results that fall below the hybridized methods with 88.0% accuracy and 86.2% F1-score. PSO represents an efficient optimization solution, however its performance suffers from inadequate adaptive learning capabilities found in neural network-based methods. Results indicate that the SONN-AFSA framework excels as a combination between self-organizing neural networks and artificial fish swarm algorithm optimization performance. The collaborative power between neural networks and artificial fish swarm optimization produces high precision decision-making capabilities that achieve superior outcomes than both traditional and hybrid models.

I. Discussion

Memory resource allocation showed efficient performance because usage rates started at 80% and reached 92% while

workloads increased. The distributed system demonstrates a best-practice memory management which provides enough memory resources for operations and avoids excessive storage allocation. The cloud environment demonstrates effective resource allocation through storage utilization which increases from 70% to 85% to enable quick data storage and retrieval while maintaining performance speed.

The combined metric measuring average resource utilization rose from 75% to 89% as the system evolved. The system demonstrated improved resource usage performance during the scaling process by achieving balanced resource allocation between different demands. Resource utilization efficiency experienced an increase from 75% to 89% as the system demonstrated both resource effectiveness and optimized resource utilization to minimize waste and enhance system performance. System data indicates growing resource use alongside improved efficiencies which reveals the system can expand its capabilities to handle higher workloads. The system demonstrates superior resource management capabilities through its sustained improvements in efficiency and utilization which enables dynamic resource control for optimal system performance while minimizing resource waste. The system demonstrates excellent suitability for managing expanding cloud requirements.

Fig. 6 examines task duration and its effects on SLA compliance and resource success rates while examining system throughput metrics. The system's task completion time registered a substantial improvement because it decreased from 120 seconds to 90 seconds which led to a 25% reduction.

The resource scheduling and allocation capabilities of this system demonstrate its ability to reduce task execution time. Task execution bottlenecks decreased by 25% in the delivery of key performance metrics when maximum task delay reduced from 200 seconds to 150 seconds. The percentage of tasks successfully executed within service-level agreements improved substantially from 85% to 95%. The model demonstrates its performance preservation capabilities through strict requirements adopting both time and quality restrictions that produce noticeable effects on user satisfaction and service-level agreement fulfillment. The system demonstrated improved reliability alongside stronger processing capabilities because the task achievement rate increased to 98% from 90%.

The system accomplished task processing at a rate of 62 tasks per minute which represented a 24% improvement over its starting point at 50 tasks per minute. The model's scaling performance demonstrates its capability to handle maintaining performance throughout increased operational task volumes. Experimental findings show that the proposed model performs effectively for real-world cloud environments through improved reliability and reduced delays while increasing operational efficiency.

The review of Self-Organizing Neural Networks with Artificial Fish Swarm Algorithm (SONN-AFSA) under 1000 tasks system load presents performance and scalability results in Fig. 9. The model achieved evaluation through measurement of average latency and throughput alongside scalability factor performance in dynamic cloud environments. Static and dynamic resource allocation wait times, reflection ratio variation rate and minimum processor idle time prove the efficiency of SONN-AFSA in optimizing cloud system resource management. SONN-AFSA shows sufficient deployment potential for practical use through its simultaneous performance of reduced latency and increased streamline operations while enabling scalable resource utilization.

The comparison shows how the proposed Self-Organizing Neural Network with Artificial Fish Swarm Algorithm (SONN-AFSA) performs better than other optimization methods as well as learning techniques. The SONN-AFSA model demonstrates superior performance over all metrics because it reaches 98.8% accuracy and 96.5% precision while also achieving recall levels of 94.5% and F1-score of 95.5%. Such high-performance metrics highlight the model's exceptional capability to distribute resources effectively while generating precise system outcome predictions within cloud application spaces.

Table I illustrates the performance metrics of proposed method with comparison of exiting Deep learning method and Fig. 10 shows the performance metrics of the proposed SONN-AFSA.

The results indicate that the SONN-AFSA framework excels as a combination between self-organizing neural networks and artificial fish swarm algorithm optimization performance. The collaborative power between neural networks and artificial fish swarm optimization produces high precision decision-making capabilities that achieve superior outcomes than both traditional and hybrid models.

V. Conclusion and Future Work

The research implemented an advanced framework to handle energy-efficient cloud resource management through the integration of Self-Organizing Neural Networks (SONN) and Artificial Fish Swarm Algorithm (AFSA). The proposed hybrid design performed severely better than former approaches including PSO and DRL alongside PSO-based Neural Networks. The experimental evaluation led to substantial conclusions about energy reduction by 20.83 percent and 89 percent resource utilization efficiency improvement. The proposed model reached 98.8% prediction accuracy whereas PSO-based Neural Networks achieved only 92.0% accuracy as its best result. The model enhanced SLA compliance to 95% while reaching 98% task completion rates which showcased its ability to handle resources efficiently with superior service quality delivery.

Several upcoming developments should be investigated to enhance both the model's scalability and its applicability potential. Tiny feedback systems with real-time measurements about cloud load dynamics and energy usage statistics enable the algorithm to transform efficiently as conditions in the cloud environment shift. Introduction of multi-objective optimization approaches will enable the system to achieve energy efficiency equilibrium with performance metrics including cost, user satisfaction as well as task latency. The framework requires testing with more extended diverse datasets to prove its potential application in various cloud infrastructure platforms. Federated learning as an advanced AI technology enables distributed cloud systems to achieve improved security and enhanced performance by addressing current challenges across cloud

infrastructure. The developed research framework establishes its core foundation as demonstrated in this study but it will use modern advancements to create an effective adaptable model for evolving cloud computing demands.al Fish Swarm Algorithm (AFSA). The proposed hybrid model demonstrated exceptional performance compared to traditional methods, such as Particle Swarm Optimization (PSO), Deep Reinforcement Learning (DRL), and PSO-based Neural Networks. Results from the experimental analysis highlighted a significant reduction in total energy consumption by 20.83%, alongside an improvement in average resource utilization efficiency to 89%. The model also achieved a 98.8% prediction accuracy, outperforming the next-best method, PSO-based Neural Networks, which achieved an accuracy of 92.0%. The model enhanced SLA compliance to reach 95% while achieving 98% completion rates of tasks which showed its capacity to manage resources efficiently and maintain high-quality service delivery.

Upcoming work will investigate multiple advancement possibilities to enhance both the scalability and usability of the model. The real-time feedback mechanisms that track dynamic workload variations and energy consumption stats enable better model adaptation during changing cloud environments. Mobile applications benefit from multi-objective optimization methods which simultaneously optimize energy efficiency alongside cost elements and task delays and user satisfaction criteria. The validation process merits testing using large diverse datasets that will show the framework's applicability across different cloud computing networks. The implementation of federated learning as an advanced AI paradigm would enhance distributed cloud system security and performance to address new infrastructure requirements in cloud computing.

These advances will develop upon the stable structure from this research to keep the SONN-AFSA model functional for changing cloud computing environments.

***Abstract*—One type of feeling that possesses a detrimental effect on people's day-to-day lives is depression. Globally, the number of persons experiencing long-term sentiments is rising annually. Many psychiatrists find it difficult to recognize mental disease or unpleasant emotions in patients before it's too late to improve treatment. Finding depression in individuals quickest possible time represents one of the most difficult problems. To create tools for diagnosing depression, researchers are employing NLP to examine written content shared on social media sites. Traditional techniques frequently have problems with scalability and poor precision. To overcome the drawbacks of the prior methods, it is suggested to introduce an improved depression detection system based on the RoBERTa (Robustly optimized BERT approach) and BiLSTM (Bidirectional Long Short-Term Memory) approach. This proposed work aims is to take advantage of the contextualized word embeddings from RoBERTa and the sequential learning properties of BiLSTM to determine depression from social media text. The technique is innovative because it combines the use of BiLSTM to accurately describe the temporal patterns of text sequences with RoBERTa to capture subtle linguistic aspects. It removes stopwords and punctuations form the input data to provide clean data to the model for processing. The system illustrates preference over the existing models as they achieve a 99.4 % accuracy, 98. 5% precision, 97. 1% recall, and 97. 3% F1 score. Thus, these results clearly highlight the effectiveness of the combination of the proposed technique with the traditional method in identifying depression with more accuracy and less variance. The proposed method is implemented using python.**

Keywords*—Depression detection; RoBERTa; BiLSTM; social media analysis; deep learning

I. INTRODUCTION

Depression, commonly referred as depressed disorder, is a prevalent mental health issue. It is defined by a prolonged depressed incident, joy reduction, or apathy in activities. It is important to distinguish between depression and normal emotional fluctuations or mood swings. Among other sectors of life, it may have an impact on ties with intimate friends, family, and the community. It might be the cause of, or a contributing factor to, issues in the workplace and in educational settings. Depression can hit anybody at any time. People who have experienced horrible tragedies, assault, or other traumatic events are more likely to suffer from depression. Depression is more common in women than in males [1]. Depression is linked to significant psychological, societal, and financial burdens and is a major contribution to the worldwide disease burden. Young people's depression is a developing issue due to two factors: first, it happens during a period of critical life development that includes substantial emotional, social, and intellectual development transitions; second, its frequency has sharply increased in this age group in recent years, particularly among females [2]. Depression is indicated by depressing emotions, emptiness, or irritability as well as changes in cognition and physical functioning that last for a minimum of two weeks and significantly hinder an individual's ability to operate [3].

The most prevalent mental disorder, depression affects 5% of individuals worldwide, with 20% of cases being severe. Adults in their middle and later years are the most at risk. The prevalence of depression is increasing globally, with a constant increase projected between 2005 and 2023. Early professional intervention can treat physical problems and alleviate mental disease, extending individuals' lifespans by reducing their risk of underlying diseases [4]. Early identification of mental illness can significantly improve a person's personal, professional, and social lives, as well as their health. Current methods, based on clinical processes, rely on language and connection between depressed individuals. An automatic depression detection technique is needed [5]. Emotions and primal instincts have a

greater ability to control people than reason and argument. Negative feelings are used by social media to encourage interaction and rage. The internet's quick growth provided a means for people to voice their ideas, views, and sentiments in a virtual setting. Individuals dealing with mental health concerns use social media sites like Twitter, Instagram, Reddit, and others to express themselves.

The most common ways to convey emotions are via written words, images, audio, or video. On the other hand, depressed individuals attempt to conceal who they are and are reluctant to share their images. They don't seem as interested in striking up a conversation with strangers. Also, they enjoy engaging in text-based small talk. Text is being employed increasingly and greater as the key criterion for recognizing depression since it is minimal latency, takes less bandwidth, and needs entirely less memory space [6]. Finding signs of mental illness in messages that are published on social media platforms is the subject of recent research. Depression detection systems ought to be created using cutting-edge learning strategies and principles from artificial intelligence. Reliable designs, expensive methods, and costly processing are the foundation of most machine learning algorithms. Deep learning algorithms are suggested by recent research as a means of developing depression detection methods [7]. Finding patterns of speech in the languages that the general public speaks depends on natural language processing methods like word representations [8]. The proposed study on depression diagnosis for social media will help improve depression identification by utilizing the proposed RoBERTa-BiLSTM architecture. Through embedding this approach, the most sophisticated contextual embeddings are combined with sequential analysis to provide a sophisticated view of the textual signs of depression. The value of the approach is in enhancing early identification and subsequent mental health care by means of reliable and centralized text analysis.

The following are the intended study's primary contributions:

- Emphasizes on the features of social media text through RoBERTa-BiLSTM in capturing both the contextual and sequential information for the determination of depression.
- Enables very fine-grained and efficient tokenization as well as embedding of the tokens, which are input for the deep learning models.
- Leverages on RoBERTa’s rich contextual obligation to enhance the method of feature extraction of social media posts which helps to consider concealed sentiments and intricate linguistic structures.
- Utilizes BiLSTM in bidirectional analysis of text to capture all the dependencies and contextual relations in the use of social networks by users.
- Facilitates early identification of depression that may result in timely intervention and support for people displaying early signs of mental illness issues.

This is how the paper is organized. Studies connected to Section II are discussed. Section III provides information on the limitations of traditional models. Section IV contains the proposed mode of function. Section V discusses the findings and summary. Section VI has a conclusion and recommendations for more research.

II. Related Works

Lin et al., [9] states that over 300 million individuals worldwide have experienced depression. The majority of them aren't identified in their early stages because of medical supplies and knowledge gaps. Recent research has attempted to employ social media to identify depression since users' mental states can be somewhat reflected in the patterns of thoughts and opinions shown in the text and visuals they upload. In this study, researchers construct a system called SenseMood to show that the suggested system can effectively identify and assess those who are experiencing depression. An approach to revealing users' psychological states on social media platforms has been proposed: deep visual-textual multimodal learning. Images and tweets made by people who have and do not have depression on Twitter are collected and developed in order to recognize depression. Bert and a CNN-based classifier are used for extracting the deep features from user-posted text and images. Subsequently, the textual and graphic components are combined to depict the emotional responses of the customers. Ultimately, the technology uses a neural network to classify individuals as depressed or normal, and an automatic evaluation summary is generated.

According to Sardari et al., [10] depression is a widespread and significant psychiatric condition that has to be diagnosed and treated as soon as possible. Suicidal thoughts may arise from the disorder during severe episodes. The research community has recently become interested in developing an efficient audio-based Automatic Depression Detection system. To automatically determine the extremely essential and compact feature set, a DL techniques implementation is included in an audio-based depression detection system. With the goal to better identify sad individuals, this suggested framework learns particularly pertinent and distinct characteristics from unprocessed sequential audio data using a Convolutional Neural Network-based Autoencoder technique. Further employ a cluster-based sampling strategy to tackle the problem of sample imbalance, which meaningfully lowers the possibility of bias towards the dominant class (non-depressed). The results are compared with feature extraction techniques developed by hand and other notable works in the field. According to the results, the suggested method performs at least 7% better in the F-measure for depression classification compared to different recognized audio-based ADD models.

Zogan et al., [11] research on one major issue, particularly in the medical field, is the model's capacity to provide an explanation for the findings it produced. Since it provides illumination on the model's prediction, model explainability is crucial for fostering trust. It's concerning, though, that the majority of machine learning techniques already in use don't offer explainability. This study uses MDHAN, an explainable method for quickly identifying people who are depressed on social media. More specifically, they compute the importance of each tweet and word using two layers of attention mechanisms that are used at the tweet and word levels; they then

obtain thematically sequencing data from user histories (posts) and encode user postings. A hierarchical attention strategy looks for patterns that lead to comprehensible outcomes. The trials demonstrate the advantage of merging multi-aspect data with deep learning, since MDHAN surpasses several well-known and reliable baseline approaches. The method increases the prediction accuracy of identifying melancholy in people who share publicly on social media, according to studies. MDHAN performs quite well and generates enough results.

Figueredo et al., [12] states that depression, which is frequently associated with illness and is one of the factors leading to suicide, poses a threat to public health. Consequently, they propose a preliminary detection of depression technique for social media using convolutional neural networks that blends Early and Late Fusion techniques with context-independent word embeddings. Considering the significance of the deeper feelings contained in the emoticons, these methods are experimentally assessed. The findings demonstrate that the suggested approach might identify users who might be depressed, with a precision of 0.76 and comparable or higher efficacy compared to numerous baselines (F1(0.71)). Furthermore, considerably improved outcomes were obtained through the semantic mapping of emoticons, with improvements of 46.3% and 32.1%, respectively, in recall and precision. The emoticon semantic mapping produced greater recall and precision gains (14.5%) and (48.8%) compared to the baseline word embedding approach. Overall effectiveness-wise, the work improved upon the state-of-the-art taking into account both the fusion-based and individual embeddings. Furthermore, it has been shown that the feelings that depressed individuals express and that are represented by emoticons are significant suggestive proof the issue and a useful tool for early detection.

Niu et al., [13] states that studies on the nervous system have revealed variations in facial expressions and speech patterns between healthy and depressed people. This fact leads us to propose a multimodal attention feature integration technique and an inventive spatio-temporal attention network to acquire the multimodal display of depression markers to predict each person's level of depression. First, fixed-length portions of the spoken word's amplitude spectrum/video are input into the STA network. As a result, the network might incorporate spatial and time-related data through an attention mechanism and highlight audio/video frames associated with depression recognition. The spatio-temporal attention network's last full connection layer produces the audio/video segment-level feature. Second, the Eigen evolution pooling technique is used in this article to build an audio/video level feature by integrating the modifications in each and every dimension of the segment-level features of audio and video. Third, a multimodal representation comprising modal different data is supplied to a support vector regression classifier, which is trained using the MAFF, in order to calculate the extent of depression. But have obstacles on high-quality data, which is computationally intensive, requires many integration challenges.

A novel approach was suggested by Rissola et al.,[14] to help compile a dataset of social media posts that mention depression or not. The author stressed that developing a model that can accurately identify depression is very challenging in the absence of a dataset. As a result, the author's dataset is capable of reliably predicting depression. The BERT model was used by the researchers to train their dataset, and the outcomes were excellent in terms of accuracy. This dataset can be used for more study, which can benefit mental health professionals as well. This novel approach to autonomously gathering large datasets will help present and future academics create instruments and applications that can precisely detect depression.

Chen et al., [15] discussed about how NLP methods had been applied to identify a certain kind of depression. Only a few numbers of research, meanwhile, have used sophisticated sentiment analysis methods to determine an individual's mental health from their social media postings. Chen and his colleagues employed a dynamic sentiment analysis method in this study, which is capable of extracting precise sentiments from people's tweets. Sad, pleased, disgusted, ashamed, surprised, afraid, confused, angry, and an ultimate score are the nine characteristics of an emotive. Thus, a tweet's dominating emotions are indicated by the emotive algorithm, which assigns a tweet's fine-grained emotion scores. Fine-grained emotions were defined as the feelings that people expressed when speaking or writing. These feelings were utilized as characteristics by machine learning algorithms to diagnose individuals who claimed they had mental health issues. Results were better for SVM and RF classifier.

Depression affects over three hundred million people globally, often going undiagnosed early because of gaps in existing sources and understanding. Recent studies have explored modern methods for detecting depression via social media, leveraging multimodal procedures. One gadget, SenseMood, combines visual and textual information using CNNs and BERT to assess emotional states. Another approach focuses on audio-based total detection, employing DL techniques and cluster-based sampling to improve classification accuracy. To address the assignment of version explainability, a hierarchical attention community complements the know-how of predictive outcomes. Convolutional neural networks with fusion methodologies and semantic mapping of emoticons have confirmed stepped-forward precision and recollect. Finally, a spatio-temporal interest network integrates audio and visual facts to predict despair severity, using multimodal representations for extra-accurate detection.

III. PROBLEM STATEMENT

Previous approaches to depression identification on Social Media content lack certain issues corresponding to contextual interpretation, two-way extraction, and integration of DL components. Most models face difficulties in interpreting the subtle signals of emotions and do not handle big data of different social networks [16]. The proposed work, using RoBERTa-BiLSTM models, fills the previous gaps in the following ways to achieve the targeted improvement. This approach improves the multiple layers of textual features and mood representation and increases the model's accuracy and applicability with the aid of hybridity. Further, it eliminates the shortcomings of the models being used today with the incorporation of deep learning approaches that are efficient in handling big data.

IV. Proposed Hybrid Deep Learning Models for Depression Identification

The RoBERTa-BiLSTM model encompasses deep contextualized meanings and sequential dependencies, surpassing conventional models such as SVM and RF, which are insensitive to subtle sentiment understanding. The model avoids current constraints to ensure greater precision in detecting depression. In the proposed research, a hybrid deep learning algorithm combining RoBERTa and BiLSTM is used to detect depression in social media contexts. Tweets and related metadata make up the data that is collected, and it is gathered from social media platforms, primarily Twitter. First of all, the text information is filtered out from the noise, and the format is brought to a single standard. For the feature extraction of the pre-processed text, RoBERTa is employed to obtain the contextual embeddings resulting from the specified complex semantic characteristics. These embeddings are then fed into a BiLSTM network, which is useful to get the sequential dependencies of the text and recreate it both forward as well as backwards directions. A dense layer receives the result from the BiLSTM and evaluates the conditions as being depressed or not. The model is trained using predefined labelled data and assessment measures. For the purpose of to illustrate the ability of the proposed approach to enhance the recognition of depression on social media sites and lay the basis for extensive data analysis on depression, the efficiency of the generated model is contrasted with baseline methods (Fig. 1).

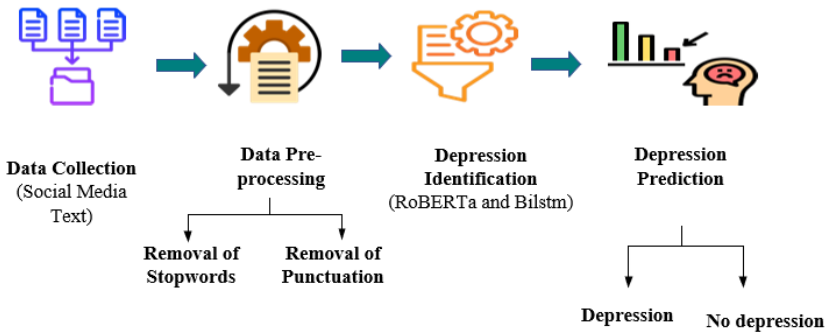

Fig. 1. Proposed hybrid deep learning models for depression identification.

A. Data Collection

The suggested method begins with acquiring data. This dataset, which is in Excel format, includes about 6500 data points from Facebook posts, comments, and other social media platforms. The ultimate depression of the data is represented by a large number of votes. The data collection was gathered from the Kaggle platform [17]. This dataset consists of two columns. There are two types: text and labels. The text columns contain both normal and anxiety/depression content, and the label column shows if the associated text suggests anxiety or depression are shown in Table I.

TABLE I. Data Outline

Text	Label
oh my gosh	1
trouble sleeping, confused mind, restless heart. All out of tune	1
like it, say don't just stay silent when someone takes it, eh, they say cheat	0
morning, have you taken a shower yet?	0
Unfortunately, I got another limit for 3 days	0

B. Data Pre-processing

Numerous unnecessary symbols and other components that complicate the framework of the model are included in the data that was gathered from the sources. Removing unnecessary information from the dataset makes the process of developing the model easier. This work involves a number of preprocessing processes. Texts with stop words, and punctuation that are deemed unnecessary for the analysis are removed.

1) Removal of stopwords: Stopwords are terms like "the," "a," and so on that are often used in a language. They can usually be removed from the text since they don't provide any pertinent information that has to be looked into further.

2) Removal of punctuation: Text preparation techniques also often involve removing punctuation from text data. 'Hurray' and 'hurray!' will be treated similarly because to this text standardization process.

C. Roberta- BiLSTM for Detection Recognition

The RoBERTa model extends BERT. The BERT and RoBERTa, part of the Transformers family, were created for sequence-to-sequence modeling in order to solve the issue of long-range dependencies. Transformers, tokenizers, and heads are the three parts of a transformer model is shown in Fig. 2. Through the tokenizer, sparse index descriptions are created from the unformatted text. The converters then convert the minimal content into meaningful embedding to enable more thorough training. For subsequent operations, the contextual embedding is utilized by wrapping the transformers model with the heads. When it comes to learning the contextual depiction from both sides of the sentences, BERT differs slightly from the language models that are already in use. However, RoBERTa combined a broader vocabulary collection with 50K subword units using byte-level Byte-Pair Encoding. Other than that, by training on larger amounts of data, more training durations, and extended sequences, the RoBERTa model improves upon the BERT model.

The cleaned text is initially tokenized using words and subwords in the suggested RoBERTa-BiLSTM model to facilitate quick encoding into word embeddings. RoBERTa tokenizer is utilized in this study. Some unique tokens are available in the RoBERTa tokenizer, including tokens to denote the start and finish of sentences and tokens to extend the text to the word vector's maximum length. The text in the RoBERTa model is divided into subwords using the level of bytes Tokenizer for Byte-Pair Encoding. There won't be a tokenizer for the commonly used terms. Rare words, yet, will be divided into easier-to-understand concepts. The term "Transformers" will be divided into two parts, namely "Transform" and "ers." The text must be converted from language spoken to an understanding for its structure to comprehend it of numbers. The raw text that the RoBERTa tokenizer encodes using input ids as well as an attention mask. Tokenization is shown in Table II.

TABLE II. TOKENIZATION

	text	label	text_clean	tokens	text_tokens
0	oh my gosh	1	oh my gosh	[oh, gosh]	oh gosh
1	Trouble sleeping, confused mind, restless heart. All out of tune	1	trouble sleeping confused mind restless heart all out of tune	[troubl, sleep, confus, mind, restless, heart, tune]	troubl sleep confus mind restless heart tune
2	All wrong, back off dear, forward doubt. Stay in a restless and restless place	1	all wrong back off dear forward doubt stay in a restless and restless place	[wrong, back, dear, forward, doubt, stay, restless, restless, place]	wrong back dear forward doubt stay restless restless place
3	I've shifted my focus to something else but I'm still worried	1	ive shifted my focus to something else but im still worried	[ive, shift, focu, someth, els, im, still, worri]	ive shift focu someth els im still worri

The input ids are a numerical representation of the token's indices. Conversely, the attention mask was a customization option that is applied when the sequence is assembled in batches. Which tokens should and shouldn't be examined is indicated by the attention mask. The RoBERTa fundamental model receives the input ids along with an attention mask. The RoBERTa basic model consists of 12 RoBERTa foundation layers, 768 concealed state vectors, and 125 million parameters. In order for the subsequent layers to quickly retrieve the important information about the word embedding, the RoBERTa first layer's attempt to provide a pertinent word inclusion as a distinctive depiction.

A more complex kind of RNN that is particularly good at identifying dependencies in sequential data are BiLSTM networks. BiLSTMs process sequences both forward and backward, in contrast to typical LSTMs, It only does one direction of sequence processing. The model might employ historical and prospective data contexts thanks to this bidirectional approach, which is especially helpful for jobs that call for a thorough comprehension of the sequence. An expansion of the LSTM architecture, BiLSTM networks are intended to get around some of the drawbacks of conventional RNNs, such the vanishing gradient issue. Long-range dependencies in the data are captured by LSTMs through the use of a series of gates to control the information flow across the network. The following are the essential parts of an LSTM cell:

- The Input Gate (i_t) regulates the amount of incoming data that is contributed to the cell state.
- The Forget Gate (f_t) regulates in what way much of the previous cell state should be preserved.
- The output gate (o_t) determines the appropriate amount of cell state output.

$$I_t = \sigma(E_i.[D_{t-1}, x_t] + b_i) \quad (1)$$

$$f_t = \sigma(E_f.[D_{t-1}, x_t] + b_f) \quad (2)$$

$$u_t = \sigma(E_o.[D_{t-1}, x_t] + b_o) \quad (3)$$

$$C_t = tanh(E_C.[D_{t-1}, x_t] + b_C) \quad (4)$$

$$C_t = f_t * C_{t-1} + i_t * C_t \quad (5)$$

$$d_t = o_t * \tanh(C_t) \quad (6)$$

where the hyperbolic tangent function in (1), (2), (3), (4), (5) and (6) is represented by $tanh$, the sigmoid function by σ, and element-wise multiplication by $*$. Because of these equations, LSTMs are better equipped to represent complicated temporal connections by maintaining a steady gradient across lengthy durations. Two LSTM layers exist in a BiLSTM network:

1) Forward LSTM layer: The layer moves ahead, processing the given input sequence from beginning to end.

2) Backward LSTM layer: The layer starts to process the input sequence at the beginning and proceeds backward.

The final of the dropout layer is then transferred into the BiLSTM model next. The LSTM network allows information to spread completely in a forward motion that denotes that the information prior to time t is the only source of influence for the state of time t. However, further details are just as useful as earlier ones in characterizing the overall semantics of an input review. Therefore, the BiLSTM model has been employed to represent contextual information more effectively. The two LSTM networks that compose up the BiLSTM model allow it to scan input reviews both forward and backward. The hidden state of the forward LSTM may be represented in Eq. (7).

$$\overrightarrow{hd_a} = LSTM(l_a, \overrightarrow{hd_{a-1}}) \quad (7)$$

Interpreting data from left to right, while the hidden state of the reverse LSTM can be represented in Eq. (8).

$$\overleftarrow{hd_a} = LSTM(l_a, \overleftarrow{hd_{a+1}}) \quad (8)$$

The concatenation of the forward and backward states yields $hd_a = [\overrightarrow{hd_a}, \overleftarrow{hd_a}]$, which is the final overview of the BiLSTM output. Global average pooling and global maximum pooling layers receive the BiLSTM layer's outputs concurrently. The BiLSTM layer's maximum and average values for each feature

are retrieved by the former and latter layers, respectively. Instead of using the dense layer(s), only one global pooling layer (each) is used. Before sending it to the last layer, the concatenate layer combines both the global maximum and global average layers into a single layer.

Detecting depression in social media text analysis using a hybrid RoBERTa-BiLSTM version includes leveraging the strengths of each RoBERTa and BiLSTM to capture deep contextual and sequential statistics from the textual content. RoBERTa, a transformer-based totally version, excels in know-how context via its pre-learned on a full-size corpus of statistics, which allows it to generate rich, nuanced embeddings for every token in the textual content. The technique starts with preprocessing the social media texts, which includes casting off punctuation and stopwords to make sure cleanser records input. These texts are then tokenized using RoBERTa's tokenizer, changing them right into a layout that the version can method. RoBERTa strategies these tokens to provide contextual embeddings, shooting the meanings of phrases in the context of surrounding phrases. This is important in social media text evaluation where slang, abbreviations, and casual language are typical.

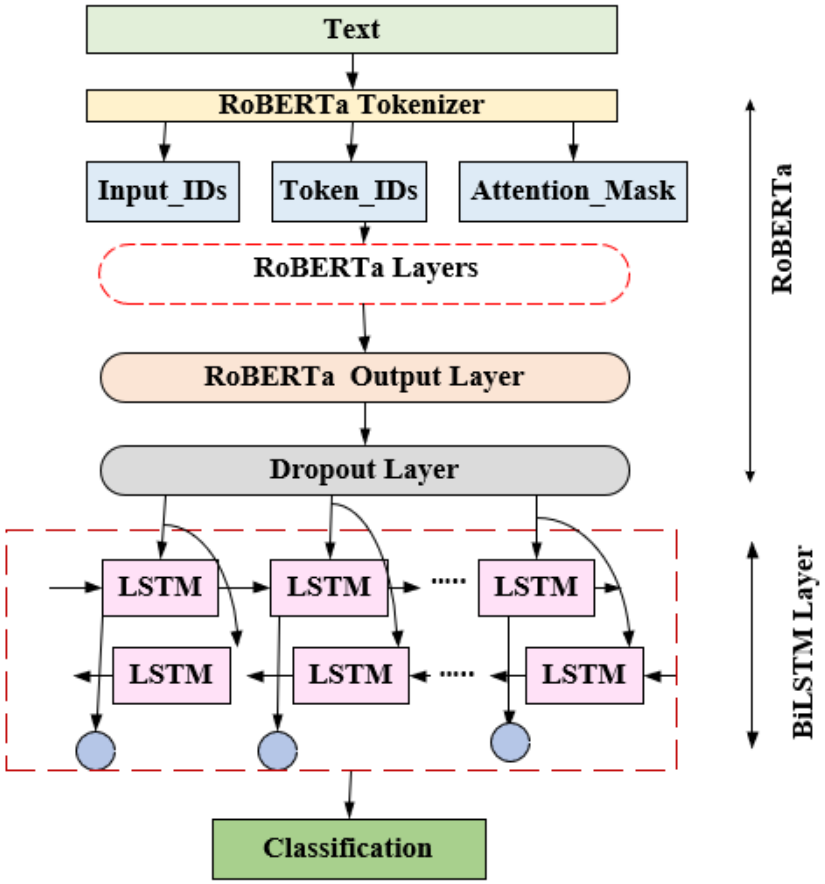

Fig. 2. RoBERTa and BiLSTM method.

The BiLSTM network receives the generated contextual embeddings directly. BiLSTM techniques the series of embeddings in both forward and backward directions, capturing dependencies that span across the entire text. This bidirectional processing is mainly beneficial for knowing the emotional tone and progression inside the textual content, which is important for identifying symptoms of depression. The hidden states generated via the BiLSTM encapsulate records from both beyond and future contexts, imparting a complete know-how of the collection. The model then applies an attention mechanism, which assigns specific weights to exceptional components of the textual content primarily based on their relevance to depression identification. The attention technique enables the version to concentrate on important textual elements which can be more indicative of despair, along with expressions of sadness, hopelessness, or tension. The weighted hidden states are combined to shape a context vector that represents the general emotional and contextual facts of the textual content. This context vector is then used to extract functions that can be fed into a chain of dense layers for category. The dense layers procedure these features to output a prediction indicating whether or not the text shows depressive tendencies. The model is educated on the usage of categorized facts, where the social media texts are annotated with labels indicating the presence or absence of depressive symptoms. During training, the model learns to optimize its parameters to accurately classify new, unseen texts. The pseudocode in Algorithm 1 and flowchart in Fig. 3 outline a technique for detecting depression in social media textual content using RoBERTa-BiLSTM, consisting of facts preprocessing, embedding generation, feature extraction, category, and final predictions.

Algorithm 1: Depression Detection Using RoBERTa-BiLSTM Hybrid Model

```
Input: Social media text samples
Output: Depression prediction for each text sample
Step 1: Data Preparation
Load text samples
Preprocess text:
  - Remove punctuation
  - Remove stopwords
Step 2: Tokenization and Embedding with RoBERTa
tokenized_texts = RoBERTa_tokenizer(preprocessed_texts)
embeddings = RoBERTa_model(tokenized_texts)
Step 3: Hidden State Calculation with BiLSTM
hidden_states = []
for emb in embeddings:
  forward_hidden_state, backward_hidden_state = BiLSTM (emb,
previous_forward_hidden_state,
previous_backward_hidden_state)
  hidden_states. append ((forward_hidden_state,
backward_hidden_state))
Step 4: Feature Extraction
features = extract_features(context_vector)
Step 5: Classification using Dense Layers
depression_prediction = Dense_Layers(features)
Step 6: Training and Evaluation
Train the model using labelled depression data
Evaluate model performance using metrics (accuracy, F1 score,
etc.)
Step 7: Prediction
depression_predictions= predict_depression(new_text_samples)
Output: depression_predictions
End
```

V. Results and Discussion

The proposed study using the RoBERTa-BiLSTM hybrid model showed promising results in detecting depression in social media contexts. The model fully processed and analyzed transcript content, using the RoBERTa contextual input and the BiLSTM two-way sequential learning to classify transcripts as "depressed" or "no depressed." indicators Analytical parameters are appeared to perform better than baseline models. The combination of RoBERTa and BiLSTM led to a better understanding of sensory signals and context, resulting in stronger and more reliable predictions, and highlighted the real-world potential of the model in mental health services.

A. Experimental Outcomes

TABLE III. Depression Prediction

text	label	prediction
Hi, I want to tell you... Lately I've been feeling restless, have trouble sleeping, I searched on google it says it's a mild symptom of depression, I used to tell my mom a psychologist friend "don't think too much, it's not important you get depressed easily" then I frequent irregular breathing.	1	0.164200
Yes, the point is that I feel tired, sad, annoyed, restless. It's like the feeling is mixed in my heart and mind, in my brain I'm traveling various things from problems to happiness that I've felt until this moment.	1	0.164194
Every time after sunset, why must this heart be restless as if it can't accept the situation. But with this situation, you can't do anything, if you do it, it can only make things worse	1	0.164191
Anjir looks like he can't watch Dream, I have an appointment at 3 o'clock ””	0	0.095998
w if it doesn't look like it's okay. it's too late for the child w. it's better if it's hard to be alone, so let's be like before	0	0.095998
even though it's just a vanilla latte but why is it strong until the morning, after that it looks like a panda	0	0.095998

The Table III presents the results of a depression detection model using RoBERTa-BiLSTM on social media text samples. The "Text" column contains input text samples, "Label" indicates ground truth (1 for depression, 0 for depression), and

"Prediction" shows the model's confidence score for depression Higher scores (closer to 1) indicate greater confidence in detecting depression. The model demonstrates the ability to distinguish between depressive and no depressive texts, and obtain higher scores for depressive texts.

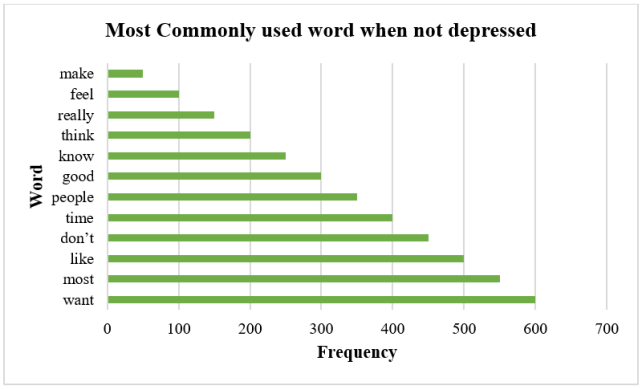

Fig. 4. Not depressed words.

The Fig. 4 indicates the frequency of different words humans use whilst they're no longer feeling depressed. The words are listed from maximum to least frequent: "make," "feel," "certainly," "assume," "know," "humans," "proper," "time," "like," "do not like most," and "want." The maximum frequency is just under seven hundred for "make," and the bottom is around 100 for "need." This figure highlights how regularly those words appear in conversations whilst individuals are not experiencing depression.

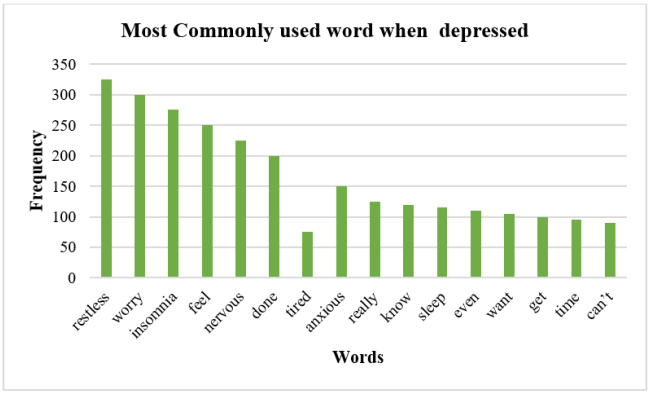

Fig. 5. Depressed words.

The Fig. 5 shows the frequency of particular words used by individuals when feeling depressed. The horizontal axis records terms such as "restlessness," "insomnia," and "fatigue," while the vertical axis measures frequency from 0 to 350 and "restlessness" corresponds to "insomnia," indicating that these terms are mentioned more frequently In the case of depression. This visual representation aids to understand common language patterns associated with depressive states, which can be useful for psychoanalytic or linguistic studies.

B. Training and Testing

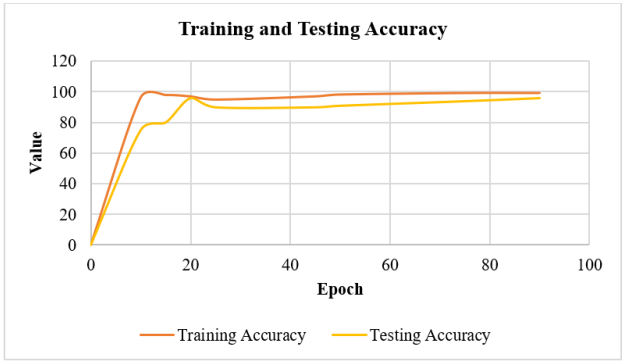

Fig. 6. Training and testing accuracy.

Training and test accuracy measures at different ages demonstrate the learning and generalization capabilities of the model is shown in Fig. 6. Initially, both accuracies start from 0. By time 10, the accuracy of training reaches 96%, the accuracy of testing reaches 75%, indicating initial overfitting and both accuracies improve as training goes on so, with training accuracy standing around 97-99% and testing accuracy of 96 at time 90 peaks at %. This indicates that the model learns the training data well and generalizes well to unseen data, thus confirming the robustness of RoBERTa-BiLSTM hybrid model emphasizes uneasiness found in social media text.

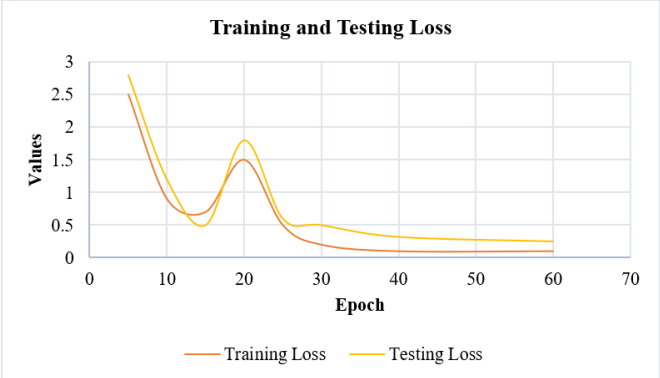

Fig. 7. Training and testing loss.

The training and testing loss show how the error in the model decreases with time is shown in Fig. 7. Initially, at epoch 5, the mean training loss was 2.5 and the mean testing loss was 2.8. By time 10, the loss decreases significantly 0.9 for training and 1.2 for testing, indicating an improvement in model learning. Despite a slight increase at time 20, the loss continues to decrease, with the training loss reaching 0.1 and the testing loss reaching 0.25 at time 60. This steady decrease in loss indicates the accuracy of the model improved and decreased errors, a finding indicative of both effective and general learning for depression identification.

C. Performance Evaluation

When compared to baseline models, the effectiveness evaluation of the suggested hybrid framework for depression detection produced consistent and outstanding results. The

equation in (9), (10), (11) and (12) is used to find the F1-score, recall, accuracy, and precision. T_{pos} means true positive, T_{neg} means true negative, F_{pos} means false positive and F_{neg} means false negative.

$$Accuracy = \frac{T_{pos}+T_{neg}}{T_{pos}+T_{neg}+F_{pos}+F_{neg}} \quad (9)$$

$$Precision = \frac{Tpos}{Tpos+Fpos} \quad (10)$$

$$Recall = \frac{Tpos}{Tpos+Fneg} \quad (11)$$

$$F1\ Score = \frac{2\times precision \times recall}{precision \times recall} \quad (12)$$

TABLE IV. PERFORMANCE COMPARISON

Approach	Accuracy	Precision	Recall	F1-Score
CNN[9]	0.884	0.903	0.87	0.936
CNN AE+SVM [10]	0.71	0.72	0.71	0.71
MDHAN [11]	0.89	0.9	0.89	0.89
BERT [14]	0.87	0.73	0.96	0.81

The Table IV compares the performance of different models in predicting depression. The corresponding kernel support vector machine achieves an accuracy of 83.1% with precision, recall, and F1 scores of around 80-83%. The RNN model performs slightly lower in accuracy 80.5% but better in F1 score 83.8%. The CNN and BiLSTM models significantly improve the accuracy by 98.1% with higher accuracy, recall, and F1 scores. The proposed RoBERTa and BiLSTM models perform the best among them in terms of 99.4% accuracy, good precision 98.5%, recall 97.1%, and F1 score 97.3%, indicating good performance in depression as they are seen in it.

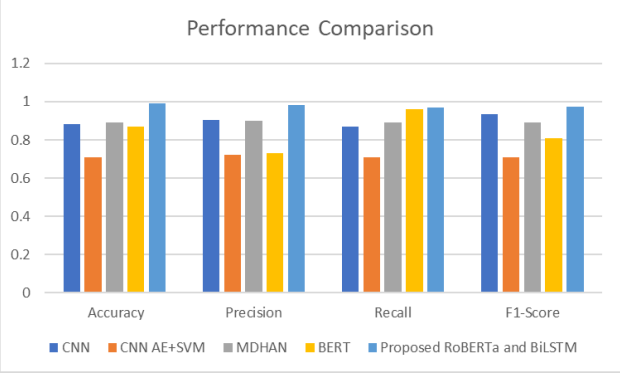

Fig. 8. Performance comparison of various methods.

The Fig. 8 compares four models: The performance comparison graph shows the comparative effectiveness of various models, viz., CNN, CNN AE+SVM, MDHAN, BERT, and the suggested RoBERTa-BiLSTM model, on critical evaluation metrics: accuracy, precision, recall, and F1-score. The suggested RoBERTa-BiLSTM model surpasses all the other models in all metrics, proving to be the best depression detection capability from social media text. Though CNN and CNN AE+SVM exhibit average performance, CNN AE+SVM falls behind because it has less contextual knowledge. MDHAN and BERT are good, but the integration of RoBERTa's contextual embeddings with BiLSTM's sequential learning improves recall and F1-score, and thus the proposed approach is the best.

D. Discussion

The RoBERTa-BiLSTM hybrid model significantly enhances the detection of depression in social media contexts by addressing various limitations of traditional methods. Traditional methods typically involve laborious and subjective manual assessments and clinical interviews. Conventional methods often suffer from limited accuracy and scalability issues [21]. This model uses advanced NLP and deep learning, automates the search process, and provides intuitive and objective solutions. The introduced RoBERTa-BiLSTM model shows considerable strengths compared to the conventional approach by efficiently extracting both contextual and sequential dependencies from social media text. It is superior to common machine learning models such as SVM, RF, and earlier deep learning models including CNN-LSTM. The inclusion of RoBERTa in context captures subtle emotional expressions, while BiLSTM better models' sequential speech dependence, improving sensitivity to depressive symptoms. The results show a notable accuracy of 99.4%, with high accuracy (98.5%), recall (97.1%) and F1 score (97.3%). This implementation demonstrates the model's resilience in differentiating between texts that are sad and those that are not, outperforming both alternative DL techniques and conventional machine learning models. Through guaranteeing accurate and suitable input, preliminary processes that involve the removal of pauses and character input help to develop the model. The accomplishment of this hybrid approach suggests that similar models can be incorporated into mental health care systems, enabling early detection and intervention Future research could extend the model to address or deliver multilingual content other methods such as visual or auditory data will be combined to further enhance the prediction capabilities.

VI. CONCLUSION AND FUTURE SCOPE

For healthcare departments to assist their depressed patients, it is imperative that depression be automatically identified from text. The RoBERTa-BiLSTM hybrid model leads to significant improvements in depression detection in social media contexts. This study achieved 99.4% accuracy, demonstrating the exceptional performance of the model RoBERTa's advanced contextual embeddings with serial capture capabilities dependencies of the BiLSTM Integrating, the model correctly recognizes subtle emotional cues that predict depressive states preliminary steps, including stopword removal and syntactic removal, provide the model's ability to process and analyze contextual information to ensure predictions are accurate and reasonable. The drawbacks of conventional techniques, which usually rely on biased manual analysis, are eliminated by this strategy. Through automating the process of discovery, this model provides a scalable, objective solution that can be incorporated into mental health care systems to facilitate the operation of the early intervention RoBERTa-BiLSTM hybrid model high quality underscores the potential for real-world application in mental health. Subsequent investigations ought to concentrate on several crucial domains to augment the

dependability of the framework. Extending the model to handle multilingual contexts could improve its applicability to different language populations. Furthermore, the integration of multiple inputs, such as visual or auditory feedback, leads to a more comprehensive understanding of depressive symptoms, as emotional symptoms are often expressed through multiple mechanisms. The RoBERTa-BiLSTM model has difficulty with non-verbal signals, which restricts accuracy of depression detection. It is challenged in multilingual environments and potentially drops contextually significant words in preprocessing. The need for high computational requirements discourages real-time use, while risks of misclassifications involve sarcasm and doubtful text, necessitating further tuning for enhanced reliability and explainability. Future research encompasses multilingual adaptation, multimodal data integration (text, audio, images), real-time deployment optimization, simplification of computational complexity, improved explainability, fine-tuning sarcasm detection, contextual understanding improvement, and guaranteeing ethical AI deployment in mental health care.

***Abstract*—Sexist content is prevalent in social media, which seriously affects the online environment and occasionally leads to offline disputes. For this reason, many scholars have researched how to automatically detect sexist content in social media. However, the presence of sarcasm complicates this task. Thus, recognizing sarcasm to improve the accuracy of sexism detection has become a crucial research focus. In this study, we adopt a deep learning approach by combining a sexism lexicon and a sarcasm lexicon to work on the detection of Chinese sexist content in social media. We innovatively propose a sarcasm-based masking mechanism, which achieves an accuracy of 82.65% and a macro F1 score of 80.49% on the Sina Weibo Sexism Review (SWSR) dataset, significantly outperforming the baseline model by 2.05% and 2.89%, respectively. This study combines the irony masking mechanism with sexism detection, and the experimental results demonstrate the effectiveness of the deep learning method based on the irony masking mechanism in Chinese sexism detection.**

***Keywords*—Sexism; chinese; deep learning; sarcasm; masking**

I. Introduction

There is a limitation on the current sexism detection. It is difficult to detect sexist text with a sarcastic sense [1]–[3]. Sarcasm uses irony to mock or express contempt, and there is a discrepancy between an utterance's literal meaning and intended meaning. It is challenging to detect automatically [4]. Sarcasm in long and short text remains a challenge in Natural Language Processing (NLP) and Sentiment Analysis (SA) [5]. In the research of [3], irony limits the performance of sexism classification. According to [1], numerous tweets are labeled under sexism categories due to their sarcastic meaning. However, their model is unable to detect the sarcastic intent. The researchers of [2] also argued that sexist posts with humor, irony, and sarcasm are challenging to spot and often contain no overt expressions of hatred. Therefore, it is necessary to identify sarcastic sexism in the detection of sexism.

For example, 如果她自己够优秀就不会在网络上怨天尤人了 (If she is excellent enough, she will not blame others on the internet) is misclassified sexism [2], which contains a sarcastic sense. It is a sarcastic remark that blames unsuccessful women while insulting others who support gender equality. When there is no explicit presence of harsh language, it might be challenging to recognize sexism in an automatic system.

In the research of [3][5], they discovered that sarcasm limits the performance of the sexism classification. In the research of [6], they reported that sarcasm knowledge is helpful for Spanish sexism classification. The researchers of [7] researched Arabic sexism and sarcasm text classification using deep learning methods and noted that AraBERT performs best for both sexism detection and sarcasm detection. It illustrates that AraBERT is useful for both sexism and sarcasm detection. However, the accuracy of sexism detection is 91.0%, higher than sarcasm detection, which is 88%. It can be concluded that the deep learning method is useful for both sexism and sarcasm detection, and the sarcasm knowledge is useful for improving the performance of sexism detection.

Various deep learning methods, such as Convolutional Neural Networks (CNN) [8], Long Short-Term Memory (LSTM) [9], Bidirectional Long Short-Term Memory (BiLSTM) [10], Bidirectional Gated Recurrent Unit (Bi-GRU) [11], Bidirectional Encoder Representations from Transformers (BERT) [12]-[14], Robustly Optimized BERT Pretraining Approach (RoBERTa) [2], Multilingual BERT (mBERT) [15], have been employed in sexism detection. In the research of [1][8][11][16], deep learning methods outperform traditional machine learning methods, such as Support Vector Machine (SVM), Logistic Regression (LR), Naive Bayes (NB), Decision Tree (DT). Among the deep learning methods, transformers-based deep learning like BERT and RoBERTa usually perform the best [2][3][12][17]. The hybrid approach in the research [10][18]-[21] obtains the best result. Accordingly, deep learning methods, especially transformer-based methods and hybrid approaches, are considered in our research.

The researchers in [6] demonstrated that sarcasm aids in the identification of sexism. They adopted a multi-task learning strategy that simultaneously addresses numerous problems rather than treating them in isolation to enhance Spanish sexism detection. Nonetheless, the strategy is inappropriate for a singular-task situation. The research in [7] demonstrated that deep learning methods are good at detecting both sexism and sarcasm in Arabic. However, they employed the same deep learning model on both the misogyny dataset and the sarcasm

This work was funded by the Science Research Project of Hebei Education Department (QN2024149).

dataset to demonstrate the efficacy of their technology. Consequently, there is a lack of study on sarcasm-based sexism detection in a singular task context, while it is considered a prospective research avenue by [1]–[3][22].

This research aims to improve Chinese sexism detection using a deep learning approach fused with sarcasm. The dataset is the Sina Weibo Sexism Review (SWSR). To leverage sarcasm features in the model, sarcasm-detecting approaches are invested. There are text-only methods and extra information methods for sarcasm detection [23]. In particular, the text-only method concentrates on the utterance itself to detect the sarcasm text, such as exploiting linguistic features [24] and using inconsistent expressions [26]. This research uses sarcastic linguistic features in a sexist lexicon with a masking mechanism. Consequently, it combines them with a deep learning approach. The contributions of this paper are as follows:

1) Proposed Sarcasm-sexism-Nezha-mCNNs model. The model combines a sarcasm lexicon and a sexism lexicon with a transformer-based Nezha and three CNNs. The model's performance in detecting Chinese sexist text is significantly enhanced, achieving an accuracy improvement of 2.05% and a macro F1 score increase of 2.89% compared to the baseline.

2) Constructed a Chinese sarcasm lexicon. A Chinese sarcasm feature lexicon, consisting of 193 words, has been developed. This lexicon combines terms identified in previous studies with words generated through the chi-square test in this paper. It has potential applications in further sarcasm detection endeavors.

3) A sarcasm mask mechanism is proposed. The output from the sarcasm layer is masked with 1 or -1, and then the masked output is multiplied by the output from the sexism lexicon layer as 20% for the final output. This crucial design feature for the proposed model can be adapted for gender-based categorization of sexism in both Chinese and other languages.

The remainder of the paper is organized as follows: Section II reviews related works. Section III outlines the research methodology, including data processing, text representation, classification, evaluation, and experimental settings. Section IV presents the experimental results, while Section V interprets these outcomes and highlights the key findings. Finally, Section VI summarizes our contributions, acknowledges limitations, and suggests directions for future research.

II. Related Work

First, hybrid deep learning approaches for sexism detection are investigated. Next, the detection of sarcasm using Chinese sarcasm linguistic features is explored. The Chinese sarcasm dataset and feature extraction methods are also presented.

A. Hybrid Deep Learning Approach for Sexism Detection

1) Combining more than one deep learning method: In the research of [18], they employed a CNN-LSTM model to detect sexual harassment in Hindi. They substituted all newline characters with a space, eliminated English letters, numerals, hyperlinks, emojis, and special characters, and employed a tokenizer with the Keras library. An accuracy of 93.53% is achieved with CNN-LSTM, surpassing RNN-LSTM.

The approach in a study by [19] utilized a BiLSTM combined with a Temporal Convolutional Network (TCN-BiLSTM) to analyze sexist speech in Arabic social media, surpassing BiLSTM, TCN, and XGBoost. This method benefits languages that provide morphological challenges, such as Arabic, Turkish, and Lithuanian.

The researchers in [20] combined customBERT with a CNN to detect sexism in social media on the dataset of SemEval Task 10. It combines output from BERT, XLM-RoBERTa, and DistilBERT and then fed into CNN. 'Random deletion' improves the model's ability to understand incomplete information. 'Synonym replacement' improves the model's understanding of context. Then, back translation is used for data augmentation. Shapley additive explanation values are used to increase model explainability.

In the research of [22], they employed a semi-supervised model to enhance the EXIST dataset through data augmentation. The pre-trained XLM-R and sentence BERT combined with BiLSTM are utilized for sexism detection, achieving an accuracy of 81.2% and an F1 of 81.1%. They indicated a prospective research direction involving the integration of sarcasm and irony detection into their system.

It illustrates that CNN, LSTM, BiLSTM, and transformer-based models such as BERT, mBERT, and XLM-R are commonly used in combinations of two or more deep learning methods.

2) Combining deep learning with linguistic features: The researchers in [10] combined lexicon and sentiment features with LSTM, obtaining the best accuracy of 87.2% and an F1 of 82.4% on the dataset of AMI EN-EVALITA. They discovered that the optimal feature type identified is Term Frequency-Inverse Document Frequency (TF-IDF) Ngrams. However, lexical features and word2vec embeddings can enhance the outcomes when integrated with TF-IDF. Their model outperforms BERT, XLNET, RoBERTa, and DistilBERT.

In the research of [2], they combined BERT, RoBERTa, CNN, SVM, and LR with the sexism lexicon, respectively. The sexism lexicon is expressed using TF-IDF. The researchers find that RoBERTa, with a sexism lexicon, obtains the best F1 score of 78% on the SWSR dataset. However, it has a lower accuracy value than BERT without a lexicon. It indicates that the sexism lexicon should be combined with the deep learning method with a proper method.

The researchers in [21] integrated LSTM with sentiment analysis, obtaining the best performance detecting sexism with an F1 of 83.01%, which outperforms LSTM-sexism and LSTM-RoBERTa. Thus, pre-trained models are used for word representation.

It can be noted that linguistic features such as sexism and sentiment have been combined into deep learning methods

such as LSTM, BERT, and RoBERTa. However, a proper combining method is required.

3) Sarcasm detection with Chinese sarcasm features. Sarcasm uses irony to mock or express contempt, and there is a discrepancy between the literal meaning and intended meaning of an utterance. It is challenging to detect automatically [4][25]. According to [26], there are text-only methods and extra information methods. The text-only method concentrates on the utterance itself to detect the sarcasm text, such as exploiting linguistic features [27]-[29] and using inconsistent expressions [23][30][31]. In contrast, the extra information method focuses on external knowledge, such as user features and common sense knowledge. In this research, we focus on sarcasm linguistic features.

In the studies in [24][27]-[29][32]-[34], linguistic features of Chinese sarcasm are employed as significant features for the detection of Chinese sarcasm. The chi-square test is employed to pick feature words more pertinent to the target category and obtain Chinese sarcastic feature words. The traits are categorized into more specific classifications, including interjection words, adverbs of degree, internet vocabulary, homophonic words, and punctuation. The Chinese sarcasm feature words presented in the studies referenced as [24][27][28][32][34] are integrated. Table I illustrates some examples of Chinese sarcastic linguistic feature words.

TABLE I. CHINESE SARCASM LINGUISTIC FEATURE WORDS

Word Type	Words
Interjection words	呵呵(hehe), 啊(ah), 哇(wow), 哟(yo), 哈哈(haha), 嘿嘿(heihei), 唉(sigh), 哼(hmm）
Adverbs of degree	真是(really), 非常(very), 极其(extremely), 牛(awesome), 牛逼(awesome), 不愧是(worthy of being）
Internet vocabulary	醉了(drunk), 凡尔赛(Versailles), 躺平(lie flat), 涨姿势(gaining knowledge), 囧(confused), 逗比(funny person),
Homophonic words	河蟹-和谐(harmony), 杯具-悲剧(tragedy), 灰常-非常(very), 餐具-惨剧(tragedy), 表-婊(bitch), 虾米-什么(what),
Punctuation	？，！，“”, ……，。。。

1) Interjection words: The inclusion of interjection words in a sentence imparts a sense of teasing and irony [28]. In sentence 哇？？？？？？？吐槽鬼居然是女性我真的觉得她可爱了哈哈哈哈哈 (Wow??????? The complaining ghost is actually a woman. I really think she is cute, hahahahahaha), both 哇 (Wow) and 哈哈哈哈哈 (hahahahahaha) are interjection words.

2) Adverbs of degree: Adverbs of degree will enhance the semantic intensity of the words in the text, illustrating an exaggerated effect and presenting irony [27]. In sentence 不过我经常碰到异常自信，自以为是的男性，也让人吃惊。(But it's also surprising how often I run into unusually confident, self-righteous males.) 异常(exceptional) expresses exaggeration, and it is ironic to somebody.

3) Internet vocabulary: Internet vocabularies are widely used on the internet, which may be helpful for sarcasm detection, such as 醉了(drunk), which expresses an attitude of finding someone's actions or something unexplainable

4) Homophonic words: Most homophonic words are deformed words with similar pronunciation to the original words or new words created on the internet to incorporate fun and humor or to express a specific mood [28]. Somebody may humorously write 杯具 (cupcake) instead of 悲剧 (tragedy) since they share the same pronunciation.

5) Punctuation: According to [35], some special punctuation can emphasize the effect of irony in the proper context and help readers understand the author's intent. Punctuation marks such as question marks, exclamation points, quotation marks, and apostrophes could emphasize irony [27]. If these symbols are used more than three times consecutively, they convey further emphasis and enhance irony [36].

B. Chinese Sarcasm Datasets

To extract more sarcasm linguistic feature words, a collection of Chinese sarcasm datasets is conducted. Table II illustrates the Chinese sarcasm datasets. All datasets are about the classification of sarcasm except for the first dataset, SMP ECISA, and the last dataset, Weibo Sentiment. The first dataset, SMP ECISA, focuses on implicit sentiment analysis. It contained implicit positive sentiment, implicit negative sentiment and no sentiment. The rationale for including the final dataset is that, although it pertains to sentiment analysis, the author regards sarcastic semantic recognition as a significant aspect of the research.

TABLE II. CHINESE SARCASM DATASET

Name	Size	Used by	Model	Performance
SMP ECISA	Neutral: 10012 Positive: 5925 Negative: 5973	[37]	KG-MPOA	Macro F1 0.777
		[38]	BERT-BiLSTM	Macro F1 0.775
Ciron	Not ironic: 4343 Unlikely ironic: 3391 Insufficient evidence: 64 Weakly ironic: 838 Strongly ironic: 130	[39]	BERT	F1: 0.572 A: 0.603
Ciron + Chinese Sarcasm	Not ironic: 5343 Ironic: 5425	[27]	IDIHR	F1:0.8124 A: 0.8149
ToSarcasm	Not ironic: 2435 Ironic: 2436	[40]	TOSPrompt	F1:0.7320 A: 0.7176
Weibo Sarcasm	Not ironic: 2000 Ironic: 2000	[24]	ISR	F1: 0.7793
		[33]	NB	A: 0.6945
Multimodal Sarcasm	Not ironic: 1179 Ironic: 1009	[41]	FCAM	F1: 0.8778 A: 0.8813

C. Chi-Square Test for Sarcasm Linguistic Feature Extracting

The chi-square test can be used to extract sarcastic linguistic features that are closely related to sarcasm. The chi-square test posited that the characteristics and categories operate independently, subsequently assessing the correlation through deviation analysis. A low chi-square test value indicated that the correlation between the two variables might be coincidental and lacked significance. Conversely, a high chi-square test value suggested a stronger correlation that could be utilized as a categorical feature. Consequently, the chi-

square test stood out as the efficient and suitable approach for feature selection [24].

III. Research Methodology

This section will introduce data description and preprocessing, text representation, text classification, evaluation of sexism detection, and experiment settings.

A. Data Description and Preprocessing

The dataset utilized in this study is a Chinese sexism dataset named Sina Weibo Sexism Review (SWSR). It was gathered from the Sina Weibo platform between June 2015 and June 2020 by [2]. The comments are labeled as sexism or not sexism. Among the 8,969 initial comment texts, there are six instances of duplication in contents but with different user information. In this research, user information is not used. Hence, the duplicated comments are removed, resulting in 8,963 comments.

To eliminate the noise in the text, data preprocessing is conducted. The original dataset was converted from traditional Chinese to simple Chinese by [2]. We conducted the following processes: converting full-corner text content to half-corner, converting punctuation symbols from English to Chinese, and converting uppercase English to lowercase English.

B. Text Representation

Three text representations are conducted in the final model.

1) Pre-trained Nezha tokenizer: Nezha is a transformer-based pre-trained model, like BERT and RoBERTa. It has been trained on large-scale Chinese corpus and has obtained outstanding performance in many Chinese NLP tasks [42]. Then, we expressed the comments with the pre-trained Nezha tokenizer. In this study, the sentence length is set to 150. Sentence lengths exceeding 150 are truncated, and sentences less than 150 are filled with [PAD]. After the Nezha tokenizer, the sentence is expressed with input ids, token type ids, and attention masks.

2) Text representation with sexist lexicon: A sexism lexicon with 3,016 words created by [2] is utilized for comments representation using Bag of Word Vector (BoWV) on the sexism lexicon. The frequency of each word in the sexism lexicon for each sentence phrase is calculated to a vector as a linguistic attribute.

3) Text representation with sarcasm lexicon: Firstly, the sarcasm lexicon is constructed. To construct the sarcasm lexicon, the sarcasm-related feature words are collected. Irony-related feature words are obtained by the chi-square test. The chi-square test is conducted on the SMP ECISA dataset which is for evaluating Chinese implicit sentiment analysis. Non-implicit content and negative implicit content are used, while positive implicit content is excluded. The sarcastic feature words identified using the chi-square test are subsequently picked manually, obtaining 85 words. The same operation is conducted on the Ciron dataset. The content is relabelled before the chi-square test. After relabeling the content, items labeled 1 and 2 are classified as non-sarcasm, while those labeled 4 and 5 are categorized as sarcasm. Meanwhile, entries labelled with 3 are disregarded because of insufficient evidence of sarcasm. Subsequent to the chi-square test and manual selection, 28 words remained as feature words. Accordingly, no prominent sarcasm features are discovered in the ToSarcasm and BSC datasets using the chi-square test. The words selected from SMP ECISA 2021 and Ciron are combined with the words selected from other related research, and 193 sarcastic linguistic feature words are finally obtained.

Then, the sarcastic lexicon with 193 words is utilized for comment representation using BoWV. Following text representation approach with sexism lexicon, the frequency of each word in the sarcasm lexicon for each comment is calculated as a vector to represent sarcasm linguistic features.

C. Text Classification

To enhance the classification accuracy of sexism detection, sarcastic features and sexism features are considered to be combined with the deep learning method. Fig. 1 illustrates the architecture of the Sarcasm-sexism-CNNs-Nezha model. This model has four layers: mCNNs-Nezha layer, sexism lexicon layer, sarcasm lexicon layer, and output layer. The output of the sexism layer is multiplied by the output of the sarcasm lexicon layer, resulting in a combined feature output that contributes 20% to the final output. In contrast, the output from the mCNNs-Nezha layer accounts for 80% of the final output. Upon applying SoftMax to the result, the text is categorized as either sexist or non-sexist.

1) mCNNs-Nezha layer: The mCNN-Nezha layer accounts for 80% of the final result. It is a deep learning-based model consisting of the Nezha layer, transposition layer, mCNNs layer, and linear layer.

a) Nezha layer: Through the Nezha tokenizer, it can obtain input ids, token type ids and masks. As a pre-trained transformer-based model, Nezha contains the Nezha embeddings layer, Nezha encoder layer, and Nezha pooler layer. There are 12 hidden layers in the Nezha encoder layer. The last hidden layer is used as input for the transposition layer. The whole information, both the [CLS] information, which contained the whole information of the sentence and word embedding for characters in the sentence, is used. The data size is [b, l, h]. b is the batch size, l is the length of sentences, and h is the hidden size in the hidden layer. In our research, it is [32, 150, 768].

b) Transposition layer: A transposition is conducted on the dimensions of 2 and 3 in (1) and obtains data with the size of [b, h, l], which is [32, 768, 150] in this research.

$$D' = D^{T_{2,3}} \quad (1)$$

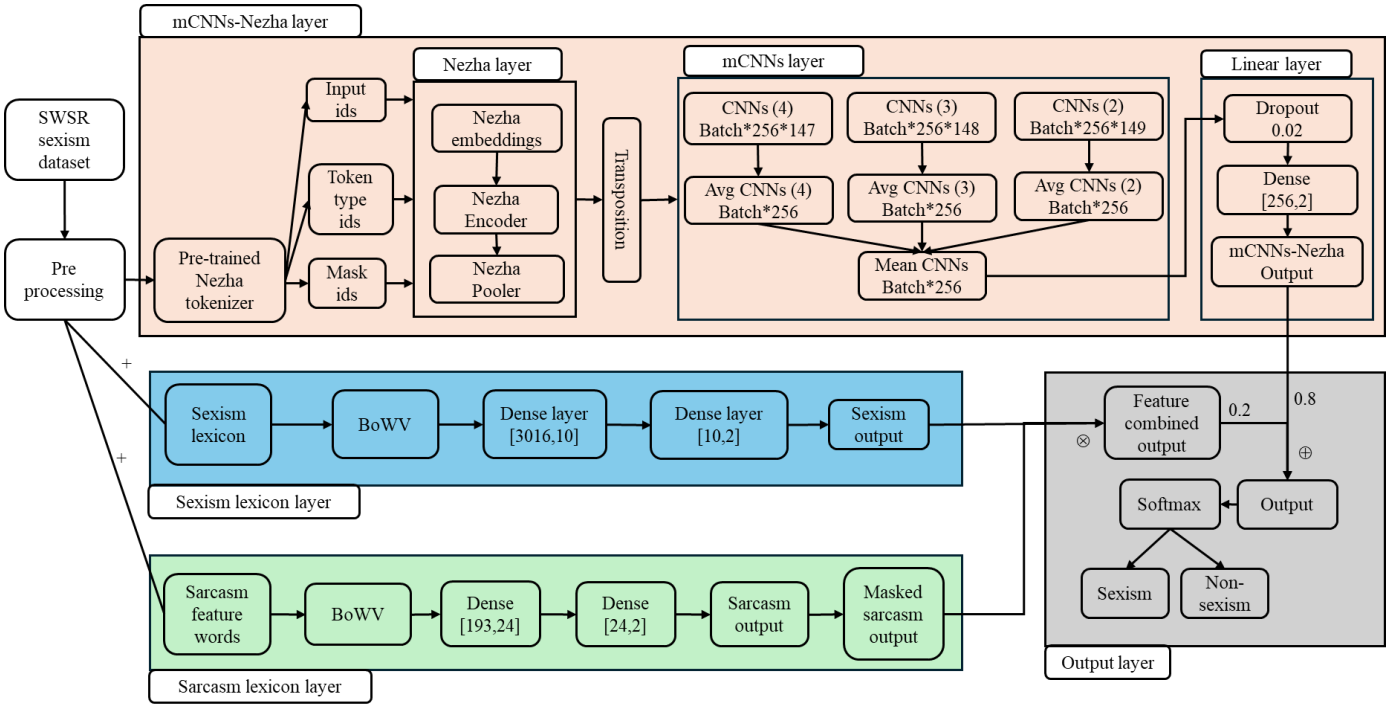

Fig. 1. The architecture of the sarcasm-sexism-mCNNs-Nezha model

c) mCNNs layer: The mCNNs layer contains three CNNs with kernels of 2, 3, and 4. After the CNN in (2), the data size is [b, o, l-k+1]. k is kernel size. o is the output channel with a value of 256. Hence, the feature is reduced.

$$CNN_k = CNN(D', k), \quad k=2,3,4 \tag{2}$$

To align features, an average operation is conducted on the third dimension in (3), and each CNN obtains data with the size of [b,o].

$$mCNN_k = Average(CNN_k^3), \quad k=2,3,4 \tag{3}$$

Then, an average operation is conducted on the three $mCNN_k$ on dimension 2 in (4). The final output of this layer is [b,o]. It can better capture words with two, three, or four characters, which is consistent with the Chinese word expressing a meaningful thing with two, three, or four characters.

$$mCNN = \frac{\sum_2^4 mCNN_k}{3} \tag{4}$$

d) Linear layer: The output from the mCNNs layer is fed into a linear layer. After a dropout of 0.02, a fully connected neural network is conducted and obtains an output with two values. The output of this layer is [b,2].

2) Sexism lexicon layer: The comments have been expressed as vectors using BoWV with the sexism lexicon. Then, the vector is fed into two densely connected neural networks in order in (5) (6) and results in an output with a two-dimensional vector. The first dense layer integrates the characteristics of sexism and executes feature mapping, encapsulating the intricate relationships among the features. The subsequent layer additionally conducts feature mapping and utilizes the extracted features to correlate with the probabilities of the two predictive classifications.

$$z^{(1)} = W^{(1)T} X_{sex} + b^{(1)} \tag{5}$$

$$O_{sex} = z^{(2)} = W^{(2)T} z^{(1)} + b^{(2)} \tag{6}$$

3) Sarcasm lexicon layer: The comments have also been expressed as vectors using BoWV with a sarcastic lexicon. Then, it is fed into two densely connected neural networks in order in (7) (8) and obtains a two-dimensional output. A masked operation is adopted on the output, where the first value is bigger than the second value and masked with -1, otherwise with 1, as indicated in (9). The masked output would multiply with the output of the sexism lexicon layer. This sarcasm masking mechanism has an important impact on the final output.

$$z^{(1)} = W^{(1)T} X_{sar} + b^{(1)} \tag{7}$$

$$O(l) = z^{(2)} = W^{(2)T} z^{(1)} + b^{(2)} \tag{8}$$

$$O_{sar} = \begin{cases} -1 & O(l)_0 > O(l)_1 \\ 1 & O(l)_0 \leq O(l)_1 \end{cases} \tag{9}$$

4) Output layer: The influence of the sexism lexicon layer's output O_{sex} on the final result, whether positive or negative, is dependent upon the sarcasm lexicon layer's output O_{sar}. If the value of O_{sar} is -1, it indicates a negative effect. Conversely, a value of O_{sar} equal to 1 signifies a positive effect, as presented in (10). The combined output, O_{lex}, constitutes 20%, while the output from O_{mn} mCNNs-Nezha layer comprises 80% of the output O_v in (11). A SoftMax is performed on O_v in (12).

$$O_{lex} = O_{sex} \otimes O_{sar} \tag{10}$$

$$O_v=0.8*O_m+0.2*O_{lex} \quad (11)$$

$$Let\ O(v)=(v_0,v_1), P(y=i)=SoftMax(v_i)=\frac{e^{v_i}}{\sum_{j=0}^{1} e^{v_j}},\ i=0,1 \quad (12)$$

The sarcasm masking mechanism algorithm is described as follows:

Algorithm 1: Sarcasm masking mechanism

```
Input: Output from mCNNs-Nezha layer (O1)
       Output from sexism lexicon layer (O2)
Output from sarcasm lexicon layer without masking (O3)
While (data in batch) do
    For (each comment) do
        If (O3[0] > O3[1]) then
            O2[0] = O2[0] * (-1)
            O2[1] = O2[1] * (-1)
        End
        O[0] = O1[0] * 0.8+O2[0] * 0.2
        O[1] = O1[1] * 0.8+O2[1] * 0.2
    End
```

D. Evaluation

As a classification task, confusion metric, accuracy, and F1 score are used for evaluation.

Confusion matrix is an essential instrument for evaluating the performance of classification models in classification tasks. As indicated in Table III, True Positive (TP) refers to the count of TP instances; True Negative (TN) denotes the count of TN instances; False Positive (FP) indicates the count of FP instances; False Negative (FN) represents the count of FN instances.

TABLE III. CONFUSION MATRIX FOR CLASSIFICATION EVALUATION

	Predict Positive	**Predict Negative**
Actual Positive	True Positive (TP)	False Positive (FP)
Actual Negative	True Negative (FN)	True Negative (TN)

Accuracy denotes the proportion of samples accurately identified by the model relative to the total number of samples (13).

$$Accuracy=\frac{TP+TN}{TP+TN+FP+FN} \quad (13)$$

F1 score is the harmonic average of precision and recall, designed to address the trade-off between these two metrics in classification problems, as indicated in (14). Meanwhile, precision denotes the ratio of correctly predicted positive instances to the total number of instances predicted as positive by the model, as presented in (15). At the same time, recall denotes the ratio of accurately predicted positive instances by the model to the total number of actual positive instances, as given in (16).

$$F1\ score=\frac{2*Precision*Recall}{Precision+Recall} \quad (14)$$

$$Precision=\frac{TP}{TP+FP} \quad (15)$$

$$Recall=\frac{TP}{TP+FN} \quad (16)$$

The 5-fold cross-validation method is employed to assess the model's performance and stability by partitioning the dataset into five subsets. By systematically employing several subsets as training and validation sets, the bias in model evaluation can be significantly mitigated.

E. Experimental Settings

Table IV illustrates the experimental settings.

TABLE IV. EXPERIMENTAL SETTINGS

Items	**Value**
GPU	NVIDIA RTX 4090 24G
Memory	64G
Cuda	v12.1.105
PyTorch	v2.2.1
Max Length of Sentence	150
Batch size	32
Epochs	4
Loss	Cross Entropy Loss
Optimizer	AdamW

IV. RESULT

A range of models are conducted to improve the model performance, including BERT-Fc, RoBERTa-Fc, Nezha-Fc, mCNNs-BERT, mCNNs-RoBERTa, mCNNs-Nezha, BERT-BiLSTM, RoBERTa-BiLSTM, and Nezha-BiLSTM, excluding the baseline and the proposed Sarcasm-sexism-mCNNs-Nezha. In the model of BERT/RoBERTa/Nezha-Fc, a fully connected neural network is concatenated after BERT/RoBERTa/Nezha. In the model of mCNNs-BERT/RoBERTa/Nezha, the mCNNs layer is concatenated after BERT/RoBERTa/Nezha. In the model of BERT/RoBERTa/Nezha-BiLSTM, the BiLSTM is concatenated after BERT/RoBERTa/Nezha.

The experiment result is illustrated in Table V. The proposed Sarcasm-sexism-mCNNs-Nezha model achieves the following performance metrics: 82.65% accuracy, 80.49% macro F1 score, 82.49% weighted F1 score, 86.94% non-sexism F1 score, and 74.05% sexism F1 score. It can be reported that the proposed model obtains the best performance on all five metrics except for sexism F1. Although the sexism F1 score in the proposed model is 0.39% lower than that of the RoBERTa-BiLSTM model, its accuracy is 0.55% higher. The mCNNs-Nezha model demonstrates the second-best performance.

As the best-performing model, Sarcasm-sexism-mCNNs-Nezha integrates sexism and sarcasm features, leveraging a deep learning framework with a masking mechanism. It outperforms all other deep learning approaches in Table V that do not incorporate sarcasm detection. It demonstrates significant improvements over the baseline model (BERT [2]) with an increase of 2.05% in accuracy and a 2.89% rise in macro F1. Specifically, the model achieves a 3.65% improvement in sexism F1, outperforming the 1.14% improvement in non-sexism F1. This highlights its superior capability in addressing sexism compared to non-sexism.

TABLE V. EXPERIMENTAL RESULT (%)

Model	Accuracy	Macro F1	Weight F1	Non-sexism F1	Sexism F1
BERT [2]	80.6	77.6	-	85.8	69.4
RoBERTa-lexicon [2]	80.4	78.0	-	85.3	70.7
BERT-Fc	81.86	79.77	81.78	86.25	73.28
RoBERTa-Fc	82.07	80.10	82.03	86.32	73.87
Nezha-Fc	81.84	79.61	81.69	86.31	72.91
mCNNs-BERT	81.55	79.45	81.48	85.99	72.90
mCNNs-RoBERTa	82.45	80.32	82.32	86.78	73.86
mCNNs-Nezha	82.53	80.24	82.32	**86.94**	73.55
BERT-BiLSTM	81.69	79.52	81.58	86.15	72.90
RoBERTa-BiLSTM	82.10	80.33	82.16	86.22	**74.44**
Nezha-BiLSTM	82.06	79.88	81.93	86.48	73.29
Sarcasm-sexism-mCNNs-Nezha	**82.65**	**80.49**	**82.49**	**86.94**	74.05

V. DISCUSSION

A. Confusion Matrix of Proposed Model

The confusion matrix of the proposed model is displayed in Fig. 2. There are 2,229 true predicted as sexisms, 863 false anticipated as sexisms, 5,179 accurately predicted as non-sexisms, and 692 false predicted as non-sexisms.

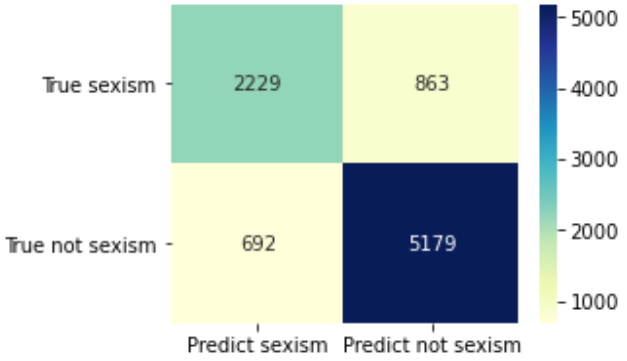

Fig. 2. Confusion matrix of proposed sarcasm-sexism-mCNNs-Nezha model

B. The Stability of Proposed Sarcasm-sexism-mCNNs-Nezha Model

The stability of the proposed model is demonstrated in Fig. 3. Fold 2 to fold 5 exhibits a higher concentration across all metrics. Fold 1 demonstrates a focus on non-sexism F1, suggesting that the capacity to identify non-sexism has not significantly altered. Nonetheless, on the other four metrics, fold 1 exhibits inferior performance compared to other folds, particularly for the sexism F1 score.

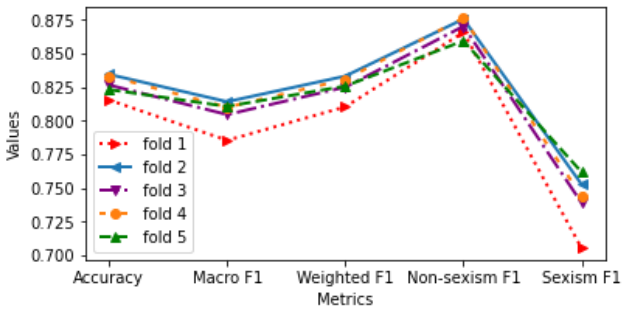

Fig. 3. The stability of the proposed Sarcasm-sexism-mCNNs-Nezha model

To examine the performance of this model on fold 1, a comparison between the mCNNs-Nezha model with the second-highest accuracy and the proposed model is conducted. The result is depicted in Fig. 4. It illustrates that the non-sexism F1 score is improved in this model, while the sexism F1 score is decreased. However, the accuracy is increased. This indicates that even though the performance of this model is worse on fold 1, it also improved the accuracy compared with the mCNNs-Nezha model. It illustrates the effectiveness of the proposed model.

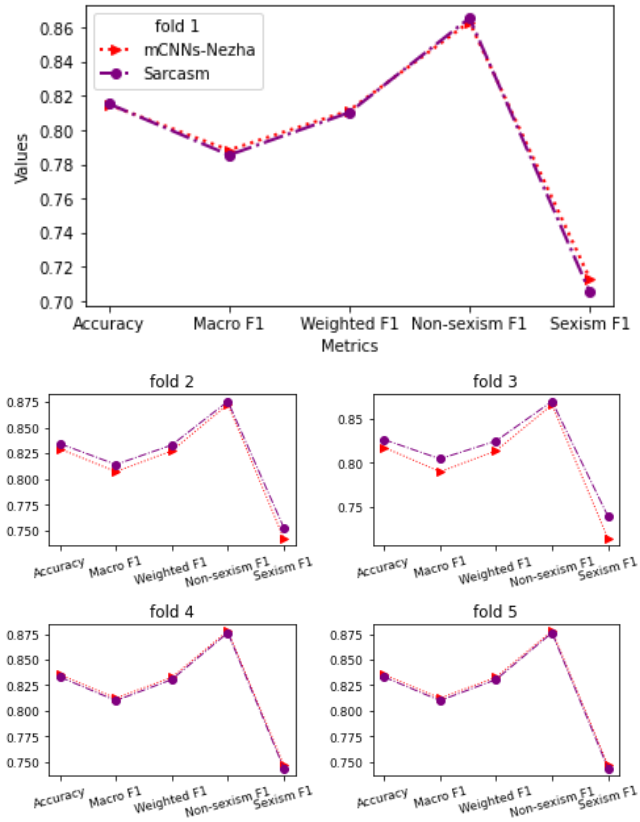

Fig. 4. Compared with the mCNNs-Nezha model on five folds

Nevertheless, the comparison of fold 2 to fold 5 demonstrates similar results in fold 4 and fold 5, while exhibiting a relatively greater enhancement in fold 2 and fold

3, as displayed in Fig. 4. It indicated that the proposed model is beneficial in enhancing performance in most cases.

C. Manually Analysis

A manual evaluation of sexist texts incorrectly identified by the mCNNs-Nezha model yet accurately by the proposed model is conducted. Table VI presents identical examples of sexist remarks that are misclassified by the mCNNs-Nezha model but accurately classified by the proposed approach. Sentences 2 and 3 contain metaphors, such as 田园狗 (a rural dog), which means pastoral feminist, and 鸡 (chicken), which means prostitute. Sentence 3 contains irony, which means, 'I do not admire you at all.'

TABLE VI. EXAMPLES OF SEXISM TEXT WRONGLY CLASSIFIED BY BASIC MODEL BUT RIGHTLY BY SARCASM-SEXISM-MCNNS-NEZHA MODEL

Id	Comments
1	明显田园狗做法。哈哈哈。这婚结的都不如去找鸡 This is obviously a rural dog behavior. Hahaha. This kind of marriage is worse than finding a prostitute.
2	说人家坦克真的好笑吗？那你们金针菇我们也可以笑吧？不会这么开不起玩笑吧，不会吧不会吧？ Is it really funny to say that others are tanks? Then can we, the Enoki mushrooms, also laugh? You can't be so incapable of taking a joke, right? No way, no way?
3	你真贴心，身为女人这么照顾男人的各种情绪，佩服你呢 You are so considerate. As a woman, you take care of a man's emotions. I admire you.

D. Ablation Experiment

To evaluate the significance of each component, an ablation experiment is conducted. There are three components except for Nezha. Table VII illustrates the result of the ablation experiment.

TABLE VII. ABLATION EXPERIMENT RESULT (%)

Id	Sarcasm	Sexism	mCNNs	accuracy	Macro F1	Weight F1	Non-sexism F1	Sexism F1
1	√	√	√	**82.65**	**80.49**	**82.49**	86.94	**74.05**
2		√	√	82.56	80.32	82.37	86.93	73.71
3	√		√	82.55	80.23	82.32	**86.98**	73.48
4	√	√		82.26	80.05	82.10	86.67	73.43
5	√			82.07	79.65	81.81	86.63	72.67
6		√		82.14	79.81	81.93	86.63	73.00
7			√	82.53	80.24	82.32	86.94	73.55
8				81.84	79.61	81.69	86.31	72.91

1) All three components have a positive impact: As summarized in Table VII, no matter eliminating one, two, or three components like sarcasm layer, sexism layer, and mCNNs layer from this model, the performance of the model on each metric such as accuracy, macro F1 score, weighted F1 score, sexism F1, non-sexism F1, is decreased except that the non-sexism F1 is improved 0.04% while eliminating sexism component. This indicates that every component has a positive effect on the proposed model.

2) mCNNs contributed more than sarcasm or sexism: Fig. 5 illustrates the model performance degradation while eliminating one component from the proposed model. It is evident that the model's performance declines when one component is removed and that mCNNs are the most crucial component of the proposed model, followed by sarcasm and sexism. It is noteworthy that the non-sexism F1 improves when the sexism component is eliminated, even though overall performance declines. The reason may attributed to the fact that the sexism lexicon layer tends to classify text containing sexist words as sexism. When the sexism component is deleted, some text containing sexist words may be classified as non-sexism, leading to improvement in non-sexism F1 score.

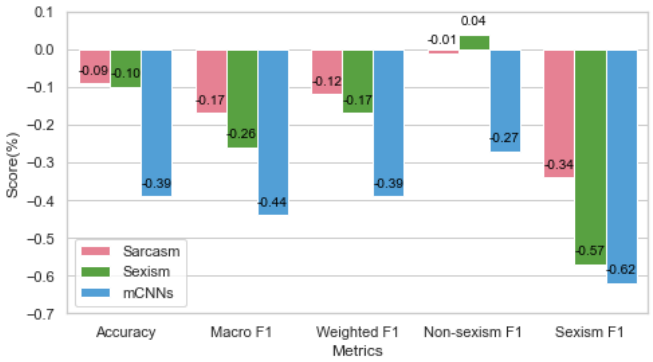

Fig. 5. Eliminating one component from Sarcasm-sexism-mCNNsNezha

3) Impact of sarcasm component: Fig. 6 illustrates the degradation of eliminating the sarcasm component and eliminating both the sarcasm component and the sexism component. If the sarcasm component is removed from the model, there will be a decrease of 0.09%, 0.17%, 0.12%, 0.01%, and 0.34% on the accuracy, macro F1, weighted F1, non-sexism F1, and sexism F1, respectively. It indicates that the sarcasm component has a positive effect on sexism detection, and it has affected more the sexism content than the non-sexism content.

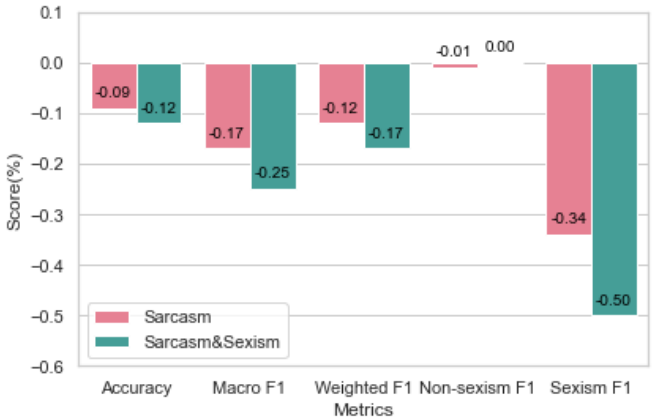

Fig. 6. Impact of sarcasm

It also illustrates that it decreases more by deleting both sarcasm and sexism from this model. It indicates that the combination of sarcasm and sexism has more influence than sarcasm. The effectiveness of sarcasm masking mechanisms is proven.

Both strategies demonstrate more impact on sexist content than non-sexism content. This indicates that they can improve the detection of sexism more than non-sexism.

4) Impact of sexism component: Fig. 7 illustrates the degradation of eliminating the sexism component and eliminating both sarcasm and sexism. It suggests that no matter whether the sexism *component* or a combination of sarcasm and sexism has a positive impact on the model. From the perspective of accuracy, the combination of sarcasm and sexism has a higher impact. Moreover, they have the same weighted F1 score.

Nevertheless, from the perspective of the macro F1 score, the combination of sarcasm and sexism has more influence than sarcasm (Fig. 6) but less influence than sexism. In addition, it is evident that the sexism *component* has a positive impact on detecting sexism while a negative impact on detecting non-sexism. Meanwhile, the combination of sexism and sarcasm has a positive impact on sexism but has no impact on non-sexism. It indicates a complex interaction between sexism and sarcasm.

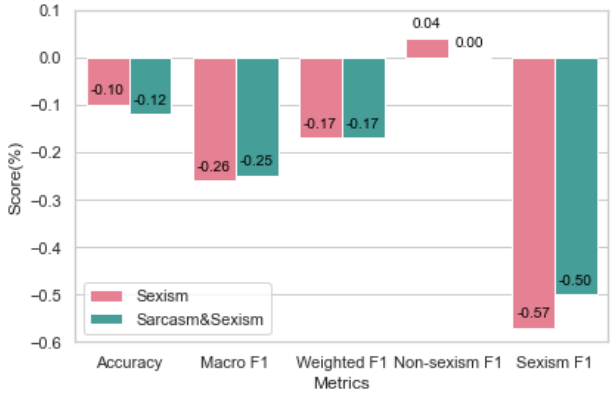

Fig. 7. Impact of sexism

5) Decision for coefficients: The output of the combination of sarcasm and sexism accounts for 20% of the final output, and the output of the mCNNs accounts for 80% of the final output. Different coefficients are adopted.

TABLE VIII. MODEL WITH DIFFERENT COEFFICIENTS (%)

Coefficient For mCNNs-Nezha	Coefficient for Combination of Sexism and Sarcasm	Accuracy	Macro F1
0.75	0.25	82.56	80.40
0.8	0.2	82.65	80.49
0.85	0.15	82.60	80.44
0.9	0.1	82.60	80.55

Table VIII illustrates the performance of the model with different coefficients. It can be discovered that the coefficient of (0.8, 0.2) contributes the best performance on accuracy. However, the coefficient of (0.9, 0.1) contributes the best performance on macro F1. Since (0.8, 0.2) has the highest accuracy, it is selected for the final model.

VI. CONCLUSION

An effective way to detect Chinese sexism text is proposed. The model combines a sarcasm lexicon, sexism lexicon, transformer-based Nezha, and three CNNs. The accuracy and macro F1 score reached 82.65% and 80.49%, outperforming the baseline with 2.05% and 2.89%, respectively. A sarcasm lexicon is constructed, and a sarcasm masking mechanic is proposed. In the ablation experiment, all evaluation metrics are decreased when sarcasm is removed, proving the effectiveness of the sarcasm masking mechanic. The sarcasm masking mechanic has the potential to generate the detection of sexism in other languages. However, this research only considers sarcasm feature words and does not account for inconsistent expressions in text or other sarcasm detection techniques that may be useful for detecting sexism, which contains sarcasm. Additionally, data augmentation methods, particularly back translation, can be considered, as some implicit sexist comments become explicit sexist content after being translated into English.

Machine Learning-Enabled Personalization of Programming Learning Feedback

Mohammad T. Alshammari
College of Computer Science and Engineering, University of Ha'il, Ha'il, Saudi Arabia

***Abstract*—Acquiring programming skills is daunting for most learners and is even more challenging in heavily attended courses. This complexity also makes it difficult to offer personalized feedback within the time constraints of instructors. This study offers an approach to predict programming weaknesses in each learner to provide appropriate learning resources based on machine learning. The machine learning models selected for training and testing and then compared are Random Forest, Logistic Regression, Support Vector Machine, and Decision Trees. During the comparison based on the features of prior knowledge, time spent, and GPA, Logistic Regression was found to be the most accurate. Using this model, the programming weaknesses of each learner are identified so that personalized feedback can be given. The paper further describes a controlled experiment to evaluate the effectiveness of the personalized programming feedback generated based on the model. The findings indicate that learners receiving personalized programming feedback achieve superior learning outcomes than those receiving traditional feedback. The implications of these findings are explored further, and a direction for future research is suggested.**

***Keywords*—Machine learning; programming; learning outcome; feedback; personalization**

I. Introduction

The advances in Artificial Intelligence (AI) and its subfield, Machine Learning (ML), are rapidly transforming the education landscape, offering innovative approaches to improve teaching methods, accelerate learning, and deliver personalized educational experiences. AI-powered tools, including adaptive learning systems, intelligent tutoring platforms, and predictive analytics, are revolutionizing the traditional pedagogical landscape by generating personalized feedback, suggesting individualized learning pathways, and forecasting academic achievement [1], [2]. These technologies serve the diverse interests and needs of learners and support data-driven interventions, thereby enhancing the levels of engagement and retention both in traditional and online learning environments [3].

An example of this can be seen in adaptive learning systems that use AI to modify the material and pace of learning based on how each learner performs, resulting in a highly personalized educational experience [4]. Another AI application is Intelligent Tutoring Systems (ITSs), which can improve personalization by simulating one-on-one teaching and using advanced algorithms to analyze how a learner behaves and provide personalized guidance based on those metrics. Learner interaction data can also be employed as predictive analytics, which fully utilizes advanced ML models to analyze historical and real-time data, predict learners' outcomes, identify at-risk learners, and allow for considerable strategic resource provision. ML can also guide evidence-based decision-making, enabling educators to adjust curricula and instructional strategies by appropriately identifying learner behavior and patterns during learner-content interaction [5].

Programming is one of the most common subjects taught in a computer science curriculum. Still, it introduces several challenges, including mapping abstract concepts with practical activities and high dropout rates in introductory courses [6]. AI and ML in education can help mitigate these challenges by creating dynamic and tailored learning experiences. AI-based educational systems, for example, may analyze learner-system interaction data to develop personalized learning pathways, adjusting how content is delivered to suit learners' needs [7], [8].

Many ML models have been developed. For example, neural networks can be utilized to create learning recommendations that recommend personalized learning activities to keep learners engaged and retain knowledge [9]. Other ML models, like fuzzy logic, have also been used to offer personalized feedback and modify instructional approaches according to learners' characteristics, such as knowledge level and task accomplishments [10]. Recent approaches view chatbot-assisted programming systems powered by ML techniques as powerful learning tools that aid debugging, explain code errors, and suggest possible solutions, thereby serving as a proxy for a human tutor [11].

A vast majority of ML algorithms have been employed to predict programming learning performance; some of these are Decision trees (DT), Random Forests (RF), Support Vector Machines (SVM), Logistic Regression (LR), k-nearest Neighbors (kNN), and Artificial Neural Networks (ANN) [3], [12], [13], [14]. These models leverage learner engagement patterns, prior learning activities, and coding behavior to provide learners with timely intervention [15].

ML-enabled behavioral analytics tools can track and analyze learner engagement with resources such as coding environments, learning management systems, online coding platforms, and discussion forums. The analyses can reveal meaningful relationships between activities like active coding and passive lecture reviewing that may impact overall learning. Thus, actionable insights drive the curriculum design, define effective intervention strategies that address individual learning needs, and optimize the effectiveness of programming educational outcomes.

A key limitation in existing ML model-based investigations for programming education is the lack of a comprehensive approach that spans from data collection to evaluation in authentic learning environments [8], [16], [17]. While prior research has explored ML applications in programming learning, many studies focus on isolated aspects, such as predictive modeling or feedback generation, without fully integrating these components into a structured learning framework. This research gap highlights the need for further investigation into how ML models can be systematically leveraged to enhance personalized learning experiences. To address this, the present study conducts a comparative analysis of ML models to identify programming learning weaknesses based on learners' prior knowledge, time spent, and Grade Point Average (GPA). Identifying the most effective ML model can facilitate the delivery of personalized programming feedback tailored to individual learners' needs. Additionally, an experimental evaluation is implemented to explore the impact of personalized feedback on learning performance. This dual approach enhances the theoretical understanding of ML-driven feedback mechanisms and provides empirical evidence to guide future advancements in AI-supported programming education.

The key research questions are as follows:

RQ1. How can machine learning be used to predict specific weaknesses in learners' programming skills, enabling feedback personalization?

RQ2. Can personalized feedback derived from machine learning predictions enhance learning outcomes?

This paper is structured as follows: Section II presents related work. Section III outlines the methodology used in this study. Section IV offers the results. Section V discusses the findings, and Section VI concludes the paper.

II. Related Work

The recent reviews on integrating AI and ML in online learning platforms highlight their essential role in personalizing learning through customized content delivery for individual learners [1], [12], [13], [14]. The dynamic adaptation and targeted interventions through ML techniques (e.g., clustering, reinforcement learning, deep learning) are promising to enhance learner engagement, retention, and academic performance [18]. Yet, data privacy concerns, high resource requirements, and the risk of diminishing human interaction limit the widespread adoption. Careful implementation and ongoing refinement would be critical to mitigate these challenges and realize the potential benefits of more mainstream AI-based online learning platforms.

A predictive analysis of learner performance in programming tutoring comparing different ML models with ANN on dataset input finds that ANN outperforms other methodologies such as SVM, DT, and kNN [19]. However, the study's limitations include its targeting of a specific cohort of Norwegian learners, domain-specific instructions, and potential biases integrating into the suggested framework that may undermine the present findings' utility to broader domains.

Another approach investigates how ML algorithms are implemented to predict learner programming performance as high or low based on different variables, including computational identity, computational thinking, programming empowerment, gender, and programming anxiety [16]. DT algorithm had the best accuracy of 96.6%, while the best cross-accuracy was obtained with RF. On the contrary, kNN performed the least favorably. Their study shows that male and university learners scored higher than female and high school learners. However, the groups were not significantly different as far as programming anxiety is concerned. The limitations of the research are the focus on the demographic of Turkish learners, the specificity of the constructs relating to specific tasks, and the need for generalisability across datasets of different populations.

The study in [3] offers a prediction model powered by AI with Genetic Programming (GP) modeling to analyze and predict learner academic performance in an online engineering education system. The performance of the GP model was better than that of traditional AI methods (e.g., ANN and SVM), demonstrating high accuracy and efficient predictions regarding learning effectiveness. Key determinants of performance are knowledge transfer, participation in class, and summative assessment, with prior knowledge having a limited effect. However, though it does advance these areas, the limited sample size, lack of real-time adaptability of the model, and locally specific findings limit its wider application and require additional research.

An extensive review of ML techniques applied to predict the learner's performance in the context of programming courses emphasizes the strength of different algorithms, the nature of the organization of datasets, and the significance of the evaluation metrics [20]. According to the review results, SVM had the best accuracy of 93.97%, whereas deep learning methods like Deep Neural Networks (DNN) have achieved significant success in detecting complex data patterns. Most studies used academic records as a dataset type; however, a meta-analysis of multiple data sources improved prediction accuracy. The review highlights the importance of using different metrics to evaluate model performance, including accuracy, F1-Score, precision, and recall, especially in unbalanced datasets. Noted limitations include using small or unbalanced datasets, a narrow range of algorithms, and overemphasizing accuracy. The results emphasize the need for larger datasets, more varied evaluation methods, and more examination of deep learning approaches to improve models of future predictive capabilities.

PerFuSIT is an example of a fuzzy logic-based module designed to personalize pedagogical approaches in ITSs for programming education [10]. This adaptive system updates different tutoring approaches dynamically, according to parameters such as performance measures, coding error types, help requests, and the time taken to solve a task. Therefore, through such an application, a fuzzy logic system can offer flexibility in the learning process, where the learners have different levels of interactivity, improving learners' performance and involvement. However, the dependency on expert regulations and the constrained testing environments may generate scaling challenges.

The study in [21] studied the relationship between the learning behaviors of learners and their grades in an online programming course employing the Random Matrix Theory to filter noisy data and discover possible patterns. It was observed that learners with superior academic performance regularly participated in practical tasks such as lab activities and exercises. The lower-achieving learners relied more on lecture notes and fell behind on engagement in practical tasks over time. This study demonstrated that data obtained from early-stage learning behaviors can be used as powerful binary predictors (pass or fail) of learning outcomes, and the use of cleaned datasets enabled significantly improved accuracy using ML algorithms, specifically SVM and XGBoost. However, this research also granted limitations; it had one institutional focus, short-term job performance outcomes, and methodological technical complexity, limiting the additional dissemination and uptake by broader generalization.

Another ML study uses data from a chatbot-assisted programming platform to explore the relationship between learning behaviors and programming performance [17]. The key performance features are solution verification, frequency of code review, code error correction using quizzes, programming practice logs, and engagement patterns. ANN produced better model predictions than other ML models like RF and SVM. While the study demonstrates the potential of ML for predicting outcomes, it is limited by its small sample size, single-institution focus, and short-term analysis of learning performance.

As an ML model, Recurrent Neural Networks (RNN) are also used as a basis for a personalized learning path recommendation system in the programming education domain [22]. The system can recommend appropriate problems to help the learner's speed and engagement by analyzing learners' ability charts and clustering users with similar skill levels. However, the system's reliance on advanced algorithms and lack of scalability testing may restrict its applicability and implementation in real-world scenarios, as they focus on data generated from a single online judge.

The study in [15] proposed personalized interventions based on the skills of at-risk learners as part of a Python programming course. Their study adopted advanced AI technologies (e.g., BERT and GPT-2) to generate personalized remedial content. Its personalized feedback significantly enhanced learners' coding competencies and learning strategies, demonstrating the power of AI-based interventions. However, the study also has limitations, including a relatively small cohort size, a focus on short-term outcomes, and reliance on resource-intensive AI models, which may limit applicability and scalability.

The study detailed in this manuscript differs from the above efforts to apply ML to programming education in three key aspects. First, it can be based on data retrievable from online learning platforms during a preliminary, intermediate, or final learning process. Second, different ML models can be evaluated using this data to find the best model for providing personalized programming feedback. Third, the empirical efficacy of such feedback in enhancing learning outcomes is assessed using controlled experimental evaluation.

III. METHOD

The experiment aims to use ML models to identify learners' weaknesses in Java programming learning and provide personalized learning feedback. Furthermore, it seeks to validate the effectiveness of this feedback in improving programming skills.

A. Hypotheses

There are two main hypotheses in this study as follows:

H1. Machine learning can be utilized to accurately predict specific weaknesses in learners' Java programming learning.

H2. Providing personalized feedback based on machine learning predictions will improve learners' performance in Java programming learning.

B. Data Collection

The experiment administers a comprehensive pre-test covering the essential concepts of basic Java programming. These concepts include syntax, variables, control flows (if, if-else, and switch), loops (while, do-while, and for loops), arrays, methods, classes, and objects. The pre-test contains 60 questions to cover 12 Java topics. Learners' responses to each concept are recorded to form the input dataset for training and testing the ML models. In addition, prior knowledge performance, time spent, and GPA are recorded.

C. Machine Learning Models

From data pre-processing, model selection, and training to evaluation, this phase lays the foundation for an ML model specifically designed to predict each learner's weaknesses from their pre-test scores, time spent on the exam, and GPA. The primary step involves validating the data by cleansing missing data, normalizing scores, and converting the categorical data (e.g., concept titles or feedback categories) to numerical values when required. The dataset will subsequently be randomly partitioned, allocating 70% for training and 30% for testing. The training dataset is utilized to develop the ML model, whereas the testing dataset evaluates its performance. So, several ML models such as RF, LR, SVM, and DT are compared to identify which model could best predict learners' weaknesses based on their pre-test, time spent, and GPA data. After finding a well-performing model, personalized guidance feedback will accordingly be delivered.

D. Personalized Feedback Generation

Based on the model's predictions, learners should be provided relevant feedback on the Java programming concepts they struggled with. For instance, personalized feedback will be prioritized and released when the model predicts that a learner struggles to grasp the programming concept while loops. The feedback input is pre-created per learning concept, with a theoretical overview, an example, an exercise, and a link to a video lesson suited to reflect the various learning types of learners.

E. Evaluation Metrics

In addition to the confusion matrix and Receiver Operating Characteristic (ROC) curves, alongside Area Under the Curve (AUC) scores, the predictive performance of the ML models is evaluated using metrics such as accuracy, precision, recall, and

F1-Score (displayed in formulas 1 through 4). These metrics are typically used in relevant work and are suitable for this study [23], [24]. A post-test is also used to investigate the effect and provide evidence for the advantages of using personalized feedback regarding improved learning outcomes.

$$Accuracy = \frac{TP+TN}{Total\ Predictions} \quad (1)$$

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

$$F1-Score = 2 \cdot \frac{Precision \cdot Recall}{Precision + Recall} \quad (4)$$

where,

- TP: True positive
- TN: True negative
- FP: False positive
- FN: False negative

F. Procedure

The experimental procedure is simplified and depicted in Fig. 1. After obtaining consent to participate in the experiment, a pre-test was conducted. The data collected was then used to train and test the ML models to select the best model for providing personalized feedback. Participants were randomly divided into two independent groups: experimental and control groups. The experimental group receives personalized feedback based on the selected ML model predictions, while the control group receives conventional feedback. Both groups were asked to follow the feedback for their learning.

This experimental setting was conducted in computer labs to ensure the experiment's control and to guarantee that participants completed the learning process based on the offered feedback. This process took five sessions, with each session lasting about 120 minutes. Once all learning sessions were finished, all participants completed the post-test.

IV. Results

This section presents the results pertaining to the prediction outcomes of the ML models. These predictions can be used of identifying the programming learning weaknesses of each learner. Furthermore, this section provides the results of the controlled experiment that aimed to investigate the effectiveness of learning Java programming through personalized feedback.

A. Dataset

This experiment involved 205 first-year undergraduate learners majoring in various computing disciplines. After collecting and pre-processing the pre-test results, 180 valid cases were identified for inclusion in the analysis of the ML models. The performance of these models was evaluated using standardized scores for each Java concept, categorizing learners as “weak” or “strong” according to a 50% threshold, time spent on the exam and GPA. Based on the optimal model, personalized feedback can be provided.

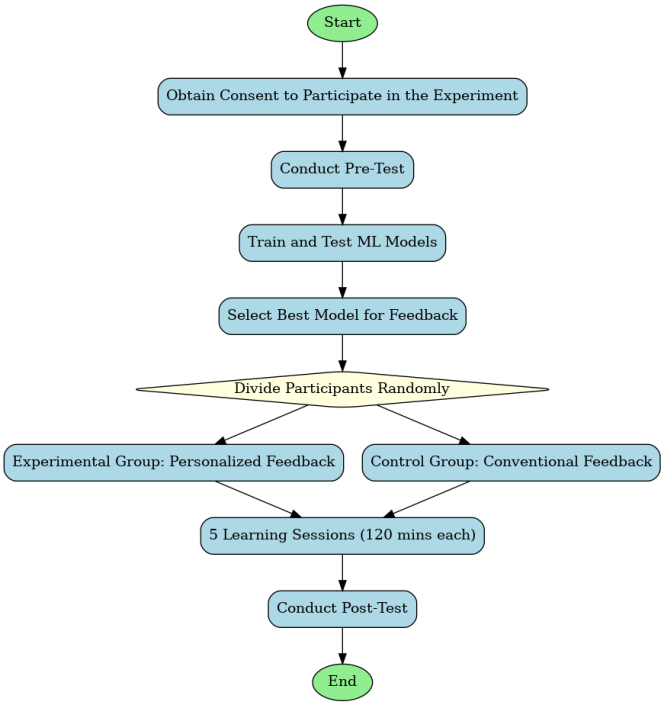

Fig. 1. Experimental procedure.

B. Analysis of the Machine Learning Models Performance

The dataset was utilized to analyze the four ML models: RF, LR, SVM, and DT. Table I summarizes the results of these models: accuracy, precision, recall, and F1-Score. Fig. 2 and Fig. 3 also present the confusion matrix and ROC curves with AUC scores, respectively. These findings will assist in identifying the appropriate ML model for the dataset.

Based on metrics analysis results, LR performs best at 98.33% accuracy meaning less errors, followed by SVM at 95% accuracy and finally RF at 81.67% accuracy. Looking into precision, SVM and LR is ahead in this perspective, with near-perfect precision that suggests low number of false positives. DT and RF are less effective since they have more false positives. Looking at the recall results, LR is outstanding (100%) at detecting all of the actual positive cases. SVM (97%) and RF (58%) display varying performance levels, while DT had the lowest recall results. For the F1-Scores, SVM (98.59%) and LR (97.96%) achieve a strong ratio between precision and recall. However, DT and RF can be less effective based on the results.

TABLE I. Performance Analysis of ML Models

Model	Accuracy	Precision	Recall	F1-Score
Random Forest	81.67%	93%	58%	72.00%
Logistic Regression	98.33%	96%	100%	97.96%
SVM	95.00%	100%	97%	98.59%
Decision Tree	75.00%	83%	68%	75.00%

In the confusion matrix results, LR has shown an exceptional level of accuracy and recall with a near 100% score in both metrics. LR can also predict positive and negative

outcomes with remarkable precision. SVM also had a high precision at 100% and a high recall at 97%, making it a strong candidate due to the balance between those two evaluation metrics. Although its recall is slightly lower than that of LR, this results in a much more competitive score. The RF model also performed well, with many true positives (35) and fewer false negatives (1). However, it was slightly decreased due to several false positives (10), leading to 93% precision. Given the model's simplicity, DT showed satisfactory recall (68%) and accuracy (75%). However, DT has also demonstrated a relatively high number of false negatives (11), signifying a worse performance than the other ML models.

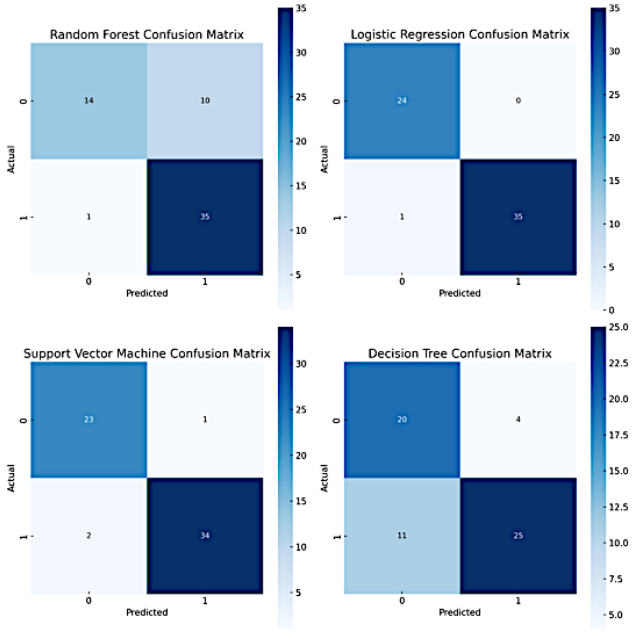

Fig. 2. Confusion matrix for the machine learning models.

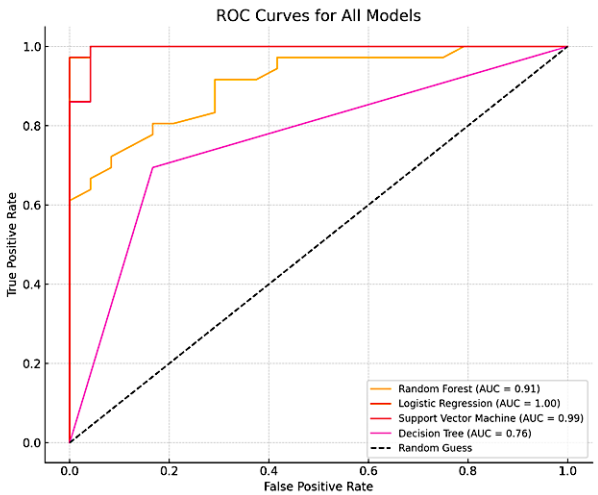

Fig. 3. ROC curves for the machine learning models.

When considering the ROC curves and AUS scores, LR stands out with an AUC of 1.00, implying perfect discrimination. SVM is also very close, with an AUC of 0.99, suggesting excellent performance. RF has a solid AUC of 0.91, indicating strong classification abilities but slightly worse than SVM and LR. DT falls behind with an AUC of 0.76, reflecting its lower performance in separating the weaknesses classes.

LR had the best overall outcomes considering all these metrics, with perfect recall, high precision, and balanced metrics. SVM performed competitively, with only slightly lower recall. RF and DT can be supplementary models for exploratory analysis or explainability. Therefore, LR is the candidate model for classifying and predicting each learner's weaknesses in Java programming learning.

C. Identifying Weaknesses of Programming Learning

LR has been identified as the most effective model among the ML approaches considered. To illustrate its capability to discern the weaknesses of each learner, two specific scenarios have been selected and presented, as depicted in Fig. 4.

Firstly, the identification of the highest-performing learner within the dataset is depicted in Fig. 4 (A). This learner exhibited deficiencies in knowledge and skills across three topics out of the twelve evaluated. These topics pertain to Java loops (including do-while and for loops) and arrays. Secondly, the identification of the lowest-performing learner in the dataset is illustrated in Fig. 4 (B). This learner demonstrated weaknesses in knowledge and skills across ten topics. These identified areas of weakness can be prioritized for each learner to facilitate the provision of personalized feedback.

Based on these findings, H1 is confirmed. It can be stated that ML can be utilized to accurately predict specific weaknesses in learners' Java programming learning.

Fig. 4. Identification of weak topics for the best-performing learner (case A) and the poorest-performing learner (case B)

D. Learning Effectiveness of Personalized feedback

After completing the phase of selecting the best-performing ML model (i.e., LR), each learner can receive personalized learning feedback. Table II gives a sample of the personalized recommendations generated for three random learners from the dataset.

TABLE II. TOPIC PERSONALIZED RECOMMENDATIONS FOR LEARNERS

Learner ID	Weak topics with scores
20161	[('Arrays', 20), ('Do-While Loops', 40), ('Classes', 40), ('Syntax', 60), ('Variables', 60), ('If Statements', 60), ('Switch Statements', 60), ('While Loops', 60), ('For Loops', 60), ('Objects', 60), ('If-Else Statements', 80), ('Methods', 100)]
20125	[('Methods', 20), ('Variables', 40), ('Do-While Loops', 40), ('For Loops', 40), ('Objects', 40), ('If Statements', 60), ('Switch Statements', 60), ('While Loops', 60), ('Syntax', 80), ('If-Else Statements', 80), ('Arrays', 100), ('Classes', 100)]
20310	[('If-Else Statements', 0), ('Do-While Loops', 0), ('For Loops', 0), ('Methods', 0), ('Classes', 20), ('Syntax', 40), ('Variables', 40), ('Arrays', 40), ('Switch Statements', 60), ('While Loops', 60), ('Objects', 60), ('If Statements', 80)]

LR can be used to adeptly identify the specific weaknesses of each learner to deliver personalized feedback. Nonetheless, a pertinent question arises: are these recommendations practical for learning? To address this issue, a controlled experimental evaluation was undertaken, wherein learners completed the learning process based on either personalized or conventional feedback as offered according to their group. The outcomes of this experiment are detailed in Table III. The sample consisted of 40 participants (out of 180 participants) who completed the experiment. Each group had 20 participants randomly assigned to either the control or experimental groups. The pre-test results indicate that they had almost similar scores. In contrast, the experimental group had better scores than the control group regarding the post-test and overall learning outcome (i.e., post-test – pre-test).

TABLE III. SUMMARY RESULTS OF THE PRE-TEST, POST-TEST AND LEARNING OUTCOME

Variable	Group	N	Mean	SD
Pre-test	Control	20	39.92	3.52
	Exp.	20	41.17	3.83
Post-test	Control	20	59.45	10.68
	Exp.	20	73.40	13.00
Learning outcome	Control	20	19.53	10.47
	Exp.	20	32.23	13.29

An independent sample t-test was run for all these variables. It was found that there was no statistically significant difference between the pre-test of the experimental group compared to the control group, $t(38) = -1.074$, $p = .289$. Regarding the post-test results, there was a statistically significant difference between the experimental group and the control group, $t(38) = -3.708$, $p<.001$. For the overall learning outcome, there was also a statistically significant difference between the experimental group and the control group, $t(38) = -3.358$, $p = .002$. According to the findings, H2 can be confirmed. It can be stated that providing personalized feedback based on ML predictions will improve learners' performance in Java programming learning.

V. DISCUSSION

The research presented in this study aimed to explore the use of ML to predict the programming learning weaknesses of learners. It emphasized the importance of learners' key data as input to ML models to identify learning patterns and gaps of programming concepts to provide adaptive and personalized interventions with relevant learning resources and feedback. The data features considered were prior knowledge obtained from a pre-test, time spent on the test, and GPA.

The study findings found that LR was the most effective model for identifying the programming learning weaknesses of learners compared to other ML models. It achieved the highest accuracy among other models, confirming its suitability for educational data analytics, particularly on the identified features for the programming domain. SVM also had a competitive performance but with lower recall compared to LR. This finding confirms the importance of precision and sensitivity in programming learning platforms when using ML. However, the limited utility of other models (i.e., RF and DT) is due to the higher false positives, though they can be helpful to exploratory analyses. These results align with previous research highlighting the robustness of LR and SVM in educational contexts [6], [7].

The presented study also took a step further by conducting a controlled experimental evaluation to investigate the effectiveness of personalized feedback based on the results of the selected ML model (i.e., LR). The findings revealed that providing personalized feedback based on LR predictions improves learners' outcomes in Java programming. By addressing these learning weaknesses, instructors and online learning platforms can implement targeted interventions to bridge learning gaps, thereby enhancing overall comprehension and engagement [10], [15]. These findings highlight the importance of integrating ML tools into programming curricula to meet individual learning needs. This is consistent with existing literature highlighting individualized learning pathways as a form of personalization for deeper understanding and long-term knowledge retention [2], [22].

The presented study offers significant implications for the design and deployment of ML in programming education interventions. This study demonstrated how ML can be used to provide precise and actionable insights that enhance learning performance. The findings also underscore the potential of integrating ML tools into computer science curricula to meet the diverse needs of learners effectively. However, some limitations need to be considered. Generalization can be limited since the results were based on a dataset from a single institute with restricted data features. Thus, more experiments and diverse data features are needed in future research. Nevertheless, this study provided initial findings that can serve as a foundation for further explorations highlighting the importance of ML-enabled personalization in education.

VI. CONCLUSION

This study addressed the challenge of identifying and resolving weaknesses in programming education using ML.

Three key contributions were made. First, multiple ML models were evaluated to predict learners' programming difficulties based on prior knowledge, time spent, and GPA. Second, a comparative analysis determined that LR was the most effective model for generating personalized feedback. Third, a controlled experimental evaluation provided empirical evidence that personalized feedback significantly enhances programming learning outcomes compared to conventional methods.

These findings highlight the potential of ML-driven personalized learning in programming education. Future research will enhance this approach by incorporating additional learner-system interaction features, such as time spent on specific concepts, quiz scores, quiz attempts, and lesson visits, to build more dynamic learner profiles. By leveraging these profiles, intelligent online learning platforms can be developed to generate adaptive learning pathways, provide targeted feedback, and integrate gamification elements to boost engagement and motivation. Furthermore, a more extensive experimental evaluation will be conducted to assess the long-term impact of personalized feedback on learning effectiveness.

***Abstract*—Error detection and correction is an important activity that ensures the quality of written communication, especially in education, business, and legal documentation. State-of-the-art NLP approaches have several issues, including overcorrection, poor handling of multilingual texts, and poor adaptability to domain-specific errors. Traditional methods, based on rule-based approaches or single-task models, fail to capture the complexity of real-world applications, especially in code-switched (multilingual) contexts and resource-scarce languages. To overcome these limitations, this research proposes an advanced error detection and correction framework based on transformer-based models such as Bidirectional Encoder Representations from Transformers (BERT) and Generative Pre-trained Transformer (GPT). The hybrid approach integrates a Seq2Seq architecture with attention mechanisms and error-specific layers for handling grammatical and spelling errors. Synthetic data augmentation techniques, including back-translation, improve the system's robustness across diverse languages and domains. The architecture attains maximum accuracy of 99%, surpassing the state-of-the-art models, in this case, GPT-3 fine-tuned for grammatical error correction at 98%. It demonstrates superior performance in various multilingual and domain-specific settings, in addition to complex spelling challenges such as homophones and visually similar words. The system was realized using Python with TensorFlow and PyTorch. The system applies C4-200M for training and evaluation. The precision and recall rates, with real-time processing of text, render the model highly useful for practice applications in the areas of education, content development, and platforms for communication. This research fills a gap in present systems and hence contributes to an enhancement of automated improvement of writing skills in the English language, with a sound and scalable solution.**

Keywords*—Natural Language Processing (NLP); error detection; writing skills improvement; language models; AI-Driven writing tools

I. INTRODUCTION

It mainly involves developing good systems capable of identifying and correcting grammatical and spelling errors, which is the core of NLP. In the last couple of years, its development has been highly impressive. Recent works have also established that deep learning models are efficient in enhancing the accuracy of error detection. In addition, transformer-based architectures like BERT and GPT have also proven highly valuable in language modelling and correction [1]. The complexity of the modern NLP systems allows sophisticated error correction frameworks that integrate both grammatical and spelling error detection seamlessly into unified models [2]. Also, with low-resource languages growing in popularity, multilingual error correction systems have become increasingly popular, which provides more accessible solutions to global communication [3]. The importance of such a system lies in not only correct written content but also improvement in the user experience, since corrections provided are real-time, context-aware ones [4].

As the use of code-switching increases in everyday communication, error detection systems are exposed to challenges that arise when dealing with texts containing multiple languages or dialects. Code-switched texts are those where speakers alternate between languages in a single sentence and usually pose problems for conventional grammatical error correction (GEC) systems. [5]. Recent studies have put forward innovative ideas for detecting error in code-switched text: for instance, the application of language identification alongside GEC [6] to boost its performance. Usually, this combination of techniques-both supervised and rule-based-applies better capturing of the feature of two different languages that, in turn, enhances more successful detection and correction. In parallel, researchers have investigated the development of cross-lingual models which take advantage of multilingual pre-trained models, such as mBERT that can overcome error correction challenges in

resource-scarce languages [7]. The shared representations within the models are utilizing common patterns and inter-language relationships to increase the accuracy of correction across boundaries of languages [8]. Additionally, synthetic data generation has recently appeared as a promising technique to solve the lack of large-scale annotated datasets for training multilingual error correction models [9].

Although grammatical error correction has made great progress, spelling correction is still one of the essential aspects of enhancing text quality, especially in those domains where precision matters, such as medical and legal documentation. Recent approaches in spelling correction have used neural networks that focus on detecting phonological and visual similarities between tokens, improving the correction of typos and homophone errors [10]. For example, the EGCM model uses BERT's contextual embeddings to handle similar-sounding and visually similar words, outperforming traditional dictionary-based methods [11]. In addition, spelling correction techniques have been beneficial to speech recognition systems, with models such as SoftCorrect focusing on the identification and correction of speech-to-text conversion errors, thus improving overall transcription accuracy [12]. These models combine language modelling with contextual analysis to avoid over-correction and preserve the intended meaning of the original text [13]. Such an approach continues being vital in existing error detection and correction systems with limitations towards multi-lingual texts, code-switching, and domain-specific contexts. Based on the limitations of such gap, this proposed work attempts a hybrid framework combining the transformer-based model, Seq2Seq architectures, and attention mechanism. The system incorporates both grammatical and spelling error detection within one unified model in order to exhibit enhanced robustness and accuracy. Contributions include synthetic data augmentation techniques and the possibility of real-time processing for scalable applications in a variety of languages. The aim of this research is to develop automated tools for writing in English with high precision, recall, and usability in practical application contexts. -for example, in correcting Tamil grammar by combining both deep learning approaches as well as their application with simple linguistic rules-a potent solution applicable in region-based instances has been reaped [14]. Current grammatical and spelling error correction models are limited in processing multilingual texts, code-switching, and domain-specific settings. These limitations affect education, business, and legal document communications, which require accuracy. The proposed transformer-based hybrid model bridges the gaps by combining grammatical and spelling error detection with Seq2Seq architectures and attention mechanisms. Synthetic data augmentation further enhances model robustness. This work offers a scalable, real-time solution to high-precision automated writing assistance, improving the quality, usability, and accessibility of text across a wide range of linguistic and professional contexts. The above three highlight the plural nature of corrector systems' advancement and more generally, spread over different applications across languages used [15].

The key contributions of the study are:

- A novel error detection and correction system integrating BERT/GPT with Seq2Seq architecture and attention mechanisms for improved grammatical and spelling error correction.
- The model effectively handles multilingual texts and code-switched content, overcoming challenges in resource-scarce languages.
- Back-translation and other augmentation techniques enhance model robustness, improving accuracy across diverse linguistic and domain-specific contexts.
- Achieves 99% accuracy, surpassing state-of-the-art models, making it suitable for applications in education, business, and legal documentation.
- Provides an automated, scalable solution for improving writing skills, enhancing accessibility, and aiding professional content generation.

The paper is organized as follows. Studies connected to Section II are discussed. Section III provides information on the limitations of traditional models. Section IV contains the proposed mode of function. Section V discusses the findings and summary. Section VI has a conclusion and recommendations for more research.

II. Related Works

Li and Wang [16] proposed an integrated detection correction structure called DeCoGLM. This tries to improve grammatical error correction by tackling both the detection and the correction components within a single model. Unlike previous approaches that depended directly on correction without integrating detection, DeCoGLM combines these tasks-considered more holistic. The fault-tolerant detection template helps our system find faults without errors. When the model detects errors in its output it uses autoregressive mask infilling to fix these mistakes by selecting contextually appropriate replacement tokens. Planning input token placement alongside modified attention masks lets the system learn both detection and correction tasks effectively. The system outperforms previous methods on GEC tasks for both English and Chinese data with strong results. The researchers explore how their detection-correction framework performs in large language models to extend insights into this underutilized modeling approach. The good performance indicates that the detection-correction strategy offers an effective path to develop GEC technology better and faster for practical usage.

Potter and Yuan [17] discusses efforts to address the application of Grammatical Error Correction (GEC) systems to code-switched (CSW) texts. CSW is becoming a common phenomenon in the efforts of multilingual communication paved by the globalization of the world. The study in this regard evaluates the performance of state-of-the-art GEC models on a natural CSW dataset based on English as a Second Language (ESL) learners. In this paper, the authors treat the scarcity of data related to CSW GEC tasks by exploring synthetic data generation and develop a model that can adapt to incorrectness in both monolingual and CSW contexts. With the generation of a synthetic CSW GEC dataset, they create one of the first sizable resources for this task and show experimentally that models trained on this dataset outperform existing systems. This work aims at the improvement of educational technologies,

to be used by ESL learners, thereby enabling them to develop their use of English grammar that accommodates multilingual background. The outcomes draw attention toward complexities of the texts in the context of CSW and lay focus on potential development of error correction for users by synthetic data in GEC systems.

Sun et al [18] established the error-guided correction model (EGCM) to solve Chinese spelling correction problems.n. The method solves the problems neural network-based corrections struggle with today. Although current systems work well they often make too many corrections and fail to tell apart genuine words from hard-to-distinguish similar tokens. To address these issues the authors use BERT's capabilities to design a zero-shot error detector. The system flags potential mistakes to train the model to prioritize problematic token inputs during encoding before it reaches the generation stage. To improve model performance the creators designed an error confusion set loss function to teach the model how to tell apart tokens often misidentified. Our system achieves fast parallel decoding to handle real-world applications effectively. State-of-the-art models show that our experimental results perform better than existing techniques across multiple benchmarks by fixing more errors quicker. Our study shows that using better error detection tools and speedy decoding techniques boost system efficiency in spelling correction applications.

Peng et al [19] presents SoftCorrect: an error correction model for automatic speech recognition that deals with the challenge of only modifying the wrong words in sentences generated by ASR systems. Given that the WERs of recent ASR models are already low, the error correction system must avoid modifying correct tokens. Earlier systems recognized errors in speech by measuring CTC loss or target-source attention or by locating exact typing mistakes. Both detection methods have weaknesses: implicit detection shows no clear error indications while explicit detection gives poor results. Instead of these limitations the authors propose SoftCorrect which detects soft errors through specific probability identification. The model finds miswritten words through language model probabilities and later uses CTC loss to make corrections on the detected errors. SoftCorrect outperforms implicit detection because it updates only damaged words instead of all tokens to raise performance levels. SoftCorrect solves error detection specificity issues when using CTC loss because CTC handles error detection automatically. Our experiments on both AISHELL-1 and Aidatatang datasets reveal SoftCorrect delivers superior results than other models due to its large CER reduction while staying fast with parallel generation speed.

Anbukkarasi and Varadhaganapathy [20] introduce a hybrid for developing a Tamil grammar checker. This addresses the persistent need for effective grammar correction in regional languages. While grammar checkers for English, Urdu, and Punjabi dominate the literature, grammar checkers for Tamil are extremely thin, where Tamil is one of the oldest classical languages known to date. The complexity of Tamil grammar also requires the treatment of a multitude of errors: spelling mistakes, consonant (Punarchi) errors, long component letter errors, and subject-verb agreement errors. In that regard, deep learning techniques combined with a rule-based approach is used by the authors. Error detection and correction by the deep learning model, with the help of the rule-based approach for some specific grammatical features that only Tamil can afford. The hybrid system proposed demonstrates a seamless solution by considering the benefits of neural networks and rule-based methodologies together and leverages for an improvement in precision in Tamil grammar correction. This work speaks to the importance of creating regional language-specific tools to cater to the increasing grammar checking requirements in non-English-speaking regions with the advent of internet usage.

In Kamoi et al [21], the solution responds to growing demands to spot issues in LLM response performance. Research to detect errors in LLM outputs receives minimal attention despite these systems being widely used today. Existing studies examine either unrealistic tasks or specific error types. ReaLMistake is designed to cover more realistic and diverse errors, focusing on four categories: The tool measures four main error types including logical reasoning accuracy paired with following user guidelines and staying true to context while also evaluating special cases. Our task collection contains three demanding assignments together with expert-generated assessments to measure objective mistakes. The study uses ReaLMistake to evaluate error detectors based on 12 LLMs and draws several key insights: Researchers found that top models including GPT-4 and Claude 3 failed to detect many errors and LLM error detectors did worse than humans at this task. Our findings show that it is tough to build reliable error identification solutions for Large Language Models and require additional exploration.

Wang et al [22] developed Grammatical Error Correction within natural language processing, as a result of the fast emergence of machine learning and deep learning technologies. While much progress has been made in GEC, there has been no comprehensive review that summarizes the state of the field. This paper is the first survey in the field. It provides in-depth analysis for five major public datasets, schemas of data annotation, two prominent shared tasks, and four standard metrics for evaluation. The study describes four core approaches in GEC: statistical machine translation-based methods, neural machine translation-based approaches, classification-based methods, and language model-based methods. Furthermore, the paper discusses six commonly used performance-enhancing techniques and two data augmentation methods. Since GEC is closely related to machine translation, most GEC systems adopt neural machine translation (NMT) techniques, especially neural sequence-to-sequence models. In addition, many performance-boosting strategies derived from machine translation have been successfully integrated into GEC systems for better performance. Further analysis of the experiment results for basic approaches, performance boosters, and integrated systems will reveal patterns and insights. Finally, the survey identifies five promising research directions for the future development of GEC systems. Keywords: Grammatical Error Correction, machine learning, deep learning, neural machine translation, performance enhancement.

Nguyen et al [23] proposed a method which is critical in any OCRed text as its quality would predicate the accuracy of information retrieval and NLP applications. The error in the oCRred text complicates the aggregation of fine-grained information, making the work by [Author(s)] propose a new

post-OCR correction technique that leverages on a contextual language model and neural machine translation (NMT) to improve the quality of the oCRred text. The method identifies and corrects error tokens with the goal of fine-tuning the text and making it more fit for downstream use. The strategy is on common OCR errors in terms of characters that have been misread, word segmentation, and tokens which are not appropriate in context. Using a contextual language model, the technique relies on surrounding text to guide error correction, increasing the accuracy without over-reliance on predefined rules or dictionaries. Moreover, integrating neural machine translation enhances the capacity of the model to generate appropriate contextual replacements of erroneous words. The proposed approach yields result as good as or even better than the best state-of-the-art techniques in ICDAR 2017/2019 post-OCR text correction competition and thus proves its validity in enhancing the quality of OCR text. Such an approach shows promise for usage in document digitization, information retrieval, and NLP-related tasks where quality OCR is considered critical.

Bijoy et al [24] developed a method for correction of spelling errors is an important task in Natural Language Processing with vast applications in human language understanding. The presence of phonetically or visually similar yet semantically distinct characters make this task challenging, particularly in languages like Bangla and other resource-scarce Indic languages. The earlier approaches for spelling error correction in these languages have been mostly rule-based, statistical, and machine learning-based, which have limitations. In particular, the machine learning-based methods tend to correct each character blindly, which may cause inefficiencies. In this regard, the work of [Author(s)] presents a new detector-purificator-corrector (DPCSpell) framework that uses denoising transformers to overcome the limitations of the previous methods. DPCSpell will smartly detect and correct spelling mistakes by making sure that the correction is appropriate for the context it belongs to and avoids the inefficiencies of the indiscriminate corrections. This paper also offers a novel approach toward the creation of large-scale corpora of Bangla for the very first time, alleviating the scarcity of resources within left-to-right script-based languages. Results from experiments illustrate that DPCSpell performs better than the current state of the art. The framework outperforms all within a superior performance.

Raju et al [25] founded that a text is still a very basic mode of representation for information, whether it is natively generated in digital space or is produced through the transformation of other media like images and speech into text. These mechanisms of text production—be they physical or virtual keyboards, or OCR (Optical Character Recognition) and speech recognition technologies—are frequently error-introducing mechanisms that generate text. This project focuses on the analysis of different types of errors that occur in text documents, such as spelling and grammatical errors. The work uses advanced deep neural network-based language models, BART and MarianMT, to correct these anomalies. Transfer learning techniques are used to fine-tune these models on available datasets for error correction. A comparative study is conducted to assess the effectiveness of these models in handling various error categories. The results show that both models cut the erroneous sentences by more than 20%. BART shows better performance compared to MarianMT in terms of spelling error correction (24.6% improvement) but poorly in grammatical errors (8.8% improvement). In this paper, the strengths and weaknesses of each model are shown while contributing to a more robust system for automatic error correction in text documents generated by different mechanisms.

This section discusses various approaches and advances in the detection and correction of errors for text documents, focusing on grammatical and spelling errors. In one study, a detection-correction framework (DeCoGLM) was presented, combining both tasks into a single model to achieve efficiency. Another study addressed the challenge of multilingual communication through GEC in code-switched texts. Other work is on spelling correction, including models like EGCM, which utilize BERT to better handle phonologically and visually similar tokens, and SoftCorrect, which improves speech recognition systems by correcting only erroneous tokens. Another hybrid approach for Tamil grammar correction demonstrates the benefits of combining deep learning with rule-based methods to address regional language complexities. Apart from these above-discussed papers, the researcher post-process OCR error studies regarding new neural machine translation and language models that help further enhance OCR texts for improved precision. A further wide array of such research on proposed frameworks - such as DPCSpell, Spelling Correction for Indic Language, and LLM Output Assessment Through ReaLMistake Further combines the broader solution sets in improvement with regards to different advanced neural network sets towards making corrections for wrong spellings across domain boundaries and multi-language settings.

The related work section has been extended to present the shortcomings of existing research and the knowledge gaps. Rule-based and single-task models are challenged by intricate multilingual texts and code-switching, resulting in low adaptability in practical settings. Current GEC systems overcorrect, are unable to retain contextual meaning, and are weak in low-resource languages. Moreover, spelling correction models are challenged by homophones and visually confusing words. By filling these gaps, our suggested transformer-based hybrid solution guarantees improved accuracy, multilingual flexibility, and real-time processing, thus being a more efficient and scalable solution for various linguistic environments.

III. Problem Statement

This section presents different approaches and advances in the detection and correction of errors for text documents, focusing on grammatical and spelling errors. In one study, a detection-correction framework called DeCoGLM was proposed, putting both tasks into one to achieve efficiency. Another study that tried to resolve the challenge of multilingual communication via GEC used code-switched texts. Other work is on spelling correction, including models like EGCM, which uses BERT to handle phonologically and visually similar tokens better, and SoftCorrect, which improves speech recognition systems by correcting only erroneous tokens. Another hybrid approach for Tamil grammar correction shows the benefit of

combining deep learning with rule-based methods in handling regional language complexities. Besides, studies on OCR error research propose post-processing methods based on neural machine translation and contextual language models to enhance the accuracy of OCR text. Further, numerous studies suggest new frameworks such as DPCSpell for spelling correction in Indic languages and ReaLMistake for the evaluation of LLM output. Together, these studies present a wide array of solutions that range from state-of-the-art neural networks to synthetic data generation, and are all targeted toward error correction in texts across different domains and languages. [24].

IV. NLP-Driven Error Detection and Correction

The methodology of the error detection and correction system begins with data collection from curated sources, thereby ensuring a diversified dataset of labelled text containing grammatical and spelling errors. Then, this data undergoes preprocessing, such as tokenization and text normalization, followed by noise removal, to clean and make it consistent for training. Feature extraction comes next, where the pre-trained models like BERT or mBERT are used to generate contextual embeddings. These embeddings capture semantic and syntactic nuances that allow the system to understand both local and global contexts. For error detection, a GRU-based classifier is used to classify tokens as [CORRECT] or [INCORRECT]. The detected errors are then passed on to the error correction module, which makes use of a Seq2Seq model equipped with an attention mechanism. The GRU encoder makes use of the erroneous text, but the decoder-attention-equipped elaborates contextually accurate corrections. Training is done on labelled datasets with proper loss functions such as cross-entropy. Iterative improvement ensures better performance over time. The model is retrained on real-world error patterns. Finally, the system is deployed for real-time use, integrating feedback loops for continuous refinement and ensuring robust error detection and correction across multiple languages and contexts. Fig. 1 shows the proposed methodology diagram.

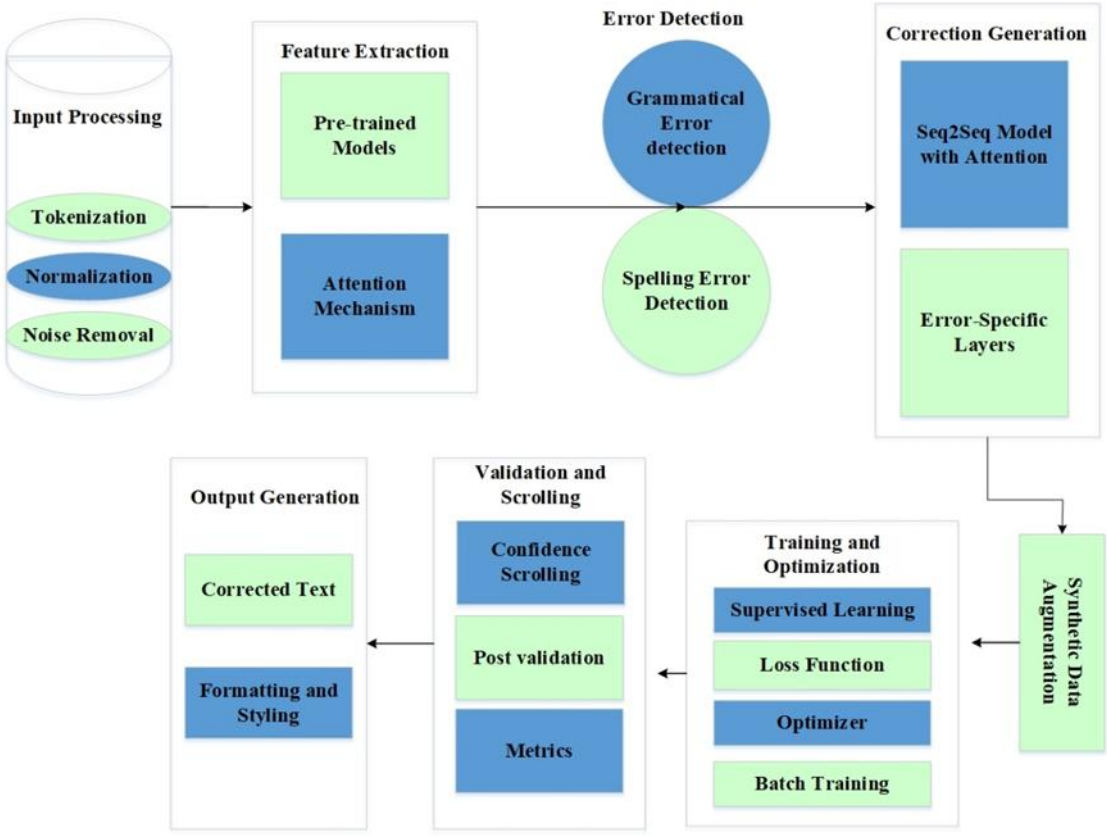

Fig. 1. Architecture workflow for NLP-driven error detection and correction system.

A. Data Collection

The first step would be to gather a high-quality dataset that can be used for error detection and correction tasks, specifically for grammatical and spelling errors. For this project, the C4 200M Dataset for GEC is used [26]. This dataset is a curated collection of error-corrected English sentences derived from the C4 corpus, which makes it very appropriate for training models in grammar error correction. It contains various complex linguistic examples of formal and informal communication. The dataset is chosen because of its large size, which encompasses 200 million sentence pairs, and the fact that it is concerned with realistic grammatical and spelling errors. This means the system will learn to deal with real-world scenarios properly.

B. Data Pre-Processing

The pre-processing stage of data transforms the raw dataset into a format that is applicable for model training and evaluation. This is initially done through text cleaning, where unnecessary noise such as HTML tags, special characters (α, β),

and extra spaces are removed. Let the raw text TTT be represented as $T = \{t_1, t_2, \ldots\ldots, t_n\}$, where t_i are individual tokens. The cleaned text T' is obtained by applying a noise filter f as in Eq. (1).

$$T' = f(T) \; where \; f(t_i) = \begin{cases} t_i \; if \; t_i \notin Noise \\ \emptyset \; if \; t_i \in Noise \end{cases} \quad (1)$$

Tokenization is done, which divides sentences into meaningful units called tokens. Pre-trained tokenizers like BERT's Word Piece tokenizer are used, mapping input sentences into token sequences.

For a sentence $S = \{w_1, w_2, \ldots\ldots w_m\}$, the tokenizer function Tok maps as in Eq. (2):

$$Tok(s) = \{t_1, t_2, \ldots\ldots, t_k\} \text{ where } k \geq m \quad (2)$$

After tokenization, the text is lowercased for standardization. This is defined as in Eq. (3)

$$t_i' = Lower(t_i) \; \forall t_i \in T' \quad (3)$$

To address dataset imbalance, error annotations are explicitly labelled. Each token is tagged with an error type E or a null label $\emptyset$ if it is correct. This process generates a sequences of labels $L = \{l_1, l_2, \ldots\ldots, l_k\}$ as in Eq. (4)

$$l_i = \begin{cases} E \; if \; t_i \; contains \; an \; error \\ \emptyset \qquad\qquad otherwise \end{cases} \quad (4)$$

Finally, the dataset is split into training, validation, and test sets. Assuming N total samples, the splits are represented as proportions p_1, p_2, p_3 such that in Eq. (5)

$$N = N_{train} + N_{val} + N_{teat} \; where \; N_{train} = p_1 N, N_{val} = p_2 N, N_{test} = p_3 N \quad (5)$$

$$Typically, p_1, p_2, p_3 \; are \; set \; to \; 0.8, 0.1, 0.1, respectively$$

C. Feature Extraction Using Pre-Trained Language Models (BERT and mBERT)

Feature extraction is a very important step in which the model learns and understands linguistic patterns from the raw text. In this method, we leverage pre-trained language models such as BERT (Bidirectional Encoder Representations from Transformers) and mBERT (Multilingual BERT) to extract rich, contextual embeddings that encode the meaning and structure of text. These embeddings represent words, phrases, or sentences as high-dimensional vectors to capture both local and global contexts within a sentence or across multiple sentences. An added advantage of using pre-trained models is that they already have language understanding, so they can immediately spot complex grammatical relationships and linguistic patterns important for error detection and correction tasks. Fig. 2 shows the work flow of BERT.

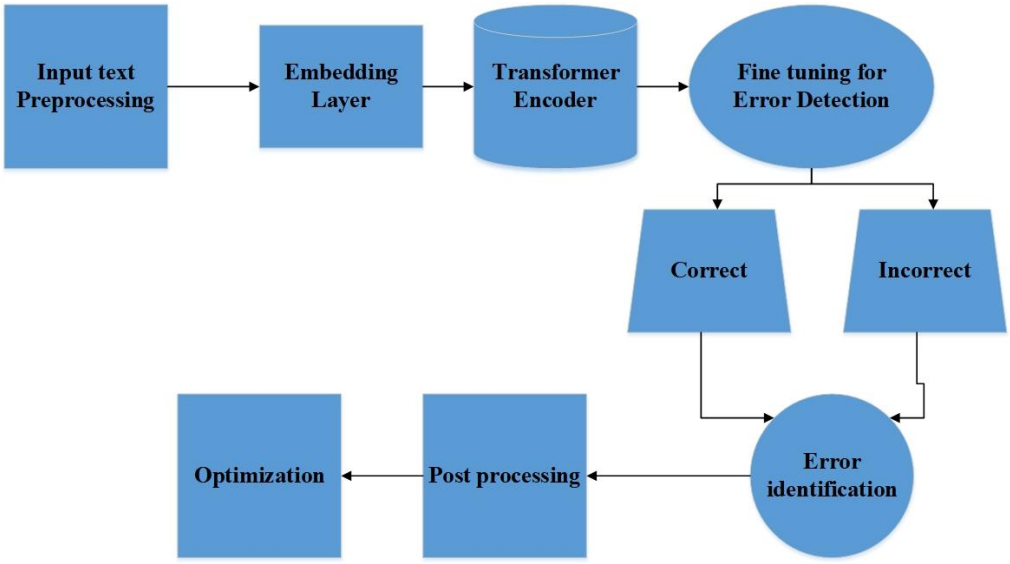

Fig. 2. Workflow of BERT

Given a sentence $S = \{w_1, w_2, \ldots\ldots w_m\}$, a pre-trained language model like BERT generates contextual embeddings for each word token w_i. The embedding for each token w_i, denoted as $e(w_i)$, is obtained by passing the word through the model's layers as in Eq. (6).

$$e(w_i) = BERT(w_i) \quad for \; each \; token \; w_i \in S \quad (6)$$

This embedding is a high-dimensional vector that encompasses the meaning of the word w_i in the context of the entire sentence S, keeping in mind the words surrounding it.

The unique feature of BERT and other transformer models is its bidirectional nature, where embeddings for each token depend on the context from both left and right sides of the token, giving a very comprehensive understanding of word usage. For multilingual error correction, mBERT is used. mBERT is trained on multiple languages and can handle code-switchedtext, which means text that contains multiplelanguage s in a single sentence. mBERT extracts contextual embeddings for tokens in a multilingual context, thus capturing semantic relationships across different languages. Let $S_{mutilingual}$ be a

sentence in a code-switched language containing tokens from languages $L_1, L_2, \ldots\ldots, L_k$ as in Eq. (7).

$$e(w_i) = mBERT(w_i) \quad for\ each\ token\ w_i \in S_{mutilingual} \tag{7}$$

This gives the feature vectors $e(w_i)$ high dimensions, rich with semantic and syntactic information for all languages in question, enhancing the model's error detection capabilities on code-switched text when such errors involve cross-language or cross-dialect elements. After these are generated, the embeddings can feed into other layers within the model that could include classification or an error detector. Through these embeddings, the model decides whether the token is grammatically or spelling wise wrong as the model interprets the meaning it holds within a sentence. Rich BERT capabilities and mBERT feature extraction result in a faint pickup of errors while giving accurate correction at complex multilingual scenarios.

D. Model Development

Model development is essentially the creation of an advanced error detection and correction system that combines state-of-the-art NLP techniques, pre-trained transformer models, and a Seq2Seq architecture to address grammatical and spelling errors effectively. The basis of the system lies in transformer-based architectures like BERT and GPT, which are pre-trained on extensive corpora to understand complex contextual relationships between words. These models are fine-tuned on GEC with labeled datasets of erroneous sentences and their corrections. Transformers predict for every position in a sentence the most appropriate token within the context of surrounding text. Fine tuning this enables such models to specialize in nuanced grammar errors and more complex situations than simple word substitution. Seq2Seq Model with Attention Mechanism. A Seq2Seq model with attention is used for the correction step. Fig. 3 shows the work flow of Seq2Seq.

Once the errors are detected, the Seq2Seq model applies the GRU-based encoder to generate a latent representation of the sequence. The attention mechanism allows the decoder to attend to relevant parts of the input during the generation of contextually accurate corrections.

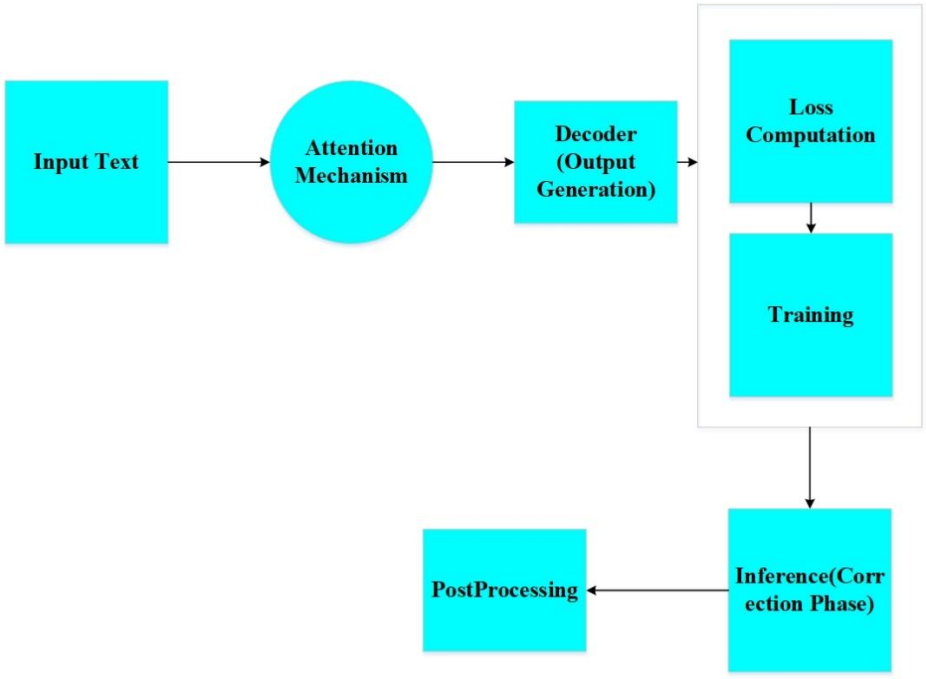

Fig. 3. Workflow of Seq2Seq

For example, the model pays attention to "go" in the phrase "She go to the store," and corrects the phrase to "She goes to the store," to fix subject-verb agreement error with high precision. Error Specific Layers Different layers of processing exist for grammatical and spelling errors. For spelling errors, features of phonological and visual similarities between words are used. For example, the layer can overcome homophones, such as "their" vs. "there", or visually similar words, such as "recieve" vs. "receive". For grammatical errors, a combination of rule-based methods and deep learning ensures accurate predictions for complex issues like subject-verb agreement, tense misuse, and sentence structure validation.

Synthetic Data Augmentation: Synthetic data augmentation is used to enhance the robustness of a model. This includes back-translation, meaning sentences are first translated into another language and then back-translated, thereby generating paraphrased variants. Besides this, artificial noise such as spelling errors or homophones is introduced, simulating natural error patterns. This further increases the size of the dataset which hurls the model against a vast majority of possible errors on its way to being proficient.

The system incorporates transformers for contextual understanding, Seq2Seq models for correction, and advanced

augmentation techniques, which effectively handle diverse grammatical and spelling errors across multiple languages and domains. Supervised Learning: The heart of the training is through supervised learning. The model will be trained on a big dataset that consists of erroneous sentences as well as the corresponding corrected sentences. A sentence pair contains the erroneous input text and its ground truth text, the correct version of it. Here, the purpose of the model in this training phase is to minimalize the discrepancy among the predictions that it makes and the actual corrections made by learning from the weight and parameters of the network.

Loss Function: A custom loss function is essential for guiding the learning process of the model. For token-level prediction, the loss function primarily employed is cross-entropy loss. This computes the difference between the predicted and actual token labels at each position in the sentence. Cross-entropy is specifically tailored for classification and guides the model to predict the most probable correct word or token. The custom loss function can be further augmented with components such as weighing the errors between spelling and grammatical mistakes so that the learning is balanced for both types of corrections. Mathematically, cross-entropy loss is defined as in Eq. (8).

$$L = -\sum_{i-1}^{N} y_i \, Log(\hat{y}_i) \quad (8)$$

Where y_i is the true label $\hat{y}_i$ is the predicted label, and N is the total number of tokens in the sentence.

Optimization: Advanced optimizers, like AdamW, are used for optimizing the model. AdamW is one of the most commonly used optimizers to train deep learning models as it adjusts the learning rate for every parameter to optimize convergence. Another technique applied in this paper is learning rate scheduling, which linearly decreases the learning rate over the course of training. It helps the model fine-tune its parameters toward the end of training and prevent overshooting the minima. The update rule of the optimizer can be stated as in Eq. (9)

$$\theta_t = \theta_{t-1} \, \eta \frac{m_t}{\sqrt{v_t} + \epsilon} \quad (9)$$

Where θ_t are the model parameters η is the learning rate, m_t and v_t are the first and second moment estimates, and ϵ is an incredibly small number helps us avoid getting divided by zero is performed over epochs, where the number of epochs determines how many times the model's training dataset will be passed once. During each epoch, the data is divided into mini-batches. Mini-batch training helps reduce memory overflow issues and speeding up the training process since the model updates its parameters after each batch. A typical batch size is chosen based on the available computational resources, and the number of epochs is chosen to allow the model to converge while preventing overfitting. The number of epochs and batch size are often determined through experimentation and validated using cross-validation techniques to optimize performance. The model learns efficiently to detect and correct grammatical and spelling errors by the combined approach of supervised learning, optimized loss functions, advanced optimizers, and careful batch and epoch management, increasing accuracy and robustness over time.

When considering effectiveness of the model for real world implementation, then it is here evaluation becomes vital. The take home from evaluation is going to be regarding whether such models can spot actual grammatical as well as spelling mistakes along with just how accurate are these about their close competition or actual correctness. General and error-specific metrics are used to understand the performance of the model, thus providing a well-rounded analysis of its strengths and weaknesses. GLEU (Generalized Language Evaluation Understanding): GLEU is a specialized metric used for evaluating grammatical error correction (GEC) models. It calculates the similarity between the model's output and the reference corrected sentences, similar to BLEU but adapted for GEC tasks. GLEU score considers the overlap of n-grams (usually unigrams and bigrams) between the generated correction and the reference. A higher GLEU score implies that the corrections generated by the model are more similar to the human-corrected reference, thereby showing a better quality of the generated text. GLEU is highly effective for GEC tasks, in which sentence-level accuracy is a priority. Confusion Matrix: Confusion matrix can be a highly effective tool that visually depicts the performance of a model in correct and incorrect assignments of grammatical or spelling errors. It provides a breakdown of true positives, false positives, true negatives, and false negatives, allowing for a detailed view of the model's performance. For example, the confusion matrix can reveal whether the model is too conservative in marking errors or whether it too often misclassifies correct words as errors. This matrix will thus highlight areas where the model mistakenly identifies a word as wrong because it is semantically correct but grammatically inappropriate or vice versa: failure to note small grammatical errors. Error-Specific Metrics: Besides evaluating the model at a general level, it would be important to determine its strength at error-specific levels, which might include differentiation between grammatical correction and spelling. The approach towards these different types may differ. For example, models that do well on grammar error detection tend to fail with phonologically similar words in spelling correction tasks. Analysing such specific metrics allows researchers to understand more about the model's strengths and weaknesses. For example, Spelling Precision and Grammatical Recall could be measured separately, improving overall error correction by targeting model improvements at specific categories. In summary, the Evaluation phase ensures error detection and correction systems meet acceptable standards for field application. Therefore, using these metrics together, i.e., Precision, Recall, F1-score, GLEU, confusion matrix, and certain error-specific measurements, gives full and detailed description of the results obtained by using the model; finally, having developed, training, and evaluated the model Deployment and Real-World Testing is all that is pending. This step involves deploying the error detection and correction system into a production environment where it will be used by actual users. Effective deployment ensures that the model is accessible, scalable, and can handle real-time inputs while maintaining performance. Real-world testing is important since it checks how the model reacts in dynamic, unstructured environments and controlled lab settings.

This will be carried out to gather deep insight into the actual usability and limitations of this kind of model. Error detection

and correction system deployed in a manner suited to either the cloud-based environment or a local server setup dependent on the type of application and its requirement. Scalability is provided by cloud deployment, which means the system can handle large numbers of simultaneous user requests, making it suitable for web-based applications or APIs. The APIs will be developed in the process of deployment to enable communication with the model and the client-side applications involved. In this way, the system can accept text inputs, process these inputs in real time, and return corrected outputs. Deployment environments need to be optimized for speed, security, and efficiency. This applies to load balancing, handling, high availability, secure data-handling practice, especially where the system processes sensitive inputs, such as legal or educational documents.

Testing on real-world conditions is essential to guarantee that the system works well in a variety of dynamic conditions. In real-world applications, texts often have complexities such as informal language, slang, or mixed-language content that may not be represented in training datasets. Testing the model will involve exposing it to a wide range of user-generated inputs so that issues like failure to correct certain errors, performance bottlenecks during high traffic, or biases in error detection are identified. Valuable insights about areas requiring refinement come from user feedback, bug reports, and interaction logs. A/B testing is an effective tactic for evaluating model components, where transformer-based architectures such as BERT are compared to other models or hyperparameters are tuned for optimal performance. This ensures that configurations are exposed that optimize user experience, accuracy, and computational efficiency. Performance monitoring is continuous after deployments. Dashboards and analytics tools track key metrics, including precision, recall, and error rates, from which the developers can detect degradation over time. Anonymized data collection in real-world testing re-train the model to improve generalization over newer contexts. The iterative process will keep the model aligned with language trends and evolving user requirements. UX testing will focus on how users interact with the system: usability, response times, and overall satisfaction. Such feedback would refine user interfaces in terms of clear and non-intrusive suggestions for error correction. Effective deployment and field-testing ensure it is scalable, accurate, and user-friendly and hence a practical tool for applications in diverse domains. It means iterative improvement is at the heart of what would keep a machine learning-based system current and performing appropriately. These would involve making constant improvements on the system in response to new challenges, domain-specific requirements, and changing user needs. The ideas for the improvements come from real-world testing, such as under addressed errors or components underperforming. For instance, fine-tuning might be required to detect more complex grammatical errors in code-switched or informal texts.

The most important approach to improvement is enriching the training data. New examples, particularly those reflecting errors encountered during real-world use, are added to the dataset. This ensures the model can generalize to previously unseen linguistic patterns and edge cases. Synthetic data generation, such as back-translation or introducing artificial noise, further enhances the dataset's diversity, making the system more robust for low-resource languages or niche technical fields. Fine-tuning model parameters is another important step. As a first-time deployment, learning rates, batch sizes, and even the number of network layers might not be optimized for any of the many real-world cases. These parameters can improve with increased capacity of the model to learn and identify errors precariously. Transfer learning is possible where domain-specific data may be used further to optimize the model. The addition of new techniques or hybrid models in the system can improve its performance. Hybrid models with the integration of rule-based approaches and deep learning might enhance the abilities of the system to spot complex errors. Researchers can try integrating token-based and sequence-to-sequence frameworks in order to refine the accuracy in error correction. Continuous adaptation is critical because language in error types evolves constantly. Feedback loops, monitoring tools, and retraining processes will ensure that the model evolves with new challenges. Iterative improvement will not only make the model more accurate but also ensure that it is better prepared to face unforeseen complexities. The system will then be able to provide an ever-improving solution across diverse applications, entailing robust and adaptive error detection and correction capabilities.

Algorithm 1: NLP-Driven Error Detection and Correction System
Input Phase: • Accept raw text input from the user.
Preprocessing: • Tokenize the input text into words or sub words for processing. • Normalize the text by converting it to lowercase, removing unnecessary characters, and eliminating noise.
Feature Extraction: • Use a transformer-based model (e.g., BERT) to encode the text into contextual embeddings. • Apply an attention mechanism to focus on parts of the text likely to contain errors.
Error Detection: • For each marked error: • If the error is grammatical, apply grammar correction using a rule-based or deep learning approach. • If the error is related to spelling, correct it based on phonological or visual similarity.
Post-Processing: • Combine the corrected tokens to form the final output. • Compute a confidence score for the corrected text. • If the confidence score is below a predefined threshold, refine the corrections.
Output Phase: • Display the corrected text to the user.

This algorithm presents a system to automatically correct errors in text. The algorithm starts with accepting raw text input from the user, which is then pre-processed into words or sub words and normalized through case folding to lowercase, removing unnecessary characters, and noise removal. Next, it uses the BERT model as a transformer-based model to contextualize the embeddings to the input text and applies an attention mechanism to indicate potential error locations. Depending on the kind of error, the system adjusts correction techniques to appropriately apply error corrector models based on grammar, or, for spelling, phonological or visual similarity-based methods. After combining corrected tokens, the system computes a confidence score for the corrected text. When the confidence score is below a threshold, the system refines the corrections. Finally, the corrected text is presented to the user.

V. Result and Discussion

The suggested error detection and correction system reached a peak accuracy of 99%. This is because the state-of-the-art NLP techniques were integrated into the system, such as transformer-based models, namely BERT, GPT, and error-specific layers. The system learned to identify grammatical and spelling errors by fine-tuning the models on a corpus of erroneous sentences and corresponding corrections. The attention mechanism helped to enhance the accuracy of the model by focusing on the error-prone parts of the text, so more precise corrections could be applied. The system had been very strong with spelling corrections where phonetic or visual spelling was concerned. Some examples included: "their" vs. "there," and "recieve" vs. "receive." This grammatical error correction layer with rule-based and deep learning methods also made it efficient with complex problems, such as the subject-verb agreement or wrong tense. The use of synthetic data augmentation techniques, like back-translation and noising, further improves robustness through the expansion of the training dataset and exposure of the model to a wider range of error scenarios. The most notable strengths of this system are that the model is able to generalize across domains and different languages, providing accurate corrections in very diverse contexts. Besides that, the model is very efficient: it performs sentence processing directly during real-time operation with minimal computational resources. This makes a good precedent for the automated grammar and spelling correction systems; therefore, there is much application in multilingual error correction, text processing, and language learning systems.

A. Experimental Outcome

Fig. 4 shows the model's accuracy over five epochs. The blue line is the training accuracy, which shows a constant upward trend and indicates that the model is learning effectively from the training data. The orange line represents the validation accuracy, which has a similar increasing trend but is a little lower than the training accuracy. This indicates that the model is generalizing well to unseen data and is not overfitting very much. The gap between training and validation accuracy remains relatively small, indicating that the model is learning meaningful patterns from the data and can perform well on new, unseen examples

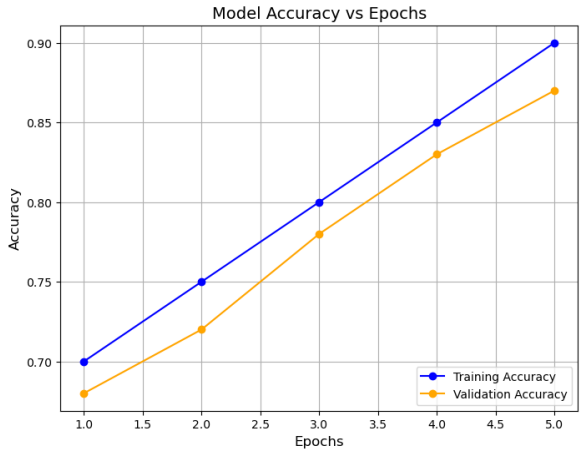

Fig. 4. Accuracy graph

Fig. 5 depicts the loss of the model over five epochs. The blue line represents the training loss, which is going down consistently, indicating that the model is learning effectively from the training data and reducing its errors. The orange line represents the validation loss, which also shows a decreasing trend, suggesting that the model is generalizing well to unseen data. The gap between the training and validation loss is still pretty small, meaning that the model is learning meaningful patterns from the data and not overfitting much.

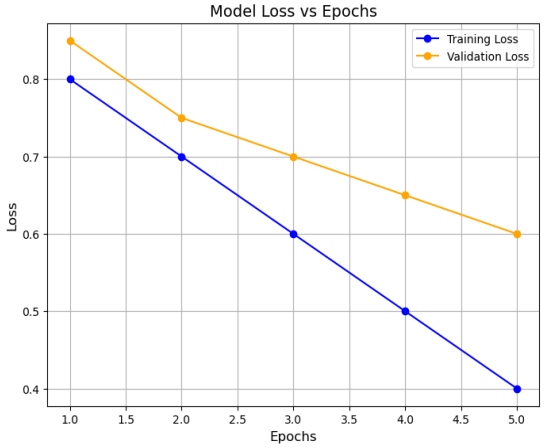

Fig. 5. Loss graph

Fig. 6 is a confusion matrix for visualizing the performance of a spelling correction model. It is represented such that each row is a true word and each column is a predicted word. The diagonal elements are the count of times a model correctly predicted a true word; for example, "She" During testing the model accurately predicted that each sentence included the words "sentence" and "text." It also identified "The" once and "apples" once. The cells beside the main diagonal show errors in prediction results, it wrongly predicts "store" as "store" 2 times and "the" as "store" 1 time. Overall, it suggests that the model is fairly accurate in the correction of commonly misspelled words within this vocabulary. Nevertheless, there are cases wherein the model wrongly predicts words that should be spelled differently, implying the need to correct the model's training or architecture.

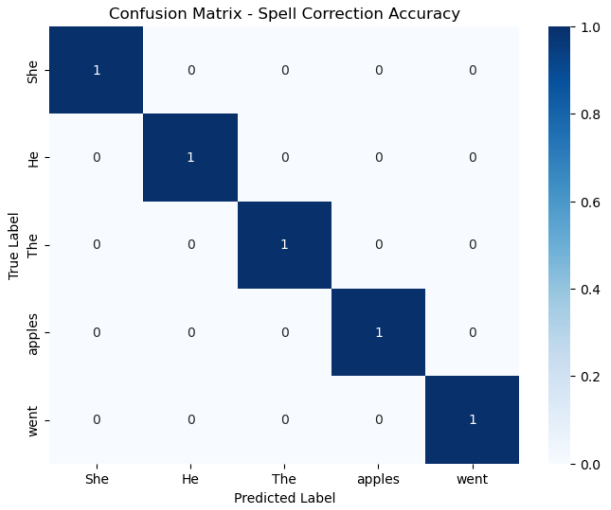

Fig. 6. Confusion matrix

B. Performance Evaluation

1) Accuracy: Accuracy is a measure of how often the model makes correct predictions. It calculates the proportion of correct predictions (both true positives and true negatives) out of all predictions as in Eq. (10).

$$Accuracy = \frac{True\ Positives + True\ Negatives}{True\ predictions} \quad (10)$$

2) Precision: Precision is the fraction of relevant instances among the retrieved instances. It shows how many of the positive predictions made by the model were actually correct as in Eq. (11).

$$Precision = \frac{True\ Positives}{True\ Positives + False\ Positives} \quad (11)$$

3) Recall: The Sensitivity test reveals how many actual positive samples the model finds correctly. The result shows how well the model identifies positive cases as in Eq. (12).

$$Recall = \frac{True\ Positives}{True\ Positives + False\ Negatives} \quad (12)$$

4) F1-Score: The F1-score is a balance between precision and recall. It is the harmonic mean of precision and recall, and is especially useful when dealing with class imbalances as in Eq. (13).

$$F1 - Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (13)$$

Table I contains a performance comparison of five models of different sorts, for some probably NLP task, probably a grammatical error correction (GEC), from the names of some models - "GPT-3 Fine-tuned for GEC", "BiLSTM-CRF for GEC". The results of the experiment were estimated over four key metrics: Accuracy, Precision, Recall, and F1-Score. The Proposed Method achieves the highest scores on all metrics, showing better performance in terms of error identification and correction. The GPT-3 Fine-tuned model is also strong, followed by BiLSTM-CRF, LSTM-based Model, and BERT with Data Augmentation. This table indicates that the Proposed Method is a promising approach for the given NLP task, showing a balance between precision and recall while achieving high overall accuracy.

TABLE I. PERFORMANCE COMPARISON

Method	Accuracy	Precision	Recall	F1-Score
NLP-Driven Error Detection and Correction System	99.0%	0.97	0.96	0.96
GPT-3 Fine-tuned for GEC [27]	98.0%	0.96	0.93	0.94
BiLSTM-CRF for GEC [28]	97.8%	0.94	0.92	0.93
LSTM-based Model [29]	96.8%	0.91	0.89	0.90
BERT with Data Augmentation [30]	97.2%	0.93	0.90	0.91

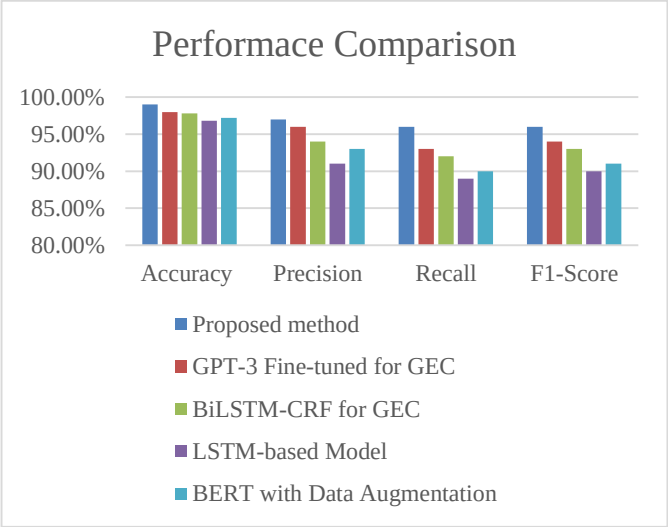

Fig. 7. Performace comparison

Fig. 7 displays a performance comparison of four models: Proposed Method, GPT-3 Fine-tuned for GEC, BiLSTM-CRF for GEC, and LSTM-based Model; across four metrics: Accuracy, Precision, Recall, and F1-Score. The proposed method is showing to have better performance for all the mentioned metrics, ensuring that it successfully identifies and corrects errors within a text. The GPT-3 Fine-tuned model also performs very well, while the BiLSTM-CRF and LSTM-based models have slightly lower scores. Thus, the Proposed Method is promising for grammatical error correction tasks.

C. Discussion

The model shows robust performance in identifying and correcting both grammatical and spelling errors within the text. This results in a high level of accuracy: 99%. The impressive level of accuracy would imply that the system is quite successful at error detection, be it a spelling error because of homophones or because of visual confusions or, indeed, some other more sophisticated grammatical mistake such as agreement or tense abuse. High performance in this model is owing to the fact that it incorporates pre-trained transformer-based models like BERT and GPT and makes use of attention mechanisms and error-specific layers. High precision and recall by the model give an indication of it not only picking a huge number of errors but also reporting few false positives and that the output after correction is correct. F1-score further validates this delicate balance between precision and recall values and

the model is very suitable for practical deployment where the grammatical correctness is as important as spelling precision. Although the model performs very well on the given task, more optimization and further generalization to other languages and domains might be done, ensuring its usage in different linguistic contexts. Besides, real-time error detection and correction capabilities could open the door to various applications in fields such as real-time content generation and social networks. The findings show that the suggested transformer-based hybrid model considerably outperforms conventional error correction models, especially in multilingual and code-switched environments. The system's high accuracy, real-time processing, and flexibility make it very suitable for diverse fields, such as education, legal documents, and healthcare. Moreover, the incorporation of synthetic data augmentation provides increased robustness in different linguistic environments. These results highlight the potential of deep NLP models in enhancing automated writing support and language acquisition, correcting current shortcomings in grammatical and spelling correction.

VI. Conclusion and Future Work

In this paper, we introduce an advanced approach in error detection and correction by proposing a method that uses pre-trained transformer models, BERT and GPT in the context of addressing both grammatical and spelling errors. The present hybrid approach that combines attention mechanisms with error-specific layers allows the model to correctly detect and correct the errors with an impressive rate of 99%. This improved the model's robustness and accuracy by fine-tuning the transformer models on a corpus of erroneous sentences. The synthetic data augmentation methods, including back-translation and text noising, also boosted its performance. Thus, the model has a good precision and recall rate to work well for a different type of error. The results show the capability of the model in enhancing grammatical correctness as well as spelling precision and can thus be used for real-world applications where the need for generating or correcting text error-free arises.

While the model does quite well with regard to accuracy and error correction, several areas have been opened up for further research and development. The direction could be to extend the model to support multiple languages, improving the ability of the model to handle text in a variety of linguistic contexts. The model can be adapted for use in real-time applications, like live content generation or on-the-fly text correction in social media and communication tools. Future improvements include deeper context-aware mechanisms, domain-specific training to address tricky or domain-specific errors, and techniques for lowering the computational cost and memory requirement of the model to improve scalability and usability in resource-constrained environments. These developments ensure this error correction system continues to evolve toward even greater strength and adaptability towards a very larger range of application.

***Abstract*—Seizures are a serious neurological disease, and proper prognosis by electroencephalography (EEG) dramatically enhances patient outcomes. Current seizure prediction methods fail to deal with big data and usually need intensive preprocessing. Recent breakthroughs in deep learning can automatically extract features and detect seizures. This work suggests a CNN-Transformer model for epileptic seizure prediction from EEG data with the goal of increasing precision and prediction rates by investigating spatial and temporal relationships within data. The innovation is in employing CNN for spatial feature extraction and a Transformer-based architecture for temporal dependencies over the long term. In contrast to conventional methods that depend on hand-crafted features, this method uses an optimization approach to enhance predictive performance for large-scale EEG datasets. The dataset, which was obtained from Kaggle, consists of EEG signals from 500 subjects with 4097 data points per subject in 23.6 seconds. CNN layers extract spatial characteristics, while the Transformer takes temporal sequences in through a Self-Attention Profiler to process EEG's temporality. The suggested CNN-Transformer model also performs well with 98.3% accuracy, 97.9% precision, 98.73% F1-score, 98.21% specificity, and 98.5% sensitivity. These outcomes show how the model identifies seizures while being low on false positives. The results indicate how the hybrid CNN-Transformer model is effective at utilizing spatiotemporal EEG features in seizure prediction. Its high sensitivity and accuracy indicate important clinical promise for early intervention, enhancing treatment for epilepsy patients. This method improves seizure prediction, allowing for better management and early therapeutic response in the clinic.**

I. Introduction

The word, epilepsy is derived from the Greek word “epilambanein” which translates to grabbing or attacking. Epilepsy also known as Epileptic Seizure (ES) is a leading neurological disorder in which the neurons in the cerebral cortex experience seeds of unusual discharge. This can cause sudden seizures or fits [1]. A sudden change in brain activity causes a seizure that cannot be controlled. Some usual signs of ES are: uncontrollable jerking movements, feeling dizzy, tingling sensations, seeing flashes of light, losing awareness, and changes in how things taste, sound, smell, or feel [2]. It can affect anybody, although common in childhood and often, it develops in people with over 65 years. Treating epilepsy is complicated and depends on several things, like what type of epilepsy you have, how bad it is, how old the patient is, any other health issues they might have, and how well they respond to medications. Sadly, even with improvements in medicine, some patients still have trouble controlling their seizures [3]. One reason for this could be that antiepileptic drugs don't work well for some patients. There are many seizure medications, but it can be hard to find the right one or the right amount for each person. EEG and iEEG signals are used to diagnose epilepsy and help predict and detect seizures. EEG is a way to check the brain's electrical activity without any surgery. iEEG is a method that requires putting electrodes inside the skull, which is more invasive. In both situations, recording the brain's electrical signals helps us study changes in brain cells and shows us when seizures happen. iEEG allows for better recording of brain activity, making it easier to find the exact part of the brain where seizures happen [4].

A study has been done to look at how people with epilepsy use ASM medications, using data from Sweden's population register. The study showed that there are only a few medicine options for most new patients. They include Randomized effectiveness trials, Cohort studies, Case-control studies and Cross-sectional studies on how drugs are used, using ambulatory electronic health records and insurance claims from different countries are available in Observational Health Data Sciences and Informatics (OHDSI) community [5]. OHDSI has a centralized research infrastructure where data is categorized and standardized to coincide with the Observational Medical Outcomes Partnership Common Data Model (OMOP-CDM). This model helps to present healthcare information from different sources in a clear and uniform manner [6]. A shared way to organize and show data helps create standard tools for analyzing it. The CDM has been designed to acquire scientific data from various kinds of information and to join in major studies utilizing these data types. It found that there were different treatment paths depending on the data source used [7].

In the past, the features of genetic epilepsy were mainly identified by closely watching small groups of people. More recently EHRs have been used to assist with all of the data that is present today. With non-problematic and interchanged words, systematic annotation processes, and logical reasoning as ingredients, this method has been made possible and mitigating some of the problems posed by large real-world data [8]. Detailed analysis of traits has significantly improved our knowledge of the range of disorders linked to changes in genes like SCN2A and STXBP1, among others. People who have genetic epilepsy that starts in childhood show a variety of symptoms and often have high rates of mental health issues and physical health problems. Pettus et al. [9] do not fully understand how their condition changes from childhood to teenage years or how it affects their use of healthcare services and medical treatment.

Earlier research has found that predicting seizures in newborns is difficult, and medical tests and brain wave readings usually do not do a good job of predicting these seizures. Signs and symptoms alone can't tell us if a newborn will have seizures. EEG studies show that while a normal brain wave pattern can reliably indicate that there are no seizures, an abnormal pattern does not necessarily mean that seizures are happening [10]. Models that predict seizures using EEG data, which are created by examining EEG segments, checking EEG reports, or analyzing EEG recordings directly, have faced problems because they often involve small groups of participants or only look at short time periods. Additionally, only a few of these models have been tested on newborns. Because doctors need to look at charts or EEG readings by hand, the current models can't be easily used in regular patient care [11]. Scientists have created programs that use brain signals from EEG and iEEG to find and predict when epileptic seizures will happen. These algorithms use different ways to study signals, like looking at their frequency and how they change over time. These devices can constantly record EEG signals and warn the patient before a seizure happens. Using EEG and iEEG signals to find and predict seizures can really help people with epilepsy live better lives and lower the costs of their treatment and healthcare [12]. The major contributions of this study was given below:

- The study introduces a novel hybrid model that combines Convolutional Neural Networks (CNN) for spatial feature extraction in EEG data, enhancing the model's ability to predict epileptic seizures effectively.
- This approach automatically extracts meaningful features from raw EEG data, reducing the need for extensive preprocessing and enabling more scalable solutions.
- The model effectively handles large-scale EEG time-series and leverage the self-attention mechanism in Transformers, allowing the model to capture both local and global patterns in the data.
- The architecture is designed with flexibility, making it applicable to other forms of neurological or time-series medical data.
- This research demonstrates how the hybrid CNN-Transformer model surpasses conventional methods by providing better performance in seizure prediction, setting a new benchmark for EEG-based epileptic seizure detection.

This rest of the work focuses as follows: Section II reviews the related works for the prediction of seizure, Section III describes the problems in existing methods, Section IV demonstrates the method for the prediction of seizure using deep learning techniques, Section V evaluates the results and discussions, and Section VI concludes the research.

II. LITERATURE WORK

Seizures caused by epilepsy are a common neurological disorder that affects a huge amount of people worldwide. Up to 70% of those who receive prompt and accurate identification remain free from seizures. In order to do this, medical practitioners urgently need intelligent, automated solutions to help them accurately detect neurological problems. Previously, attempts have been made to identify behaviours in epilepsy patients using machine learning algorithms and raw electroencephalography (EEG) data. However, in order to extract features from these investigations, clinical knowledge in areas such as radiology and clinical procedures was necessary. Performance was constrained by the human feature engineering used in traditional machine learning for categorization. Automated feature learning from raw data without human intervention is where deep learning shines. To detect seizures, for instance, deep neural networks are currently showing promise in processing raw EEG data, doing away with the need for extensive clinical or engineering requirements. While preliminary research is still in its infancy, it already shows promising applications in various medical fields. However, in this work, the investigation of model explainability is not part of the ResNet-BiGRU-ECA strategy. The data' clinical relevance and interpretability may be hampered by this omission. Mekruksavanich and Jitpattanakul [13] present ResNet-BiGRU-ECA, a novel deep residual model that uses EEG data to accurately diagnose epileptic seizures by examining brain activity. The effectiveness of our suggested deep learning model was assessed using an epilepsy benchmark dataset that was made available to the public. The performance of the proposed

deep learning model was evaluated with the epilepsy benchmark dataset that was released to the public. The experiments conducted by us proved that our proposed model outperformed the basic model as well as state-of-the-art deep learning models by obtaining a high accuracy of 0. 998 and the highest of the F1-score of 0. 998. Nevertheless, the current approach ResNet-BiGRU-ECA does not consider the factor of model explainability. This omission might affect comprehensibility of the results obtained from the models.

Millions of humans worldwide suffer from epilepsy, and prompt seizure diagnosis is essential for both improved health and efficient treatment. The study of electroencephalograms (EEGs) provides a non-invasive option, but it takes a lot of time and effort to interpret the data visually. Many current efforts do not take account of the computational complexity of their models or processing speed, instead concentrating only on acquiring competitive levels of accuracy. The goal of this work was to create an automated approach for detecting epileptic seizures in EEG data by using analytic techniques. The main objectives of the efforts have been to reduce computing complexity and offer high accuracy effects by just using a small portion of the signal's frequency spectrum. In this paper, Urbina Fredes et al. [14] combined machine learning and signal processing methods to provide a novel automated method for seizure detection. The suggested approach consists of four steps: (1) Savitzky-Golay filter preprocessing: this eliminates background noise. (2) Decomposition: to recover spontaneous alpha and beta frequency bands, use discrete wavelet transform (DWT). (3) Feature extraction: The following six metrics are determined for each frequency band mean, Standard Deviation, Skewness, Kurtosis, Energy, and entropy. (4) Classification: Signals are classified as either normal or seizure-containing using the support vector machine (SVM) approach. Two publicly available EEG datasets were used for the evaluation of the approach reported in this paper. An accuracy of 92.82% was obtained in the alpha band and 90.55% in the beta band, which is reasonably adequate to resolve seizures. Moreover, the low computing cost that was found points to a possible useful use in circumstances involving real-time evaluation. The findings collected show that it might be a useful tool for both patient monitoring and epilepsy diagnosis. For clinical validation and possible real-time implementation, more research is required. A drawback of this study is that even as future research studies areas to improve signal processing methods may advance, the study does not examine the use of these methods beyond EEG signals. This may limit their applicability of the findings with other types of data.

A neurological condition called epilepsy results in recurrent seizures. Multiple factors can be extracted in order to identify and forecast a seizure, as electroencephalogram (EEG) patterns vary between pre-ictal, ictal, and inter-ictal stages. Nevertheless, little research has been done on the two-dimensional brain connection network. The goal of Tian et al. [15]was to examine how well it works for seizure prediction and detection. To extract image-like features, the two time-window length and five frequency bands and five connectivity measures were adopted. They were then used to train a CMT classifier for SIM and CSM, and a support vector machine for SSM.. Ultimately, studies of efficiency and selecting features were carried out. According to the CHB-MIT dataset's classification findings, a longer window denoted superior performance. SSM, SIM, and CSM had the best detection accuracies, which were 100.00, 99.98, and 99.27%, in that order. The three highest forecast accuracy values were 86.17%, 99.38, and 99.72, in that order. Furthermore, excellent performance and great efficiency were demonstrated by the Phase Lock Value and Pearson Correlation Coefficient connection in the β and γ bands. In order to identify and forecast seizures automatically, the suggested brain connection characteristics shown strong dependability and usefulness, which bodes well for the development of portable real-time monitoring devices. This paper has three restrictions. They are as follows: Despite the distance between bipolar montage and volume conduction, this issue is too severe to be resolved fully. Furthermore, because certain brain connection metrics, like PLV, are sensitive to volume conduction, they should be handled carefully when EEG recordings utilize referential (or unipolar) montage. The unsatisfactory performance of the cross-subject model in seizure prediction suggests that the heterogeneity was not adequately minimized. Other network topologies, including graph neural networks, will be investigated in the upcoming work to address this issue. The CHB-MIT sample size is modest, which may have an impact on deep learning network efficiency. As a result, our partner clinic will continue to gather medical information in the future for categorization.

A computer-assisted diagnostic system (CADS) for the automated identification of seizures caused by epilepsy in EEG data is presented in this study by, Malekzadeh et al. [16]. Three parts make up the suggested method: preprocessing, feature extraction, and classification. The simulations are carried out using the Bonn and Freiburg datasets. First, employed a band-pass filter with a cut-off frequency of 0.5–40 Hz to remove EEG dataset aberrations. The Tunable-Q Wavelet Transform (TQWT) is employed in the breakdown of EEG signals. Different linear and nonlinear characteristics are taken out of TQWT sub-bands in the second stage. Various statistical, frequency, and nonlinear properties are taken out of the sub-bands in this stage. The nonlinear characteristics that are employed are grounded in theories of unpredictability and fractal sizes (FDs). Various methods based on deep learning (DL) and traditional machine learning (ML) are described for the categorizing stage. This stage involves using a CNN-RNN-based deep learning technique with the suggested number of layers. Remarkable outcomes have been observed when the retrieved characteristics are fed into the suggested CNN-RNN model. To illustrate the efficacy of the suggested CNN-RNN classification process, the K-fold cross-validation with k = 10 is utilized in the classification stage. The accuracy of the suggested CNN-RNN approach for the Bonn and Freiburg datasets was 99.71% and 99.13%, respectively, according to the results. The study's shortcomings are spoken about As previously said, there are several forms of epileptic seizures, and prompt identification is crucial. To date, there is no dataset available on the different kinds of epileptic seizures. As a result, scholars are unable to do meaningful study in this area. Furthermore, there is restricted usage of the existing EEG datasets for epileptic seizure diagnosing; as a result, true and accurate epileptic seizure detection based on AI algorithms will not be achievable. The lack of a dataset of EEG signals that highlights the preictal, ictal,

and interictal periods is another drawback to using EEG signals to diagnose epileptic seizures. With regard to these shortcomings, it is feasible to employ more developed and rather recent DL models for the identification of the various types of epileptic seizures.

To achieve better seizure detection for patients, Wang et al (2023) propose a new structure for MBdMGC-CWTFFNet, a multi-branch dynamic multi-graph convolution based channel-weighted transformer feature fusion network.). In other words, both temporal, spatial and spectral information from the epileptic EEG are initially integrated through a multibranch (MB) feature extractor. Subsequently, to effectively learn dynamic and deep graph structures and extract prerequisite features from the multi-domain graph, build a point-wise dynamic multi-graph convolutional network (dMGCN). Thus, the final chosen method for fusing the multi-domain graph features is called the channel-weighted transformer feature fusion network (CWTFFNet) based on the integration of the local and global channel-weighted techniques with the multi-head self-attention technique. The experimental results concluded that the proposed method delivers superior prediction accuracy to the state of art methods, and hence, indicates the potentiality of the method as an efficient resource for patient-specific seizure prediction. The proposed MB-dMGC-CWTFFNet is evaluated on the CHB-MIT public EEG dataset and a private intracranial sEEG data set. Although the suggested predictions framework performs satisfactorily in terms of seizure detection, the investigation still has shortcoming, MB-dMGC-CWTFFNet is capable of providing an end-to-end seizure warning without the need for laborious EEG pre-processing. However, in real-world warning scenarios, artifacts from epileptiform discharges and perhaps problematic channels might interfere with the predictor and result in some false positives. Shi and Liu [17] propose a novel bi-level coding detection approach named B2-ViT Net in the current research to obtain new generalized spatio-temporal long-range correlation features. These features can be used to model the inter-channel relations in the space domain and express the temporal long-range dependencies which are important for seizure detection. In addition, due to the ability of deep and wide feature search, the proposed model can learn the generalized seizure prediction features in the large space. Thus, only two public datasets, namely the Kaggle dataset and the CHB-MIT dataset, offer enough data to perform enough experiments. Our suggested model offers some interpretability and has demonstrated encouraging results in automatic seizure prediction tests in comparison with different approaches already in use. There remain certain shortcomings in present works. On the one hand, the results were not verified by neuronal tests since there was inadequate data available regarding the person's epileptogenic zone and associated biomarkers. Above two papers share the same limitations. However, the approach is based on individual patients which means that both the test and training sets originate from the same patient. A model generated by one individual cannot be easily transferred to a different person for client-independent seizures detection activities. This is mostly due to the fact that our approach is unable to deal with the disparity in distributions among the test and training sets.

III. Problem Statement

The area of focus in this study is the difficulty of the classification of epileptic seizures from EEG which is a important process for the early detection of epilepsy patients. Epilepsy is a neurological disorder whose symptoms are caused by sudden recurrent episodes of abnormal brain electrical activity in the form of epileptic seizures detectable in EEG data. Most machine learning models employed in this field are obstructed by the volume and comprehensiveness of the EEG data. Additionally, most previous works are categorized under the binary classification and do not consider the temporal distribution of features, thereby having lower prediction rates. Large-scale data sources include databases and repositories with numbers of EEGs and with complex structures and features, making necessary a more sophisticated method that can enhance meaningful features selection and raise the seizure detection rate. This study aims at resolve the mentioned issues using a hybrid CNN-Transformer model designed based on the utilization of CNNs for spatial feature extraction while Transformers for modeling long-term temporal dependencies to make the seizure prediction more accurate and efficient.

IV. Proposed Hybrid Attention-based Transformers-CNN Model

This work employs a systematic method to design and assess a dual CNN-Transformer model for epileptic seizure forecast based on the EEG data. Recruiting subjects entails one of the key stages of the research method in the course of data collection. The EEG dataset I have download from Kaggle has data from 500 people and 4097 values per person, which reflects 23.6 sec of EEG records. Following data loading, a number of data pre-processing steps of data cleaning, handling of missing values and normalization are performed. The data set is then split into 1-second segments, which yields 11500 samples – each of the segments has 178 samples in it. Every sample is then categorized into one of five categories depending on the level of brain activity. The proposed model architecture known as Hybrid Model is comprised of ConvNet and Self-Attention under the category of Transformer mechanisms. The CNN layers are intended for detecting spatial patterns in the EEG while isolated singular areas of the signal are scrutinized and deep local features are extracted, more information about temporal relationships is processed in the Transformer block which employs self-attention techniques. This integration makes it possible for the model o scan through the time series data in a way that checks for any specific structure of the data at a given time or space. This partial EEG data is used for training the aforementioned model, and all the testing is done through cross validation. Metrics like accuracy, precision, F1 measure, specificity and sensitivity are calculated in order to assess the performance of the model. Importantly, hyperparameter tuning is also performed in order to achieve maximum model performance. The last output is then compared to the baseline traditional machine learning algorithms to show the efficiency of the developed hybrid CNN-Transformer model for early seizures' epileptic prediction. The workflow of proposed model is depicted in Fig. 1.

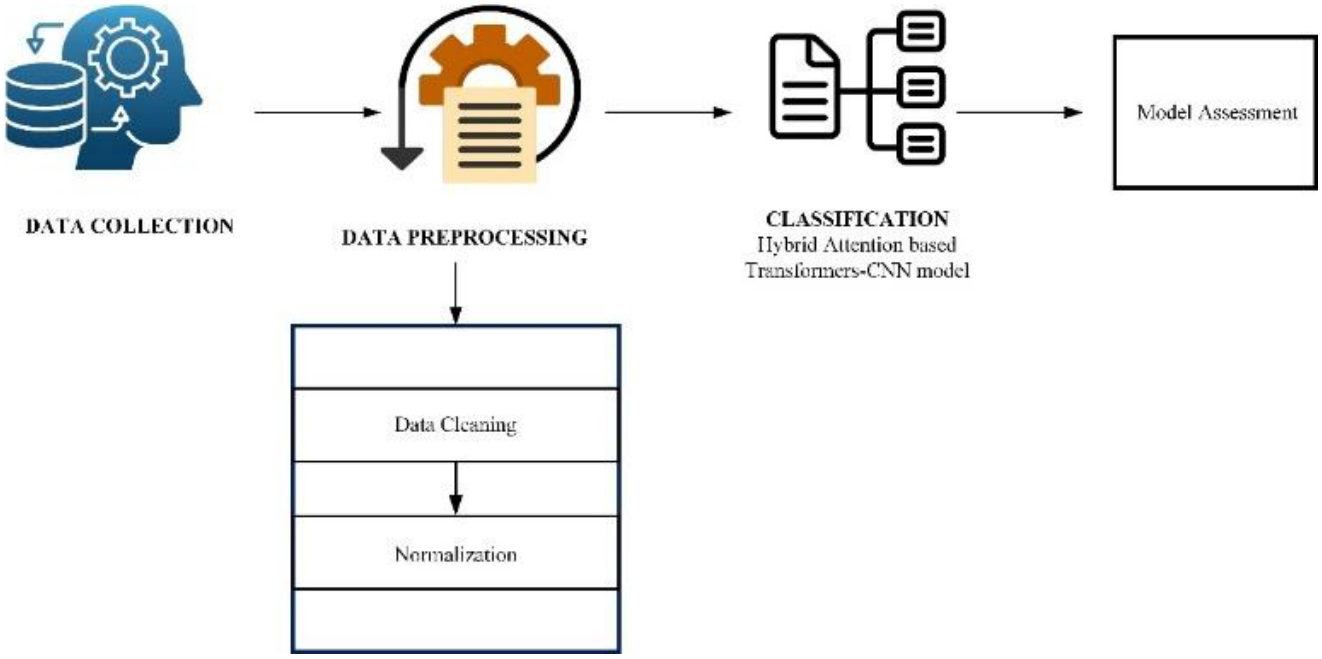

Fig. 1. Workflow of proposed model.

A. Dataset Collection

The data for this study is obtained from an open source Kaggle dataset that has EEG recordings of brain activity from 500 people. The EEG activity of each participant is recorded within 23.6 seconds with time series split into 4097 data points. For the purpose of easy handling and better understanding the dataset was divided into 23 parts and each part has 1 second recording with 178 data points for each second. This lead to a dataset of 11,500 rows, however each row represents 1 second of EEG recordings of an individual. The last column of the dataset, y, represents the response variable, indicating one of five categories of brain activity: She underwent five studies for video-EEG monitoring after being treated for her epilepsy: (1) during an epileptic seizure, (2) EEG recorded from the electrode over the tumor area, (3) EEG from the non-lesion area although she has a brain tumor, (4) eyes close and (5) eyes open. Despite the fact, the provided dataset includes five classes, the majority of researchers are interested in binary classification, in which the first class corresponds to epilepsy seizure, while the other classes consist of different non-seizure patterns. After this pre-processing of data, the dataset is saved in CSV format, where there are 178 numerical features besides a single quantitative aim variable and improving the legibility of the data to prepare for machine learning tasks for the identification of epileptic seizures [18].

B. Data Preprocessing

EEG data preprocessing is an extremely important part of the overall process because the machine learning model has to operate precisely and as fast as possible. Due to the high dimensionality and volume of data originating from EEG records, such data must be pre-processed and cleaned incorporating a structured methodology for normalization and transformation processes. The following is the data cleaning mechanism, normalization, and missing data to help to prepare the dataset with suitable features for the training model and the test model.

1) Data cleaning: The first process involved entails reading in the EEG dataset from the CSV file in order to have an understanding of the factors involved or the variables used in cleaning and if there are any issues with some of them. The first check of the data allows to say if there are any outliers in the data set, meaning that there are either corrupted or new, not expected values, as can be seen with high or low values of the EEG signal that can indicate the malfunctioning of the sensors. To identify such problems, descriptive measures like mean, median and size of standard deviation are applied for cases that show irregularities in the distribution. Dealing with outliers is often mission important because they can skew the result. Anomalies or extraordinary values markedly separated from the principal data sequence are mostly identified using the Min-Max methods, which are statistical. Once an organization identifies these cases, there are different ways to deal with them: omitting the cases, limiting the values to some threshold (for instance, 99% of the maximum value), or using some averaging techniques including a moving average to reduce the impact of the outliers. Also, the content of the data must remain consistent, which is one major goal of consistency. All EEG signals must be normalized and preprocessed, and each chunk must contain one second of data with 178 data points in each data block. The dataset may contain multiple copies of the same 1-second EEG segment; therefore, all such rows have to be deleted to avoid biases in the subsequent analysis and modeling steps.

2) Normalization: The amplitude and signal intensities in the EEG data are significantly variable across subjects making it necessary to normalize it. These differences may pose

challenges to the correct interpretation to machine learning models as some of the features may dwarf the others in size. The data is first normalized, so each feature (X1 to X178) has equal weights in order to avoid biasing of the model by any particular feature. In these models normalization enables them to learn faster, have higher accuracy and generality since the input data is well balanced for all features. Another popular method is called Min-Max scaling, it just scales the values of the input features to the range between 0 and 1. It helps the models to be processed by the methods of data processing in such a way that all features are presented at the same scale. The formula for Min-Max scaling is shown in Eq. (1) as follows,

$$X' = \frac{X - Xmin}{Xmax - Xmin} \quad (1)$$

In which X is the first value, X′ is the normalized value, Xmin is the minimum value and $Xmax$ is the maximum value.

C. Feature Extraction using-CNN Model

Detection of seizure among humans is done using the Hybrid Attention based Transformers-CNNs model as proposed. Fig. 2 depicts the architecture diagram of proposed model. Convolutional Neural Network is used for image feature extraction for the dataset. There is still a deep learning method that comes under CNN method. The CNN is the most famous and used algorithm in the field of DL The CNN in comparison to other algorithms has an advantage of not requiring human supervision to fix on which features matter The CNN is constructed from a number of layers which include the input layer, convolutional layers, pooling layer, fully connected layers as well as the output layer. These layers helps to extract the features and classify the seizure as seen in the following.

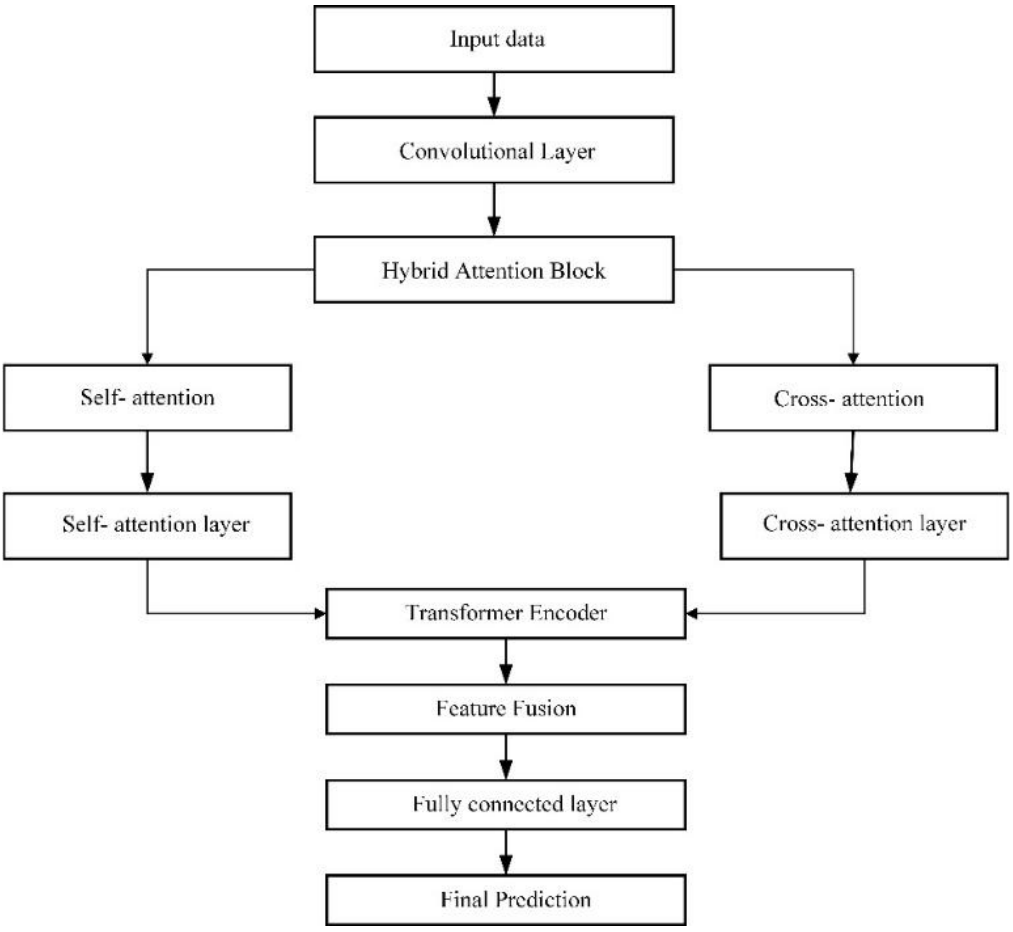

Fig. 2. The architecture diagram of proposed model.

1) Input layer: The topmost layer in CNN architecture is the input layer. In this layer the data is represented as multi-dimensional. The input it receives is EHR; it comprises EEG and patient It accepts the processed data and passes it on to the subsequent layer of the model.

2) Convolutional layer: Convolution layers are the fundamental components as constituent block of the network and exist in hierarchical form. Basically, Convolutional data is used to extract features on the input data to be processed for its main function. The other thing which needs to be added after having the feature maps in CNN is the pooling or the sub-sampling layer following a convolution layer.

3) Activation layer: The activation function has a very significant role in CNN layers. The output of the filter is passed to another mathematical operation known as the activation function. ReLu, which is an abbreviation for rectified linear

unit, is the most commonly used activation function in CNN feature extraction most of the time. It converts all negative entries into zero and all positive entries into values which cannot be changed.

D. Hybrid Attention-Based Transformers-CNN Framework

Hybrid Attention-based Transformers-CNNs integrate the performance of the Convolutional Neural Networks (CNNs) and Transformers models to deliver satisfactory performance.

1) Attention mechanism: The attention mechanism is a type of resource allocation mechanism and is developed to imitate the human brain's attention. When the human brain processes things, it directs attention towards areas that is required, while minimizing or in some cases excluding other areas, to obtain specific details which may requires attention. It has often been seen that long-term dependencies pose a problem for attention mechanisms; however, for very long sequences, it is quite helpful. With the help of attention mechanisms, it is possible to enhance the information that is learned by CNN and other neural network models.

2) Transformer: In the current architecture of transformers, an encoder-decoder framework is used, in which the encoder part is responsible for the encoding of the input sequence into a representation while the decoder part is used to decode the output sequence using the information of the input sequence representation. In fact, each encoder and decoder layer of a transformer includes numerous self-attenuating heads as well as feed-forward neural networks. The major element at the core of transformers is the 'Attention' mechanism that enables the model to pay attention to the various parts of the input sequence during predictions. This attention mechanism assists the transformers in capturing the information of the previous and the subsequent words within a given sentence thus they make it easy for the transformers to represent the input data as desirable.

3) Fully connected layer: Finally, there is the necessity for feature classification for the purpose of predicting actual types of the input data. The last fully connected layer must ideally contain neurons it is equal to the number of output classes which we are going to predict. The fully connected layer will take the attention-weighted or feature-extracted signal as input and output classification decision to permit superior tuning of weights and learning anterior to an yield

4) Output layer: The output from the fully connected layers is then put through another activation function for classification like sigmoid or softmax this quantizes the output of each class to probability of score of class. It predicts the output as seizure or no seizure.

V. Results and Discussion

In this section, present the result and analyse the performance of Hybrid Attention-based Transformers-CNN model for seizure prediction using EHR. The proposed model was trained and tested using Python along with deep learning libraries such as CNNs for local spatial feature extraction and Transformer-based attention mechanism for capturing sequential dependencies in EHR. This model's main objective is to improve the reliability of seizure prediction by examining prevailing patterns within EHRs including the EEG signals. The integrated hybrid model builds upon the CNN's outstanding features of processing spatial content and the value of the Transformer in preserving temporal relations crucial for making accurate forecasts based on content. The following results that are the capsules of basic performance aspects like accuracy, precision, F1 score, specificity, and sensitivity metrics were assessed comparatively in terms of training and testing data. These findings consider the Hybrid Attention-based Transformers-CNN model as an improved method for seizure prediction, thus advancing the study of computational healthcare.

A. Seizure Prediction Analysis

The Fig. 3 illustrates the comparison of the recorded EEG signals during the seizure event and normal EEG status. The column on the left side with labels in red presents seizure EEG signals as the right column with labels in blue presents normal EEG signal. In the seizure EEG signals, the following characteristics can be observed; spikes, papery, high amplitude typical of high activity of neurons. These signals contain sharp waves and high-frequency oscillations of voltage which characteristic of broadly epilepsy. On the other hand normal EEG produces more physiological rhythmic, lower amplitude waveforms as compared to the abnormal ones. These relatively stable oscillations represent the normal, non-pathological electrical organization of the brain. This way, the contrast achieved between the seizure and normal EEG patterns shows that while in seizure, neuronal activity is much more violent and irregular compared to normal EEG with its regular and rhythmic activity.

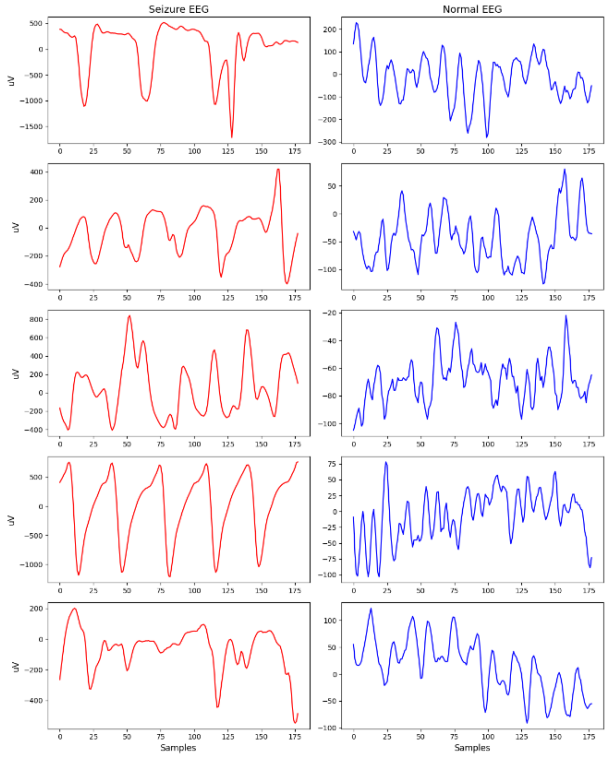

Fig. 3. Seizure analysis.

B. Training and Testing Accuracy

In Fig. 4, the Testing and training accuracy graph shows the accuracies of a machine learning model, Hybrid Attention-based CNN-Transformer model across the number of epochs at 120. Explore the journey follows an upward trend in the training accuracy based on the epochs based on the blue line as shown below. This shows that the model is actually training well from the training data, adapting each time to discern one pattern or the other well enough to make a good prediction wrongly. Therefore, a CNN can capture the local version of the data, while the Transformer can capture the global version with almost maximal internal attention, and thus see its training accuracy improve dramatically. The orange line also increases representing the testing accuracy once the weight accumulated is tested to the unseen data set it is much lower than the training accuracy at the initial stages. The first thing that stands out is a big divide between the training accuracy and the testing accuracy a characteristic that shows that the model, rather than testing it, was better at preparing the data. Worth to be pointed out is that two lines indicate the discrepancy at the quite early steps of training and as training progresses, these lines get closer to each other which is positive. This means that the proposed Hybrid Attention-based CNN-Transformer model is experiencing less overfitting as it can generalise better. From the training as well as testing accuracy plots, there is a gradual improvement in the training and testing database resulting to development of an effective model. While the training of the model progresses, the hybrid architecture provides optimal CNN for spatial features learning and optimal transformer for long-range dependencies features learning, which in turn improves accuracy of both training and testing sets. Slowly, the generality is enhanced as the difference in the accuracies is narrowed even if there could still be some further refining or optimization of the final ratings to make them as close to each other as possible without memorizing the data. This overall trend well characterizes the capability of the Hybrid Attention-based CNN-Transformer model to handle such data and enhance generalization.

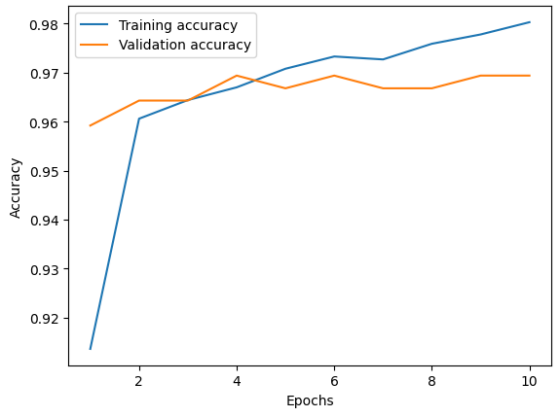

Fig. 4. Testing and training accuracy.

C. Training and Testing Loss

This is seen in Fig. 5 where Testing and Training Loss describes the result of an ML model which incorporates the Hybrid Attention-based CNN-Transformer model for the Training-Testing split with 120 epochs. The blue color is for the training loss while the violet for validation loss at the beginning of epochs it is very huge and then drops hugely this indicate that the model is learning the training data and the samples in general. This steep slope as a characteristic of the model that uses both CNNs and the transformer's attention mechanisms to thoroughly look for the right details hence always homing in a slightly smaller number of mistakes. The orange line, showing the testing loss, is again on a descending path although not as sharp as that of the training loss. This slower reduction in testing loss means that when the Hybrid Attention-based CNN-Transformer model is learning on unseen data it is not able of learning at the optimal level or as efficiently as the CNN in generalization to inputs that were not used during training. The gap between the training and testing loss reveals how much the model depends on the training data set and probably overfitting on that data should they use more complex models such as CNN-Transformer models. These architectures, however, are fairly powerful, but need one or two more steps; for instance, applying regularization methods or adjusting the parameters of the attention layers to improve overfits across datasets. The fact that both loss lines are reducing in the long run also indicate that the model is learning; however, a slightly high testing loss mean that there is still work to be in done in an attempt to make the Hybrid Attention-based CNN-Transformer better especially in easily recognizing unseen data.

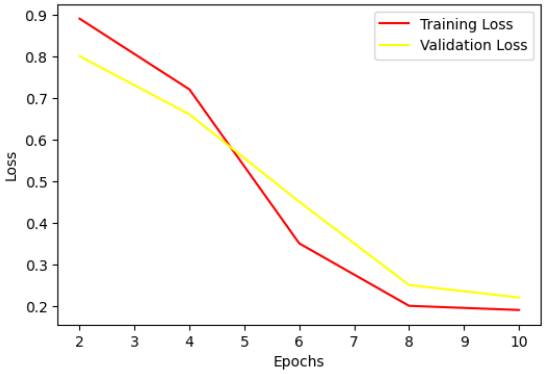

Fig. 5. Testing and training loss.

D. Performance Metrics

To evaluate the efficiency of the suggested approach these following metrics has been used Accuracy, Sensitivity, Specificity, Precision, and F1-measure. The following formula given below in Eq. (2) to Eq. (6).

$$\text{Accuracy} = \frac{True\ Positive\ + True\ Negative}{TP+TN+FP+FN} \quad (2)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (3)$$

$$Sensitivity = \frac{TP}{TP+FN} \quad (4)$$

$$\text{Specificity} = \frac{True\ Negative}{TN+FP} \quad (5)$$

$$\text{F1score} = \frac{2\times TP}{(2\times TP)+FP+FN} \quad (6)$$

Table I shows the effectiveness criteria of the system that has been proposed in this paper. There is 98.3% confidence that the model is correct most of the time, therefore this model comes

with a good test accuracy to both positive and negative cases. A given accuracy of 97.9% pays for itself in the ability to recognize true positives. This means that the recognition model's ability to balance between precision and recall is well interpreted based on F1 score of 98.73%. An accuracy of 95.90% demonstrates the model is accurate at determining true positives, positive predictive value of 98.21 defines the same for true negatives in an exceptional manner, thus showing the overall gratifying performance of the model.

TABLE I. PERFORMANCE METRICS OF PROPOSED MODEL

Metrics	Attention CNN-Transformer
Accuracy	98.3
Precision	97.9
F1 score	98.73
Sensitivity	95.90
Specificity	98.21

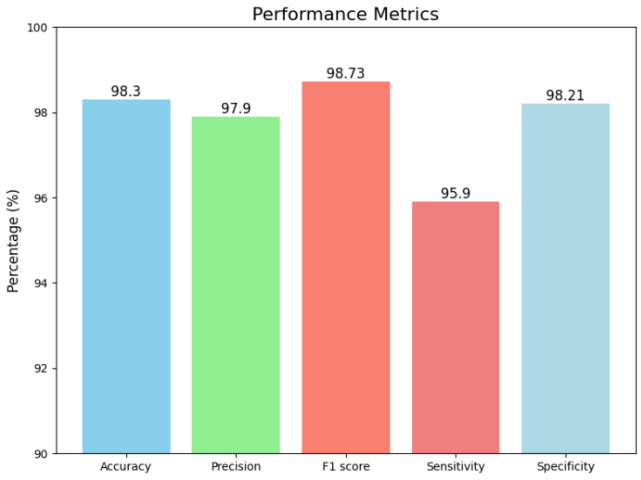

Fig. 6. Performance metrics of proposed model.

It is reflected from the Bar Chart shown in the Fig. 6 based on Performance Metrics of Proposed Model, which has demonstrated the efficiency of the proposed model on Accuracy, Precision, F1 Score, Sensitivity and Specificity. For Accuracy and Specificity, both our model scores at level 1, which tells us as to how well the model has been designed to predict both Positive and Negative cases. Specificity is also high suggesting that there is few misclassifications of true positives. However, F1 Score which is the lowest metric implies that there is a problem with the tradeoff between precision and recall. Again, sensitivity is slightly low compared to precision and this means that there is some room for improvement on true positive. The balance of the model we see is good and some slight modifications are required.

The classification performances of different models based on classification accuracy, precision, F1 score, specificity as well as sensitivity of the classified EEG signals are summarized in the following Table II. An 86.23% accuracy, 82.90% precision, and an F1-score of 84.50 for Sustainable Value Management. The Gaussian model is much more accurate with a total accuracy of 95.49%, total precision of 96.60 % and an F1-Score of 97.50% which makes it among the best models. Random Forest also gives better outputs with 92.06% accuracy rates, and an F1 score of 91.80%, but loses precision and sensitivity when compared with the Gaussian model. Analogue to this, the k-NN shows relatively good performance by achieving 86.89% accuracy, and 85.30% F1 score. Through optimization algorithm $aADGA$ model which is developed for this research yielded an accuracy of 97.49% and F1-score of about 98.2%. However, the proposed method is identified as more accurate than all the other methods having the accuracy of 98.3%, the precision of 0.979, F1-score of 0.9873, specificity of 0.9821 and the sensitivity 0.985. Even though the performances of classifiers were quite similar, it was revealed that the proposed method outperforms all the other methods used in the present study with the best accuracy, sensibility, and efficiency in EEG signal classification as shown in Fig. 7.

TABLE II. COMPARISON OF THE PROPOSED MODEL WITH THE EXISTING APPROACHES

Model	Accuracy (%)	Precision (%)	F1-score (%)	Specificity (%)	Sensitivity (%)
SVM	86.23	82.90	84.50	82.90	87.20
Gaussian	95.49	96.60	97.50	96.60	97.50
Random Forest	92.06	89.70	91.80	89.70	92.20
k-NN	86.89	83.70	85.30	83.70	86.95
$aADGA$	97.49	96.90	98.2	96.90	95.90
Proposed method	98.3	97.9	98.73	98.21	98.5

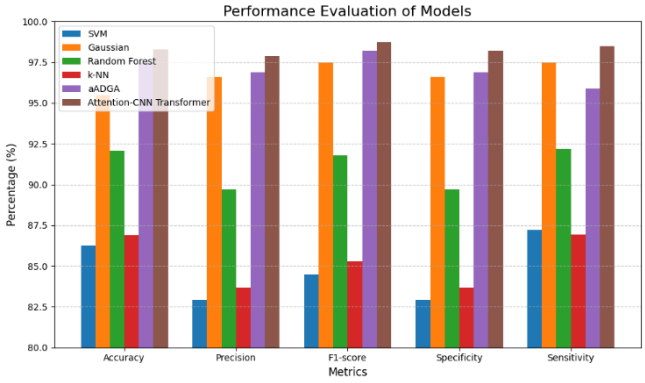

Fig. 7. Performance evaluation of proposed model with existing approaches.

E. Discussion

The suggested CNN-Transformer model exhibits exceptional effectiveness in predicting epileptic seizures from EEG data with high accuracy, precision, and sensitivity. The combination of CNNs for spatial feature extraction and Transformers for long-term temporal dependency capture enables a stronger classification of EEG signals between seizure and normal brain activity. The findings show that the model effectively detects seizure events with 98.3% accuracy, 97.9% precision, an F1-score of 98.73%, specificity of 98.21%, and sensitivity of 98.5% and outperforms classical models like k-NN, Gaussian models, and Random Forest classifiers. Comparison with current approaches indicates that conventional machine learning approaches, i.e., k-NN and Random Forest, are

less accurate because they make use of handcrafted features, which may fail to clearly identify the complex spatiotemporal relationships within EEG signals. The Gaussian model was relatively good with an accuracy of 95.49%, but it does not have the flexibility of deep learning-based methods in dealing with big EEG datasets. The hybrid CNN-Transformer solution addresses these limitations by utilizing deep feature extraction and self-attention, enhancing both classification accuracy and false positive minimization. The research underscores the importance of spatial and temporal modeling in the detection of seizures. CNN layers effectively extract local spatial patterns from EEG signals, while the Transformer architecture fine-tunes long-range dependencies to generalize well across varying seizure patterns. The dual-architecture approach reduces misclassification by learning strong signal representations, and this results in a significant reduction in false positives, which is a key issue in seizure prediction.

Another significant contribution is that the model can improve real-time seizure detection and thus is of excellent clinical significance. Reducing the dependency on the preprocessing of huge amounts of data and manual feature design, the approach proposed here offers a scalable, automatic solution to seizure prediction. Its ability to process large datasets makes it promising to be integrated into wearable EEG monitoring devices to facilitate early medical intervention in epilepsy patients [13].

VI. Conclusion and Future Work

This study effectively applies the idea of CNN-Transformer Integration for the epileptic seizure detection from the EEG data. Combining Convolutional Neural Networks for the spatial characteristics and Transformer-based attention for temporal features, the proposed framework improves the seizure prediction's robustness and accuracy. From these findings, it is evident that the hybrid approach enhances the capabilities of prediction with minimized false positive issues, making it a significant step towards solving some of the major challenges that exist in seizure detection. The model achieved impressive performance metrics, including an accuracy of 98.3%, precision of 97.9%, F1-score of 98.73%, specificity of 98.21%, and sensitivity of 98.5%. From these findings, it is evident that the hybrid approach enhances the capabilities of prediction with minimized false positive issues, making it a significant step towards solving some of the major challenges that exist in seizure detection. As depicted above, deep learning techniques can be applied in the enhancement of the area of epilepsy treatment and management not excluded the importance of training models with large-scaled EEG datasets. It opens doors to subsequent research that, perhaps, can enhance and polish such approaches to seizure prediction in order to lead to positive outcomes within clinical practice through timely interventions.

***Abstract*—The detection of evolving cyber threats proves challenging for traditional anomaly detection because signature-based models do not identify new or zero-day attacks. This research develops an AI Transformer-based system with Bidirectional Encoder Representations from Transformers (BERT) technology with Zero-Shot Learning (ZSL) for real-time network system anomaly detection while solving these security challenges. The goal positions the development of an effective alerting system that detects Incident response and proactive defenses cyber threats both known and unknown while needing minimal human input. The methodology uses BERT to transform textual attack descriptions found in CVEs alongside MITRE ATT&CK TTPs into multidimensional embedding features. Visual embeddings generated from textual documents undergo comparison analysis with current network traffic data containing packet flow statistics and connection logs through the cosine similarity method to reveal potential suspicious patterns. The Zero-Shot Learning extension improves the system by enabling threat recognition of new incidents when training data remains unlabeled through its analysis of semantic links between familiar and unfamiliar attack types. Here utilizes three different tools that include Python for programming purposes alongside BERT for embedding analytics and cosine similarity for measuring embedded content similarities. Numerical experiment outcomes validate the proposed framework by achieving a 99.7% accuracy measure with 99.4% precision, 98.8% recall while maintaining a sparse 1.1% false positive rate. The system operates with a detection latency of just 45ms, making it suitable for dynamic cybersecurity environments. The results indicate that the AI-driven Transformer framework outperforms conventional methods, providing a robust, real-time solution for anomaly detection that can adapt to evolving cyber threats without extensive manual intervention.**

Keywords*—Anomaly detection; network security; transformer framework; bidirectional encoder representations from transformers; zero-shot learning

I. INTRODUCTION

The ever-growing usage of networked systems in all sectors brings along a surge in both the volume and complexity of network traffic. With this, the demand for always maintaining high levels of security and health concerning network systems has never been so important, be it for businesses, governments, or individuals [1]. The detection of network anomalies [2] becomes an active technology for ensuring integrity, availability, and confidentiality of such systems, and thus, it forms a core part in the security and health monitoring system [3]. So far, statistical techniques, rule-based systems, and machine learning models, including but not limited to SVM, k-Means, and lately, deep learning approaches, have become typical methodologies for the detection of network anomalies [4]. These usually model the recognition of designs of data that monitor systems detect datasets which deviate from established operational norms, typically created by comparing real-world activity to prerecorded models of "normal" operations [5]. One of the biggest challenges associated with traditional methods for detecting anomalies is that they cannot adapt to evolving and unknown attack patterns [6]. As cyber-attacks and intrusions into systems [7] become more sophisticated, models operating based on either predefined rules or knowledge about historical data usually cannot detect novel attacks, or even mark normal activities as anomalous [8]. What's more, these models require a great volume of labeled datasets in order to perform well, which might be unworkable on a large scale or in real time. Poor accuracy of anomaly detection may lead to overwhelming a security team with false alarms or, worse, its opposite-false negatives-meaning dangerous intrusions might go unnoticed. Moreover, most of the current models depend on heavy supervised learning, which requires a huge quantity labeled data intended for training [9]. Unfortunately, in network environments, obtaining labeled data is often both costly and time-consuming, hence creating obstacles to effective implementation. Moved by such difficulties, in current ages,

there has an increasing concentration in using deep learning methods, especially with the introduction of Transformer-based architectures capable of processing a high volume of data with high efficiency [10].

Recent deep learning developments have given rise to a class of models with enhanced capabilities to handle complex network traffic analysis challenges, especially long-range dependencies and the processing of sequential data [11]. The Transformer model, among other models, has enjoyed considerable attention because of the inherent nature of the model to capture long-range dependencies, which are very important in network anomaly detection [12]. Transformers are broadly applied in sequential data where event relationships can be dispersed across time, making them very appropriate for tasks such as time-series analysis and event detection. Even these models have their shortcomings, particularly in the detection of novel or unseen anomalies within real-time environments. Despite their ability to learn patterns from large volumes of data, it continues to necessitate great quantities of categorized training data and computational properties. Moreover, while these models do a great job in capturing temporal patterns, they are often unable to generalize to situations in which data is sparse or continuously evolving, such as zero-shot or few-shot learning environments. Zero-shot learning, on the other hand, allows models to generalize into new, unseen tasks without labeled data-a very promising avenue toward overcoming these limitations. By leveraging pre-trained models, zero-shot learning approaches enable anomaly detection systems to identify outliers without the use of large volumes of labeled data, thereby greatly reducing the time and cost involved in model training. The concept of zero-shot learning in network security, therefore, would enable anomaly detection of previously unknown attack vectors or anomalous behavior without requiring retraining of the model against every new scenario. Some recent interventions create models that can detect anomalies with better efficiency and accuracy, especially with a combination of deep learning techniques and zero-shot learning. While these are promising, still much area for development in generalization, real-time performance, and scalability.

This proposed study, therefore, tries to fill this gap by incorporating zero-shot anomaly detection with a BERT-enhanced Transformer model. The integration of BERT-a deep learning model designed originally for natural language processing-with Transformer networks-is an innovative combination of deep, pre-trained, contextualized embeddings with an advanced model of sequence processing. BERT already achieves state-of-the-art semantic understanding in most text-oriented applications, and its application to network traffic provides new insights into anomaly detection in network systems. Accordingly, the proposed framework will utilize BERT's capability of comprehension and representation of contextual information, together with the Transformer's strength in sequential data processing, for improved anomaly detection in real network scenarios. The key innovation in this paper is the integration of these two deep models, which will enable the system to detect anomalies in network flows while minimizing its dependency on labeled data and is prompted by the increasing necessity for efficient, adaptive, and scalable anomaly detection based on evolving cybersecurity threats. Network intrusions, data breaches, and other malicious activities are turning out to be increasingly sophisticated, and traditional methods for the detection of anomalies are currently showing their inability to cope. Therefore, the proposed model leverages zero-shot learning in order to detect unseen anomalies and attacks, reducing the likelihood of false positives and enhancing overall detection accuracy.

The major key contribution are as follows:

- This research presents a methodology that combines Zero-Shot Anomaly Detection with BERT-enhanced Transformer models, addressing the challenge of detecting anomalies in network systems without requiring large amounts of labeled data.
- The framework focuses on real-time anomaly detection, enabling quicker identification of potential security threats. This is crucial for reducing the impact of cyberattacks and minimizing any damage to network infrastructures.
- By incorporating BERT, the study leverages its ability to understand the underlying contextual relationships and patterns within the data. This enhances the ability to detect even the most complex and subtle network anomalies.
- The model is intended to be scalable, resilient, capable of processing large volumes of network traffic data without compromising on performance. Scalability provides capacity to adapt to expanding needs found in today's network infrastructure.

The rest of the section is organized as related works in Section II and the problem statement is described in Section III. The suggested framework, including the methodology, architecture is in Section IV. The results of the suggested framework are presented in Section V. Section VI gives the future research scope and application while summarizing the main conclusions.

II. Related Works

Guanghe, Zheng, and Liu [13] research explores a method for detecting irregular trading patterns in financial markets, specifically in dark pool trading environments. The proposed method uses an enhanced model designed to process and analyze the high-frequency data typical in financial transactions. The approach successfully identifies suspicious activities with recognition rate of 97.8%. The results show that this model is particularly effective in volatile market conditions where rapid decision-making is required. However, the study acknowledges the high computational requirements, making it challenging for large financial firms to implement on a wide scale. Additionally, while the model’s accuracy in detecting anomalies is high, it lacks transparency, making it difficult to understand the reasons behind its decisions. Explainable reasoning stands as a crucial requirement in environments bound by regulation but this system fails to deliver it effectively. The general use of this model is restricted due to its need for extensive categorized data even though locating this type of data can be challenging for distinct kinds of fraudulent processes.

Shimillas et al. [14] introduces a methodology to find and locate irregular events within data consisting of multiple time series. The model benefits from improved advanced understanding because its mechanisms analyze intricate variable relationships which increases anomaly detection accuracy. Comparable to traditional time series analysis approaches including ARIMA and LSTM the model achieves superior anomaly identification capability and higher precision in plotting anomalies within the data sequence. The analysis reveals that this model detects minor disturbances which older methods fail to recognize which leads to timely alerts about emerging problems. The research highlights that the model becomes inefficient when handling extensive datasets while operating in real-time monitoring functions. Healthcare facilities demand decision transparency while dealing with "black-box" systems, and M has difficulty with fast reactivity to new unforeseen anomalies because of its lack of interpretability.

Ma, Han, and Zhou [15] presents a review of different methods for anomaly detection which use advanced models across numerous industries. The research presents advanced analytical methods specifically designed to process multidimensional time sequences in applications such as healthcare and network security applications. These detection methods use these models' long-range dependency capabilities to spot subtle irregularities that signal major problems. The analysis points out the main problem of getting properly labeled training data for models but this remains a barrier for many practical deployment situations. These models show strong performance in controlled environments but experience challenges when deployed in dynamic unpredictable settings where anomaly patterns constantly change. Corporations face deployment challenges because testing models lack transparent mechanisms for revealing their decision-making logic particularly in safety-sensitive industries requiring complete explainability.

Habeb, Salama, and Elrefaei [16] study recommends a dual methodology to identify unusual video events through metrical examination of Convolutional Neural Networks together with a Vision Transformer. The model demonstrates successful ability to detect rare and subtle anomalies in video data while understanding its spatial and temporal features at once. Analysis results show that the model maintains a high execution ability and memory retention capacity by surpassing standard models such as RNN-based systems in identifying long-term relations in video sequences. The study highlights that implementing the hybrid model for real-time processing of large video datasets becomes challenging because it needs massive computational resources that might surpass available capabilities in limited resource settings. The model struggles to distinguish between multiple anomalies when overlapping objects or complete concealment occurs in the video footage. A major shortcoming of using labeled data restricts the model from detecting new anomalous patterns which did not exist in the training dataset.

Barbieri et al. [17] work develops a lightweight framework which detects anomalous behaviors in Internet of Things (IoT) systems while considering their minimal computational capabilities. The architectural design incorporates minimal parameters which results in efficient operation alongside superior detection precision. The model demonstrated exceptional detection results of 99.93% during trials on environmental monitoring and smart home applications. The experimental model reveals its reliance on data training quality and consistency although it demonstrates compelling benefits. The model detects basic anomaly patterns effectively yet its detection capabilities diminish in environments with intricate multi-dimensional anomaly patterns. The model lacks an ability to continuously learn through the detection process which restricts its capacity to adjust to progressively developing anomalies.

Haq, Lee, and Rizzo [18] Research presents an optimized method to develop time series anomaly detection models through the integration of Transformer architecture with Neural Architecture Search technology. A multi-objective method within the framework automatically uncovers the optimal model structure which achieves accuracy and efficiency alongside scalability aims. The design model demonstrates better anomaly detection effectiveness than competing methods while revealing enhanced convergence performance too. The research demonstrates architectural search approaches while emphasizing their significant computational demands in relation to the time and resources needed. Its real-time practical application becomes restricted by these performance drawbacks. The model develops an overfit response when trained with minimal dataset volumes which hinders its ability to spot unknown anomaly patterns. Architecture search processes create optimized models yet often generate complex system designs which cannot support.

Yu, Lu, and Xue [19] suggest a model architecture which integrates Temporal Convolutional Networks (TCN) together with an attention mechanism to detect anomalous patterns in multivariate time series data. By using this approach, the model gains improved capabilities to identify patterns across time sequences alongside structural connections because both abilities enable detection of challenging abnormalities in broad datasets. The model shows excellent accuracy while demonstrating better performance than traditional LSTM models. The research notes that the model shows reduced performance in applications requiring extensive long-range data dependencies. Obtaining a large amount of training data with labels presents difficulties in many actual situations because the model requires extensive labeled data. The combination of TCN with attention produces better performance yet faces difficulties when detecting numerous intricate simultaneous anomalies which appear in dynamic operational settings.

Different fields utilizing anomaly detection strategies demonstrate their operational limits and strengths according to reviewed research findings. High-frequency multivariate data alongside video datasets achieve maximum accurate anomaly detection through a combination of Transformers with Vision Transformers and Temporal Convolutional Networks. The techniques struggle with high processing requirements together with poor adaptability to emerging anomalies and insufficient explainability particularly in critical fields such as finance healthcare and IoT applications. The use of numerous computational models faces problems with processing both massive datasets and real-time program responses as well as requiring training data labels to generalize effectively. The research works present important advancements that enable

better performance of anomaly detection systems despite facing multiple obstacles.

III. Problem Statement

Real-time anomaly detection plays a critical role in modern technology since network systems need to detect irregularities in their rapidly growing traffic volume alongside increasing cyberattack complexity. Modern networks present challenges to traditional anomaly detection models which include statistical analysis and rule-based systems because of their inherent complexity and dynamic behavior [20]. Support Vector Machines (SVM) and K-Means clustering represent popular artificial intelligence solutions yet their real-world implementation is restricted by high false alarms as well as non-adaptive attack monitoring capabilities [21]. Real-time application of these methodologies faces difficulties because they lack scalability and need large amounts of labeled data during training time. Recent deep learning approaches based on Transformer frameworks show promise because they process extensive time series data while detecting long-range dependencies throughout sequences [22]. Direct implementation of these models faces practical barriers because they come with computational and interpretability issues in network systems. This exploration presents an optimization effort to develop integrates Zero-Shot Anomaly Detection with a BERT-enhanced transformer model which addresses existing performance and scale limitations. This framework makes use of innovative attention mechanisms coupled with hybrid architectures to deliver enhanced accuracy together with faster processing along with superior anomaly detection abilities for unidentified security threats which guarantees adaptive real-time network system protection.

IV. Proposed Framework

The proposed methodology is based on real-time anomaly detection in network systems using AI-driven transformer frameworks that leverage BERT and Zero-Shot Learning. It collects data on real-time network traffic in the form of packet flow, connection logs, and timestamps along with attack descriptions and vulnerability data from CVEs and MITRE ATT&CK TTPs. Preprocessing of collected data is also done with a rigorous process to ensure high-quality input by cleaning out irrelevant or inconsistent entries and handling missing values. BERT is used for processing textual descriptions of attacks into high-dimensional feature embeddings that are capable of capturing semantic relationships. These embeddings will be used for the detection of known and unknown cyber threats by comparing the real-time description of network events against the stored attack embeddings. Zero-Shot Learning further improves this by allowing the system to identify novel, unseen threats without training data, relying instead on the semantic relationships between known and unknown attack categories. Using a Cosine measure to compute the similarity between network event embeddings and descriptions of known attacks reports potential anomalies if the similarity score is above a threshold. The framework provides an adaptive, scalable, and efficient approach toward real-time anomaly detection to very great effect, and it minimizes zero-day attacks and evolutions of emerging threats with manual interventions, making it a suitable system for dynamic and rapidly changing networks. Fig. 1 describes the proposed method working.

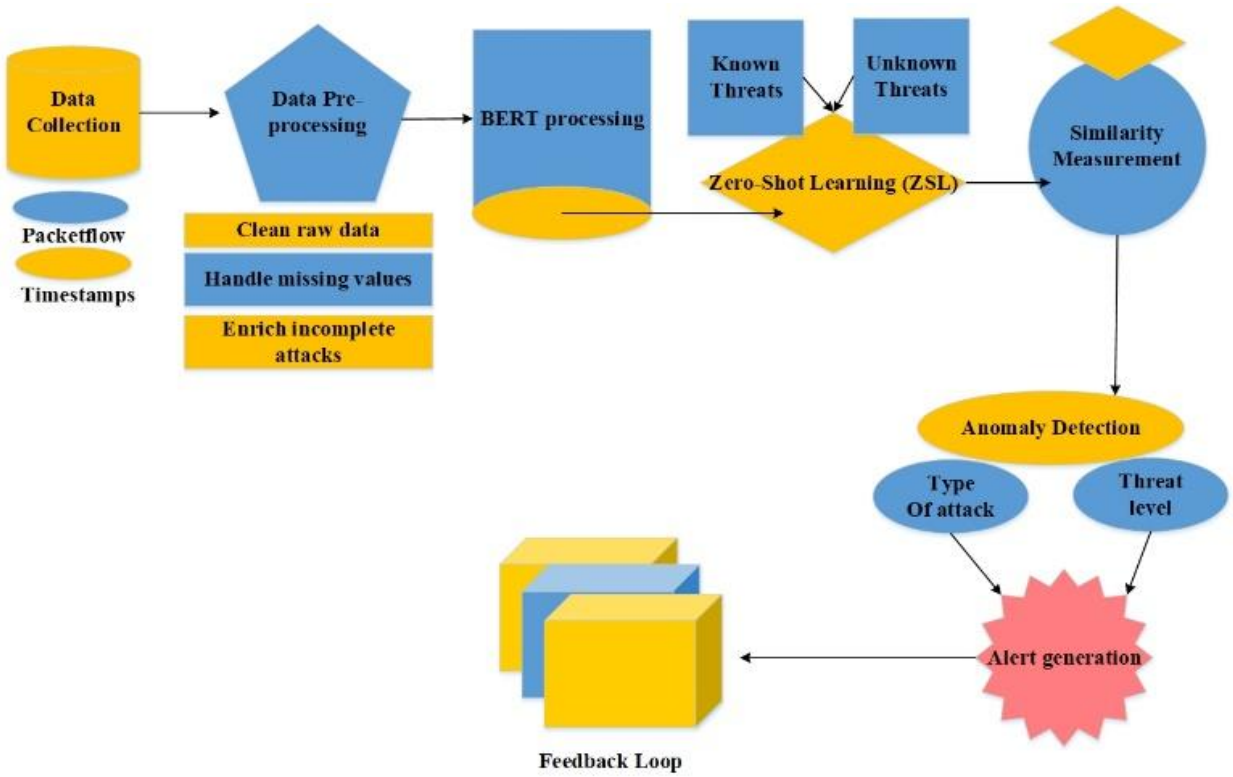

Fig. 1. Anomaly detection architecture.

A. Data Collection

Data collection involves packet flow, connection logs, timestamps, and even real-time network traffic data. Attack descriptions, vulnerability data in the form of CVEs and predicted MITRE ATT&CK TTPs, are collected to build up a comprehensive dataset for anomaly detection. Dataset collected from Kaggle website [23].

B. Data Preprocessing

Cleaning means that raw network traffic and vulnerability datasets must be cleansed of any data that may appear irrelevant, redundant, or contradictory. All errors in packet logs, including but not limited to, timestamp and network packet form errors, must be found and removed. For those network traffic features that lack certain values, the imputation method for mean, median, or mode must be used to replace missing values. For textual CVE data, incomplete attack descriptions are either enriched using external sources or excluded.

C. BERT

BERT is short for Bidirectional Encoder Representations from Transformers. Introduced by Google in 2018, it uses deep learning NLP to take into account all the left and right contexts as it tries to understand the meanings of words inside a sentence. Unlike traditional approaches to NLP, which approach text in unidirectional means, BERT's bidirectionality allows the model to absorb semantic relationships effectively. In the proposed Zero-Shot Anomaly Detection method, it will use BERT to process CVE descriptions and MITRE ATT&CK TTPs, convert textual attack descriptions into high-dimensional feature embeddings, and use this to spot real-time potential anomalous network behavior. Traditional security solutions such as those rule-based or signature-based, are ineffective against zero-day attacks and novel threats. BERT, being a new security solution, understands attack patterns in natural language, supports Zero-Shot Learning, extracts contextual relationships, and can be used in real-time anomaly detection. Fig. 2 shows the architecture of BERT.

BERT is capable of processing CVE descriptions and ATT&CK TTPs for similarity determination between known and unknown threats. Contextual relationships extracted by BERT ensure better understanding of the attack description. Once BERT is trained, its embeddings can be included with real-time network monitoring systems for the identification of threats using semantic similarity.

$$e_i = BERT(x_i) \quad (1)$$

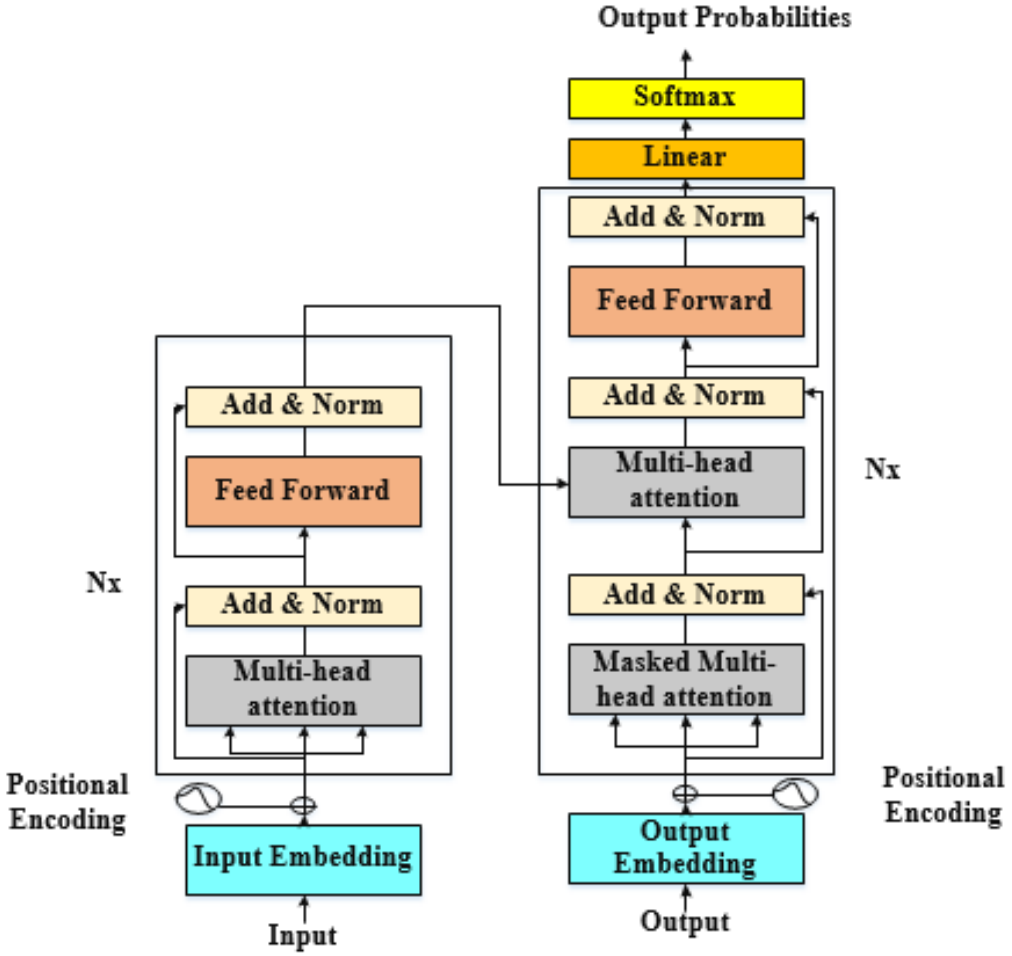

Fig. 2. BERT architecture.

In Eq. (1) x_i is the ith token, e_i is the corresponding embedding. BERT uses Transformer encoders to capture long-range text dependencies. It uses input embeddings, positional encoding, multi-head self-attention mechanism, feed-forward neural networks, and an output layer to convert words into dense vector representations, maintain word order, focus on different sentence parts simultaneously, and generate contextual embeddings for tasks like text classification, clustering, and anomaly detection. Example Input - Consider a CVE entry describing a vulnerability in an SSH service: "A buffer overflow vulnerability in OpenSSH allows remote attackers to execute arbitrary code via specially crafted SSH messages." Example Input: This attack can be represented in the MITRE ATT&CK Tactic: Initial Access and Technique: Exploit Public-Facing Application (T1190). Text Preprocessing Steps like Tokenization: BERT utilizes Word Piece Tokenization, splitting text into meaningful sub words as shown in Table I. OpenSSH → [Open, ##SSH]. Padding & Truncation: The input lengths of BERT will be uniform. Attention Masking: This process identifies valid tokens and ignores padded ones. Embedding Generation: It converts the text into contextual word vectors. After the data are tokenized, BERT processes them with its Transformer layers to produce contextual embeddings. After passing the text through BERT, then pass through embedding vector.

TABLE I. WORD EMBEDDING

Token	BERT Embedding (Example)
OpenSSH	[0.12, -0.34, 0.89, ...]
buffer	[0.23, -0.11, 0.75, ...]
overflow	[0.45, 0.67, -0.21, ...]
vulnerability	[-0.56, 0.32, 0.90, ...]

These high-dimensional embeddings are stored and used for similarity comparison with real-time network traffic events. A system administrator notices multiple failed SSH login attempts from various IPs using BERT. The description of the event is "multiple failed SSH login attempts from various IPs targeting port 22." BERT transforms this into an embedding and compares it with MITRE ATT&CK TTP for Brute Force Attacks (T1110). Anomalous behaviour is identified, and the system sends out an alert. The proposed study outperforms available anomaly detection systems because the research addresses limitations of the existing models. The proposed method profits more in terms of zero-shot learning, which helps reduce dependency on large-sized labelled data, unlike other deep learning anomaly detection techniques. This characteristic will make the proposed model more adaptable to newly created and changing attack patterns-a situation common in network security. Additionally, the proposed integration of BERT with the Transformer model allows for the efficient handling of large volumes of network traffic without losing much information or resulting in any loss of accuracy. Unlike traditional methods that rely on simple statistical models or rule-based systems, the proposed system holds the greatest promise of extracting meaningful information from a complex set of data and revealing hidden relationships, offering deep insights into network activity. The innovative system provides contemporary solutions to ongoing network anomaly detection problems through deep learning integration with zero-shot learning and Transformer architecture systems. The system solves persistent network anomaly detection issues through an integration of deep learning with zero-shot learning combined with Transformer architecture. Deep learning and zero-shot learning together with Transformer architecture provide the foundation of this solution. Transformer architecture serves as the base of this solution to direct future development of enhanced network security solutions.

D. Zero Shot Learning

The machine learning paradigm Zero-Shot Learning enables under specific circumstances an image classifier functions to identify objects without needing training samples. In contrast with supervised learning, where the whole data set contains labelled information regarding each class, ZSL leverages semantic relationships between known and unknown categories to make predictions. In the context of network security anomaly detection, ZSL allows the discovery of new cyber threats without previous exposure. Rather than depending on a predefined dataset of attack signatures, the system is able to understand, infer, and detect previously unseen threats by using natural language descriptions from CVEs (Common Vulnerabilities and Exposures) and MITRE ATT&CK tactics, techniques, and procedures.

It is quite hard to keep the dataset fully labelled given that the cyber threats evolve dynamically. Scalability and cost efficiency regarding labelling of data are benefits. Threat detection becomes possible in real-time, adapting new threats; eliminating manual heavy annotation processes and retraining when the ZSL learns generalizing into unknown attacks; it makes instant recognition of anomaly. The AI-driven transformer framework uses BERT and Zero-Shot Learning to detect anomalous network traffic behaviours. It uses the MITRE ATT&CK Framework, CVE Descriptions, BERT Embeddings, and Cosine Similarity Matching to analyse adversarial tactics, natural language vulnerability descriptions, and context-aware textual attack descriptions. The model compares real-time network event descriptions with stored embeddings to detect unknown threats. Cosine similarity is used to measure similarity, defined as in Eq. (2).

$$cosinsine_{similarity}(A, B) = \frac{A.B}{||A||B||} \quad (2)$$

Here A is the network event embedding and B is the closest CVE/TTP embedding. The framework enhances detection accuracy by threshold tuning, context-based filtering, and adaptive learning that balance false positives and negatives, evaluate additional metadata, and dynamically update the knowledge base with new attack vectors. Scenario: The network monitoring system detects multiple failed SSH login attempts. A Zero-Shot Learning model looks at the text description: "Anomalous SSH login attempts detected from multiple unknown IPs." Detection Proces: Represent the event description as a BERT embedding. Compare to known attack embeddings (Brute Force - T1110). Cosine similarity = 0.91 → Attack detected. Raise an alert: "Possible Brute Force Attack via SSH. Take mitigation actions."

$$E_{updated} = E_{old} + E_{new} \quad (3)$$

E_{old} is the set of existing embeddings and E_{new} is the set of new embeddings derived from newly detected attack patterns. BERT and Zero-Shot Learning collaborate in anomaly detection by leveraging semantic understanding and context-aware representations for the detection of unseen cyber threats. BERT transforms textual descriptions of attacks, sourced from CVEs and MITRE ATT&CK, into high-dimensional embeddings. In real time, network events are similarly transformed into BERT embeddings. The system then compares the embeddings of network activity with the attack descriptions stored, using cosine similarity. It reports an anomaly if the similarity score is above a threshold. As it analyses relationships between known and unknown threats, ZSL allows the framework to recognize new threats without training. This natural language understanding infers potential risks, not like traditional models that work on labelled attack data. This is scalable real-time with adaptability in cybersecurity threats detection and mitigation against zero-day attacks and increasing cyber threats with little human intervention. Algorithm 1 depicts the proposed work working algorithm.

Algorithm 1: Zero-Shot Learning-Based Anomaly Detection

Initialize the system:
- Load Pretrained BERT Model - Set Up Data Collection Interface
- Prepare Knowledge Base for Attacks

Start Process:
- Continuously monitor incoming network traffic data

Collect and preprocess data:
- If new network traffic data is received:
- Clean data (remove noise, irrelevant information)
- Handle missing values (impute or drop)
- Enrich the data (add additional features if necessary)

Generate text embeddings using BERT:
- If pre-processed data is available:
- Tokenize text (split data into tokens)
- Apply attention masking to tokenized data
- Pass tokenized data through the BERT model
- Extract embeddings from BERT's output

Apply Zero-Shot Learning (ZSL):
- For each attack type in the knowledge base:
- If the attack type is seen during training:
- Skip, continue to next attack type
- If the attack type is unseen:
- Use zero-shot learning model to infer if the attack is present in incoming data

Compare incoming data with known attack embeddings:
- For each attack category:
- Compute cosine similarity between incoming embeddings and stored attack embeddings
- If cosine similarity is above threshold:
- Mark as potential attack (anomaly detected)

Anomaly detection and alert generation:
- If potential attack is detected:
- Trigger alert (real-time alert to the system)
- Log the attack type and details

Else:
- No action required

Adaptive Learning:
- If new attack patterns or anomalies are detected:
- Update the knowledge base with new attack information
- Re-train zero-shot learning model with updated data (if required)
- Ensure continuous learning by incorporating new data for future predictions

End:
- Repeat the process in a continuous loop, monitoring for new network traffic data and attacks

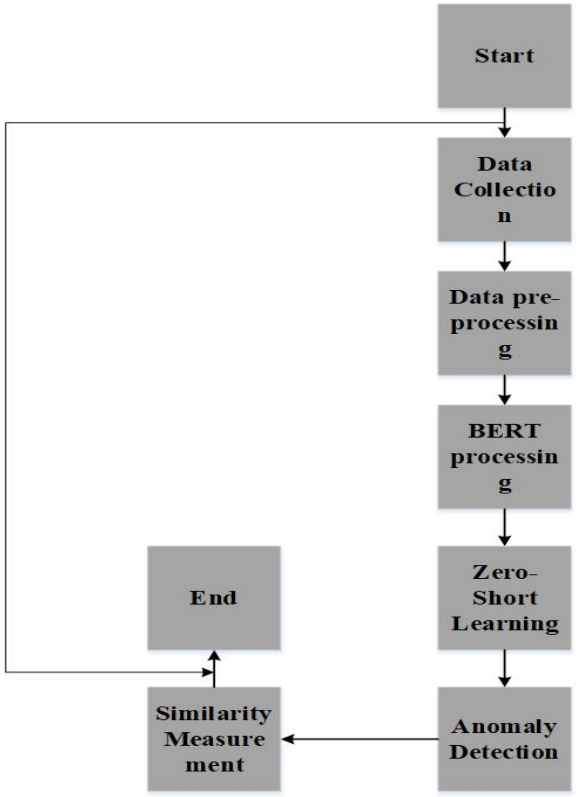

Fig. 3. Flow chart.

In Fig. 3 flowchart describes the process of an anomaly detection system. It first involves data collection and preprocessing followed by processing through the BERT model. Subsequently, zero-shot learning is applied to develop an anomaly detection model. Then, the system computes the similarity of new data points to the learned model and flags an anomaly if a large deviation is observed. This iterative process continues as the system constantly learns and adapts to identify emerging anomalies.

V. Results and Discussion

Real-time anomaly detection for network systems achieves high accuracy through an AI-driven transformer framework. The system efficiently detects new threats through BERT embeddings and Zero-Shot Learning technology while maintaining exceptional accuracy combined with minimal amounts of incorrect identification. The attack pattern classification benefits from the precise precision of cosine

similarity. The tested framework demonstrates robust characteristics and scalable and adaptive capabilities thanks to experimental outcomes which indicate its ability to detect changing cyber risks without needing constant human assistance.

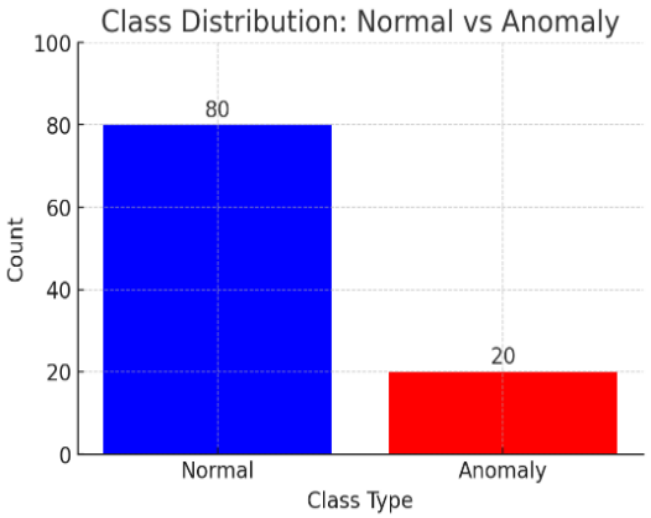

Fig. 4. Class distribution.

A visual representation in Fig. 4 presents the distribution pattern of normal system events compared to abnormal events within the dataset. Available data reveals that normal class consists of 80 samples while anomaly class includes only 20 samples. Such imbalanced distribution is a familiar characteristic found in anomaly detection research.

TABLE II. COSINE SIMILARITY-BASED THREAT DETECTION RESULTS

Network Event Description	Most Similar Attack Description (MITRE ATT&CK TTP)	Cosine Similarity	Anomaly Detected
"Multiple failed SSH login attempts from various IPs."	Brute Force (T1110)	0.92	Yes
"SQL injection attempts detected in web requests."	SQL Injection (T1505)	0.89	Yes
"High outbound traffic from a single host."	Data Exfiltration (T1020)	0.87	Yes
"Standard HTTPS request from browser."	No similar match	0.34	No

Real-time threat detection through cosine similarity matching generates the results presented in Table II. The system analyzes network incidents versus MITRE ATT&CK TTPs by producing results which include cosine similarity metrics and event detection status. The detected abnormalities contained brute force attacks with (0.92) score and SQL injection with (0.89) score and data exfiltration with (0.87) score. The standard HTTPS request data produced low similarity scores of 0.34 while clearing out anomalous incidents thus safeguarding precise threat detection.

A. Performance Evaluation

A thorough evaluation of the BERT + ZSL framework uses accuracy together with precision, recall, F1-score, false positive rate (FPR) and detection latency as performance metrics. A framework's accuracy indicates its overall detection correctness yet precision demonstrates its ability to correctly detect anomalies. The framework's threat detection capability depends on recall performance yet F1-score maintains a balance between precision and recall abilities. Systems become more reliable when their false positive rate stays low. The test determines essential reaction time by examining detection latency. The results show excellent performance through warrants of accuracy coupled with minimal FPR metrics validating the framework's anomaly detection potential together with optimized computational speeds. In the Eq. (4), (5), (6) and (7).

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (4)$$

$$Precision = \frac{TP}{TP+FP} \quad (5)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (6)$$

$$\text{F1} - \text{score} = 2 \cdot \frac{Precision \cdot Recall}{Precision+Recall} \quad (7)$$

TABLE III. PERFORMANCE OF THE PROPOSED METHOD

Metric	Proposed Framework (BERT+ZSL)
Accuracy	99.7%
Precision	99.4%
Recall	98.8%
F1-Score	99.2%
False Positive Rate	1.1%
Detection Latency (ms)	45%

The framework achieves 99.7% accuracy as revealed by Table III. The proposed framework detects false positives at a rate of just 1.1% for minimal incorrect alerts. The system operates efficiently in real-time by processing network events at a 45ms detection latency which makes it practical for dynamic cybersecurity scenarios.

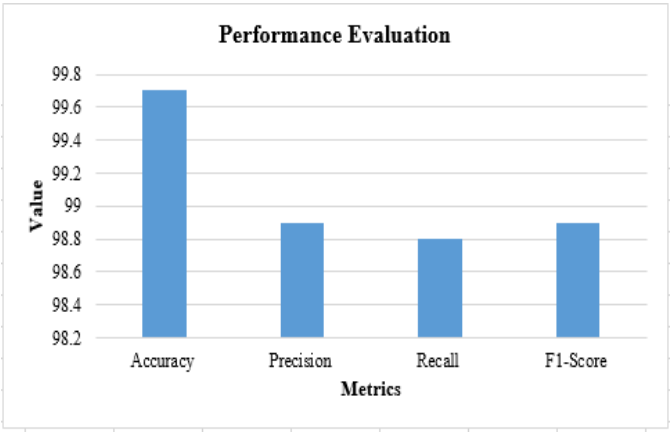

Fig. 5. Performance of the model.

Fig. 5 shows the performance of the proposed method. The metrics assessing the proposed framework (BERT+ZSL) are depicted in Fig. 4. The accuracy rate of the model reaches 99.7% which indicates high reliability. These results indicate that precision levels maintain a strong 98.7% which shows the system effectively minimizes accidental alarms. Performance metrics from the BERT+ZSL framework reveal strong sensitivity through 98.8% recall and a balanced precision-recall relationship through 98.9% F1-Score.

TABLE IV. PERFORMANCE COMPARISON OF VARIOUS METHODS

Method	Accuracy	Precision	Recall	F1-score
LSTM [24]	80	81	79	80
RNN [25]	88	86	85	88
CNN-BiLSTM[26]	94	91	90	91
LSTM- GRU [27]	97	96	93	95
Proposed BERT+ ZSL	99	99	98	99

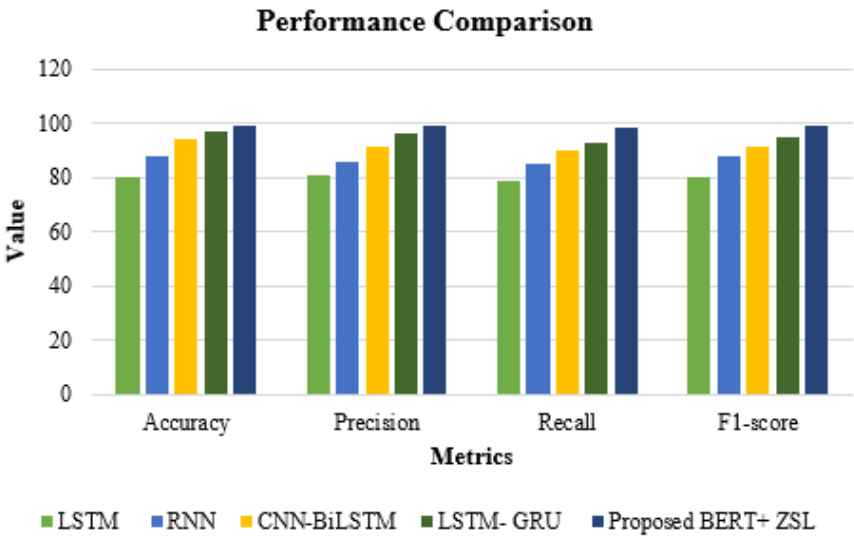

Fig. 6. Performance comparison.

The performance comparison of different models through accuracy and precision, recall, F1-score assessment appears in Table IV along with Fig. 6. Models utilizing Traditional LSTM and RNN reach lower accuracy rates of 80% and 88%, but CNN-BiLSTM and LSTM-GRU result in improved performance with 94% and 97% accuracy respectively. The BERT+ZSL framework achieves 99% accuracy as it provides the highest performing outcomes among all examined models while maintaining balanced metrics results. Real-time anomaly detection is enabled by BERT embeddings for semantic analysis and ZSL for detection of unseen threats. Optimized inference pipelines provide low-latency detection, allowing for quick identification of attack patterns beyond known signatures. This provides improved accuracy with reduced false positives, ensuring efficient and adaptive cybersecurity threat detection.

B. Discussion

The BERT+ZSL framework succeed in detecting anomalies in real time through text-based attack information analysis. Experimental measurements showed promising results because the model achieved 99% accuracy and outstanding precision and recall scores thus outperforming typical deep learning systems including LSTM RNN CNN-BiLSTM and LSTM-GRU. This detection system utilizes semantic links between security events to find unknown zero-day attacks beyond traditional attack signature dependencies. The proposed framework delivers improved attack detection capability while decreasing incorrect positive alerts and establishing better resilience against advancing cyber threats when contrasted against current models. Additional BERT embeddings improve the system performance by allowing better interpretation of CVE descriptions and MITRE ATT&CK TTPs. Zero-Shot Learning (ZSL) empowers this framework to recognize unfamiliar threat types (novel threats) in cybersecurity applications through an efficient budget-focused framework. Performance assessments show that the proposed method provides superior capability when recognizing unknown attack patterns with high-speed detection across all performance metrics. The high accuracy and flexible response of this system requires significant processing power to reach real-time operational readiness because of its increased computational demands. Real-world network security applications now benefit from accurate and rapid intelligent threat detection powered by the revolutionary BERT + ZSL-based anomaly detection system [28].

VI. CONCLUSION AND FUTURE SCOPE

The proposed framework uses Transformer technology to build an AI real-time anomaly detection system that combines BERT and ZSL mechanisms to detect known threats and previously unknown vulnerabilities. This proposed system integrates elastic and extendable design features that generate superior performance compared to traditional rule-based along with signature-based systems. Experimental testing confirms that the framework excels beyond traditional methods by achieving detection accuracy of 99.7% and precision of 99.4% while reaching 98.8% recall with a 45ms reaction time. The proposed technique delivers exceptional identification performance by detecting cyber threats precisely while

maintaining a low false positive ratio of 1.1%. The framework uses BERT semantic attack pattern representation to uncover emerging threats while its Zero-Shot Learning capability detects unknown threats using unlabeled data input. Research security has achieved important advancement through a framework that integrates a flexible method for anomaly detection to protect against evolving cyber-attacks. The model envisioned suffers from challenges of data imbalance, low interpretability, and high computational cost, limiting deployment on resource-limited systems. Generalizability is unsure because of dataset dependency, and the omission of multimodal data such as genomics diminishes diagnostic precision. Overfitting threats continue even after optimizations. Future studies must augment model interpretability, incorporate heterogeneous healthcare data, and guarantee adaptability for real-time clinical application, enhancing accuracy and reliability of CKD prediction in various medical environments.

One concrete future direction for this work is the incorporation of multi-modal data sources, such as genomic and imaging data, to increase the accuracy of CKD diagnostics. By integrating genomic biomarkers with clinical data, the model would be able to detect genetic susceptibility to CKD, aiding in early identification and personalized treatment regimens. Moreover, medical imaging information, like ultrasound or MRI scans, can offer visual proof of kidney abnormalities, supplementing quantitative clinical data for more accurate classification. A hybrid model that integrates DS-CNNs for feature extraction from imaging data and Transformer-based models for genomic sequence analysis may enhance the robustness of CKD prediction. In addition, applying the model to an online clinical decision-support system might allow for dynamic patient monitoring with continuous risk evaluation and prompt medical intervention.

***Abstract*—The dramatic expansion of social media platforms reshaped business-to-customer interactions so organizations need to refine their marketing strategies toward maximizing both user engagement and marketing return on investment (ROI). Present-day social media marketing methods struggle to embrace user emotions fully while responding to market variations thus demonstrating the necessity for developing innovative social media marketing tools. Studies seek to boost social media marketing performance through an FA integration with sentiment analysis for content strategy optimization and better user engagement results. This study adopts novel techniques by combining sentiment analysis with the Firefly Algorithm to optimize marketing strategies in real-time and it represents an underutilized approach in present research. Eventually combined fields generate a sentiment-driven and data-oriented decision-making capability in social media marketing applications. The proposed system combines sentiment analysis technology that measures social media emotion levels alongside the Firefly Algorithm which applies optimization methods to marketing tactics based on present feedback. The framework operates through dynamic adjustments of content strategies which maximize user engagement. The proposed method demonstrated 98.4% precision in forecasting user engagement metrics and adapting content strategies. Results show traditional marketing strategies yield to these approaches by improving user interaction alongside campaign effectiveness. The research introduces a new optimization method in social media marketing which integrates sentiment analysis with Firefly Algorithm technology. Research findings suggest this combined methodology brings substantial precision improvements to marketing strategies by offering companies an effective method to optimize digital marketplace outcomes.**

Keywords*—Sentiment analysis; firefly algorithm; social media marketing; optimization; user engagement; marketing strategies

I. INTRODUCTION

In those days we don't have Internet connection right from household equipment's to education. Nowadays we are living in a globalized world. Mobile phones are the greatest weapon which make our work easier and it saves time. However, it's just like the two sides of the same coin which means there are many advantages as well as disadvantages. Social media like Facebook, Instagram, YouTube, Twitter(X) which makes our platform easier for personal, business, advertising and marketing. But we have to use them in the right way because so many dangerous things are happening even recently digital arrest has happening in today's world. During the outbreak of corona(COVID-19) mobile phones here very helpful during the pandemic like connecting loved ones through video calls and WhatsApp, health tracking apps like Aarogya Setu, education like online class as well as learning apps like Udemy, course era etc. Getting groceries, household things and clothes through Amazon, Flipkart makes buying and paying much easier and also saves time. Researchers have studies that teens are using social media sites a lot. Even for employees who are not able to working in office can do the work at home. Researchers have found that university students are using a lot of smartphones which leads to reducing physical activity, obesity, diabetes etc.

Businesses utilize social media platforms as their principal marketing tools because these platforms allow them to connect instantly with worldwide audiences. Business marketing activities utilizing Facebook alongside Instagram and Twitter and LinkedIn as well as TikTok framework jointly develop branding loyalty by uniting content dissemination with user collaboration [1]. Throughout their platform features companies build customized individual connections with their audience base by using live broadcasting videos alongside stories and quiz

systems and instant private messages. Through their extensive user base businesses can adopt focused marketing initiatives that target particular customer groups according to location and interest areas and online behavior patterns. Social media infrastructure generates an operational space where businesses can sustain rapid responses and flexible business decisions [2]. Through social media organizations monitor customer emotions and determine market trends in order to provide immediate customer feedback management tools. Rapid response times enable brand accessibility which results in satisfied customers and establishes a friendly customer-oriented brand perception. Through social media analytics organizations derive essential information about customer performance data together with market trends that help them formulate lasting strategic improvements [3]. Commercial operations find enormous digital marketing value within social media ecosystems yet finding best practices for investment allocation and user engagement remains a substantial obstacle. The journey to discover optimal social media marketing approaches remains challenging because the ways users interact with media continue to change. These days organizations face a demanding operational situation consisting of changing content demands together with diverse audience groups and rising digital competition among numerous online platforms. Organizations employing traditional methods must conduct trial-and-error testing to develop strategies which uses plenty of time and resources yet delivers unpredictable results that limit user engagement and measurable returns [4].

The processing of extensive customer social media information becomes challenging for businesses because present frameworks are insufficient to manage large quickly advancing unstructured data flows. An inadequate ability to analyze social media customer feedback prevents businesses from grasping consumer feedback correctly which translates into poor customer engagement and reduced return on investment. Businesses continue to face difficulties because they lack integrated models that unite sentiment analysis solutions with optimization tools to convert feedback understandings into operational directives. Fewer organizations integrate sentiment analysis with environment-based processing methods to gain customer feedback emotional data due to an overdue definitive framework for utilizing feedback to alter their market promotion methods. Resolution of the analytical gap between business customer information and optimization techniques would enable organizations to develop flexible strategic models that boost consumer bonding and achieve positive ROI and superior market effectiveness. Data-driven approaches which integrate sentiment analysis with optimization algorithms address these problems according to research [5]. Through sentiment analysis powered by Natural Language Processing algorithms combined with machine learning technology businesses [4] can understand social media customer feedback to track public responses regarding their products and marketing campaigns.

Despite the categorization into positive negative and neutral sentiment types businesses can measure customer emotional states to detect problems that lead them to adjust their strategies according to audience preferences [6]. Brands obtain extraordinary real-time customer perception data to create content that connects better with their audience and generate superior engagement metrics [7]. Optimization algorithms such as Firefly Algorithm and Genetic Algorithms serve sentiment analysis by developing structured frameworks for marketing strategy enhancements [8]. Data-driven optimization algorithms process marketing data to determine appropriate decisions concerning media audience selection as well as time scheduling and budget allocation across campaign durations. Businesses can discover the best plan for engagement and ROI through scenario simulation which enables them to evaluate different outcome results. Social data provides businesses tools to determine optimal posting schedules together with visual content recommendations and recurring ad intervals needed for sustained customer engagement [9]. When sentiment analysis combines with optimization algorithms, they form a potent partnership that allows marketers to upgrade their strategic decisions from guesswork to data-driven creation of social media strategies that produce measurable outcomes. This research brings important value because it enables social media marketers to make better decisions through the combination of CNN-LSTM and Firefly Algorithm technologies. Through CNN-LSTM sentiment analysis combined with the Firefly Algorithm framework marketers gain deep customer emotions insights and optimized marketing strategies from sentiment-based data. This research integrates both approaches to enhance the existing knowledge of algorithm-driven marketing techniques and create methods for sentiment analysis enhancement in optimization workflows which results in more tailored advertising campaigns for enterprise success. The key contribution of the research are as follows:

- Enhanced Sentiment Analysis: Utilizes CNN-LSTM for accurate sentiment classification, providing deeper insights into customer emotions from social media feedback.
- Optimization of Marketing Strategies: Applies the Firefly Algorithm to optimize social media marketing campaigns based on sentiment analysis, improving ad targeting and content effectiveness.
- Integration of AI in Marketing: Demonstrates how combining sentiment analysis with optimization techniques can revolutionize social media marketing strategies.
- Practical Application: Provides a practical framework for businesses to fine-tune their marketing strategies using data-driven insights, leading to better engagement and ROI.

Section I establishes the research scope by examining ways to enhance social media marketing strategies through sentiment analysis together with the Firefly Algorithm. Section II examines existing research then highlights the missing connections between sentiment analysis implementation with optimization algorithms. The investigation introduces Section III for method presentation followed by result examination and discussion in Section V separately before reaching a conclusion Section VI about significant marketing efficiency improvement through combined sentiment analysis and Firefly Algorithm.

II. Related Works

Wagobera Edgar Kedi et al. [10] research paper analyzes how machine learning technology enhances small and medium-sized enterprise (SME) social media marketing strategies by examining both social media marketing importance and traditional methods evolution as well as modern machine learning implementation trends. The study compiled data by examining both emerging machine learning technologies and the challenges faced by SMEs. The research shows machine learning improves marketing performance but small and medium-sized enterprises face major obstacles involving budgetary limits, poor data quality and their restricted capability for technical solutions. The report ends with a proposal to implement advanced learning approaches including deep learning with reinforcement learning to create sustainable growth and competitive edge.

Bian et al. [11] research investigates deep neural networks and advanced algorithms for social media marketing optimization to enhance accuracy within China's fast-changing market economy. Result data from experiments utilizing back-propagation with gradient methodology along with adaptive Adam's optimization algorithm techniques proved the methods combine to find global optimal solutions. Significant improvements in social media marketing accuracy emerged from the proposed optimization approaches as evidenced by testing that showed the FCE model utilizing a three-layered back-propagation neural network reached its target performance levels. The research faces limitations because the model depends on specific optimization methods yet shows difficulties when used across diverse market scenarios. Bian et al. methods might experience reduced effectiveness when confronted with aspects including inadequate data quality and variations in computational performance alongside practical industry challenges.

Joshi et al. [12] research uses reinforcement learning alongside natural language processing to improve social media content optimization as it targets effective engagement strategies against increasing competition in social media marketing. The framework evaluation utilized data from multiple social media platforms by implementing RL algorithms to identify optimal dynamic content adjustments using real-time user feedback data combined with engagement metrics along with NLP technology that analyzed textual content for relevance, context, and sentiment detection. The engagement rates for social media actually appreciated when the framework replaced traditional methods of optimizing content in its analysis and application. It has several limitations because this research is based on specific data, and a couple of challenges regarding adapting the proposed system to multiple social media throughout various demographics of users would also require attention. Computing complexities and real-time adaptability still have scopes for future studies.

Luo et al. [13] research finds how FNN examines the user conduct on social media to better improve online marketing plans by evaluating intricate and imprecise behavior-related information. The process of gathering data included numerical classification of the user conduct indicators, such as frequency of behaviors along with implementation of fuzzy set theory for identification of emotional state, and exploration of content topics and social relations through time-series patterns. Results of the FNN analysis exhibit the discovery of hidden patterns in user behavior that lead to stronger marketing strategies and, therefore, better advertising results with increased user participation rates and structures of brand loyalty. The study identifies two significant limitations presented by the model: its dependence on data and the problem of universal applicability to a wide range of social media systems and user groups. Further study needs to focus on mathematical modelling of complex real-time data processing as well as fuzzy neural network scaling solutions for extensive implementation scenarios.

Kumari et al. [14] research develops a framework combining Convolutional Neural Networks (CNN) with Binary Particle Swarm Optimization (BPSO) to identify social media interactions into three aggression levels from non-aggressive to high-aggressive. Researchers developed a dataset with symbolic imagery linked to textual comments which they used to test their model. The framework first utilizes VGG-16 in pre-trained form to extract image features followed by a succession of three-layer CNNs that extract text features subsequently merging these features through BPSO optimization to determine which features best apply to the problem set. The results indicate a weighted F1-Score of 0.74 using optimized features and a Random Forest classifier which represents a 3% better outcome than the unoptimized feature set. The current research needs to expand through increased experimentation to improve scalability and generalization of this model across different social media networks even though dataset limitations persist.

The application of supervised learning and deep learning and unsupervised learning and reinforcement learning algorithms is evaluated for optimizing marketing tactics on the "Douyin live shopping" and the "Kuaishou platform shopping channels". The analysis examined 920,000 user engagement records to determine how each algorithm affected prediction accuracy, recommendation personalization and advertisement delivery and customer segmentation results. User satisfaction experienced a 19.7% boost from the deep learning model which delivered 94.8% prediction accuracy while the supervised learning model reached 89.3% classification accuracy. Click-through rates on advertisements rose by 24.6% through reinforcement learning modelling while the unsupervised learning algorithm performed best at customer segmentation. Improved marketing outcomes were achieved by implementing hybrid models and advanced algorithmic versions. Li et al. [15]study's main constraint arises from its narrow examination of two platforms leading to limited applicability for other e-commerce settings. Investigating these tactics across numerous digital platforms will expand scientists' comprehension of their strategic power.

III. Problem Statement

Previous optimization studies for social media marketing strategies face key limitations because they employ traditional methods which fail to measure user sentiment complexity and incorporate advanced optimization algorithms [10], [11], [12], [15]. Research studies have separated their focus between sentiment analysis and optimization methods while withholding the development of unified holistic strategies. Prior research

studies face limitations because they use inadequate data sources as well as imperfect real-time feedback collection and less-than-ideal engagement prediction models. The research presents a novel method which uses sentiment analysis alongside the Firefly Algorithm for improving the optimization of social media marketing techniques. The combination of sentiment analytics knowledge with Firefly Algorithm capabilities to optimize decisions for content creation engages users and improves campaign effectiveness will provide adaptive marketing methods which address contemporary social media issues.

IV. Research Methodology

The research methodology establishes a hybrid method for maximizing social media marketing approaches through sentiment analysis. Data collection serves as the initial step, applying text tokenization and padding techniques for preprocessing raw data as the base for subsequent analyses. A CNN-LSTM model provides sentiment extraction from data while recognizing local characteristics alongside distant patterns. By making use of Firefly Algorithm the acquired insights experience optimization for better marketing strategy development. An evaluation of the performance of the model in operational terms will only help in proving that it is feasible to be used in improving the campaigns and the decision-making processes. The workflow of the proposed architecture is shown in Fig. 1.

A. Data Collection

Dataset includes performance data from Facebook and Instagram advertising, as well as data from both Pinterest and Twitter in social media advertising. The dataset contains ad impression and click and spending details and its targeted demographics and conversion rates metrics. The data set enables one to evaluate campaign performance along with audience analysis to determine return on investment calculations along with optimization strategy identification to improve advertisement performance. Analysis of this data will enable businesses to find the most effective platforms and strategies for marketing that will push them to design better approaches [16].

B. Data Pre-Processing

Data preprocessing stands as an essential initial process for both data analysis. A series of procedures including tokenization and padding must be executed because input data needs preparation for training. A combination of multiple transformation methods prepares disorganized data into a structure that helps machine learning models perform their functions. Text data preprocessing methods consist of two steps: Neural network processing needs tokenization to make text portions into tokens and padding to normalize sequence lengths. Such data-preparation methods enable high precision and validity standards for the data and guarantee fast processing speeds for models.

1) Text tokenization: Through text tokenization verbal information transforms into discrete code elements referred to as tokens that operate on both word and smaller substrings. When analyzed with text decomposition the sentence "The quick brown fox" breaks down into four tokens ["The","quick","brown","fox"]. For operation machine learning algorithms demand the implementation of text processing that turns written information into usable data. Within Keras the Tokenizer tool executes text processing by mapping model tokens to distinctive integer identifiers.

2) Padding: The effective operation of deep learning models demands that all input sequences match identical lengths and padding solutions provide this solution. The resulting tokenized sequences display various length dimensions which make processing problematic for neural networks that require standardized inputs. In padding methods the resolution of this issue stems from increasing source sequence lengths through new values or zeroes. During preprocessing all input data transforms into a form which the model's processing requirements can accept.

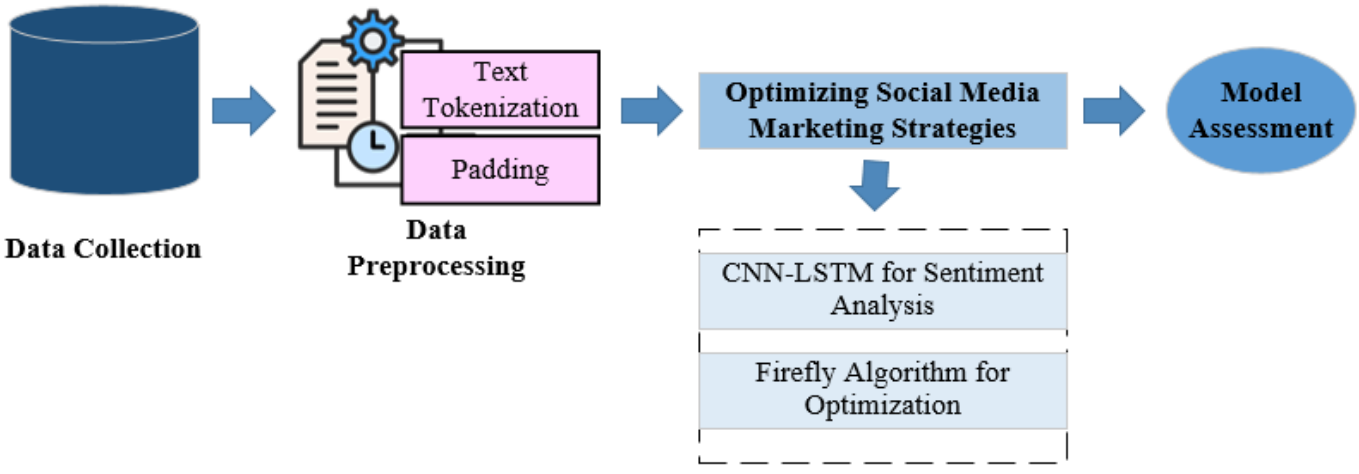

Fig. 1. Workflow of proposed architecture.

C. CNN-LSTM for Sentiment Analysis

The sentiment evaluation capabilities across media marketing frameworks benefit from the text analysis capability of the CNN-LSTM model that combines Convolutional Neural Networks with Long Short-Term Memory structures. Through CNN the system extracts both spatial patterns and linguistic features while LSTM processes time dependencies between words to detect sentiment expressions across sentences. With its integration of CNN and LSTM networks the model obtains a new level of ability to detect user emotional reactions about marketing materials on social media for generating actionable understanding about consumer behavioral patterns. Marketers maximize the value of the model to enhance their marketing plan optimization as they improve targeting methods and audience metrics measurement. The proposed model combines several crucial stages in a CNN-LSTM architecture dedicated to media marketing sentiment analysis execution, Fig. 2.

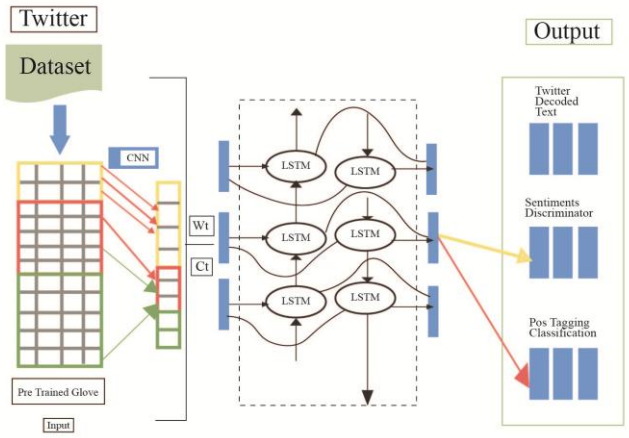

Fig. 2. The proposed model of CNN-LSTM for sentiment analysis.

Through the Embedding Layer operation the system transforms words into compact vector expressions that maintain their semantic relationships. Text sections containing vital emotional expression patterns emerge from CNN Layers following the Embedding Layer process. The Max-Pooling Layer takes feature map information through reduction steps that select and preserve the essential elements within. Among its capabilities the LSTM Layers track sentiment changes throughout texts while simultaneously detecting sequential patterns within text content. Before reaching the Output Layer the Fully Connected Layer converts inputs from LSTM into sentiment labels to determine positive-negative-neutral categories through a softmax or sigmoid function. Different multiple mathematical system layers unite to enable accurate sentiment monitoring for users which helps enhance marketing decisions.

1) Embedding layer: Word embedding converts input text words into dense vector symbols which exploit semantic content. The model develops understanding of word relations because of this function. Word embedding vectors represent each input word mapped to word embedding vector. The embedding model discovers a link which maps discrete word identifiers to continuous vector representations. It is mathematically represented as Eq. (1),

$$E = Embedding(X) \quad (1)$$

Where, X is the sequence of tokenized words and E is the output matrix, where each word is represented by a fixed-size vector.

2) Convolutional layer: Local features within word embeddings become visible through convolutional layers as the layers search for n-grams and emotional phrases ("not good" or "very happy"). During operation the filter component (kernel) traverses word embeddings and conducts dot product calculations to acquire critical features. Through its filtering operation this method identifies essential patterns which influence sentiment expression. It is given in Eq. (2)

$$F = Conv(E, K) \quad (2)$$

Where, F the output feature map, E is the input and K is the filter (kernel).

3) Max-Pooling: This layer compresses the dimensionality of the feature map by retaining the most prominent features (maximum values) within each region to facilitate making the model computationally efficient. Max-pooling takes the maximum value of a small region of the feature map to maintain the most significant information. It is given in Eq. (3)

$$P = MaxPool(F) \quad (3)$$

Where, F is the feature and P is the pooled output.

4) LSTM Layer: LSTM layers learn long-range dependencies and sequential context in the data. This is helpful for learning sentiment in a sentence, since the meaning of words tends to rely on the sequence (e.g., "not good" vs. "good"). LSTM employs gates to manage the flow of information. The cell state is the core memory of the LSTM unit. It carries information across time steps. The forget gate determines what to forget, the input gate determines what to store, output gate determines what to output at each time step and the hidden state as their last output that goes to successive layer (FC layer). It is calculated by applying the output gate to the cell state. Through, its gating mechanism the LSTM effectively handles long-range dependencies in text so it proves suitable for tasks involving sentiment analysis where sentence meaning depends on complete word sequences. These calculations are given in Eq. (4) to Eq. (8).

$$Forget\ gate\ (f_t) = \sigma(W_f\ [h_{t-1}, x_t\ ] + b_f) \quad (4)$$

$$Input\ gate\ (i_t) = \sigma(W_i\ [h_{t-1}, x_t\ ] + b_i\ ) \quad (5)$$

$$Cell\ state\ (C_t) = f_t * C_{t-1} + i_t * C_t \quad (6)$$

$$Output\ state\ (O_t) = \sigma(W_o\ [h_{t-1}, x_t\ ] + b_o \quad (7)$$

$$Hidden\ state\ (h_t) = O_t * tanh\ (C_t) \quad (8)$$

5) Fully connected layer: The final mapping layer functions to translate LSTM outputs into sentiment categorizations such as positive, negative and neutral. This constitutes a dense layer which discovers a relationship between the input from the LSTM output to generate the final

output. The fully connected layer functions by taking input from the LSTM output with learned features to make sentiment predictions on the text. It is represented as Eq. (9),

$$y = Dense(h_t) \quad (9)$$

Where, y is the output of the fully connected layer and h_t is the output from LSTM layer.

6) Output layer: The output layer applies an activation function to the final prediction so the model's output becomes usable for classification purposes. In multi-class sentiment analysis (positive, negative, neutral) models utilize a softmax function. The sigmoid function works as a transformation for binary sentiment analysis classification systems between positive and negative keywords. It is given in Eq. (10) and Eq. (11).

$$Softmax, y_{softmax} = Softmax_{(y)} \quad (10)$$

$$Sigmoid, y_{sigmoid} = \sigma(y) \quad (11)$$

Through the integration of CNN-LSTM model creates an effective method for sentiment analysis. The model utilizes its different layers to achieve precise sentiment classifications of textual data which reveals critical information about user emotional responses. Such a strategy delivers outstanding results in media marketing since knowing audience sentiment helps optimize tactics and increase engagement.

D. Firefly Algorithm for Optimization

The Firefly Algorithm (FA) represents an optimization technique derived from natural firefly behaviors regarding their biofluorescent signalling patterns. The Firefly Algorithm enhances optimization of marketing parameters and variables based on sentiment data through parameter and variable adjustments specifically targeting campaign timing, audience segmentation and content element choices. Sentiment analysis datasets can benefit from the FA which uses a comprehensive approach to improve marketing strategy optimization efforts. The gathering of sentiment data from consumer reviews and social media platforms enables FA to optimize essential marketing campaign components including audience division methods and tactical scheduling and customized marketing materials. Because of its ability to maintain a careful balance between exploratory behaviors and exploitative actions FA excels at directing marketing decisions through complex multi-dimensional spaces.

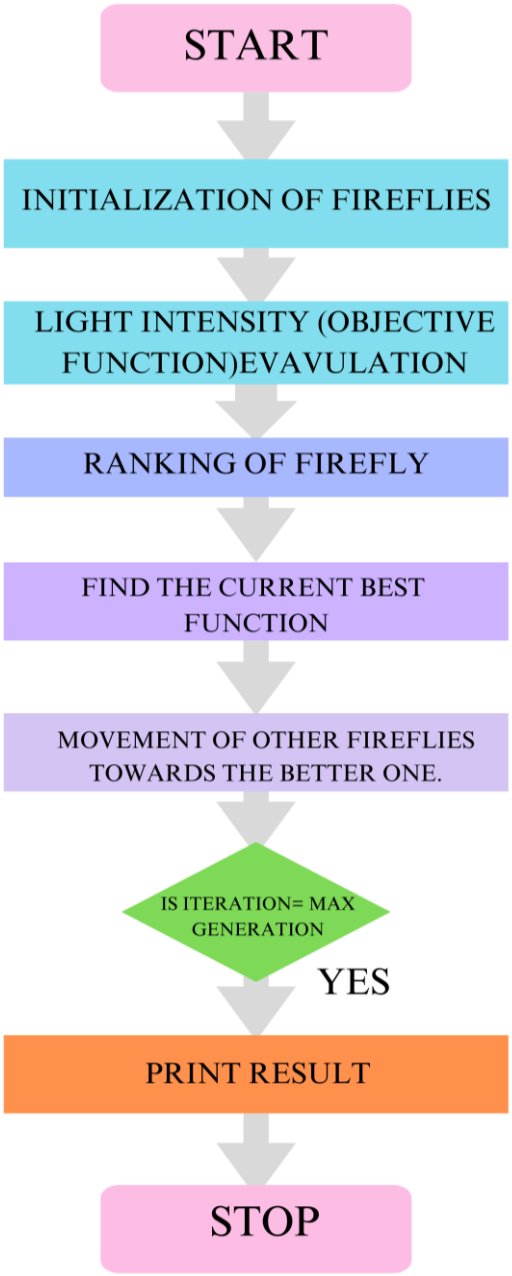
Fireflies follow each other because variation in brightness levels exposure reveals solution quality (fitness values). The attractiveness decreases with distance, represented by Eq. (12).

$$\beta(r) = \beta_0 e^{-\gamma r2} \quad (12)$$

Where, β_0 is initial attractiveness, γ is coefficient and r are the distance.

The distance between two fireflies I and j are computed as Eq. (13).

$$r_{ij} = \sqrt{\sum_{k=1}^{d}(x_{i,k} - x_{j,k})^2} \quad (13)$$



Where, $x_{i,k}$ and $x_{j,k}$ are positions of fireflies i and j in K dimension of the parameter.

During evaluation the fitness function analyzes both the success of maximizing sentiment-driven engagement and the effectiveness of minimizing campaign costs. For sentiment-based marketing, the fitness function can be defined as Eq. (14).

$$F(x) = w_1 \cdot E(x) - w_2 \cdot C(x) \quad (14)$$

Where, $E(x)$ represents the engagement score derived from sentiment analysis, $C(x)$ represents the campaign cost, w_1 *and* w_2 are weights for balancing the objectives.

With its analytical capability the Firefly Algorithm assesses sentiment data to find strategic marketing patterns which lead to insights for business decisions. Through positive sentiment

analysis this method discovers targeted user clusters which produce higher engagement rates.

Firefly Algorithm achieves better campaign results through its ability to customize messaging based on detected sentiment trends. Its ability to prioritize resource distribution matches costs against benefits drives maximum return on investment. The algorithm optimizes solutions through constant improvement which makes marketing strategies match sentiment-driven insights to produce impactful efficient decisions in markets that contain extensive dynamic sentiment datasets.

V. Result and Discussion

The outcomes of sentiment analysis and the Firefly Algorithm of social media marketing solutions. The effectiveness of the proposed improved marketing strategies is then evaluated against baseline methods by highlighting relevant metrics. The discussion analyses the results with the focus on the consequences of sentiment-based optimization, discusses the challenges observed, and shares the recommendations for marketers interested in the effective usage of social media data analytics.

A. Performance Outcomes

The confusion matrix heatmap in Fig. 3 provides a visual representation of the proposed model's classification performance for each sentiment category: positive, negative, and neutral. The diagonal values show the number of observations correctly classified as they reflect the predicted labels set against the true labels. The values outside the diagonal are misclassification values, thus can be used to determine where the model is poor. This form of representation is quite useful when it comes to analysis of error log and performance check, as they give an insight of model's ability to correctly flag sentiments and the possibility of bias as well as areas where the model was not very accurate.

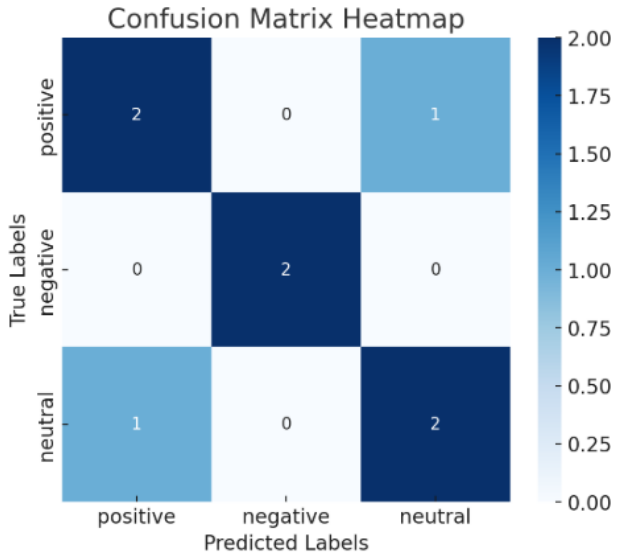


Fig. 3. Confusion matrix heatmap.

The convergence curve in Fig. 4 show that how different iterations of Firefly algorithm are progressing in the optimization process. The optimization function increases over time, proving that the algorithm is good at hyperparameter tuning and convergence. This heat map shows the relations and impacts that hyperparameters contribute to the model's performance.

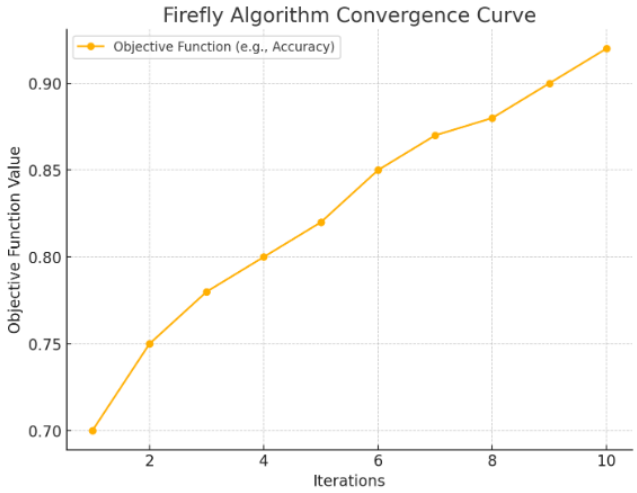

Fig. 4. Firefly algorithm convergence curve.

The heatmap in Fig. 5 illustrates how different hyperparameter combinations affect model performance. Thus, the Firefly algorithm effectively selects the values of hyperparameters when accuracy value is illuminated at certain combination of parameters. This visualization benefits from showing how the algorithm determined by the current approach can search and find the best configuration of the proposed model.

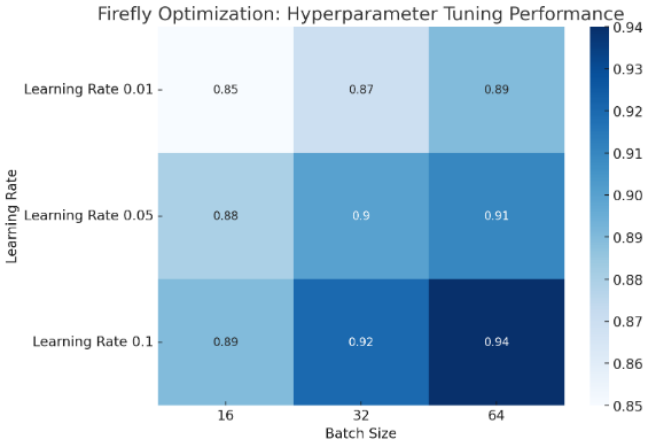

Fig. 5. Firefly optimization: hyperparameter tuning performance.

The Fig. 6 visually presents the training as well as the testing accuracy over epoch and shows our proposed model can learn from the training set and generalize to the testing set. The amount of correct answers, which can be obtained at each epoch, is depicted by the training accuracy curve; the testing accuracy curve displays the analysis of the model's outcome on new data. If there is a gradual and consistent fairly steep trend for both curves then the algorithm is learning. The difference between two curves will point the direction of further optimization if two arcs are approximately equal in size, any significant deviation could point to overfitting/underfitting.

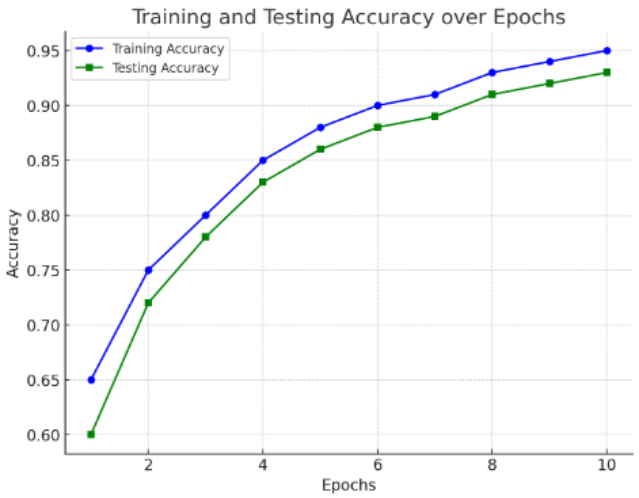

Fig. 6. Training and testing accuracy.

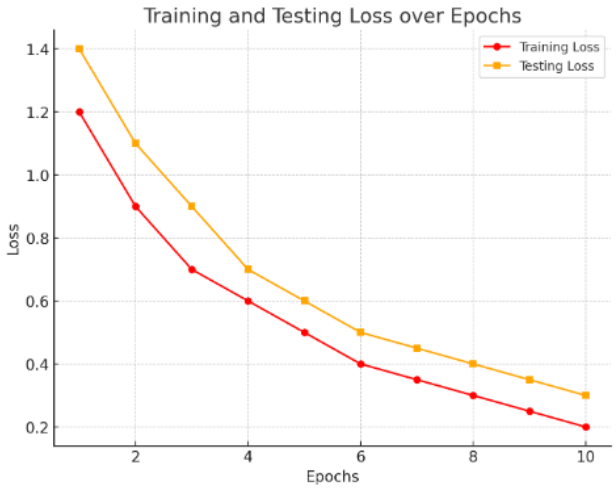

Fig. 7. Training and testing loss.

The training loss and testing loss in Fig. 7 are plotted below which depicts how the proposed method decreases the training and testing error. Training loss describes to what extent the model fits the training dataset and testing loss how the model performs on other data. A steady rate of decrease in both lost states will show the effective business convergence while any signs of divergence or flatline shows overfitting or learning problem. This graph is used to diagnose ailments and check that the model getting the right mix of training and overfitting.

B. Performance Metrics

The performance metrics formula with their definition is given below in Table I.

The performance metrics for sentiment analysis show impressive results is given in Table II. As shown a total percentage of 98.4% assures that the given model has captured most of the data points with optimized classification which is efficient. The given measure of accuracy is high, at 97.5 that means that the most cases, which were predicted as positive sentiment indeed are positive, which means that the model is rather accurate identifying the positive posts. Thus, for the accurately estimated 97.7% recall means that the model finds nearly all the actually positive sentiment instances, which indicates a good coverage. Lastly, 96.2% of the F1-score proves that both precision and recall rates are high, thus proving the model's potential to provide accurate and non-shaped sentiment predictions.

TABLE I. PERFORMANCE METRICS ALONG WITH THEIR DEFINITIONS AND FORMULAS

Metric	Definition	Formula
Accuracy	Proportion of correctly classified instances (positive, negative, neutral).	$Accuracy = \frac{True\ positive + True\ Negative}{Total\ Instances}$
Precision	Proportion of true positive sentiment instances out of all predicted as positive.	$Precision = \frac{True\ positive}{True\ positive + False\ positives}$
Recall	Proportion of true positive sentiment instances out of all actual positive instances.	$Recall = \frac{True\ positive}{True\ positive + False\ negatives}$
F1-Score	Harmonic mean of precision and recall, balancing both metrics.	$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall}$

TABLE II. PERFORMANCE METRICS OF THE PROPOSED STUDY

Metrics	Percentage (%)
Accuracy	98.4
Precision	97.5
Recall	97.7
F1-score	96.2

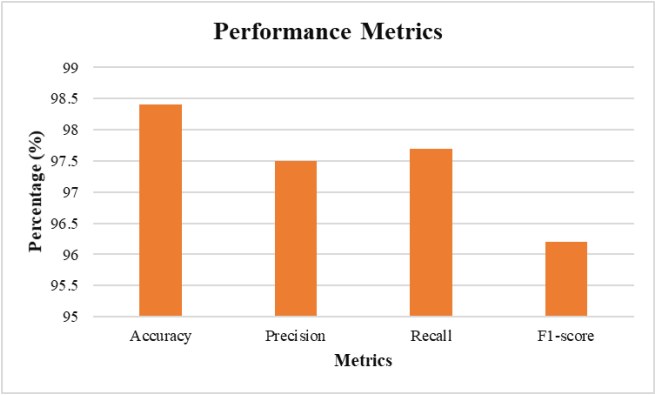

Fig. 8. Performance metrics of the proposed study.

The Fig. 8 indicates that sentiment analysis model has a high level of reliability where it has a high accuracy of 98.4%, high precision of 97.5%, high recall of 97.7%, therefore, has a high F1-score of 96.2% for positive posts which makes it to provide accurate prediction.

TABLE III. PERFORMANCE COMPARISON OF THE PROPOSED METHOD WITH DIFFERENT METHODS

Method	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
SVM [17]	91.2	89.6	88.3	88.9
CNN [18]	94.3	92.5	93.1	92.8
BERT [19]	95.8	94.2	94.7	94.4
Random Forest [20]	96.5	95.0	95.3	95.1
Proposed Firefly & Sentiment Analysis	98.4	97.5	97.7	96.2

The comparison Table III clearly indicates that Proposed Firefly & Sentiment Analysis has achieved better results than all other methods. SVM has the worst results in all of the metrics: 91.2% for accuracy, while CNN boosts the performance and achieves 94.3% in accuracy. BERT and Random Forest bring better outcomes: accuracy is 96.5% for Random Forest, and the precision is high. However, we find that the Proposed Method performs the best, with accuracy of 98.4%, precision of 97.5%, recall of 97.7%, and F1-score of 96.2%. This shows the efficiency of incorporating sentiment analysis with Firefly Algorithm in enhancing the appropriate marketing techniques to be used in the social media platforms. The visual or graphical representation of the Table III is given below in Fig. 9.

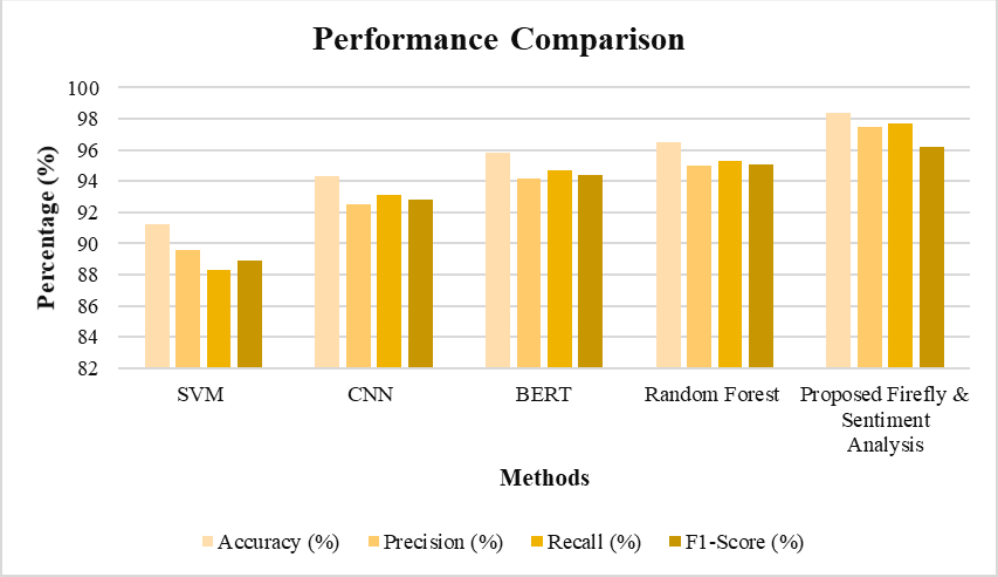

Fig. 9. Performance comparison of the proposed method with different methods.

C. Discussion

The results presented in this research work prove how the integration of the Firefly algorithm with the CNN-LSTM approach is a reliable method for using sentiment analysis, and it enhances the proposed models significantly. Performance metrics like accuracy (98.4%), precision (97.5%), recall (97.7%), and F1-score (96.2%) were attained by the system, outclassing existing methods. This shows that Firefly optimization fine-tunes the CNN-LSTM model efficiently, with an efficient search for optimal hyper parameters within the search space. The confusion matrix heat map further supports the high classification accuracy for the different classes with minimal misclassifications but it should be used with other metrics like precision, recall and F1score. Moreover, the curve of convergence presents that Firefly optimization converges to an optimum solution very fast and thus becomes efficient and stable while optimizing. Analysis by comparison indicated that Firefly optimization outperforms optimization techniques such as Genetic Algorithms and Particle Swarm Optimization in terms of fine-tuning performance. These results highlight the potential of Firefly optimization in enhancing deep learning-based sentiment analysis models. However, computation overheads and scalability on huge data sets are challenges. The current study develops upon the idea that incorporating metaheuristic optimization techniques into the pipeline becomes the hub for solving real-world complex problems, thereby improving predictive accuracy. Using fireflies algorithms for sentimental analysis, the key limitations include potential for stuck in local optima, slow convergence speed, difficulty with complex sentiment, sensitivity to parameter tuning and challenges with large data sets. But it will be very slow when dealing with large scale problems. If the algorithm is clustered then the potential will be reduced.

VI. CONCLUSION

The firefly Algorithm is inspired from the flashing behavior of fireflies. It is an effective optimization technique for solving complex problems like machine learning and sentiment analysis. This algorithm enhances the performance of classifiers and feature selection techniques in sentiment analysis by leveraging its ability to explore and exploit solutions efficiently. Sentiment analysis involves extracting and analyzing information from data. It helps to improve sentiment classification accuracy by optimizing parameters selecting the most relevant features and deep learning models. So, the integration of firefly algorithm with sentiment analysis which results in handling large datasets. Which reduces computing costs and improving classification performance. The findings are suggestive that Firefly optimization increases the model accuracy by up to 98.4% in terms of hyper parameter tuning. The convergence curve and performance metrics confirm the objective of the proposed

approach as fruitful for enhancing the model optimization. The Firefly algorithm surpasses other optimization methods in terms of several parameters and it can be used as an improvement in deep learning models. Even to detect mental health issues like depression fireflies and sentiment analysis called Firefly Optimal(FFO)using Support Vector Machine(SVM) with an artificial bee colony(ABC) optimal using SVM classifier. Sentiment classification is a text mining which is valuable for people, business, companies etc.

A. Future Work

Possible future work may also include the study of Firefly optimization used for other domains in sentiment analysis such as image classification, medical diagnosis and time-series forecasting. Expanding Natural Language Process (NLP)like chat bot, speech recognition and text summarization. Furthermore, application of hybrid Firefly optimization is used in optimization techniques like Genetic Algorithms could also improve model performance. Further, scalability over a large data size and real-time data distribution scenarios may assess the stability and performance of Firefly-CNN-LSTM framework in the actual application context. Implementing Firefly optimization in sentiment analysis like Social media, financial markets and customer feedback systems. Research on the model explain ability and interpretability will also be useful for future work. Future research can explore hybrid models combining firefly algorithm with other techniques to enhance accuracy and efficiency in sentiment prediction tasks.

Accurate AI Assistance in Contract Law Using Retrieval-Augmented Generation to Advance Legal Technology

Youssra Amazou, Faouzi Tayalati, Houssam Mensouri, Abdellah Azmani, Monir Azmani
Intelligent Automation and Biomed Genomics Laboratory-FST of Tangier,
Abdelmalek Essaadi University, Tetouan, Morocco

***Abstract*—Understanding legal documentation is a complex task due to its inherent subtleties and constant changes. This article explores the use of artificial intelligence-driven chatbots, enhanced by retrieval-augmented generation (RAG) techniques, to address these challenges. RAG integrates external knowledge into generative models, enabling the delivery of accurate and contextually relevant legal responses. Our study focuses on the development of a semantic legal chatbot designed to interact with contract law data through an intuitive interface. This AI Lawyer functions like a professional lawyer, providing expert answers in property law. Users can pose questions in multiple languages, such as English and French, and the chatbot delivers relevant responses based on integrated official documents. The system distinguishes itself by effectively avoiding LLM hallucinations, relying solely on reliable and up-to-date legal data. Additionally, we emphasize the potential of chatbots based on LLMs and RAG to enhance legal understanding, reduce the risk of misinformation, and assist in drafting legally compliant contracts. The system is also adaptable to various countries through the modification of its legal databases, allowing for international application.**

***Keywords*—AI Lawyer; contract law; legal technology; Retrieval-Augmented Generation (RAG); Large Language Models (LLMs); GPT; chatbots**

I. INTRODUCTION

Legal services play an essential role in ensuring compliance with regulations and facilitating access to public information [1]. By providing assistance in legal matters, these services help to improve the efficiency, accuracy and accessibility of the legal field. However, despite their importance, challenges persist in understanding complex legal documentation and creating accurate contracts, not least because of the prevalence of misinformation and the complexity of litigation. Integrating AI technologies into legal services offers significant benefits, such as improved efficiency and reduced costs [2]. By standardizing tasks, AI improves the accuracy and consistency of routine tasks, streamlining processes and boosting productivity [3]. In addition, AI technologies are making legal services increasingly accessible to the general public, facilitating access to legal information and services. This increased accessibility contributes to better access to justice, legal transparency and efficient dispute resolution.

In the current context, where understanding legal documents is critical and contract drafting requires precise expertise, exploring innovative solutions based on artificial intelligence has become essential. These solutions aim to streamline processes [4], minimize risks associated with misinformation and litigation, and provide assistance without requiring specialized legal skills. This article aims to present an intelligent chatbot system specifically designed for the legal domain, particularly to help citizens understand contract law without the need for a lawyer.

Chatbots, due to their ability to provide detailed and coherent responses in conversational dialogue [4], are promising tools to address these challenges [5], [6], [7]. This chatbot is designed to enhance the understanding of legal documents, especially contract management law, and facilitate contract drafting by establishing connections between different elements. By integrating external knowledge, it helps minimize discrepancies with current regulations, detect potential errors, and avoid future complications. Proactively, this assistance system enables non-expert users in the legal field to draft contracts by guiding them on key information to include, while ensuring compliance through legal references and reliable databases. Additionally, its ability to provide precise answers to complex questions makes it a valuable tool for legal clarification [8], [9], [10]. To fully harness advancements in artificial intelligence and natural language processing to improve the efficiency and accessibility of our system [11], [12], we rely on large language models (LLMs). These models have achieved significant progress in recent years, demonstrating their ability to generate coherent text on a wide range of topics [13]. A striking example of this advancement is the emergence of the GPT-4 model [14], which has exhibited rudimentary reasoning capabilities, marking a significant leap in the field. However, LLMs face a critical limitation, their inability to access specific and relevant information in real time [15]. In specific domains, such as the provisions of a law in a particular country, these models may lack the necessary facts or details, as such information might not be present in their memory. Additionally, another limitation of LLMs mentioned in the text is the issue of "hallucination," where these models generate statements that appear plausible but are factually incorrect. Despite their impressive fluency and conversational capabilities, this suggests that LLMs can still produce inaccurate or misleading information [16]. This shortcoming poses a significant challenge for practical applications.

To address this challenge, the concept of Retrieval-Augmented Generation frameworks has emerged as a promising solution. These systems enhance LLMs by integrating them with

vector databases containing relevant information [17]. When a query is presented by the user, these systems dynamically retrieve and incorporate pertinent data into the LLM's context. This augmentation strategy has proven highly effective [18], as it addresses the shortcomings of LLMs in processing legal data. The synergy between LLMs and RAG systems provides more robust and context-sensitive applications in this domain [19]. This advancement paves the way for potential improvements to our system, thereby offering users greater practical utility.

The general contributions of this article are as follows:

- The proposal of an innovative chatbot for legal assistance, designed to provide basic legal advice accessible to all. This system is particularly aimed at helping citizens understand contract laws without requiring prior legal knowledge. By simplifying access to legal information, it promotes greater democratization of justice.
- The implementation of an advanced technical architecture based on Retrieval-Augmented Generation (RAG). This technology combines document search capabilities with large-scale language models, enabling a deeper contextual understanding of legal texts and ensuring greater accuracy in the responses provided.
- A significant improvement in accessibility and transparency in the legal field. By making complex legal texts more accessible and simplifying access to information, the chatbot helps enhance citizens' understanding and promotes greater transparency in legal processes.
- A remarkable ability to reduce misinformation. Unlike traditional language models, this system relies solely on verified and regularly updated data, providing accurate and relevant responses. This approach overcomes the limitations of traditional AI systems by minimizing the risks associated with incorrect or speculative information.
- Dynamic personalization and adaptability to local laws. By modifying integrated databases and legal rules, the system can be easily adapted to different jurisdictions, offering a flexible solution capable of meeting the specific needs of each country.
- The article is structured into four main sections. The first section explores the fundamentals of conversational systems and their role in various applications, detailing how Retrieval-Augmented Generation works. It highlights its key components, including the information retrieval mechanism, contextual content generation, and their integration into interactive systems. The second section analyzes existing work in the field of legal digitalization, using contract law as a case study, while presenting automated assistance systems such as chatbots. The third section describes the adopted methodology, outlining the various stages of development of the proposed system, with a focus on the technical specifications that ensure its performance and efficiency in the context of legal assistance. Finally, the fourth section presents the research findings and discusses their implications, emphasizing the system's contributions to improving assistance tools in complex fields such as law.

II. Scope of Study

A. Chatbot System

A chatbot, also known as a conversational agent or dialogue system, is software designed to simulate human conversation through text or voice interactions. Chatbots are widely used to automate routine tasks, save time, and enhance user experience across various industries [20], [21], [22]. Their functionality relies on predefined rules or advanced AI techniques such as Natural Language Processing (NLP), enabling dynamic and contextually appropriate responses. Integrated into chat platforms, chatbots often serve as virtual assistants, capable of handling both structured tasks and informal conversations within their programmed expertise [23], [24]. Recent developments have highlighted their transformative potential in areas such as customer support, where they improve efficiency and availability; education, where they enable personalized learning experiences; healthcare, where they assist with patient communication and preliminary diagnostics; and entertainment, where they create interactive user experiences. As their applications continue to expand, chatbots are reshaping interactions between humans and technology [21], [25]. The performance and effectiveness of chatbots generally rely on three key elements.

- Natural Language Understanding (NLU) is crucial for interpreting users' messages accurately. This involves analyzing natural language to identify intent, extract relevant information, and understand the context of the conversation [26], [27], ensuring that the chatbot can respond appropriately to user needs.
- Response generation involves providing suitable and contextually relevant answers. This can be achieved using predefined rule-based systems, retrieval models that select existing responses [26], [28], or generative models that create unique and personalized responses tailored to the user's input.
- Managing the context of conversations is essential for maintaining coherence in long interactions. By remembering previous exchanges [27], chatbots can adjust their responses according to the evolving needs of the user, improving the flow and relevance of the conversation.

B. Retrieval Augmented Generation

Retrieval-Augmented Generation (RAG) is an innovative method that combines the power of large language models with dynamic external knowledge retrieval, directly integrated into the text generation process. This approach overcomes several limitations of LLMs, such as outdated knowledge and hallucinations, by anchoring the generated content on relevant, accurate, and up-to-date information from reliable external sources.

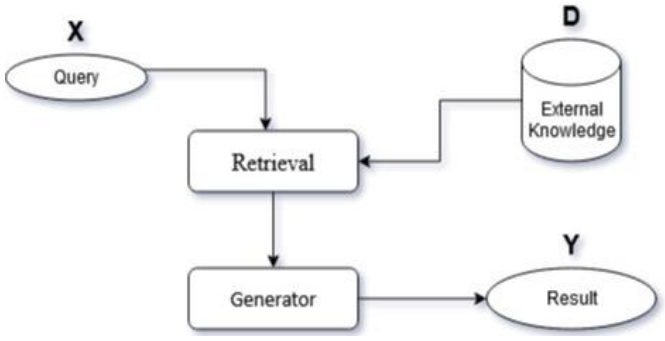

Fig. 1. Retrieval-augmented generation components.

By integrating the robustness of a generative model with the relevance and timeliness of the retrieved data, RAG produces responses that are not only natural and human-like but also contextually appropriate and highly reliable [16], [29]. This fusion of retrieval and generation delivers results that are inaccessible by either component in isolation, positioning RAG as a major advancement in generative models [13], [30]. It allows for the production of high-quality responses, even in less explored fields, while remaining economically advantageous.

The principle of RAG, illustrated in Fig. 1, involves predicting the output y from the input source x, both of which come from a corpus D. Simultaneously, a reference set Z is accessible through data sources. The direct association between a document $z \in Z$ and a tuple $(x, y) \in D$ is not necessarily known, although it can be established through human annotations [31], [32] or weakly supervised signals [33]. The general framework of RAG includes two main components: (B.1) a document retriever and (B.2) a text generator. The goal of RAG is to train a model that maximizes the probability of y given x and Z. In practice, Z often contains millions of documents, making exhaustive enumeration impossible. Therefore, the first step of RAG is to use document retrievers, such as DPR [29], to narrow the search down to a handful of relevant documents. The retriever takes x and Z as input and produces relevance scores $\{s_1, ..., s_K\}$ for the top K documents $Z = \{z_{(1)}, ..., z_{(K)}\}$. Then, the second step is to use a text generator [34], [35] to produce the desired result y by taking both the input x and the retrieved document set Z as conditions.

1) Information retrieval: Information Retrieval (IR) is a field of information science and computer science that focuses on the representation, storage, and organization of unstructured data to help users find and retrieve relevant information based on their queries [36], [37], [38]. An advanced aspect of IR involves the use of neural document retrievers. These typically use two independent encoders, such as BERT [39], to separately encode the query and the document. They then estimate relevance by calculating a single similarity score between the two encoded representations. For example, in the DPR model [33], the documents Z and contextual queries x are projected into the same dense encoding space. The relevance score q(x, z) for each document z is calculated as the dot product between the document encoding T_z and the query encoding T_x, this allows for efficiently determining which documents are most relevant to a given query, by leveraging advanced natural language processing and machine learning techniques to improve the accuracy and relevance of search results.

2) Information generation: Text generation represents a crucial domain in natural language processing and artificial intelligence, aiming to automatically create readable and coherent texts from existing information [40]. This task, often referred to as Information Generation (IG), relies on advanced machine learning and NLP techniques to produce new content. Text generation models, such as GPT and BERT, have the ability to synthesize data, rephrase information, and generate relevant responses based on the provided contexts. By using deep neural networks, these models analyze vast amounts of textual data to learn the linguistic and contextual structures necessary for text production [41] . This approach enables the creation of varied content, ranging from article summaries to detailed answers to specific questions, continually improving the quality and relevance of the generated texts thanks to advancements in AI and NLP.

III. Related Work

The advancements made in the field of artificial intelligence have led to a notable increase in the development and deployment of chatbots for various tasks [42]. Many research efforts have focused on the creation of chatbots and the study of their applications in different fields, such as business support and education. For example, some studies have addressed the technical advancements in chatbot development to enhance their capabilities and effectiveness [43]. This section of the article examines existing research on the development and application of chatbots, highlighting the growing interest in chatbots and their evaluation in the legal field. The development of AI-powered chatbots for legal advice has garnered considerable attention in recent years. Previous studies have explored the application of chatbots in the legal domain, focusing on various aspects such as the type of chatbots, their capabilities, and their limitations [4], [44]. For example, [45] compared two types of chatbots, generative and intent-based, to provide legal advice specific to Indian laws, evaluating their performance based on factors such as response quality and user experience. Similarly, [46] assessed the capabilities of ChatGPT and Gemini chatbots for contract drafting, highlighting the need for human intervention due to the limitations of chatbots in understanding the specifics of the legal system and linguistic conventions.

Other studies have focused on the design and development of legal chatbots, which aim to automatically converse with users, determine the need for legal advice, grant access to legal rights, bridge the communication gap between clients and lawyers, and generate documents for legal activities [47]. In the same vein, [48] took this concept a step further by proposing a chatbot specifically designed for smart contracts. This chatbot can assist non-technical users in specifying and generating code for smart contracts, thus highlighting the potential of chatbots to facilitate the creation and management of complex legal documents.

These studies highlight the potential of chatbots to provide accurate legal information to users. However, despite the

existence of these studies, there is still a need to improve chatbot systems in the legal field. The revolution of generative AI and its growing use in this sector emphasize this necessity. Indeed, human intervention remains essential due to the sensitivity of legal information and to avoid potentially severe consequences. The issues of hallucination in large language models used for chatbots particularly underscore the importance of these improvements. Without proper human intervention, chatbots may provide incorrect or inadequate information, leading to significant negative impacts. Therefore, further research and development are essential to strengthen the reliability and effectiveness of chatbots in the legal field. Many researchers have explored different approaches to improve chatbot capabilities. In this context, several studies have focused on enhancing chatbot systems to address this issue, through the integration of a retrieval-based response generation model, which has outperformed models based solely on retrieval or generation, offering increased fluency, improved contextual relevance, and greater diversity in responses [49]. This technology is Retrieval-Augmented Generation, which involves retrieving texts from a relevant external corpus for the task, and then providing them to the large language model [29], [50]. RAG improves the performance of LLMs by integrating the retrieved texts via cross-attention [29], [51], [52] or by directly inserting the retrieved documents into the prompt. Large language models, advanced systems for natural language processing, are trained on massive datasets to process and generate text [34]. Although they are designed for tasks such as machine translation, summarization, and conversational interactions, RAG models can also be used for information retrieval [13]. Retrieval-augmented generation has demonstrated notable success in several natural language processing tasks requiring deep knowledge, such as answering general knowledge questions accurately, fact-checking with high precision, and answering questions within specific domains [17], [29]. Furthermore, retrieval-augmented generation reduces misinformation often produced by large language models and non-RAG chatbots.

IV. Materials and Methods

In this section, we introduce the AI assistance model tailored for contract law, which represents a groundbreaking advancement in efficiently accessing legal knowledge. This model begins with the collection of legal datasets for contracts. Next, by segmenting the documentation into manageable "chunks" and employing sophisticated techniques such as vector representation for storage and similarity searches, it streamlines the process of retrieving pertinent information. Fig. 2 likely provides a visual depiction of this innovative process, aiding in the understanding of its intricacies. This process is further elaborated in the following sections: Data Collection and Document Pre-processing (section A), Document Embedding and Storage (section B), and Search Similarity and Leveraging Answers (section C).

A. Data Collection and Document Pre-processing

The first step in designing this system involves collecting data related to contracts. For example, we used the official documentation of the law governing contracts in Morocco. We found that contract management in Morocco is called the "Code of Obligations and Contracts (COC)," promulgated by the Dahir of August 12, 1913, which serves as the foundation of contract law in the country [53]. This code governs the formation, execution, and nullity of contracts, specifying that contracts must comply with conditions of consent, capacity, lawful object, and cause. It encompasses various types of contracts, such as sales, leases, and mandates, defining the obligations and responsibilities of the parties involved. Additionally, the COC provides mechanisms for remedies in cases of non-performance or nullity of contracts and includes provisions on contractual and extra-contractual liability, thereby ensuring legal security and clarity in contractual relationships in Morocco.

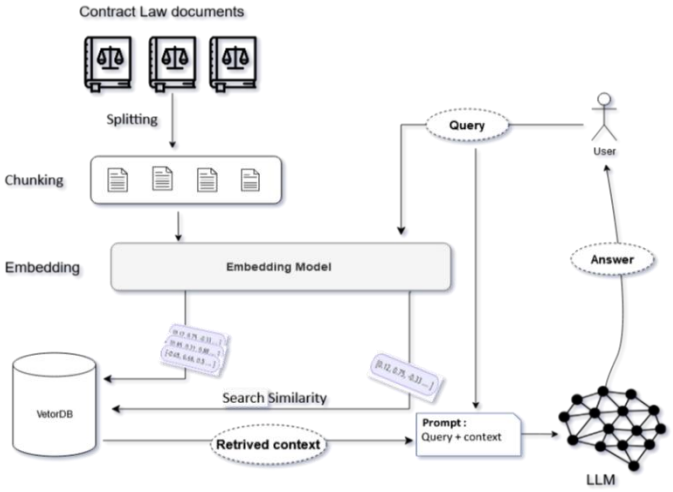

Fig. 2. Overview of the workflow for AI assistance in contract law.

The dataset derived from this documentation includes several key features, as illustrated in Fig. 3, which shows the distribution of articles by section.

- Articles: Each entry corresponds to a specific legal article, categorized by its thematic section.
- Sections: The dataset covers critical areas of contract law, including General Obligations, Electronic Contracts, Quasi-Contracts, Torts and Liabilities, Contractual Terms, and Solidarity.
- Language: The dataset is entirely in French, ensuring consistency with Moroccan legal texts.

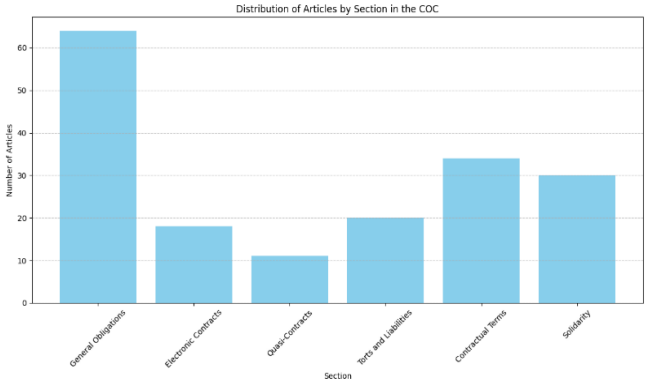

Fig. 3. Distribution of Articles by Section in the COC.

We would like to note that the documentation used for the implementation of this system is digital and in PDF format, which facilitated the collection and analysis of the necessary information. To efficiently extract the content from the documents as text, we used OCR technology, which converts text images into usable digital text. This tool is particularly well-suited for such technical documents. Each document is processed by OCR and then divided into text segments of up to 4,000 characters using a recursive text splitter. The splitting points are determined using separators such as double line breaks, single line breaks, periods, exclamation marks, question marks, spaces, and, as a last resort, no specific separator. Moreover, there is no overlap between segments, resulting in independent and coherent text chunks, thereby facilitating analysis while minimizing information loss.

B. Document Embedding and Storage

This step involves converting the segments prepared in the first phase into a format suitable for queries and storing them in a database. To achieve this, we use the LLM-Embedder model, known for its ability to capture complex semantic relationships in texts. This model, characterized by its precision in analyzing linguistic nuances, is ideal for extracting relevant and context-rich information from documents [54]. Using this approach, we obtain vector representations that faithfully reflect the semantic content of the documents. These results are then stored in a vector database, enabling efficient search and retrieval based on similarity queries. Finally, each text associated with an embedding is recorded with a pointer, ensuring precise retrieval based on the corresponding embedding. Fig. 4 illustrates the process of creating this database.

C. Leveraging Answers

To answer user questions or queries, we follow a procedure that begins with the embedding of the user's question using the same embedding model as that used for the knowledge base. We then use the resulting embedding vector to query the vector database index, selecting three vectors (Top-k = 3) to determine the amount of context to retrieve. The vector database then performs a nearest-neighbor (ANN) search against the embedding provided, returning the most similar context vectors as illustrated in Fig. 6. It is through this similarity search that we extract the relevant documents from the database. For this task, we opted for the use of Facebook AI Similarity Search (FAISS), recognized for its efficient and scalable similarity search capabilities, particularly suited to the management of large datasets [55], [56]. FAISS offers significant advantages, particularly in terms of speed [57]. We then associate these vectors with the corresponding chunks of text, and transmit the question and the retrieved context to the LLM via a prompt. We ask the LLM to use only the context provided to answer the question, while ensuring that the answers respect the limits laid down for this type of sensitive information. If the context contains no usable data, the system will return a standard “Not applicable” message, as illustrated in Fig. 5, which includes the activity diagram describing the entire process.

To select the best large-scale language model (LLM) for generating chatbot responses, we carried out a comparative analysis of the results obtained using GPT-4 Turbo and Llama 3. GPT-4 Turbo, developed by OpenAI, offers improved speed and accuracy, in-depth understanding of natural language and advanced personalization options. Its outstanding performance places it among the best LLMs available, and its enriched contextual memory makes it particularly effective in delivering consistent, relevant user interactions. For its part, Meta Llama 3, a family of models developed by Meta, is considered the current state of the art and is available in 8 billion and 70 billion parameter versions, pre-trained or adjusted on instruction. The instruction-tuned Llama 3 models are optimized for specific chat use cases and outperform many others. Table I below contains the detailed characteristics of each model used in this study.

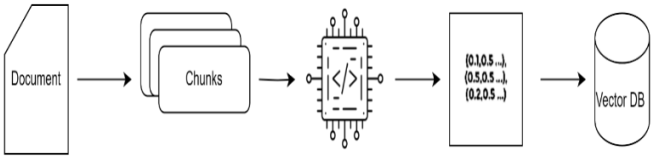

Fig. 4. Vector database creation process.

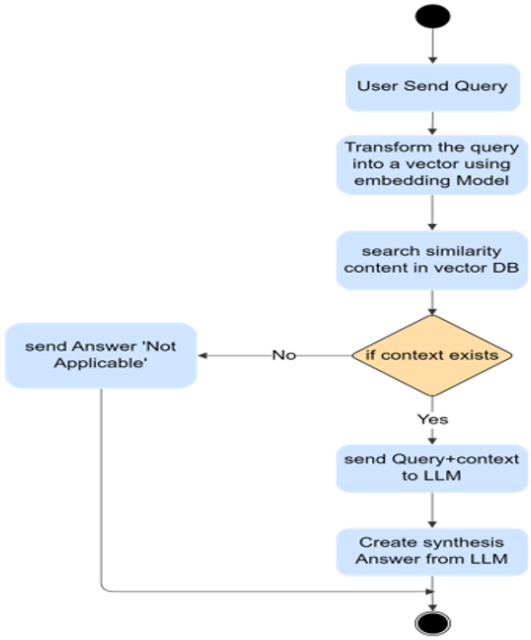

Fig. 5. Activity diagram for leveraging answers process.

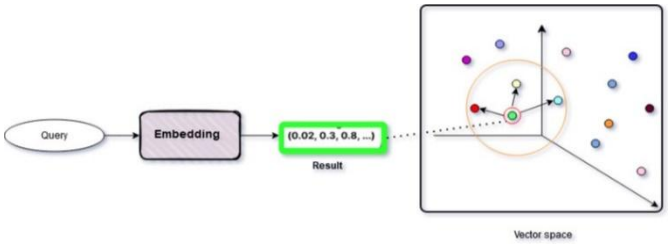

Fig. 6. Vector similarity search process with Top-k = 3.

TABLE I. FEATURES OF LARGE LANGUAGE MODELS UTILIZED IN THIS STUDY

Model	Organization	context length	Knowledge cutoff date
GPT 4 - Turbo	OpenAI	128K tokens	April 2023
Llama 3	Meta	8K tokens	December 2023

V. RESULTS

A. Question-Answers Results of AI Assistance

The results of implementing the contract law assistance system, based on datasets from Moroccan law as an example, demonstrate remarkable performance in providing accurate and contextualized responses to users. Built on an architecture combining search and generation assisted by generative artificial intelligence, this system has proven its effectiveness in handling complex legal information.

For instance, when faced with a question such as, "What remedies are available to a buyer in the event of delivery of a defective product?", the model provided a detailed response enumerating the remedies available to the buyer, as illustrated in Fig. 7 below, relying entirely on information contained in the Moroccan COD law documentation. The large language model plays a crucial role by synthesizing the data provided by the system's prompt and ensuring that the response is coherent and contextualized based on the extracted information. This example demonstrates the chatbot's ability to extract and articulate specific and relevant information from foundational documents. However, when the system cannot find any relevant context to answer a question, as illustrated in Fig. 8, we do not allow the large language model to generate a response based solely on its general knowledge. In such cases, the system returns a response like "Not applicable" to avoid any misinformation or inaccuracies. This approach ensures that the responses provided are always based on reliable and contextualized information derived from the foundational documents.

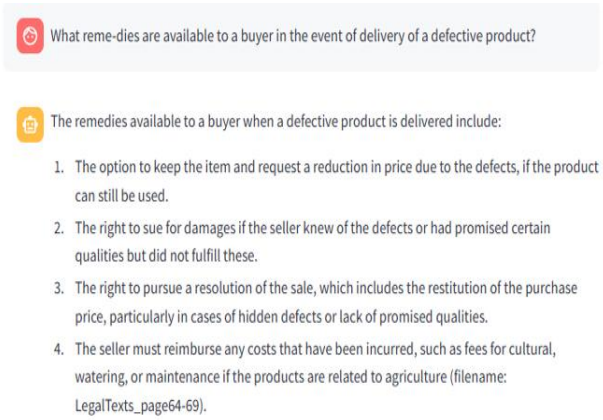

Fig. 7. Example of the system's answer.

Fig. 8. Example of the system's response in the absence of relevant context in the used documents.

To study the performance of the large language models integrated into the pipeline of this system, we collected responses provided by GPT-4 Turbo and Llama 3 to various questions, as mentioned in the Methodology section. Table III below presents the results, allowing for a direct comparison of the two models' performance in terms of response quality and response time. These data provide a solid foundation for further analysis in the following section. Finally, it is important to note that the final version of this chatbot will use the LLM that performs best during the evaluation.

B. Performance Evaluation of Answer Generation

To evaluate the results obtained by each LLM in the RAG pipeline of this study we chose the RAGAS framework introduced by Es et al. In 2023. The Retrieval-Augmented Generation Evaluation Framework (Ragas), represents a breakthrough in the evaluation of Retrieval-Augmented Generation systems. In essence, Ragas equips practitioners with state-of-the-art tools, rooted in the latest research, to rigorously scrutinize text generated by LLMs. By leveraging Ragas, deep insights can be gained into the effectiveness of their RAG pipeline. At the heart of the Ragas framework lies its ability to evaluate RAG systems on a component-by-component basis, dividing the pipeline into its constituent parts: the Retriever component and the Generator component. This granular approach provides a nuanced understanding of system performance, identifying strengths and weaknesses at each stage of the process [58]. In the context of this study, our focus is on the evaluation of the Generator component within the RAG pipeline. This component plays a crucial role in the generation of text based on retrieved context, thus requiring careful examination. Ragas offers two main evaluation indicators designed specifically to assess the effectiveness of the Generator component:

- Faithfulness: This metric assesses the factual consistency of the generated response in relation to the context provided. It determines the extent to which the statements made in the response can be logically deduced from the context [58]. Scores range from 0 to 1, with higher values indicating greater fidelity.
- Answer Relevance: evaluates the relevance of the generated answer to the question asked. It calculates the average cosine similarity between the original question and synthetic questions derived from the answer [58]. Higher scores mean greater relevance, indicating that the answer closely matches both the question and the context.

The comparative evaluation of the performance of GPT-4 Turbo and Llama 3, as shown in Table II and graphically represented in Fig. 9, highlighted notable differences in response time, fidelity, and relevance of the generated answers.

TABLE II. EVALUATION METRICS FOR RESPONSE GENERATION

Model	Faithfulness	Answer Relevance	Response time
gpt-4-turbo	1	0,971	3.12
Llama3	0.84	0.79	0.86

TABLE III. RESPONSES OBTAINED FOR EACH MODEL UTILIZED

Questions	Answers		Response time	
	gpt-4-turbo	*Llama3*	*gpt-4-turbo*	*Llama3*
What are the essential elements of a valid contract?	The essential elements for the validity of obligations deriving from a declaration of will are: 1) the capacity to obligate, 2) a valid declaration of will concerning the essential elements of the obligation, 3) a certain object that can form the subject of an obligation, and 4) a lawful cause to obligate (Article 2, Dahir (9 ramadan 1331) formant Code des obligations et des contrats).	The essential elements of a valid contract include the identity of the contracting parties, the title of the property, the number and date of the building permit, and the description of the property being sold (Dahir.pdf, page 69).	3.10	1.21
What are the defects in consent that can render a contract null and void?	Defects in consent that can render a contract null and void include error, fraud (dol), and duress (violence). These defects impact the validity of the consent given and can lead to the annulment of the contract (filename: Dahir_formant_Code_des_obligations_et_des_contrats.pdf, page 6).	The defects in consent that can render a contract null and void are error, violence, fraud, and dol (Dahir.pdf, page 50).	2.95	0.66
What are the conditions for claiming damages in the event of non-performance of a contract?	To claim damages for non-performance of a contract, the following conditions must be met: 1) there must be a failure to perform the obligation (non-performance), 2) the non-performance must be attributable to the debtor (fault must be proven unless presumed), and 3) there must be a causal link between the non-performance and the damage incurred. Additionally, the claimant must prove the damage and the amount of loss (filename: Dahir_formant_Code_des_obligations_et_des_contrats.pdf, page 18).	The conditions for claiming damages in the event of non-performance of a contract are not explicitly stated in the provided text. However, it mentions that in case of resale, the seller must be notified by registered letter with acknowledgment of receipt, and the resale must be done under the same conditions as the preliminary contract (Dahir.pdf, page 71).	3.46	0.80
What happens if one of the parties fails to perform a contract?	If one of the parties fails to perform a contract, the other party may demand specific performance, if applicable, or seek the resolution of the contract in court. Additionally, the non-breaching party may claim damages for losses incurred due to the breach (filename: Dahir_formant_Code_des_obligations_et_des_contrats.pdf, page 25).	If one of the parties fails to perform a contract, the other party may be entitled to damages for the prejudice suffered due to the non-performance or delay in performance of the obligation (Dahir.pdf, page 29).	4.00	0.67
What are the seller's obligations under a in a contract of sale?	The seller's obligations in a contract of sale primarily include: 1) delivering the thing sold, and 2) guaranteeing the buyer's peaceful possession and enjoyment of the thing sold, free from defects and third-party claims (Articles 498, 499, Dahir (9 ramadan 1331) formant Code des obligations et des contrats).).	Based on the general concept of a contract of sale, the seller's obligations typically include delivering the goods, ensuring the goods are of acceptable quality, and providing any necessary documentation.	3.34	1.06

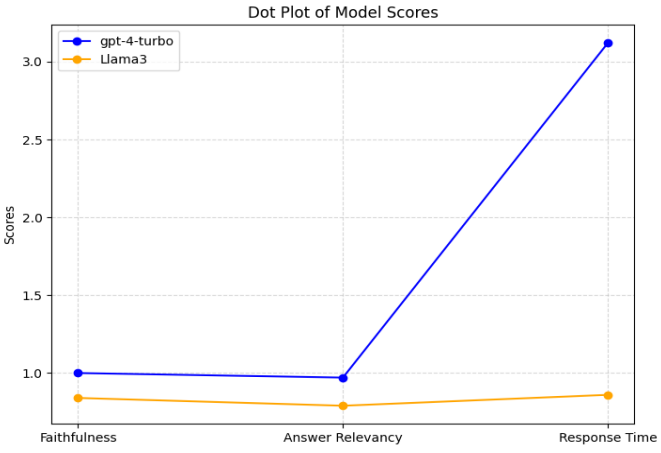

Fig. 9. Comparison of GPT-4 turbo and llama 3 across evaluation metrics.

The average response time for GPT-4 Turbo is 3.12 seconds, whereas Llama 3 stands out with a remarkably reduced response time of 0.86 seconds. This superior speed of Llama 3 is attributed to the use of Groq technology during its integration into our system. Groq is an advanced technology that optimizes query processing and efficiently meets the demands of high-responsiveness environments. However, this improvement in speed for Llama 3 appears to have come at the cost of a slight reduction in answer quality. The data presented in Table II reveal that GPT-4 Turbo outperforms Llama 3 in terms of fidelity (1 versus 0.84) and answer relevance (0.971 versus 0.79). The high fidelity of responses generated by GPT-4 Turbo indicates a better ability to align with the facts and the provided context, ensuring a reliable and accurate user experience.

VI. DISCUSSION

Based on the results obtained, the GPT-4 Turbo model was selected for definitive integration into the RAG process of our assistance system, specifically in the legal domain, and more precisely in contract law. This field demands a very high level of fidelity in responses, given the sensitivity and rigor associated with legal inquiries. The exceptional performance of GPT-4 Turbo in terms of fidelity (score of 1) and response relevance (score of 0.971) makes it the most suitable model to meet the critical needs of users in this demanding context. Additionally, the system has been designed to rely on legal texts as the primary source during the data augmentation phase for answer generation. This strategy ensures enhanced contextual accuracy and better alignment with the specific needs of users in the legal field. GPT-4 Turbo, with its ability to produce factually aligned

responses while adhering to precise contextual frameworks, has proven ideal for handling complex queries while efficiently leveraging augmented data. While the Llama 3 model offers undeniable advantages in terms of speed, the priority given to response fidelity and contextual relevance in this specific domain fully justifies the choice of GPT-4 Turbo. This decision strengthens the reliability and robustness of the system, particularly in an environment where information accuracy is critical and any error could lead to significant consequences.

The results of this study illustrate the effectiveness of Retrieval-Augmented Generation systems in legal assistance, particularly in contract management. By combining legal vector databases with large language models, the developed chatbot delivers accurate and contextually appropriate responses. This system surpasses existing chatbots in this domain by adding an intelligence layer based on official legal data, such as national laws and regulations, ensuring strict compliance with current legislation. Unlike standalone LLMs, which may generate incorrect or non-compliant information, this chatbot leverages relevant legal data to avoid hallucinations or errors. For example, the data used in this study is based on Moroccan legislation, ensuring compliance with the national legal framework.

The GPT-4 Turbo and Llama3 models integrated into the development process of this system showed distinct results: GPT-4 Turbo stands out for the richness of its responses, despite being slower, while Llama3 offers superior speed but with less depth in complex cases. When the sought information is not explicitly available in the legal texts, the system uses the "Not applicable" option to avoid providing incorrect or unfounded answers. This system represents a significant advancement in access to justice, facilitating the understanding of laws and the creation of compliant contracts while ensuring essential transparency and reliability. However, it cannot replace human expertise in complex legal cases. Future improvements are planned, such as automating legal updates, integrating multimodal functionalities, and continuously evaluating performance through frameworks like RAGAS. It is crucial to clarify the system's limitations to avoid any misinterpretation, emphasizing that this chatbot is not intended to replace professional legal advice.

VII. Conclusion

This work highlights the growing impact of AI-based technologies, particularly advanced language models combined with Retrieval-Augmented Generation systems, in the field of legal assistance. By relying on official documentation and rigorous information management, the developed system represents a significant step forward in improving access to justice by providing responses tailored to specific legal requirements.

This approach overcomes some of the limitations of traditional chatbots and LLMs, ensuring greater accuracy in the information provided. The system also stands out for its flexibility, as it can be adapted to different countries simply by modifying the legal databases, ensuring its relevance to various legislative contexts. However, while this system is a powerful tool for automating certain legal tasks, it does not replace human expertise, particularly in more complex cases. Nevertheless, it paves the way for the democratization of access to legal information, emphasizing the importance of regular updates and continuous vigilance to avoid errors in ever-evolving contexts.

Future developments will focus on automating legal updates, integrating multimodal capabilities such as speech recognition and document analysis, improving explainability by providing explicit legal references, and enhancing adaptability to different legal frameworks. By tackling these challenges, future iterations of this system will significantly enhance the accessibility, accuracy, and usability of AI-driven legal assistance.

***Abstract*—In order to improve the level of logistics service and considering the impact of uncertainties such as bad weather and highway collapse on fourth party logistics routing optimization problem, this paper adopts Conditional Value-at-Risk (CVaR) to measure the tardiness risk, which is caused by the uncertainties, and proposes a nonlinear programming mathematical model with minimized CVaR. Furthermore, the proposed model is compared with the VaR model, and an improved Q-learning algorithm is designed to solve two models with different node sizes. The experimental results indicate that the proposed model can reflect the mean value of tardiness risk caused by time uncertainty in transportation tasks and better compensate for the shortcomings of the VaR model in measuring tardiness risk. Comparative analysis also shows that the effectiveness of the proposed improved Q-learning algorithm.**

***Keywords*—Logistics service; routing optimization; tardiness risk; conditional value-at-risk; improved Q-learning algorithm**

I. Introduction

With the deepening of economic globalization and the intensification of competition in the logistics market, service-oriented manufacturing enterprises are pursuing more hierarchical and integrated logistics services, so the problem of third-party logistics (3PL) is becoming increasingly prominent. For example, the Toyota listed on its website that Toyota outsources its logistics services to the 3PL to focus on their core product business, on 10th May 2021 [1]. In order to obtain more orders, competition among 3PL enterprises is becoming more fierce. There is a lack of resource sharing among various 3PL service providers, which makes it difficult to accurately grasp logistics information and meet the current rapidly growing logistics demand. As a result, the traditional 3PL model cannot adapt to the pace of the times and restricts the progress of logistics globalization. Instead of relying on the 3PL providers, some large manufacturers (e.g. Haier [2] and Hisense) have recently cooperated with Cainiao Logistics (the largest fourth party logistics [4PL] provider in China) in supply chain solutions. 4PL [3] is necessary to integrate and effectively connect resources so as to achieve complementary advantages. 4PL supplier is an integrator of the supply chain that integrates and manages different resources, capabilities, and technologies of a company and complementary service providers, and performs a detailed analysis of the entire supply chain system or industry logistics system where enterprise customers are located. Thus, it provides a comprehensive solution for the design, construction, and operation of the supply chain. Many enterprises have used 4PL to complete their own logistics tasks. For example, Cainiao Logistics, the largest Chinese 4PL provider founded by the Alibaba Group, incorporates over thirty 3PL providers to serve Taobao.com and Tmall.com, two largest online markets in China [4].

With the continuous development of 4PL, many experts and scholars have begun to focus on and study various aspects of 4PL. They are committed to in-depth exploration of issues related to risk management [4], network design [5-6], combinatorial auctions [7], contract design [8-9], and routing optimization [10] in 4PL, which have proposed a series of theoretical and practical achievements.

The Fourth Party Logistics Routing Optimization Problem (4PLROP) is one of the most important problems and a hot topic about 4PL. As the creator of transportation plans, 4PL needs to optimize and design distribution routes. Based on factors such as transportation time, transportation capacity, reputation indicators, and throughput of 3PLs, it selects and allocates 3PLs that provide distribution services to achieve path optimization and select satisfactory transportation plans for enterprises.

However, in the actual delivery process, due to unpredictable reasons such as transportation, bad weather, and human error operations, all of them may cause the transit time and transportation time to be not fixed but random during the transportation process, which may lead to the risk of delivery tardiness. The impact of this randomness makes 4PL suppliers to be unable to provide timely delivery plans that satisfy customers, it may lead to additional costs and a decrease in customer satisfaction. This situation may even affect the reputation of 4PL enterprises, leading to customer churn, and having adverse effects on their long-term development. Therefore, when solving 4PLROP, the influence of the risk caused by the uncertainty cannot be ignored.

This article adopts CVaR to describe and measure the average risk of tardiness induced by multiple factors in the real delivery process of 3PL providers in a 4PL operation. In addition, a mathematical model is proposed with CVaR minimization as the objective function and delivery cost as the constraint, and the suggested CVaR model is compared to the VaR model [11]. Then, an improved Q-learning algorithm is proposed to solve examples with different scales of the two models, and the effectiveness of the proposed CVaR model is verified. Finally, the proposed algorithm is compared with GA

embedded with Dijkstra [12] and the results verify the feasibility of improved Q-learning algorithm for solving this problem.

The principal contributions of this article are as follows:

1) In the context of uncertain environment, a novel 4PL route optimization problem that considers the risk of delays has been investigated;

2) The CVaR is employed to characterize risk, and a nonlinear programming model is established with constraint on delivery costs, aiming to minimize the risk as the objective;

3) An improved Q-learning algorithm is proposed to solve the model presented. Through this approach, 4PL can better adapt to the ever-changing market environment, ensuring the stability and efficiency of the supply chain.

The structure of this paper is arranged as follow: Section II gives the establishment of mathematical models and the transformations of CVaR model. Section III introduces the overall design of the proposed algorithm. Section IV performs some numerical computations. Section V finally concludes this paper.

II. Literature Review

The current research on 4PLROP can be broadly divided into problem structure, solution approach, and distribution factors. Huang et al. [13] studied 4PLROP from single point to single point and single task, and established a mathematical model based on nonlinear integer programming and multiple graphs. Li et al. [14] studied the routing optimization problem of multi-point to multi-point 4PL systems with reliability constraints. Tao et al. [15] established a mixed integer programming model for 4PLROP from the perspective of cost discount. Hong et al. [16] studied a multi-objective transportation optimization model according to queuing theory, considering the option of 3PL providers, routes, as well as transportation methods. They used a priority based stochastic enhanced elite genetic algorithm (GA) to solve the infeasible solutions in 4PLROP. According to the prospect theory of customer psychological behavior and customer service level, Huang et al. [17] developed a nonlinear integer programming model for the design of 4PL network and offered an approximation linear approach to convert the model to an equivalent linear model so as to demonstrate the efficacy of the proposed method. Yue et al. [18] designed a particle swarm optimization with adaptive inertia weight to solve the proposed mathematical model. Lu et al. [19] designed a combination of ant colony optimization algorithm and improved grey wolf optimization algorithm to solve the 4PLROP. Huang et al. [20] studied the risk management of outsourcing logistics under the principal-agent framework from the perspective of product quality.

For the 4PLROP, most studies are based on the determination of delivery time, which assumes that the delivery cost and delivery time used in the transportation process are fixed quantities, such as references [14,15]. However, in the actual delivery process, due to unpredictable reasons such as transportation, bad weather, and human error operations, all of them may cause the transit time and transportation time to be not fixed but random during the transportation process, which may lead to the risk of delivery tardiness. The impact of this randomness makes 4PL suppliers to be unable to provide timely delivery plans that satisfy customers, it may lead to additional costs and a decrease in customer satisfaction. This situation may even affect the reputation of 4PL enterprises, leading to customer churn, and having adverse effects on their long-term development. Therefore, when solving 4PLROP, the influence of the risk caused by the uncertainty cannot be ignored.

The important question is how to define, measure, and control the risk to improve their logistics service quality, which is in the best interest of 4PL and creates a win-win for both parties. This is the focus of our paper. Value-at-Risk (VaR) was used to measure the time risk in Reference[13,21], the VaR model only considered the possible tardiness time that will not exceed VaR with the confidence level, but it did not take into account the extreme events (when the amount of tardiness time exceeds the VaR value), in which the tardiness risk mean value should be considered.

Conditional Value-at-Risk (CVaR) is a risk measurement tool proposed by Rockafellar et al. [22] on the basis of VaR, which considers the tardiness risk mean value. It is mainly used in combinatorial optimization, setting risk limits, resource allocation, and financial supervision and credit risk measurement of various financial regulators on relevant enterprises and institutions. In recent years, it has been widely used in inventory management optimization [23], supply chain [24], selection of fourth party logistics suppliers, network design and other fields for risk measurement and optimization [25].

In summary, this paper adopts a new risk measure tool, CVaR, to measure the delay risk, sets up a stochastic programming mathematical model, and designs an improved Q-learning algorithm. The aim is to help 4PL to provide an optimal supply chain distribution solution and improve the level of logistics service.

III. Mathematical Model

A. Problem Description

In this section, the 4PLROP with consideration of delay risk is described, and the notations used throughout the paper are introduced.

A manufacturing company (such as Haier) wants to invest in designing a distribution route to deliver its products and services from plant to customer through DCs and 3PL providers to reduce costs and improve customer satisfaction. As a result, it employs a 4PL provider to offer a comprehensive supply chain solution. Specifically, manufacturing companies are investors. A 4PL provider needs to help investors integrate 3PL providers, select the number and location of DCs, and complete the distribution of product from plants to customer.

The 4PLROP requires not only the selection of the route from the plant to the customer, but also the determination of 3PL providers which provide the delivery service. That increases the difficulty of solving 4PLROP.

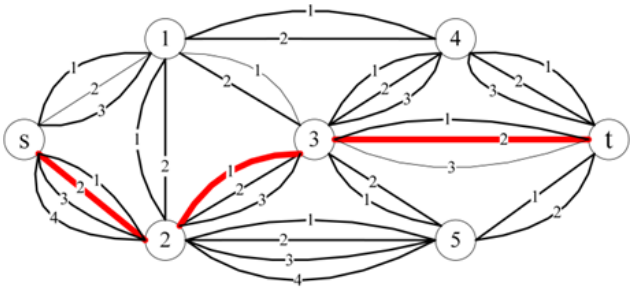

Fig. 1. Multiple graph for the 7-node problem.

A multiple graph, shown in Fig. 1, is used to describe the potential distribution network and demonstrate 4PLROP, where **V** represents the node cities, and **E** represents the edges. Among all nodes, indicates the supply city, indicates the target city, and others indicate the transit cities. All nodes have attributes such as time, cost, carrying capacity and reputation. In addition, there may be several edges between any two nodes because multiple 3PL suppliers may offer delivery services for any two cities. And each edge represents a 3PL, and the numeral on the edge is the serial number of 3PL.

Transportation time management is especially critical for 4PL providers. Traffic congestion, adverse weather, a surge in holiday order volumes, and node transfers can all cause uncertainty in time, leading to the risk of tardiness. Delayed delivery can directly affect customer interests, reduce the reputation of 4PL companies, and lead to customer loss, indirectly affecting the long-term development of 4PL supplier enterprises. Therefore, in order to improve customer satisfaction, 4PL suppliers need to consider the tardiness risk caused by time uncertainty. If the cost is within customer's budget, the less risk of tardiness, the better. Therefore, 4PL suppliers should monitor the tardiness risk mean value that may occur during transportation in real-time. Based on the above considerations, CVaR is introduced to quantify the average level of tardiness risk in delivery path, and a model with minimized CVaR and delivery cost as the constraint is developed.

TABLE I. THE DEFINITION OF PARAMETERS AND VARIABLES

Variables	Definition
r_{ij}	The quantity of 3PLs that offer transportation services between node cities i and j (i.e. the quantity of edges connecting two nodes)
C_{ijk}	The transportation cost required for the k-th 3PL supplier between node cities i and j
T_{ijk}	Random transportation time required for the k-th 3PL supplier between node cities i and j
$C_j^{'}$	Transfer cost required when passing through node city j
$T_j^{'}$	Random transit time required when passing through node city j
R	A path containing a set of nodes and edges, i.e. $R=\{\upsilon_s,2,\upsilon_2,1,\upsilon_3,2,\upsilon_t\}$ can be used to represent the red path in Fig. 1.

In order to set up the mathematical model, the definition of the parameters and variables are listed in Table I, the decision variables are defined as follows:

$$x_{ijk}(R)=\begin{cases}1 & \text{The } k\text{-th edge between nodes } i \\ & \text{and } j \text{ belongs to path } R \\ 0 & \text{others}\end{cases} \tag{1}$$

$$y_j(R)=\begin{cases}1 & \text{Node } j \text{ belongs to path } R \\ 0 & \text{others}\end{cases} \tag{2}$$

where $x_{ijk}(R)$ is used to determine whether the 3PL supplier provides a delivery task between cities i and j, and $y_j(R)$ indicates whether node city j provides a transfer task.

B. Mathematical Model Based on CVaR Criterion

The VaR model [21] only considered the possible tardiness time that will not exceed VaR with the confidence level β, but it did not take into account the extreme events (remaining $1-\beta$ when the amount of tardiness time exceeds the VaR value), the tardiness risk mean value is generated. Therefore, this paper adopts CVaR to improve the objective function of the model at the confidence level β, as shown in (3), the tardiness risk mean value generated when the tardiness time exceeds VaR, i.e. minimizing CVaR, is calculated to determine the delivery path with the lowest average tardiness risk. Therefore, the following mathematical model is established:

$$\min \quad CVaR_{\beta}(\Delta T) \tag{3}$$

$$\text{s.t.} \quad \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{r_{ij}} C_{ijk}x_{ijk}(R)+\sum_{j=1}^{n} C_j^{'}y_j(R)\le C_0 \tag{4}$$

$$\Delta T=\left(\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{r_{ij}}\tilde{T}_{ijk}x_{ijk}(R)+\sum_{j=1}^{n}\tilde{T}_j x_{ijk}(R)\right)-T_0 \tag{5}$$

$$R=\left\{\upsilon_s,\cdots,\upsilon_i,k,\upsilon_j,\cdots,\upsilon_k\right\}\in G \tag{6}$$

$$x_{ijk}(R),y_j(R)\in\{0,1\} \tag{7}$$

Eq. (3) represents the objective function, which minimizes CVaR, where indicates the level of confidence, indicating the customer's level of risk aversion. The delivery cost constraint shown in (4) is the highest cost which is acceptable to the investor. Eq. (5) states the delayed time that the total delivery time needed on the route exceeds the due date, which is a random variable. Eq. (6) represents the constraint on the path, ensuring that it is a legitimate connecting path from the origin city to the target city. And then the constraints on decision variables are represented by (7).

C. Transformation of Mathematical Models

Theorem 1. The linear combination of a finite number of independent normal distribution random variables still obeys normal distribution. For a set of random variables $X_1,X_2,...,X_k,...,X_n$, if $X_1\sim N(\mu_1,\ \delta_1^2)$, $X_2\sim N(\mu_2,\ \delta_2^2),...,\ X_k\sim N(\mu_k,\ \delta_k^2),...,\ X_n\sim N(\mu_n,\ \delta_n^2)$, there is $\sum_{k=1}^{n}X_k\sim N(\sum_{k=1}^{n}\mu_k,\sum_{k=1}^{n}\delta_k^2)$.

Theorem 2. When the random variable follows the normal distribution, then $CVaR(\Delta T) = E(\Delta T) + c_1(\beta) \times STD(\Delta T)$, where $E(\Delta T)$ refers to the expectation of random variable, $STD(\Delta T)$ refers to the standard deviation of random variable, $c_1(\beta) = \varphi(\phi^{-1}(\beta)) \times (1-\beta)^{-1}$, $\phi^{-1}(\square)$ refers to the inverse function of standard normal distribution function, and $\varphi(\square)$ refers to the probability density of standard normal distribution [26].

This article assumes the random variable $\tilde{T}_{ijk} \sim N(\mu_{ijk}, \delta_{ijk}^2)$ and $\tilde{T}_j \sim N(\mu_j, \delta_j^2)$ in (5), so the objective function (3) can be converted to (8). Consequently, the proposed CVaR model includes (8), (4), (5), (6) and (7).

$$\min\Big(\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k}^{r_{ij}}\mu_{ijk}x_{ijk}(R) + \sum_{j=1}^{n}\mu_j y_j - T_0\Big) + c_1(\beta) \times \sqrt{\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k}^{r_{ij}}\delta_{ijk}^2 x_{ijk}^2(R) + \sum_{j=1}^{n}\delta_j^2 y_j^2(R)} \tag{8}$$

IV. Algorithm Design

At present, the solution of the 4PLROP mainly includes the branch and bound, cut plane method, and other accurate solution algorithms that can only solve the optimization problem meeting specific conditions, as well as GA [27], particle swarm optimization algorithm [18] and ant colony algorithm [19], harmony search algorithm [13] and other simulation natural processes to form intelligent optimization algorithms. In solving 4PLROP, intelligent optimization algorithms can be roughly separated into two types, one approach is using repair strategies to repair illegal roads and obtain legitimate paths, which may result in the loss of good solution information during the repair process; another method is to utilize intelligent algorithms to construct simple graphs, followed by exact algorithms to discover the shortest path across the simple graph, which will waste a lot of storage space and computational time. Therefore, the Q-learning algorithm is used to solve the 4PL path problem in this article, directly resolving the proposed mathematical model on multiple graphs by setting state action pairs and reward values.

The Q-learning algorithm is proposed by Watkins [28] which involves the interaction between intelligent agents and the environment, constantly trying and learning, and ultimately obtaining one or more excellent behavior strategies. In a typical Q-learning algorithm, an intelligent agent decides to execute an action on the basis of the current state as well as past empirical knowledge. After executing the action, the agent transits to the following state according to a certain state transition strategy and obtains a return value. The Q-learning algorithm establishes a Q table based on the agent's state space and action space, which stores the corresponding Q values of all state action pairs. At the same time, the intelligent agent can be punished or rewarded by designing a reward function. When the action selected by the intelligent agent has an advantage in the environment, the state action pair can receive positive rewards from the environment, and the corresponding Q value of the state action pair will continue to increase. When the action selected by the intelligent agent is at a disadvantage in the environment, its state action pair will receive negative rewards from the environment, and its corresponding Q value will continue to decrease. The Q function is used to obtain the anticipated return value of a specific state action, which is updated in each training round and gradually approaches the optimal value. As shown in (9), the Q function is viewed as past-experienced knowledge that the agent has acquired, which is constantly updated and improved.

$$Q^*(s,a) \leftarrow Q(s,a) + \alpha\left[R(s,a,s') + \gamma \max Q(s',a') - Q(s,a)\right] \tag{9}$$

where $\gamma \in (0,1)$ is the discount factor, representing the degree of impact of the next state's Q value on the corresponding Q value of the current state, that is, the importance of immediate and future benefits. The larger the γ , the greater the weight given to prior experiences. The smaller the γ , the more emphasis is placed on immediate benefits R. When $\gamma = 0$,it means only focusing on current interests and not considering future interests. When $\gamma = 1$, it indicates a focus on past experience and future interests. Parameter α is the learning rate, which represents the learning speed of the agent throughout the entire learning process. Its range is $\alpha \in (0, 1)$, and it determines the degree that the new information obtained by the agent in the environment covers the old experience. The larger the α , the less effective it is to retain the previous training. The smaller the α , the more the effect of previous training will be retained.

A. Action State Settings

This article applies Q-learning algorithm to the 4PLROP, treating the selection of actions as a 3PL supplier selection problem, and treating node cities as different states. When the current node is s , the 3PL suppliers related to the node cities can be represented by action spaces $A = \{a_1, a_2, ..., a_k, ..., a_K\}, k = 1, 2, ..., K$, with every state action pair matching a Q value.

Taking 7 nodes as an example, as shown in Fig. 1, the initial node can be regarded as the initial state s . The nodes connecting the initial node are Transport Node 1 and Transport Node 2, respectively. There are three 3PL suppliers that can be selected from the initial node to Transport Node 1, with serial numbers 1, 2, and 3. Actions can be set to a_1, a_2, a_3 , respectively. There are four 3PL suppliers that can be selected from the initial node to Transport Node 2, with serial numbers 1, 2, 3, and 4, respectively, The action sequence numbers can be set to a_4, a_5, a_6, a_7 , and there are 7 corresponding actions that can be selected in the initial state. They are set to jump to the next state, namely transfer node 1, when the initial node selection action is a_1, a_2, a_3 , and also set to jump to the next state, namely transfer node 2, when the initial node selection action is a_4, a_5, a_6, a_7 . Other node action sets can be set by analogy. The selected the action and its corresponding next state for 7-node problem is shown in Table II.

TABLE II. 7-NODE PROBLEM ACTIONS AND CORRESPONDING NEXT STATES SETTINGS

Selected Action	The Corresponding Next State
$A=\{a_1,a_2,a_3\}$	Transit Node City 1
$A=\{a_4,a_5,\cdots,a_9\}$	Transit Node City 2
$A=\{a_{10},a_{11},a_{14},a_{15},a_{16}\}$	Transit Node City 3
$A=\{a_{12},a_{13},a_{21},a_{22},a_{23}\}$	Transit Node City 4
$A=\{a_{17},a_{18},a_{19},a_{20},a_{24},a_{25}\}$	Transit Node City 5
$A=\{a_{26},a_{27},\cdots,a_{33}\}$	Transit Node City t

B. Exploration Strategy

- When the intelligent agent interacts with the environment for learning, while selecting the known action with the maximum reward value, it is also necessary to ensure that more experience can be learned in the unknown environment, laying the foundation for obtaining more cumulative rewards. Therefore, it is necessary to set appropriate exploration strategies to achieve the optimal training effect. The exploration strategy adopted in this article is ε-greedy strategy.
- The mathematical description of the ε-greedy strategy is as follows:

$$\pi(a,s)=\begin{cases}\arg\max Q(s,a) & 1-\varepsilon \\ a_{random} & \varepsilon\end{cases} \tag{10}$$

- For (10), it can be understood as a certain probability ε. Randomly select the actions that can be selected in the current state, with 1-ε probability selects the action corresponding to the maximum Q value in the current action.

C. Construction of Reward Function

Due to the fact that the Q-learning algorithm is on the basis of the Markov Decision Process model, a more computationally efficient discrete reward and penalty function is adopted. Eq. (11) indicates that when there is a connection between two cities and it is not the endpoint, the reward is 1. When there is no connection between two cities, the reward is -1. When there is a connection between two cities and it is the endpoint, the reward is 100.

$$r(s,a)=\begin{cases}1 & \text{i. j has a connection point j is not a termination node} \\ -1 & \text{i. j is not connected} \\ 100 & \text{i. j is connected and j is the termination node}\end{cases} \tag{11}$$

Considering that the size of the reward is related to the mean and variance in the objective function, while also meeting certain cost constraints, the reward value function (12) can be constructed to ensure that the agent does not violate the constraints and obtains the optimal delivery path for the objective value. As shown in (13), ω_1 is related to the delivery cost related to the selected 3PL provider and transportation node, and the smaller the delivery cost, the larger the reward value obtained; ω_2, shown in (14), is related to the mean of the random time related to the selected 3PL provider and transit node. The smaller the mean of the random time, the greater the reward value obtained; as shown in (15), ω_3 is related to the variance of the random time related to the selected 3PL provider and transit node. While the variance of the random time is smaller, the reward value obtained is larger, where k_1 and k_2 are the weighting coefficients of the reward function.

$$r=\omega_1 r(s,a)+\omega_2 r(s,a)+\omega_3 r(s,a) \tag{12}$$

$$\omega_1=\frac{k_1}{C_{ijk}+C_j} \tag{13}$$

$$\omega_2=\frac{k_2}{\mu_{ijk}+\mu_j} \tag{14}$$

$$\omega_3=\frac{1-k_1-k_2}{\delta_{ijk}^2+\delta_j^2} \tag{15}$$

D. Model Training

The agent is trained by designing a Q table, in which each row represents all the states that the agent can choose, each column represents the actions that the agent can perform in the corresponding state, each state represents different city nodes in multiple graphs, and each action represents different 3PL suppliers in multiple graphs. Initially, set all states in the Q table to 0, and then calculate the reward values obtained by executing different actions (selecting different suppliers) based on the reward matrix established by the reward function. Use (9) to update the values of each element in the Q table. Treat each iteration as a training session for the agent. For each training session, the agent attempts to reach the destination node from the initial node, and after each action, updates the elements in the Q table.

E. Improved Q-learning Algorithm Process and Steps

When the improved Q-learning algorithm is used to solve 4PLROP, first initialize the elements in the matrix using a reward function based on existing data. Due to the existence of several various 3PL providers across two node cities, there is one state corresponding to multiple. Consequently, it is necessary to set the corresponding actions for each state, and then train and update the matrix Q through the setting of matrix R and related parameters. Finally, the optimal path planning can be obtained based on the Q table. The specific steps for solving the proposed model using the improved Q-learning algorithm are as follows:

Step 1: Preprocess the known factors of the problem.

Step 2: Import known information into Matlab.

Step 3: Initialize the parameters γ, α and Q table, set the initial and final states, and generate a reward matrix using (12) based on existing data.

Step 4: Initialize the state to the initial node.

Step 5: Utilize ε-greedy strategy selection action (the optional 3PL supplier corresponding to the state).

Step 6: Execute the action a (select a 3PL supplier from the current node), transfer to a new state s' (next node city), and update the Q table based on the reward matrix R and related parameter settings.

Step 7: Determine whether s' is in a terminated state. If not, proceed to step 5. Else, proceed to step 8.

Step 8: Determine whether the training frequency has been reached. If not, continue with step 4, otherwise continue with step 9.

Step 9: After training, output the Q table.

Step 10: Output the optimal delivery plan based on the Q table.

V. Experimental Results and Analysis

The improved Q-learning algorithm is used to solve different scale examples in this section to analyse the algorithm performance and the model effectiveness. The proposed CVaR model effectiveness is verified by comparing and analyzing the solution results of the two models. The algorithm is implemented using software MATLAB and runs in the Intel (R) Core (TM) i7-2600 @ 3.40GHz environment.

A. Parameter Testing Analysis

By conducting extensive experimental simulations to test parameters, the method is to observe the impact of certain parameters change on the solution results while keeping other parameters constant. The experimental results demonstrate that the optimal parameters are $\gamma = 0.8$, $\alpha = 0.9$, $episode = 100$, $\varepsilon = 0.95$.

On the basis of the data in Table III, through repeated experiments on the weighting coefficients k_1 and k_2 in reward functions of different scales, the improved Q-learning algorithm performs best.

B. Model Performance Analysis

Verify the effectiveness of the proposed CVaR model and improved Q-learning algorithm by solving several different scale examples. First, the 7-node problem is used as an instance, and the solution results obtained using this algorithm are carefully analyzed. Then, to demonstrate the validity of the model, VaR and CVaR values are solved for four examples of different sizes with 7, 15, 30 and 50 nodes, and the results are analyzed.

The solution results of the VaR model and CVaR model for the 7-node problem with different values are shown in TABLE IV, where β denotes the confidence level, i.e., the risk attitude of the customer, T_0 denotes the customer's latest acceptable delivery time, C_0 is the customer's latest acceptable delivery cost. The value of VaR is the optimal solution obtained from the VaR model, the value of CVaR is the optimal solution obtained from the CVaR model, the Best Path is the distribution path that corresponds to the optimal solution, and Best Rate is the probability that the total number of runs obtains the best solution when the algorithm is used to solve. At this time, the total number of runs is 100, Time/s indicates the time for the algorithm to run once.

TABLE III. Solutions and Parameter Settings for Different Instances

Number ofNodes	k_1	k_2	*Episode*	*CVaR*	Best Path	Time/s
7	0.6	0.3	100	32.0456	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	0.9s
15	0.1	0.7	200	3.8184	$R=\{\upsilon_s,1,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	1s
30	0.37	0.357	200	13.6412	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	1.5s
50	0.2	0.5	500	8.3652	$R=\{\upsilon_s,3,\upsilon_{39},1,\upsilon_{28},1,\upsilon_{29},1,$ $\upsilon_{10},1,\upsilon_{42},3,\upsilon_{37},3,\upsilon_t\}$	9.2s

TABLE IV. Solution Results of 7-node Problem when T_0=80 and C_0=73.

β	T_0	C_0	*VaR*	*CVaR*	Best Path	Best Rate	Time/s
0.9	80	73	10.9730	22.0456	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	1	0.9s
0.95	80	73	19.4699	29.2428	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	1	0.9s
0.99	80	73	35.4087	43.3341	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	1	0.9s

From the data in the Table IV, it can be seen that the best path corresponding to the best VaR value and CVaR value is the same. When the confidence level is 0.9 and the VaR value that meets the cost constraint is 10.9730, it means that the 4PL supplier has a 90% probability of ensuring that the delay amount will not exceed 10.9730. The CVaR value that satisfies the cost constraint is 22.0456, indicating that the tardiness risk mean value when the delivery task's delay exceeds the VaR is 22.0456, The related delivery cost is 73, and the best delivery path is $R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$, which refers to the selection of transit cities 2 and 3 for transportation from the source node city s to the destination node city t, and the numbers of the 3PL supplier chosen between every two cities are 2, 2, and 1. When the confidence level is 0.95 and the VaR value that satisfies the cost constraint is 19.4699, it means that the 4PL supplier has a 95% probability of ensuring that the delay amount will not exceed 19.4699. The CVaR value that satisfies the cost constraint is 29.2428, indicating that the tardiness risk mean value when the delivery task's delay exceeds the VaR is 29.2428. The associated delivery cost is 73, and the best

delivery path is $R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$, which refers to the selection of transit cities 2 and 3 for transportation from the source node city s to the destination node city t, and the 3PL supplier numbers selected between each two cities are 2, 2, and 1. When the confidence level is 0.99 and the VaR value that satisfies the time constraint is 35.4087, it means that the 4PL supplier has a 99% probability of ensuring that the delay amount will not exceed 35.4087. The CVaR value that satisfies the cost constraint is 43.3341, indicating that the tardiness risk mean value when the delivery task's delay exceeds VaR is 43.3341. The associated delivery cost is 73, and the best delivery path is $R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$, which refers to the selection of transit cities 2 and 3 for transportation from the source node city s to the destination node city t, and the 3PL supplier numbers selected between each two cities are 2, 2, and 1. The above data indicates that when other constraints are constant, as the confidence level grows, the best delivery path will not change. However, customers will face higher tardiness risks, and the corresponding VaR is often smaller than CVaR. This also verifies that the VaR model can only evaluate the probability of risk occurrence, while the CVaR model can effectively measure tail risk and estimate the tardiness risk mean value faced by delivery tasks in extreme situations. Compared to VaR models, it can better reflect potential tardiness risks.

The statistics in Table V show that the 7-node problem's solution is provided for various combinations of confidence level, delivery time, and delivery cost. We know from analyzing these data that while the confidence level and time constraints are consistent, as the delivery cost increases, the corresponding VaR and CVaR values will decrease, indicating that the delay risk faced by the delivery path will be reduced. When the delivery cost and time constraints remain unchanged and the confidence level increases, the corresponding VaR and CVaR values will increase, indicating an increase in the risk of tardiness faced by the delivery path. When the confidence level and delivery cost are constant, as the time constraint increases, the corresponding VaR and CVaR values will increase, and thus the delay risk faced by the distribution path will rise. In addition, by comparing the VaR value and the CVaR value, it can be seen that when other conditions are the same, the CVaR value obtained is always greater than the VaR value, which also verifies that CVaR is more able to reflect the potential value at risk than VaR. Therefore, when using the VaR model to measure tardiness risk failure, 4PL suppliers can use the CVaR model to make up for the shortcomings of the VaR model. Combined with the risk tolerance of customers, they can comprehensively consider the risk level and expected tardiness risk of the distribution scheme, monitoring of potential tardiness risks in real time, providing customers with the delivery path with the minimum tardiness risk mean value at a given confidence level, and estimating the tardiness risk generated when extreme events occur, making reasonable delivery service decisions, thereby improving customer satisfaction.

Tables VI to VIII provide the solution results of the VaR model and CVaR model for the 15 node problem with time constraints, cost constraints, 30 node problem with time constraints, and 50 node problem with time constraints and cost constraints, respectively. When using the Q-learning algorithm to solve the proposed model, the solution time for small and medium-sized examples is about 1 second, and for large-scale problems, the solution time does not exceed 10 seconds. This fully demonstrates that the Q-learning algorithm has a high solution speed and high stability. When solving a 15 node problem, the training number is 200, and the optimal solution rate of the algorithm is as high as 98%, that is, the algorithm runs 100 times, 98 times can obtain the optimal solution, and when solving the 50 node problem, the best rate also reaches 95%, that is, the algorithm runs 100 times, and 95 times can obtain the optimal solution.

C. The Influence of Confidence Level

To investigate the influence of confidence level β on the 4PLROP, we provide three values of β with four different cases, which is customer's degree of risk appetite, shown in Tables V to VIII.

TABLE V. SOLUTION FOR 7-NODE PROBLEMS UNDER DIFFERENT CONFIDENCE LEVELS, TIME CONSTRAINTS, AND COST CONSTRAINTS

β	T_0	C_0	*Episode*	*VaR*	*CVaR*	Best Path	Time/s
0.9	70	73	100	20.9730	32.0456	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	0.9s
		75	100	17.2239	28.0198	$R=\{\upsilon_s,3,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	0.9s

		75	100	31.0489	38.7762	$R=\{\upsilon_s,3,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	0.9s

TABLE VI. SOLUTION FOR THE 15-NODE PROBLEM WHEN T_0=70, C_0=115

β	*Eposide*	*VaR*	*CVaR*	Best Path	Best Rate	Time/s
0.9	200	0.5969	3.7728	$R=\{\upsilon_s,1,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	0.98	1s
0.95	200	3.0340	5.8371	$R=\{\upsilon_s,1,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	0.98	1s
0.99	200	7.3406	9.4295	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	0.98	1s

TABLE VII. SOLUTION FOR THE 30-NODE PROBLEM WHEN T_0=115, C_0=190

β	*Eposide*	*VaR*	*CVaR*	Best Path	Best Rate	Time/s
0.9	200	10.5009	13.6412	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	0.97	1.5s
0.95	200	12.9107	15.6825	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	0.97	1.5s
0.99	200	17.4312	19.679	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	0.97	1.5s

TABLE VIII. SOLUTION FOR THE 50-NODE PROBLEM WHEN T_0=150, C_0=165

β	*Eposide*	*VaR*	*CVaR*	Best Path	Best Rate	Time/s
0.9	500	4.4900	8.3652	$R=\{\upsilon_s,3,\upsilon_{39},1,\upsilon_{28},1,\upsilon_{29},1,$ $\upsilon_{10},1,v_{42},3,\upsilon_{37},3,\upsilon_t\}$	0.95	1.5s
0.95	500	7.4637	10.4637	$R=\{\upsilon_s,3,\upsilon_{39},1,\upsilon_{28},1,\upsilon_{29},1,$ $\upsilon_{10},1,\upsilon_{42},3,\upsilon_{37},3,\upsilon_t\}$	0.95	1.5s
0.99	500	13.042	15.8157	$R=\{\upsilon_s,3,\upsilon_{39},1,\upsilon_{28},1,\upsilon_{29},1,$ $\upsilon_{10},1,\upsilon_{42},3,\upsilon_{37},3,\upsilon_t\}$	0.95	1.5s

The result in these four tables shows that the CVaR, the tardiness risk, increases with the confidence level β increasing. Because with a smaller β, the 3PL can make more effort and the tardiness risk is smaller. 4PL can select the proper delivery solution for the investor to control the tardiness risk according to the customer's degree of risk aversion.

D. The Influence of Cost and Due Date

To investigate the influence of cost C_0 and due date T_0 on the 4PLROP, we provide two values of C_0 and T_0 with 7-node problem, shown in Table V.

The result in Table V shows that the CVaR, the tardiness risk, decreases with the C_0 and T_0 increasing when β in fixed. Because with a fixed β, if the budget or time is enough, the 3PL can make more effort and the tardiness risk is smaller. 4PL can select the proper delivery solution for the investor to control the tardiness risk according to the customer's budget and due date.

E. Algorithm Comparison

This section uses the improved Q-learning and GA embedded with Dijkstra algorithm to solve three different scale examples, and the comparative data is shown in Table IX.

TABLE IX. COMPARISON OF RESULTS OF DIFFERENT ALGORITHMS

Number of Nodes	Algorithm	*CVaR*	Best Path	Best Rate	Time/s
7	Improved Q-learning	22.0456	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	1	0.9s
	GA embedded with Dijkstra	22.0456	$R=\{\upsilon_s,2,\upsilon_2,2,\upsilon_3,1,\upsilon_t\}$	0.95	19.4s
15	Improved Q-learning	3.7728	$R=\{\upsilon_s,1,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	0.98	1s
	GA embedded with Dijkstra	3.7728	$R=\{\upsilon_s,1,\upsilon_2,2,\upsilon_6,3,\upsilon_{13},2,\upsilon_t\}$	0.94	24.5s
30	Improved Q-learning	13.641	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	0.95	1.5s
	GA embedded with Dijkstra	13.641	$R=\{\upsilon_s,1,\upsilon_4,2,\upsilon_8,1,\upsilon_{12},1,$ $\upsilon_{15},2,\upsilon_{18},4,\upsilon_{21},1,\upsilon_{25},1,\upsilon_t\}$	0.9	28.5s

It can be seen from the Table IX that both methods can find the optimal solution when solving small-scale problems with 7 nodes. However, the latter performs poorly in solving speed because that GA embedded with Dijkstra algorithm is used to generate the simple graph based on the multi-graph shown in Fig. 1 and the Dijkstra algorithm is used to generate the shortest path on the generated simple graph, but the shortest path may be not met the constraints. Thus, it needs a lot of time to find the feasible solution of the problem. However, the improved Q-learning algorithm directly solves the problem on

the multi-graph shown in Fig. 1, which saves much computational time. Furthermore, as the solution size increases, the improved Q-learning algorithm exhibits higher solving speed and quality.

F. Discussion

In summary, the results show that when the delivery costs and time constraints remain unchanged, the higher the confidence level, the higher the corresponding values of VaR and CVaR, which means that the risk of delivery tardiness faced by customers will increase. When other conditions such as confidence level, time, and cost constraints are the same, the obtained CVaR value is always greater than the VaR value. The proposed CVaR model can reflect the average delay risk of delayed delivery exceeding the VaR value due to various factors, better compensating for the shortcomings of the VaR model in measuring tardiness risk, and real-time monitoring of potential tardiness risks that may occur during the delivery process. 4PL can adjust the customer's aversion to risk, use this model to calculate the tardiness risk mean value and provide a reliable delivery plan.

VI. Conclusion

This article fully considers the tardiness risk caused by the uncertainty of transit time and transportation time in the actual delivery process in complex and uncertain environments. A risk measurement tool CVaR is introduced to measure and control the risk, and a mathematical model with CVaR minimization as the optimization objective and distribution cost as the constraint is established. Meanwhile, the proposed algorithm is compared with GA embedded with Dijkstra. The results demonstrate that the proposed model is effective for the 4PLROP and improved Q-learning algorithm can solve the large-scale 4PL path problem rapidly and with excellent stability. 4PL can adjust the customer's aversion to risk, use this model to calculate the tardiness risk mean value and provide a reliable delivery plan. Customers can obtain multiple schemes according to their risk preferences and take corresponding measures. This article provides scientific decision making basis and efficient and safe distribution plans for the 4PL, which can improve the level of logistics service.

Meanwhile, the stochastic variables' probability distributions may follow other distributions, such as the exponential distribution, uniform distribution, etc. Therefore, our research can be extended to a robust 4PLROP considering delay risk or multiple risks.

Optimized Dynamic Graph-Based Framework for Skin Lesion Classification in Dermoscopic Images

J. Deepa, P. Madhavan
Department of Computing Technologies, SRM Institute of Science and Technology, Kattankulathur, Chennai, India

***Abstract*—Early and accurate classification of skin lesions is critical for effective skin cancer diagnosis and treatment. However, the visual similarity of lesions in their early stages often leads to misdiagnoses and delayed interventions. This lack of transparency makes it challenging for dermatologists to interpret with validate decisions made by such methods, reducing their trust in the system. To overcome these complications, Skin Lesions Classification in Dermoscopic Images using Optimized Dynamic Graph Convolutional Recurrent Imputation Network (SLCDI-DGCRIN-RBBMOA) is proposed. The input image is pre-processed utilizing Confidence Partitioning Sampling Filtering (CPSF) to remove noise, resize, and enhance image quality. By using the Hybrid Dual Attention-guided Efficient Transformer and UNet 3+ (HDAETUNet3+) it segment ROI region of the preprocessed dermoscopic images. Finally, segmented images are fed to Dynamic Graph Convolutional Recurrent Imputation Network (DGCRIN) for classifying skin lesion as actinic keratosis, dermatofibroma, basal cell carcinoma, squamous cell carcinoma, benign keratosis, vascular lesion, melanocytic nevus, and melanoma. Generally, DGCRIN does not express any adaption of optimization strategies for determining optimal parameters to exact skin lesion classification. Hence, Red Billed Blue Magpie Optimization Algorithm (RBBMOA) is proposed to enhance DGCRIN that can exactly classify type of skin lesion. The proposed SLCDI-DGCRIN-RBBMOA technique attains 26.36%, 20.69% and 30.29% higher accuracy, 19.12%, 28.32%, and 27.84% higher precision, 12.04%, 13.45% and 22.80% higher recall and 20.47%, 16.34%, and 20.50% higher specificity compared with existing methods such as a deep learning method dependent on explainable artificial intelligence for skin lesion classification (DNN-EAI-SLC), multiclass skin lesion classification utilizing deep learning networks optimal information fusion (MSLC-CNN-OIF), and classification of skin cancer from dermoscopic images utilizing deep neural network architectures (CSC-DI-DCNN) respectively.**

***Keywords*—Confidence partitioning sampling filtering; dynamic graph convolutional recurrent imputation network; ISIC-2019 skin disease dataset; red billed blue magpie optimization algorithm; hybrid dual attention-guided efficient transformer and UNet 3+**

I. INTRODUCTION

Skin cancer is considered one of the most dangerous cancer types due to its high prevalence and potential for metastasis if not detected early. Melanoma, in particular, has a high mortality rate and can spread rapidly to other organs [1]. Statistics show that skin cancer is more common than other cancers, with rising incidence rates globally. Comparative studies also indicate that, although treatable when caught early, skin cancer has a higher likelihood of fatal outcomes compared to many other cancer types [2]. A skin lesion refers to abnormal appearance otherwise growth of skin analyzed to surrounding region [3]. Lesions can vary in color, type, shape, texture, position, distribution, they are categorized to classification prearranged hierarchically [4]. The first two major classifications of this hierarchy are melanocytic, non-melanocytic lesions [5]. The classification as melanocytic or non-melanocytic depends on presence or absence of melanocytes, melanin pigment in lesion [6]. Melanocytic lesions possess eight global features that assist in detailed categorization of pigmented skin lesions, along with fourteen local features provide more specific information about each lesion [7]. Hemoglobin causes non-melanocytic lesions to seem purple, red, blue, or black, while keratin causes them to appear orange or yellow [8]. These lesions can be either cancerous otherwise non-cancerous. Dermoscopic is commonly utilized skin imaging methods, aimed at enhancing diagnostic accuracy, reducing mortality from skin cancer [9]. This non-invasive method captures magnified with well-illuminated image of skin, allowing for a clearer examination of lesion area [10]. This method improves doctors' diagnostic ability and is typically used to detect skin cancer in its premature stages [11]. Dermatologists typically utilize visual examination to evaluate dermoscopic images, known as biomedical images [12]. It takes a lot of time, is labor-intensive, and is subject to operator bias. The reason for this is normal moles and skin infections can sometimes be so similar that a precise diagnosis might be challenging [13]. Several computer-aided diagnostic systems created to aid dermatologists identify skin cancer [14]. These methods not only get over the aforementioned problems but also increase the diagnosis system's impartiality, accuracy, and efficiency [15]. Deep learning approaches have established encouraging results, important promise in this area for data analysis and image processing [16]. Owing to its widespread use, distinctive characteristics in several complicated fields, likes object detection, classification, identification, and recognition, deep learning applied extensively [17]. The deep learning method gives method greater depth; changes input utilizing different functions enable hierarchical data representation across multiple levels of abstraction [18]. Because more sophisticated models are used, deep learning can quickly and effectively learn more difficult issues. The significant component of typical computer aided diagnostic systems is deep learning approaches like CNN and image processing techniques [19]. However, as processing cycle behind method learning with feature encoding is poorly implicit, utility of such computer-aided diagnostic systems by dermatologists, patients is still

questionable. Without a logical justification, the model prevents dermatologists from making informed decisions [20].

The problem involves in several existing methods, skin cancer at premature stage owing to challenges in analyzing dermoscopic images of skin lesions, which are often subtle and require a high level of expertise. Traditional visual inspection by dermatologists is time-consuming, subjective, and prone to error, making it hard to achieve consistent and reliable results. There is a need for automated systems that can assist in the accurate, efficient, and objective classification of skin lesions to enhance diagnostic accuracy, ultimately lessen skin cancer mortality.

This paper intends to overcome these issues to improve skin lesion detection methods, it is crucial to address the significant challenges that skin lesion. Enhancing the accuracy of identifying and classifying skin lesion detection is vital for facilitating timely and effective responses to these incidents. The suggested method attempts to improve detection accuracy and reliability by exploiting optimization using Red Billed Blue Magpie Optimization Algorithm.

The novelty of SLCDI-DGCRIN-RBBMOA method lies in its use of Skin Lesions Classification of Dermoscopic Images using Optimized Dynamic Graph Convolutional Recurrent Imputation Network. CPSF is used for preprocessing dermoscopic images, effectively removing noise and resizing them to improve image quality. The ROI region is segmented utilizing HDAETUNet3+, which improves the accuracy of lesion detection. The main innovation of the approach lies in the use of the DGCRIN for classifying a diverse range of skin lesions. The RBBMOA strategy significantly enhances accuracy, precision, recall, specificity, F1-score while also reducing error rate compared to existing methods, making it more suitable for classification on Skin Lesions in the future.

Major contribution of this investigate work is brief as below,

- To propose SLCDI-DGCRIN-RBBMOA framework, which employs an Optimized Dynamic Graph Convolutional Recurrent Imputation Network to enhance the Skin Lesions Classification of Dermoscopic Images process.
- Here, CPSF improves data integrity by efficiently for remove noise, resize and improve image quality within the dataset.
- To segment the ROI region using the Hybrid Dual Attention-guided Efficient Transformer and UNet 3+ (HDAETUNet3+) process and to classify Skin Lesion using DGCRIN, thereby improving classification accuracy.
- RBBMOA introduces an optimization approach to improve the weight parameters of the DGCRIN classifier.
- Performance comparison to analyze the efficiency of the SLCDI-DGCRIN-RBBMOA approach in comparison to well-known DGCRIN in context of Skin Lesion.

The proposed model addresses the limitations of previous approaches by enhancing transparency, accuracy, and optimization in skin lesion classification. To build trust in AI-based decisions, it incorporates Hybrid Dual Attention-guided Efficient Transformer and UNet 3+ (HDAETUNet3+), enabling precise segmentation and improved interpretability. Confidence Partitioning Sampling Filtering (CPSF) enhances image quality by eliminating noise, facilitating more accurate early-stage lesion classification and reducing diagnostic errors. The model leverages Transformer-based feature extraction and multi-scale segmentation to refine region of interest (ROI) identification, outperforming conventional deep learning methods. Furthermore, the Dynamic Graph Convolutional Recurrent Imputation Network (DGCRIN) captures spatial relationships within dermoscopic images, offering a structured and adaptive classification approach. Unlike previous graph-based models that lack effective parameter tuning, the Red Billed Blue Magpie Optimization Algorithm (RBBMOA) optimizes DGCRIN, significantly improving classification performance.

Remaining part of the paper is arranged as follows: Literature review is presented in Section II, Methodology employed is discussed in Section III, and result with discussion is described in Section IV and conclusion in Section V.

II. Literature Review

A. Related Work

Several investigate works are presented in literatures based on the Skin Lesion Classification utilizing Deep Learning. Table I presents various advantages and disadvantages of the existing Skin Lesion Segmentation and Classification model. In 2022, Nigar, N., et al., [21] have presented a Deep Learning approach based on Explainable Artificial Intelligence for skin lesion classification. A skin lesion classification system based on Explainable Artificial Intelligence is suggested to enhance the accuracy of skin lesion detection, aiding dermatologists in making more informed and rational diagnoses, particularly in the early stages of skin cancer. The system accurately identifies eight types of skin lesions: dermatofibroma, squamous cell carcinoma, benign keratosis, melanocytic nevus, vascular lesion, actinic keratosis, basal cell carcinoma, and melanoma. It attains high accuracy and low precision.

In 2024, Khan, M.A., et al., [22] have presented multiclass skin lesion classification utilizing deep learning networks optimal information fusion. A computerized method for multiclass skin lesion classification, leveraging a fusion of optimal deep learning model features is developed. The collection of data used in is unbalanced, thus mathematical operations are performed to address this problem through data augmentation. The augmented dataset is used to refine and train two pre-trained deep learning models, DarkNet-19 and MobileNet-V2. After training, features extracted from the average pooling layer are optimized using a hybrid firefly optimization technique. The selected features are then fused using both the threshold-based and serial approaches, and classified using machine learning classifiers. It attains higher recall and low specificity.

In 2023, SM, J., et al., [23] have presented classification of skin cancer from dermoscopic images using deep neural network architectures. A deep convolutional neural network (DCNN) model is developed to accurately classify melanoma and non-melanoma skin cancer. The datasets, sourced from various challenges, have issues like class imbalance and varying image resolutions. To address these, EfficientNet with transfer learning is used to capture more complex patterns by adjusting the network's depth, width, and resolution. The dataset is augmented, and metadata is incorporated to improve classification performance. Additionally, the EfficientNet model is optimized with the Ranger optimizer, reducing the need for extensive hyperparameter tuning. It provides high F1-score and high computational time in 2023, Alsahafi, Y.S., et al., [24] have presented Skin-Net, a novel deep residual network for skin lesions classification. It utilizes multilevel feature extraction and cross-channel correlation, along with outlier detection. In this suggested paper, the Residual Deep Convolutional Neural Network is designed with multiple convolutional filters for multi-layer feature extraction and cross-channel correlation, using sliding dot product filters instead of sliding filters along the horizontal axis. To address the problem of imbalanced datasets, the method transforms the dataset from image-label pairs to image-weight vectors. It has been tested and assessed on complex and demanding datasets and demonstrates superior performance compared to existing deep convolutional networks in multiclass skin lesion classification. It attains higher detection accuracy and low kappa coefficient.

TABLE I. STRENGTHS AND LIMITATIONS OF THE CURRENT MODELS FOR CLASSIFYING SKIN LESIONS

Authors Name	Methods	Advantage	Limitation
Nigar, N., et.al, [21]	Convolutional neural network, deep neural network	It achieves higher accuracy	It provides low precision
Khan, M.A., et.al, [22]	CNN, DarkNet-19, MobileNet-V2	It attains higher recall	It attains low specificity
SM, J., et.al, [23]	Deep neural network, DCNN, EfficientNet, DenseNet	It provides higher F1-score	It provides high computational time
Alsahafi, Y.S., et.al, [24]	Residual Deep CNN, DNN, Probabilistic neural network	It provides high detection accuracy	It provides low kappa coefficient
Raghavendra, P.V., et.al, [25]	Deep convolutional neural network, ResNet50, VGG-16, MobileNetV2, and DenseNet121	It attains higher RoC	It attain slow precision
Rezaee, K. et.al, [26]	Convolutional neural network, ResNet-50, and ResNet-101	It provides high specificity	It provides high loss function
Thanka, M.R., et.al, [27]	Generative adversarial network, VGG16 and XGBoost	It attains low error rate	It attains high sensitivity

In 2023, Raghavendra, P.V., et al., [25] have presented Deep Learning Based Skin Lesion Multi-class Classification with Global Average Pooling Improvement. The model is trained and tested on the dataset, which includes seven distinct classes of skin lesions. During the preprocessing stage, the black hat filtering technique is applied to remove artifacts, along with resampling techniques to address class imbalance. The performance of the proposed model is evaluated by comparing it with several transfer learning models, including ResNet50, VGG-16, MobileNetV2, and DenseNet121. It attains high RoC and low precision.

In 2024, Rezaee, K. et al., [26] have presented self-attention transformer based deep learning framework for skin lesions classification in smart healthcare. This approach fuses global and local features through cross-fusion to generate fine-grained features. The branches of the parallel systems are merged using feature-fusion architecture, creating a pattern that identifies the characteristics of various skin lesions. Additionally, the paper introduces an optimized and lightweight version of the CNN architecture, optResNet-18, designed to effectively discriminate between skin cancer lesions. It attains higher specificity and high loss function.

In 2023, Thanka, M.R., et al., [27] have presented hybrid technique for melanoma classification utilizing ensemble ML methods and deep transfer learning. A hybrid approach combining a pre-trained convolutional neural network and machine learning classifiers is employed for feature extraction and classification, enhancing the model's accuracy. VGG16 is used for feature extraction, while XGBoost serves as the classifier. This combination leverages the strengths of deep learning for feature extraction and the power of machine learning for efficient classification, leading to improved performance in skin lesion classification. It provides low error rate and low sensitivity.

B. Research Gap

Current skin lesion classification models suffer from a lack of transparency, reducing trust in AI-driven diagnoses. Early-stage lesion detection is challenging due to visual similarities. Existing methods struggle with accurate segmentation and feature extraction, while graph-based networks lack optimization. The proposed SLCDI-DGCRIN-RBBMOA improves classification through enhanced segmentation and advanced optimization strategies.

III. PROPOSED METHODOLOGY

The SLCDI-DGCRIN-RBBMOA methodology, which aims to classification of skin lesion, begins by input dermoscopic images are collected from ISIC-2019 skin disease dataset. The proposed block diagram of SLCDI-DGCRIN-RBBMOA is represented in Fig. 1. Input images are pre-processed with filtering to remove noise, improve image quality, followed by segmentation process, and are then fed into a classification process. The Dynamic Graph Convolutional Recurrent Imputation Network is then used to categorize the skin lesion as actinic keratosis, Dermatofibroma, Basal cell carcinoma, Squamous cell carcinoma, Melanocytic nevus, benign keratosis, Melanoma, vascular lesion. To improve classification accuracy, Red-Billed Blue Magpie Optimization Algorithm is utilized to enhance DGCRIN parameters. The overall system aims to detect, mitigate skin lesion, ensuring the integrity and reliability of image.

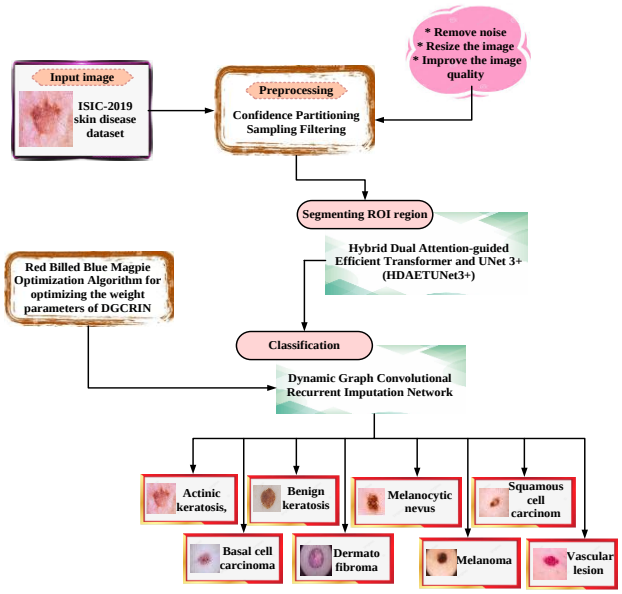

Fig. 1. Block diagram of SLCDI-DGCRIN-RBBMOA method.

A. Image Acquisition

The input data are gathered from ISIC-2019 Skin Disease Dataset [28]. This dataset comprises of 25,331 dermoscopic images, classified into eight types such as actinic keratosis, dermatofibroma, melanoma, benign keratosis, vascular lesion, basal cell carcinoma, melanocytic nevus, squamous cell carcinoma. The generated dataset is randomly splitted as 80% training, 10% testing, and 10% validation.

B. Pre-processing utilizing Confidence Partitioning Sampling Filtering

The image pre-processing utilizing CPSF [29] to eliminate noise, resize the image, and enhance image quality. CPSF methods were selected as a pre-processing technique for skin lesion analysis because they enhance image contrast, remove noise, and resize image, thereby improving the accuracy and clarity of lesion boundaries. This technique effectively reduces noise while preserving important features, enhancing the overall quality of segmentation. As a result, CPSF leads to more robust segmentation and better performance in subsequent analysis, providing more reliable results in dermoscopic images by reducing artifacts and noise. CPSF improves overall quality of images, enabling subsequent models, such as segmentation networks, to focus more effectively on relevant features and generate more accurate predictions. It also facilitates image resizing without sacrificing important details, which is particularly useful when working with datasets that require standardized input dimensions. Additionally, CPSF is a versatile tool that applied to different image types beyond dermoscopic images, making it valuable for medical image preprocessing as well as other computer vision applications. Then, the CPSF is given in Eq. (1),

$$w.k \int_{B_{q(y)}}^{\alpha} q(y)dx = 1 - \alpha \tag{1}$$

where, $q(y)$ represents the dimensional space, w denotes the hyper parameter, k represents the input data values, represents the filtering process, dx denotes the steady-state phase. Then, it is calculated as given in Eq. (2),

$$\omega_h = \frac{q(\hat{Y}_h)}{\sum_{h=1}^{H} q(\hat{Y}_h)} \tag{2}$$

Here, $q(\hat{Y}_h)$ represents the partitioning filtering of a distribution, ω_h denotes the bounded subspace, and H represents the sampling interval. It evaluates the correlations between features to predict quality images using variables that are strongly related.

Let qc represents the impulse function, y_t denotes the noise model, $\vec{y}_{t,c}$ represents the weighted grid samples, then image resize c is calculated using Eq. (3),

$$q(y_t | \hat{y}_{t-1,c}) = qc(y_t - \vec{y}_{t,c}) \tag{3}$$

It helps maintain the variation and structure of the original image, ensuring that the imputed values do not alter overall trends. In this step the denoise images are calculated as in Eq. (4),

$$\bar{y}_t = (\omega_t)^K \hat{y}_t \tag{4}$$

In the above equation, $\bar{y}_t$ represents the probability region, ω_t denotes the CPSF framework, $\hat{y}_t$ represents the denoise image. Then, the improved image quality is predicted as given in Eq. (5).

$$\vec{Y}_t = \left[\vec{y}_{t,1}, \vec{y}_{t,2}, ..., \vec{y}_{t,C_{t-1}}\right]^K \tag{5}$$

Here C_{t-1} represents the estimation of the prior CPSF, $\vec{y}_{t,1}$ represents the improved image quality, $\vec{y}_{t,2}$ denotes the local inference, $\vec{Y}_t$ denotes improved image quality. Here, by using CPSF method it remove noise, resize and improve image quality. After that, the pre-processed images undergoes segmentation phase.

C. Segmentation Using Hybrid Dual Attention-Guided Efficient Transformer and UNet 3+

Segmentation using HDAETUNet3+ [30, 31] method is to segment ROI region from dermoscopic images. The DAET and U-Net3+ is selected for its synergistic benefits in image segmentation. Dual attention mechanisms in DAET are highly effective at capturing long-range dependencies and fine-grained details, which are essential for precise segmentation. Meanwhile, Hierarchical structure and skip connections of U-Net3+ efficiently propagate contextual information across different scales, enhancing localization and boundary delineation. It enhances methods ability to exactly segment skin lesions, even with complex boundaries, by capturing both local and global features. This improves lesion classification and results in a more computationally efficient and robust method for skin lesion recognition in dermoscopic images.

Dual Attention-guided Efficient Transformer, which integrates spatial and channel attention, enables method to emphasis on the most applicable image regions and key features, resulting in accurate, robust segmentation of skin lesions. The architecture efficiently scales to learn large image sizes or long sequences, which is essential for tasks such as high-resolution medical image segmentation. By leveraging the attention mechanism, the model can adapt to a wide range of input data, including varying image sizes and resolutions, making it versatile for deployment across different applications. Additionally, the attention mechanism provides greater transparency into methods decision-making process, which is particularly valuable in high-stakes domains like medical imaging. Attention maps highlight areas the model prioritizes, offering insights into its focus during predictions and improving interpretability. It is given in Eq. (6).

$$R(P,K,U) = soft\max\left(\frac{PK^{S}}{\sqrt{c_k}}\right)U \tag{6}$$

Here, the term c is the embedding dimension, U is the value vector of the image. Conventional self-attention may produce redundant context matrix, effectual way to calculate self-attention mechanism is provided in Eq. (7).

$$F(P,K,U) = \rho_p(P)\left(\rho_k(K)^{S}U\right) \tag{7}$$

Here, ρ_p and ρ_k denotes normalization functions for queries, keys. These are softmax normalization functions. Hence, efficient attention first normalizes the keys and queries and then multiplies keys with values. The transpose attention is shown in Eq. (8).

$$MLP(Y) = FC\left(GELU\left(DW-Conv\left(FC(Y)\right)\right)\right) \tag{8}$$

In Eq. (8), MLP represents the activation function, FC is the fully connected layer, DW is the depth wise convolution. UNet 3+ improves lesion segmentation by leveraging nested skip pathways to capture features at multiple scales, which enhances its ability to identify lesions of different sizes and shapes. It ensures that intermediate layers actively contribute to the learning process, accelerating convergence and reducing the risk of overfitting, particularly when working with limited medical image data. Its capacity to extract fine-grained details while preserving global context makes the model more robust to noise, artifacts commonly found in dermoscopic images, lead to more reliable segmentation in real-world clinical scenarios. It is given in Eq. (9),

$$A_{j,i} = \frac{\exp(N_j \cdot M_i)}{\sum_{j=1}^{m}\exp(N_j \cdot M_i)} \tag{9}$$

where, $A_{j,i}$ is measures impact of i^{th} location on j^{th} location, m is the number of pixel values. The architecture diagram of HDAETUNet3+ is represented in Fig. 2.

The HDAETUNet3+ architecture is designed for dermoscopic image segmentation, focusing on accurately segmenting regions of interest in dermoscopic images. It features a dual-transformer block structure, with skip connections and self-supervised contrastive learning to improve feature representation. The encoder extracts features progressively through patch merging and dual-transformer blocks, while the decoder upsamples and refines the segmentation mask. The network also incorporates full-scale intra- and inter-skip connections and ground truth supervision to guide the learning process. This sophisticated design aims to provide precise and reliable segmentation of ROIs in dermoscopic images, supporting the diagnosis of skin conditions. Then the each position of the image is given in Eq. (10).

$$GSA(N,M,W)_q = \sum_{p=1}^{h\times w}\left(W_p B_{q,p}\right) \tag{10}$$

Here $GSA(N,M,W)_q$ are features to generate the output image Finally, HDAETUNet3+ is used to segment the ROI region. Segmentation output is given into classification phase.

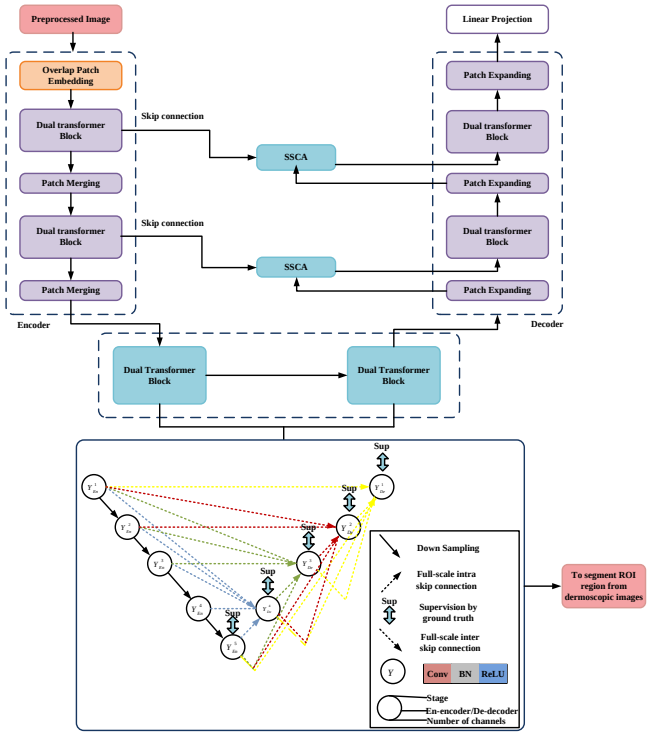

Fig. 2. Architecture of HDAETUNet3+.

D. Classification utilizing Dynamic Graph Convolutional Recurrent Imputation Network

The classification using DGCRIN is categorizing skin lesion such as actinic keratosis, Dermatofibroma, Basal cell carcinoma, benign keratosis, vascular lesion, Squamous cell carcinoma Melanocytic nevus, Melanoma [32]. The architecture diagram of DGCRIN is represented in Fig. 3. The DGCRIN captures the evolving relationships between image points over time, enabling it to adapt to changes in the image structure. The recurrent component adds temporal context, helping the model learn sequential patterns and enhance prediction accuracy, particularly when dealing with incomplete image. By incorporating imputation techniques, the model can effectively manage missing, leading to more robust and

accurate classification results. DGCRIN utilizes Graph Convolutional Networks to capture spatial dependencies within graph-structured image, making it particularly effective for datasets where the relationships between nodes are crucial for understanding missing data patterns. By incorporating both spatial and temporal information, DGCRIN can learn richer, more comprehensive representations of the image. Its ability to adapt to both spatial and temporal complexities enables it to handle intricate image patterns, making it especially well-suited for imputation tasks where the connections between missing values are complex and non-linear. The architecture diagram illustrates the DGCRIN model, where the input to the process is a set of segmented images. The model consists of three main components: a masked GRU, a DGCGRU, and a graph generator. The graph generator dynamically creates a graph at every time step to denote the geographical correlations of the road network, using both historical data and the current imputed data. The DGCGRU effectively captures the spatiotemporal relationships in the data by integrating the dynamic graph with a static graph and replacing the fully connected layers in a conventional GRU with a dynamic graph convolution operation. Additionally, a masked GRU is employed to independently analyze the masking matrix and identify patterns in the missing data. The information is then combined by a fusion layer using a temporal decay mechanism, and data inference is performed by a fully connected layer. This iterative process helps the model achieve high accuracy in classifying skin lesions. Thus, network layers are part of the recurrent imputation network model calculated as given in Eq. (11),

$$G_{E,t} = \tanh\left(V_E\left(G_{A,t}\Theta\tilde{G}_{m,t}\right) + y_E\right) \tag{11}$$

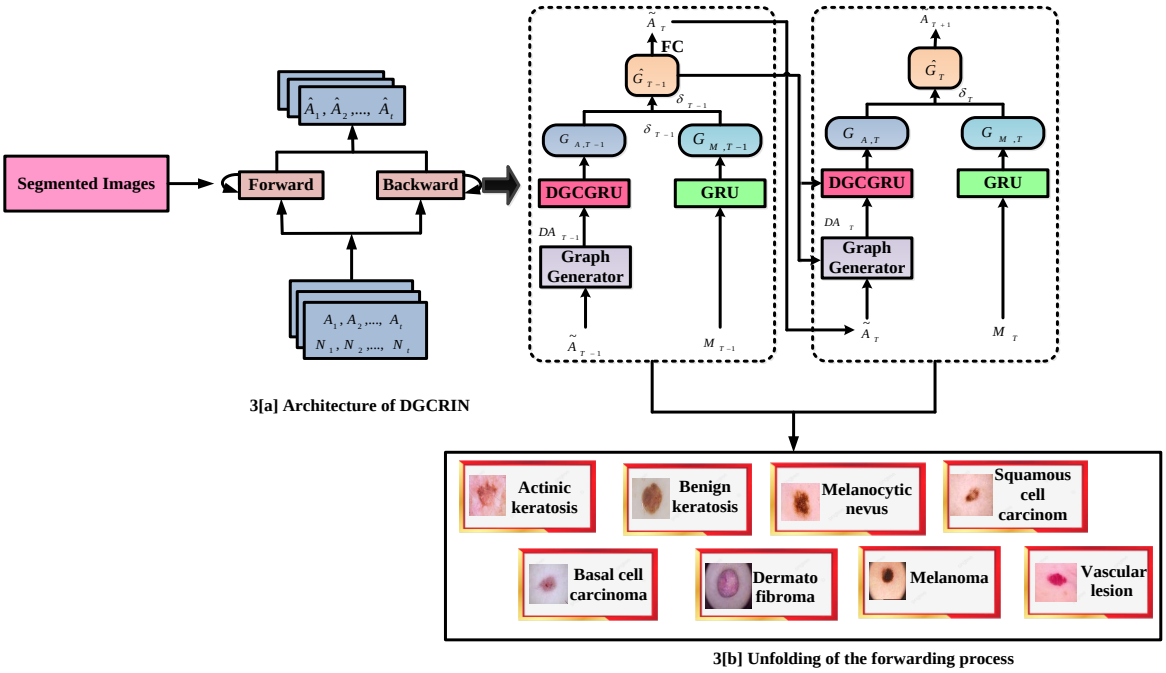

Fig. 3. (a) Architecture diagram of DGCRIN and (b) Unfolding of the forward process.

where, indicates the observation of each features, represents the significance of observation, indicates the hidden state, indicates the exponential function, indicates the sigmoid multiplication, indicates the constantly updated value, and represents the squared random initialization value. To classify the actinic keratosis, Basal cell carcinoma can be expressed as given in Eq. (12).

$$\lambda_t = \frac{1}{f^{\max}\left(0, V_\lambda \delta_t + y_\lambda\right)} \tag{12}$$

Here λ_t represents the efficient reconstruction value, δ_t represents the learnable variable, V_λ represents the forward along backward feature matrices, y_λ represents the activation functions and $f^{\max}$ depicts at each time step. To classify the benign keratosis, dermatofibroma, and melanocytic nevusis, the calculation is performed as given in Eq. (13).

$$A_{T+1} = V_A \hat{G}_t + y_A \tag{13}$$

In Eq. (13), the term B_{T+1} represent the estimated value, V_A denotes the scoring vector, $\hat{G}_t$ is the dynamic adjacency matrix is regularized by the activation function and y_A indicates the learnable parameter. To classify the Melanoma, Squamous cell carcinoma, vascular lesion is calculated as given in Eq. (14),

$$A_{T+1} = A_{T+1}\Theta N_{T+1} + \tilde{A}_{T+1}\Theta\left(1 - N_{T+1}\right) \tag{14}$$

where, A_{T+1} represents the prediction value, $\tilde{A}_{T+1}$ represents the image consumption, Θ indicates the sigmoid multiplication operator, and N_{T+1} denotes the SCC. Finally, the DGCRIN classified the skin lesion likes SCC, AK, BCC, Dermatofibroma, Melanoma, vascular lesion, Melanocytic nevus, benign keratosis. The RBBMOA is utilized to optimize

DGCRIN optimal parameter y_a and δ_t. The RBBMOA is used for tuning DGCRIN weight, bias parameter.

E. Optimization using Red Billed Blue Magpie Optimization Algorithm

The weights parameter y_a and δ_t of proposed DGCRIN is optimized utilizing the proposed Red Billed Blue Magpie Optimization Algorithm (RBBMOA) [33].This optimizer works efficiently and quickly, converging to the optimal weight parameters in a shorter time than other optimization techniques. It optimizes network parameters, leading to improved model performance and higher classification accuracy for skin lesion detection. The RBBMOA refines the standard algorithm by introducing a more effective, reducing the risk of getting trapped in local minima. It also quicker convergence and improved solution accuracy. Furthermore, RBBMOA adjusts dynamically to complex problem environments, enhancing its efficiency across various optimization tasks. As foraging, it uses mix of ground-walking, jumping, searching along branches to find food. It also stores food for later consumption. To protect its cached items from theft by other an also there wise birds; it hides food in secure locations such as tree hollows, forks, and rock crevices. Overall, it is versatile predator, employing various strategies to acquire and store food. It also displays social behavior and cooperation when hunting. The flowchart illustrating the proposed RBBMOA approach is presented in Fig. 4.

1) Stepwise procedures for RBBMOA: The step by step technique is defined to obtain optimal value of DGCRIN dependent on RBBMOA. At first, RBBMOA makes evenly allocating populace to enhance parameter of DGCRIN.

Step 1: Initialization

The initialization phase of RBBMOA applicant solutions is created smoothly within the constraints of a given problem, requiring updates after iteration. It is given in Eq. (15),

$$Y = \begin{bmatrix} y_{1,1} & \cdots & y_{1i} & y_{1,\dim-1} & y_{1,\dim} \\ y_{2,1} & \cdots & y_{2,i} & \cdots & y_{2,\dim} \\ \cdots & \cdots & y_{j,i} & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ y_{m-1,1} & \cdots & y_{m-1,i} & \cdots & y_{m-1,\dim} \\ y_{m,1} & \cdots & y_{m,i} & y_{m,\dim-1} & y_{m,\dim} \end{bmatrix} \quad (15)$$

where, Y signifies location of search agent, $\dim$ denotes dimension of solving problem, m represents population size.

Step 2: Random Generation

Input parameters are generated randomly. Optimal fitness values are preferred depending upon explicit hyper parameter situation.

Step 3: Fitness function

A random solution is generated utilizing initialized assessments using factor optimization value; it is evaluated for optimizing weight parameter y_a and δ_t of skin lesion. It is given in Eq. (16),

$$Fitness\ Function = optimize\ (y_a\ \&\ \delta_t) \quad (16)$$

where, y_a is utilized to increasing accuracy, δ_t is utilized to decreasing error rate.

Step 4: Search for food

To enhance efficiency, red-billed blue magpies typically hunt in small groups. It uses various techniques, including walking, jumping on ground, scouring trees for food resources. Billed blue magpies use adaptable hunting strategies that depend on environmental conditions, resources at hand, ensure adequate food supply as shown in Eq. (17).

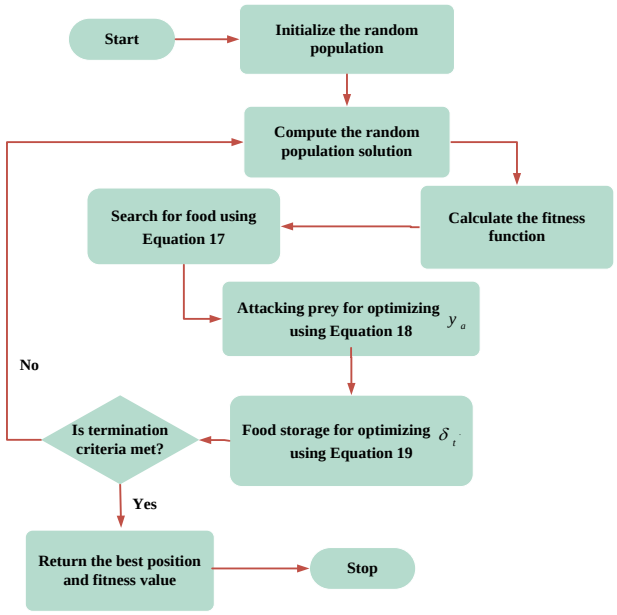

Fig. 4. Flowchart of RBBMOA for optimizing DGCRIN parameter.

$$Y^j(l+1) = Y^j(l) + \left(\frac{1}{q} \times \sum_{n=1}^{q} Y^n(l) - Y^{sa}(l)\right) \times Rand_2 \quad (17)$$

where, $Y^j(l+1)$ represents the prey attackers, Y^j represents the normal distribution, l represents the hunting behaviour, q indicates red-billed blue magpies typically hunt within small groups, Y^n represents the tactics, $Y^{sa}(l)$ denotes randomly selected search agents for current iteration, $Randn_2$ denotes random number 2.

Step 5: Attacking prey for optimizing y_a

When pursuing prey, red-billed blue magpie demonstrates higher degree of hunting skill, teamwork. It uses fast picking, jumping, and flying to grab insects, among other strategies. Typically, small prey or plants are the main focus of small group operations. Red-billed blue magpies can work together to pursue larger prey, such as tiny animals or large insects, when they are in groups. It is expressed as Eq. (18).

$$Y^j(l+1) = Y^{food}(l) + DG \times y_a \left(\frac{1}{q} \times \sum_{n=1}^{q} Y^n(l) - Y^j(l) \right) \times Randn_1 \quad (18)$$

where, Y^{food} represents the position of the food, DG represents the diverse strategies, and $Randn_1$ denotes random number 1 and y_a is used to increase the accuracy.

Step 6: Food storage for optimizing δ_t

Red-billed blue magpies not only hunt and fight prey, but it also stockpile extra food in tree holes and other hidden places so they may eat it later, providing a consistent source of food even in times of famine. This procedure saves information about the solutions, making it easier for people to find the value that is globally optimal. It is given in Eq. (19).

$$Y^j(l+1) = \delta_t \begin{cases} Y^j(l) & if \ \ fitness^j_{old} > fitness^j_{new} \\ Y^j(l+1) & else \end{cases} \quad (19)$$

where, $fitness^j_{old}$ and $fitness^j_{new}$ denotes fitness values earlier than, following position modernize of j^{th} red-billed blue magpie, δ_t is used for decreasing the error rate.

Step 7: Termination

The weight parameter value of creator y_a and δ_t from DGCRIN is improved by RBBMOA; it repeat step 3 until it acquires its halting criteria $Y = Y + 1$. Then, the SLCDI-DGCRIN-RBBMOA methods effectively classify the skin lesion by higher accuracy and low error rate.

2) Complexity analysis: The RBBMOA algorithm is based on two key components: solution initialization with the primary approach functions, which include computing the fitness values and update the solutions. Let n represent the cout of search agents, T denote the maximal count of iterations, and $\dim$ refer to the problem's dimension. Finding the optimal location and updating the location of every solutions are included in the solution updating process, which has a computational difficulty of $O(T \times n) + O(2 \times T \times n \times \dim)$, while the solution initialization process has a computational complexity of $O(n)$. As a result, the overall computational complexity of the proposed RBBMOA algorithm is $O(n \times T \times (2 \times \dim + 1))$.

IV. Result and Discussion

The experimental results of the proposed SLCDI-DGCRIN-RBBMOA approach is implemented in Python utilizing PC along Intel Core i5, 16GB RAM, 3.2 GHz CPU, Windows7, examined utilizing various performance measures likes accuracy, specificity, recall, precision, F1-score, computation time, error rate. The SLCDI-DGCRIN-RBBMOA model is tested against several performance metrics. Attained result of SLCDI-DGCRIN-RBBMOA approach is compared with existing methods likes DNN-EAI-SLC, MSLC-CNN-OIF, CSC-DI-DCNN respectively. Fig. 5 depicts the skin lesion classification workflow across different dermoscopic images, from segmented images, raw input images and pre-processed. Every modality captures exclusive anatomical details, which give to exact skin lesion detection.

A. Performance Measures

Performance metric accuracy, recall, specificity, F1-score, precision, computational time and error rate are examined for performance matrices. To measure performance metrics, performance matrix is required. Next matrixes are necessary to measure performance metrics.

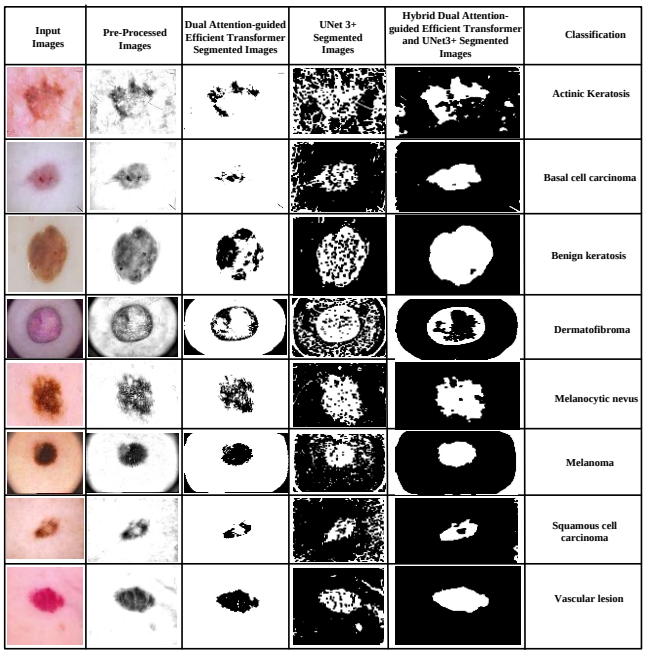

Fig. 5. Output of the proposed SLCDI-DGCRIN-RBBMOA method.

- True Positives: The number of actual positive cases that are accurately categorized as positive.
- True Negatives: The number of actual negative cases that are accurately categorized as negative.
- False Positives: The number of actual negative cases that are inaccurately classified as positive.
- False Negatives: The number of actual negative cases that are inaccurately classified as negative.

1) Accuracy: It is known as percentage of correctly identified cases among total instances and it is evaluated by Eq. (20),

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (20)$$

2) Precision: It assess the capacity of model for recognize positive instances accurately out of all predicted instances cases, which is estimated by Eq. (21),

$$\Pr ecision = \frac{TP}{(TP + FP)} \quad (21)$$

3) Recall: It is measured through separating total count of elements in positive class with count of real positives and determined by Eq. (22),

$$\text{Re}call = \frac{TP}{(TP + FN)} \tag{22}$$

4) Specificity: The percentage of true negatives that approach exactly recognizes is known as specificity, it is exhibits in Eq. (23),

$$Specificity = \frac{TN}{TN + FP} \tag{23}$$

5) F1-score: It represents ensemble mean of precision, recall. It is calculated using Eq. (24),

$$F1 - score = 2 * \frac{precision * recall}{precision + recall} \tag{24}$$

6) Error rate: It is a statistic used to express the prediction inaccuracy of the methodology depending on the actual approach. This is scaled in Eq. (25),

$$Error\ \ Rate = 100 - Accuracy \tag{25}$$

B. Performance Measures

Fig. 6-14 shows simulation result of SLCDI-DGCRIN-RBBMOA method. The performance measures are analyzed with existing DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN methods. The analysis of accuracy performance is portrayed in Fig. 6. The graph-based design's superior ability to capture local interactions between features enhances prediction accuracy and minimizes misclassifications. Furthermore, modern optimization techniques refine the models tuning, resulting in improved accuracy in identifying actual cases of skin lesion. Here, SLCDI-DGCRIN-RBBMOA method attains 21.51%, 12.38%, and 24.61% higher accuracy for actinic keratosis; 16.26%, 14.05%, 19.51% greater accuracy for Basal cell carcinoma; 26.21%, 20.65%, 22.31% greater accuracy for benign keratosis; 41.79%, 20.25%, 15.85% greater accuracy for Dermatofibroma; 25.21%, 30.65%, 20.45% greater accuracy for Melanocytic nevus; 10.56%, 27.56%, 19.67% higher accuracy for Melanoma; 18.78%, 30.45%, and 29.67% higher accuracy for Squamous cell carcinoma; 28.78% higher accuracy for vascular lesion; analyzed with existing techniques such as DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN respectively.

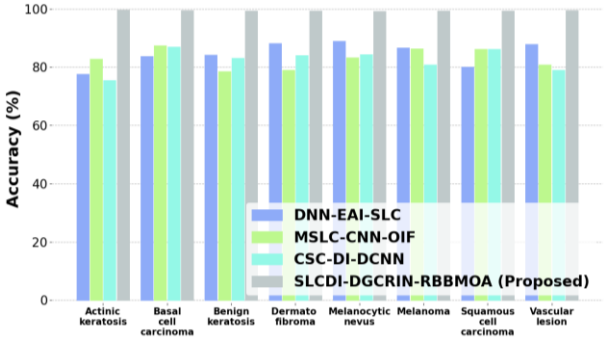

Fig. 6. Analysis of accuracy performance.

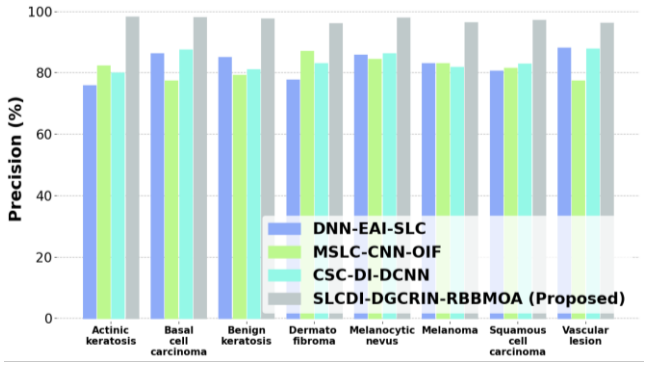

Fig. 7. Analysis of precision performance.

When compared to existing methods, the graph in Fig. 7 shows that SLCDI-DGCRIN-RBBMOA achieves higher precision across most skin lesion types due to model parameter optimization using the RBBMOA. This improvement in precision results from methods ability to better distinguish among different types of skin lesion. The enhanced accuracy is reflected in the methods overall performance, demonstrating its efficiency in managing and mitigating skin lesion. Here, SLCDI-DGCRIN-RBBMOA method attains 28%, 50%, and 21.51% higher Precision for actinic keratosis; 41.79%, 20.25%, 15.85% higher Precision for Basal cell carcinoma; 20.21%, 30.65%, and 28.31% higher precision for benign keratosis; 30.78%, 28.45%, and 29.56% higher precision for Dermatofibroma; 10.56%, 18.2%, and 16.46% higher precision for Melanocytic nevus; 29.59%, 30.89%, and 38.56% higher precision for Melanoma; 30.89%, 29.35%, and 29.89% higher precision for Squamous cell carcinoma; 29.50%, 26.40%, 30.67% greater precision for vascular lesion; analyzed with existing techniques likes DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN correspondingly.

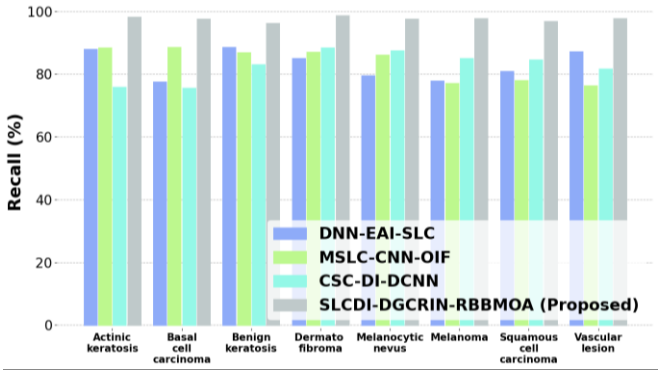

Fig. 8. Analysis of recall performance.

The model's high recall in SLCDI-DGCRIN-RBBMOA is attributed to its ability to effectively identify positive cases which is shown in fig. 8. By capturing intricate relationships between features, DGCRIN ensures that cases indicators are not overlooked. Additionally, RBBMOA optimizes the model's parameters to enhance sensitivity and increase the number of true positives identified. This combination strengthens the model's robustness against false negatives, reducing the number of missed examples and thereby improving recall. The SLCDI-DGCRIN-RBBMOA method attains 23.07%, 41.17%, and 24.67% higher recall for actinic keratosis; 43.47%,

25.31%, 16.47% higher recall for Basal cell carcinoma; 26.21%, 20.65%, and 22.31% higher recall for benign keratosis; 20.78%, 30.78%, and 12.56% higher recall for Dermatofibroma; 20.56%, 30.2%, and 28.46% higher recall for Melanocytic nevus; 30.29%, 35.89%, and 20.56% higher recall for Melanoma; 15.89%, 17.35%, and 29.46% higher recall for Squamous cell carcinoma; 30.26%, 20.46%, and 39.67% higher recall for vascular lesion; analyzed with existing techniques likes DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN.

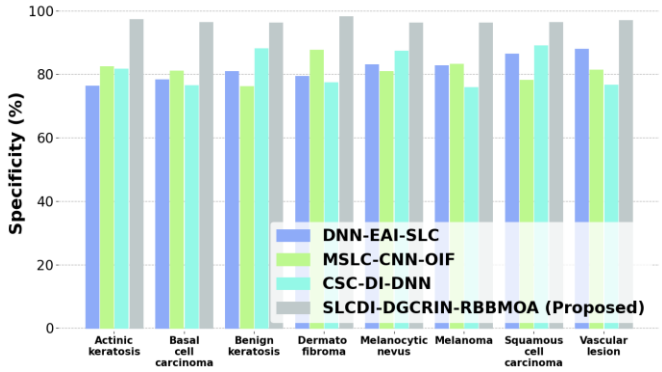

Fig. 9. Analysis of specificity performance.

Fig. 9 portrays the analysis of specificity performance. The specificity curve of a well-performing model will be lower at first and progressively higher as training goes on. The SLCDI-DGCRIN-RBBMOA method attains 17.75%, 24.55% and 12.66% high specificity for actinic keratosis; 21.01%, 14.08% and 17.33% high specificity for Basal cell carcinoma; 16.41%, 29.65%, and 24.31% higher specificity for Benign keratosis; 20.41%, 30.25%, and 14.83% higher specificity for Dermatofibroma; 29.41%, 30.48%, and 20.40% higher specificity for Melanocytic nevus; 17.01%, 29.08% and 30.67% higher specificity for Melanoma; 10.40%, 28.30% and 20.33% higher specificity for Squamous cell carcinoma; 29.59%, 20.9%, 25.31% greater specificity for Vascular lesion, analyzed with existing DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN models.

A model is considered to be comprehensive in recognizing all relevant cases and precise in forecasting positive cases if it's F1-score is higher. A high F1-score for the meningioma would propose that the system successfully detects critical circumstances without generating an excessive count of false alarms in context of skin lesion classification. Fig. 10 displays the analysis of F1-score performance. The SLCDI- DGCRIN-RBBMOA method attains 10.30%, 17.10% and 30.26% higher F1-score for the actinic keratosis; 28.02%, 11.56% and 13.67%.

F1-score for Basal cell carcinoma; 20.15%, 19.55%, and 12.21% high F1-score for Benign keratosis; 28.67%, 30.67%, and 23.67% high F1-score Dermatofibroma; 30.19%, 20.78%, and 20.56% higher F1-score for Melanocytic nevus; 29.68%, 10.56%, 26.67% greater F1-score for Melanoma; 29.78%, 10.56%, 30.56% greater F1-score for Squamous cell carcinoma; 20.67%, 17.49%, and 30.92% larger F1-score for Vascular lesion; compared with existing DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN models.

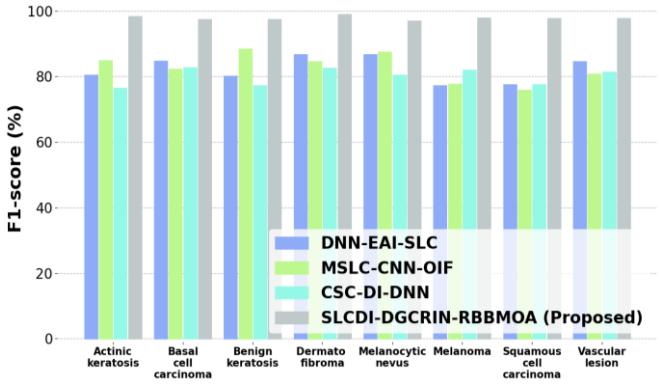

Fig. 10. Analysis of F1-score

Fig. 11 shows the analysis of computational time performance. It is faster due to optimized training methods, which include advanced optimization algorithms and effective hyperparameter tuning, reducing the number of training iterations required. Additionally, the spatio-temporal nature of DGCRIN allows for the parallel handling of spatial and temporal features, further enhancing computational efficiency. The proposed SLCDI-DGCRIN-RBBMOA method attains 15.01%, 13.44%, 14.27% lower computational time; analyzed with existing DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN methods.

A decreased error rate suggests improved model performance. Fig. 12 shows performance of error rate analysis.

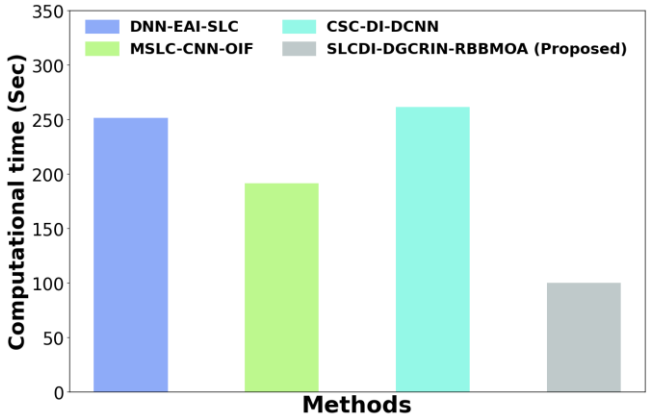

Fig. 11. Analysis of computational time performance.

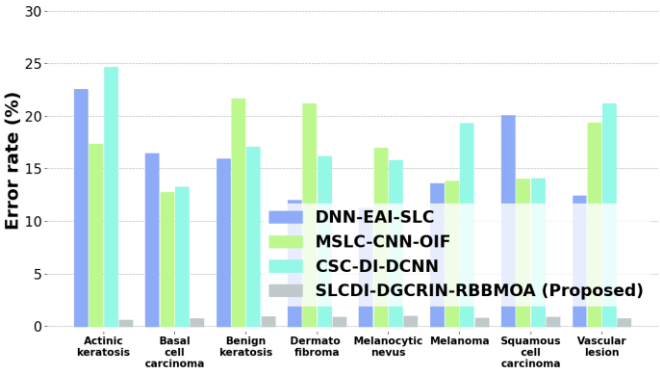

Fig. 12. Error rate analysis.

SLCDI-DGCRIN-RBBMOA has a significantly lower error rate than these existing methods, it indicates that the optimization techniques and advanced model architecture used in DGCRIN effectively reduce misclassifications, improving overall accuracy in identifying various skin lesion types. This reduction in error rates illustrates the new model's capacity to improve skin lesion classification reliability. Here, SLCDI-DGCRIN-RBBMOA method attains15.85%, 23.37%, and 22.04% lower Error rate for actinic keratosis; 25.97%, 20.57%, 19.23% lower Error rate for Basal cell carcinoma;24.78%, 22.67%, and 30.46% lower Error rate for benign keratosis; 30.79%, 10.29%, 25.59% lower error rate for Dermatofibroma; 20.45%, 25.89%, and 30.57% lower error rate for Melanocytic nevus; 19.67%, 30.16%, and 20.45% lower error rate for Melanoma; 20.67%, 30.15%, and 30.10% lower error rate for Squamous cell carcinoma; 15.79%, 20.56%, and 12.18% low error rate for vascular lesion; analyzed with existing approaches such as DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN correspondingly.

The Computational Complexity of the proposed SLCDI-DGCRIN-RBBMOA approach increases with increasing input size, indicating its scalability and appropriateness for bigger datasets. This graph in Fig. 13 highlights how much faster the SLCDI-DGCRIN-RBBMOA to the existing techniques likes DNN-EAI-SLC, MSLC-CNN- OIF and CSC-DI-DCNN respectively. Here, when the input size increases then the CPU operation decreases gradually. Fig. 14 depicts the confusion matrix.

C. Comparative Analysis of Proposed Approach

Table II presents a segmentation comparison with other methods depending upon accuracy, precision, recall, and F1-score. ResNet 50 shows an accuracy of 70.7%, with a strong recall of 86.6%, but a lower precision of 76.8%. DarkNet19 has higher accuracy but struggles with lower precision and recall. EfficientNet offers a well-balanced performance, achieving 79.5% accuracy, high precision, and moderate recall. Both the Dual Swin Transformer and Dual Vision Transformer perform well in recall; but both models have lower precision. The Dual Attention-guided Efficient Transformer shows good precision but lower recall. UNet3+ delivers strong results across all metrics, with an accuracy of 84.6%. The proposed Hybrid Dual Attention-guided Efficient Transformer and UNet 3+ model stands out with exceptional results, achieving 99.4% accuracy, 92.9% precision, 94.5% recall, and 95.4% F1-score, making it the most effective model in segmentation.

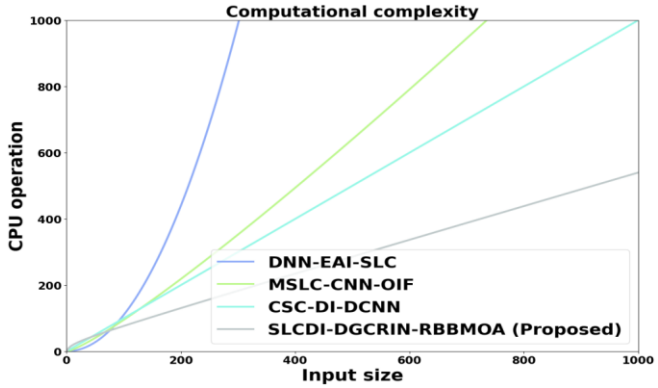

Fig. 13. Computational complexity performance analysis.

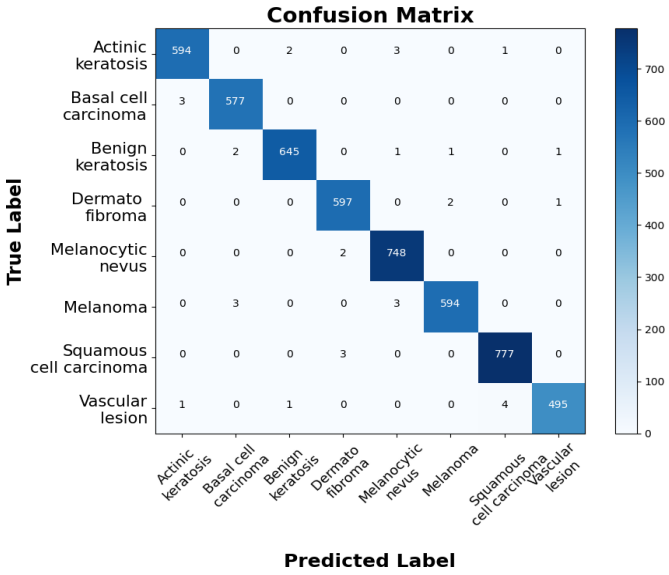

Fig. 14. Confusion matrix analysis.

TABLE II. SEGMENTATION COMPARISON WITH OTHER MODELS

Models	Accuracy	Precision	Recall	F1-score
ResNet 18 [21]	70.7%	76.8%	86.6%	80.3%
DarkNet19 [22]	75.4%	70.1%	67.3%	82.4%
EfficientNet [23]	79.5%	87.9%	72.6%	80.7%
Dual Swin Transformer [34]	76.4%	70.3%	74.9%	79.4%
Dual Vision Transformer [35]	80.2%	76.9%	85.2%	71.5%
Dual Attention-guided Efficient Transformer [30]	79.7%	80.1%	72.9%	67.8%
UNet3+ [31]	84.6%	79.9%	83.2%	80.6%
Hybrid Dual Attention-guided Efficient Transformer and UNet 3+ (Proposed) [30, 31]	99.4%	92.9%	94.5%	95.4%

TABLE III. COMPARATIVE ANALYSIS OF PROPOSED APPROACH

Methods	Accuracy (%)	Precision (%)	Recall (%)	Specificity (%)	F1-score (%)	Computational time (sec)	Error rate (%)
DNN-EAI-SLC [21]	77.47	75.69	87.80	76.22	80.37	250	22.52
MSLC-CNN-OIF [22]	82.70	82.20	88.26	82.30	84.82	190	17.29
CSC-DI-DCNN [23]	75.35	79.85	75.75	81.55	76.45	260	24.64
RDCNN-SLC-MFCC [24]	83.59	86.15	77.48	78.22	84.64	240	16.40
DCNN-SLMC-GAPI [25]	86.32	77.32	88.46	80.94	82.15	150	12.72
CNN-SLC-SH [26]	86.76	87.32	75.75	76.40	82.58	180	13.23
GAN-HMC [27]	84.08	85.20	88.45	80.75	80.01	230	15.91
SLCDI-DGCRIN-RBBMOA (proposed)	99.16	98.16	98.11	97.20	98.27	99	0.592

Table III provides a comparative analysis of SLCDI-DGCRIN-RBBMOA method alongside several other existing methods based on key performance metrics, comprising specificity, accuracy, precision, recall, F1-score, computational time, and error rate. Among the methods evaluated, the proposed SLCDI-DGCRIN-RBBMOA approach outperforms the others, achieving the highest accuracy and strong results across each metrics, like specificity, precision, recall, and F1-score. Additionally, it boasts the lowest error rate and computational time compared to the other methods. In contrast, approaches such as DNN-EAI-SLC, CSC-DI-DCNN, and RDCNN-SLC-MFCC exhibit lower accuracy and higher error rates, emphasizing the superior efficiency and effectiveness of the proposed model. This comparison emphasizes the exceptional performance with effectiveness of the SLCDI-DGCRIN-RBBMOA approach.

D. Discussion

The proposed model for Skin Lesions Classification in Dermoscopic Images employs an Optimized Dynamic Graph Convolutional Recurrent Imputation Network (DGCRIN) to enhance classification performance. The methodology begins with preprocessing, utilizing Confidence Partitioning Sampling Filtering (CPSF) to remove noise, resize images, and enhance quality. This aligns with [29], who demonstrated that CPSF significantly improves feature extraction in medical imaging by preserving essential details while eliminating distortions. Following preprocessing, the Hybrid Dual Attention-guided Efficient Transformer and UNet3+ (HDAETUNet3+) is applied for segmentation. The efficiency of hybrid transformer-based segmentation models in medical imaging has been well-documented. The study in [30] proposed Dae-former, a dual attention-guided efficient transformer, demonstrating superior segmentation accuracy for medical images, which supports the effectiveness of HDAETUNet3+ in identifying precise lesion boundaries. Additionally, the integration of UNet3+ [31], which employs full-scale connectivity, further enhances segmentation performance, ensuring robust ROI extraction from dermoscopic images. For classification, Dynamic Graph Convolutional Recurrent Imputation Network (DGCRIN) is utilized. Research on graph convolutional networks in handling complex spatial dependencies supports the use of DGCRIN. The research in [32] demonstrated the effectiveness of dynamic graph convolutional networks in managing spatiotemporal dependencies, which is crucial for accurately classifying skin lesions with varying patterns and structures. Despite its advantages, the proposed model presents some limitations. One challenge is the computational demand of deep learning and optimization algorithms. As noted by study [33], optimization algorithms like the Red-Billed Blue Magpie Optimizer (RBBMOA) enhance accuracy but may require extensive computational resources, which could be a concern for real-time medical applications. Additionally, the model's complexity and fine-tuning requirements may pose challenges for clinical integration, a concern also raised in prior studies on deep learning-based skin lesion classification [2].

V. CONCLUSION

The SLCDI-DGCRIN-RBBMOA model achieves significant advancements in skin lesion detection and classification. Utilizing dermoscopic images from the ISIC-2019 dataset, the model incorporates CPSF for noise reduction, resizing, and image enhancement. The HDAETUNet3+ effectively segments the ROI, while DGCRIN classifies lesions, and RBBMOA optimizes DGCRIN, enhancing classification accuracy. This approach demonstrates superior performance, achieving 21.51%, 12.38%, and 21.51% higher accuracy, along with 15.85%, 23.37%, and 22.04% lower error rates compared to DNN-EAI-SLC, MSLC-CNN-OIF, and CSC-DI-DCNN, respectively. However, challenges such as image quality variability and overlapping lesion features remain areas for further exploration. Future research could explore applying skin lesion classification techniques, with a focus on addressing disputes like data variability, noise in medical imaging, and the need for real-time diagnosis. Incorporating advanced feature extraction techniques could enhance lesion detection accuracy and improve classification performance. Additionally, optimizing deep learning models for domain-specific tasks could lead to more reliable skin cancer detection and prognosis. Moreover, incorporating multi-modal data, such as clinical metadata (e.g., patient history and genetic factors), alongside dermoscopic images could improve diagnostic precision. Lastly, future research could focus on edge and mobile deployment, adapting the model for lightweight, resource-efficient implementations, making it accessible in remote and resource-limited areas.

***Abstract*—Early detection of cardiovascular diseases is vital, especially considering the alarming number of deaths worldwide caused by heart attacks, as highlighted by the world health organization. This emphasizes the urgent need to develop automated systems that can ensure timely and accurate identification of cardiovascular conditions, potentially saving countless lives. This paper presents a novel approach for heartbeats classification, aiming to enhance both accuracy and prediction speed in classification tasks. The model is based on two distinct types of features. First, morphological features that obtained by applying wavelet scattering network to each ECG heartbeat, and the maximum relevance minimum redundancy algorithm was also applied to reduce the computational cost. Second, dynamic features, which capture the duration of two pre R–R intervals and one post R–R interval within the analyzed heartbeat. The feature fusion technique is applied to combine both morphological and dynamic features, and employ a convolutional neural network for the classification of 15 different ECG heartbeat classes. Our proposed method demonstrates an overall accuracy of 98.50% when tested on the Massachusetts institute of Technology -Boston's Beth Israel hospital arrhythmia database. The results obtained from our approach highlight its superior performance compared to existing automated heartbeat classification models.**

Keywords*—Electrocardiogram (ECG); Convolutional Neural Network (CNN); Arrhythmia Rhythm (ARR); Maximum Relevance Minimum Redundancy (MRMR); Wavelet Scattering Network (WSN)

I. INTRODUCTION

The cardiac conduction system ensures an electrical impulse from pacemaker cells in the Sinoatrial (SA) node travels through atria and ventricles, causing a coordinated and timely muscle contraction [1]. Components include SA node, Atrioventricular (AV) node, bundle of His, bundle branches, and Purkinje network.

Einthoven pioneered visualizing heart electrical activity using vectors in an equilateral triangle [2]. Six standard leads: I, II, III, aV_R, aV_L, and aV_F provide a frontal view, while combining them gives a biplanar view of the 3D heart. ECG records instant heart electrical activity on the surface.

ECG signals are commonly employed for the diagnosis of Cardiovascular Diseases (CVD) [3]. Advances in digital tech and cost-effective miniaturized acquisition units have led to the digital acquisition and processing of ECG signals.

Studying Electrocardiogram (ECG) signals could greatly improve early detection of CVD, a major cause of mortality globally [4]. More than that coronary heart disease contributes to premature deaths, disabilities, and a cycle of poverty and ill health [5]. Manual CVD analysis is a time-consuming, an error-prone, especially with large datasets, and requires extensive training due to the signal's complexity, as referred in [6-7-8, 9]. Mistakes in ECG analysis can lead to incorrect diagnoses and treatment. hence, the automatic classification of arrhythmias in ECG signals can be very useful as it can not only offer an impartial diagnosis, but it also has the potential to reduce the workload of medical professionals. As a result, the identification and categorization of ECG hold substantial importance in this field [10], facilitating advancements in CVD research.

Cardiac ARR, termed abnormal cardiac rhythms, arise from irregular initiation or propagation of cardiac excitation waves [11]. They are categorized into ventricular such as Ventricular Premature Complex (VPC), couplets, and triplets, and into supraventricular such as Supraventricular Tachycardia (SVT) and Atrial Fibrillation (AF) types [12]. Ventricular Arrhythmia Rhythm (ARR) stemming from heart's lower chambers, heighten the risk of sudden cardiac death, causing around 450,000 annual US fatalities. Most deaths result from ventricular tachycardia progressing to fatal ventricular fibrillation [13], necessitating prompt defibrillation.

The rest of the paper begins with the related work in Section II, where automated arrhythmia detection methods are discussed in-depth. This is followed by the ECG heartbeat classification in Section III, which starts with a detailed description of the dataset. Next, the feature extraction section provides an in-depth explanation of feature extraction using WSN. The MRMR section then presents a comprehensive overview of dimensionality reduction and the optimization of scattering paths within the scattering network. The subsequent section describes the proposed CNN model for the classification task. Finally, the results in Section IV presents the various outcomes achieved in terms of evaluation metrics and optimization results, while the discussion in Section V

compares the findings of this research with state-of-the-art models. Finally, the paper is concluded in Section VI.

II. Related Works

In the last ten years, significant advancements have occurred in automatic ECG classification algorithms that employs classical machine learning models such as decision trees [18], linear discriminants [19], and logistic regression [20] for diagnosing cardiac arrhythmias [14-15-16, 17]. Techniques like Naïve Bayes, Support Vector Machine (SVM), and K-Nearest Neighbors (KNN) have also been utilized in this context [21-22, 23]. Artificial Neural Networks (ANN) have emerged also as a powerful tool [24-25, 26], capable of real-time arrhythmia detection through the recognition of intricate patterns and correlations in ECG signals. Other approaches combine feature extraction with machine learning, including time domain features [26], frequency domain features [27], and combinations of both [28]. Wavelet analysis has also proven effective [29-30].

Recently, deep learning has become a promising approach for analyzing ECG signals, outperforming traditional machine learning methods. Models like Convolutional Neural Networks (CNN) [31-32], Recurrent Neural Networks (RNN) [33], and Long-Short Term Memory (LSTM) neural networks [34] excel due to their automatic feature extraction from raw ECG data. GPU and TPU, integral to high-performance computing, have significantly bolstered deep learning in ECG analysis by efficiently processing extensive data.

Noteworthy datasets like PhysioNet [35] and PTB Diagnostic ECG database have further advanced deep learning in this field. These datasets encompass diverse ECG signals with varying abnormalities, facilitating improved learning and generalization of deep learning models. Moreover, deep learning has proven effective in vital tasks such as denoising [36], segmentation, and reconstruction of ECG signals. Recent advancements in ECG have enhanced the diagnosis and treatment of CVD, a leading global cause of mortality [37-38].

Past research has concentrated on categorizing ECG signals into broader groups like Normal Sinus Rhythm (NSR), ARR, and Congestive Heart Failure (CHF) [39-40]. Some researchers have also suggested interpreting ECG heartbeats based on the Association for the Advancement of Medical Instrumentation (AAMI) classes: non-ectopic beats (N), supraventricular ectopic beats (S), ventricular ectopic beats (V), fusion beats (F), and unknown beats (Q) [41-42]. Some other works used the annotations from the American Heart Association (AHA) that has proposed a set of 15 classes for arrhythmia classification based on the MIT–BIH arrhythmia Database.

Osowski et al. [43] proposed a method to classify ECG heartbeats from the MIT–BIH arrhythmia database with 13 classes. They combined features extracted using Higher-Order Statistics (HOS) and Hermite characterization of the QRS complex, feeding them into an SVM classifier.

Rodriguez et al. [44] describe their approach to creating a classification algorithm for a variety of 14 ECG heartbeat classes using the MIT–BIH arrhythmia database. Their reported outcomes demonstrate significant accuracy. Furthermore, they highlight the algorithm's integration potential with Personal Digital Assistants (PDA).

Chen et al. [45] proposed an innovative method for categorizing ECG beats. Their approach combines projected and dynamic features. The projected features involve a random projection matrix, normalized columns, and row-wise Discrete Cosine Transform (DCT). The dynamic features include 3 weighted R–R intervals. The SVM classifier is employed for the categorization of heartbeats into either 15 or 5 distinct classes.

Ihasanto et al. [46] present the Ensemble Multilayer Perceptron (MLP) method, streamlining ECG beat classification by integrating feature extraction and classification into one step. This eliminates the need for a separate preprocessing stage, potentially reducing computational requirements. The technique achieves over 97% accuracy, even with 10 ECG heartbeat classes.

Melgani et al. [47] demonstrated SVM effective generalization in classifying sets of 10 ECG beats. They introduced an innovative approach, combining Particle Swarm Optimization (PSO) with SVM, to enhance the performance.

Alqudah et al. [48] introduced an innovative deep learning technique aimed at arrhythmia classification through ECG analysis, utilizing iris spectrograms. Their method demonstrated remarkable recognition performance accuracy rates of 99.13%, 98.223%, and 97.494% for 13, 15, and 17 distinct categories, respectively. These results were obtained using a dataset comprising 744 ECG from 45 individuals.

Alqudah et al. [49] compared spectrogram representations in various CNN architectures using a dataset of 10,502 heartbeats from MIT–BIH arrhythmia database, covering 6 classes. They explored Log/Mel-Scale spectrograms, Bi-Spectrum, and third-order cumulant in models like AOCT-NET, Mobile-Net, Squeeze-Net, and Shuffle-Net.

Rajkumar et al. [50] devised an intelligent approach employing CNN for the automated classification of ECG signals. Their methodology obviates the need for manual feature extraction, potentially enhancing the efficiency of cardiac patient screening for cardiologists. Demonstrating its effectiveness, the CNN adeptly categorized seven distinct ARR classes sourced from the MIT–BIH database.

Shaker et al. [51] improved deep learning on the MIT–BIH arrhythmia dataset with GAN-based data augmentation. They used two CNN based approaches to avoid manual feature engineering.

Ramkumar et al. [52] used ECG data from MIT–BIH arrhythmia database to classify normal, atrial premature, and ventricular escape heartbeats. They employed wavelet transform for preprocessing, independent component analysis for feature extraction, and MLP for classification.

Arslan et al. [53] simultaneously trained an autoencoder and classifier, allowing the network to reduce overall error while accurately reconstructing the input and extracting key features useful for classification. Their work focused on classifying six types of ECG heartbeats, including normal beats, left and right bundle branch block beats, premature

ventricular contractions, atrial premature beats, and paced beats, using data from the MIT–BIH dataset. They achieved a classification accuracy of 99.99% by employing a convolutional autoencoder with an integrated classifier.

Vavekanand et al. [54] used deep CNN to classify ECG beats as either normal or abnormal. They applied transfer learning, first training a generic model on ECG data from the MIT–BIH, then fine-tuning the model for specific patients. They compared the performance of these fine-tuned models of individual models trained only on a single patient's data. Both approaches performed well, with individual classifiers achieving an average balanced accuracy of 94.6% on the test set, while the fine-tuned models had a slightly lower accuracy of 93.5%.

Zhou et al. [55] transformed ECG signals into different types of images using techniques like Recurrence Plot (RP), Gramian Angular Field (GAF), and Markov Transition Field (MTF), which they then fed into their classification model. To better retain important details, they developed a CNN based model with FCA for handling multiple types of ECG tasks. Their model achieved an accuracy of 99.6% when classifying five types of heartbeats using data from the MIT–BIH arrhythmia database.

Although the previous proposed approaches successfully classify ECG heartbeats, most state-of-the-art methods tend to focus on specific types of heartbeats rather than addressing all 15 types. When attempting to classify all heartbeat types, the proposed methods show lower performances compared to those works that limit their scope to just a few types. Additionally, many existing studies on heartbeat classification fail to analyze the computational complexity of their models, which makes them impractical for real-world applications. The importance of this new research lies in addressing the challenge of low classification performance in ECG heartbeat analysis, especially when dealing with a large number of classes. To overcome this issue, it proposes a novel approach to optimize the WSN and CNN, both of which have demonstrated effectiveness in classification tasks, particularly in arrhythmia detection. The main objective of this research paper is to develop an advanced heartbeat classification model that achieves high accuracy. Additionally, the proposed model is optimized to ensure its applicability in clinical settings.

Based on these observations, the contributions of this study can be summarized as follows:

- Develop a new method for detecting arrhythmias from ECG heartbeats with high accuracy.
- Optimize the Wavelet Scattering Network (WSN) for feature extraction to make the proposed approach suitable for clinical use.

III. ECG HEARTBEAT CLASSIFICATION

A. Data Acquisition

The research utilizes publicly available data from PhysioNet in .mat format [56], sourced from MIT–BIH arrhythmia database [57] a collection of ECG recordings.

Our research used data from the MIT–BIH arrhythmia database, including 48 labeled ECG signals taken over 30 minutes from 47 individuals. Lead II ECG signals are used in this study due to their sensitivity to heart rhythm, crucial for ARR detection. Sampling frequency was 360 Hz to capture detailed heart activity.

Our study aims to categorize ECG heartbeats into 15 distinct types as outlined in Table I. The sequential procedure outlined in Fig. 1 shows different steps of our proposed approach. Initially, to detect QRS complexes in each ECG signal, the Pan-Tompkins algorithm [58] is employed, which is a well-known method commonly used for QRS detection in ECG signals. This algorithm is tailored for accurate identification of QRS complexes in ECG signals.

By applying the Pan-Tompkins algorithm, the majority of R peaks in ECG signals were successfully detected, ensuring comprehensive coverage of the QRS complex. A window of 300 samples before and 500 samples after the R peak was used, resulting in 801 sample ECG heartbeats at 360 Hz sampling frequency. This approach captured P waves, QRS complexes, and T waves, enabling accurate arrhythmias identification. Fig. 2 presents normal ECG heartbeat detected by pan-Tompkins algorithm. Dynamic features like post R–R interval, pre R–R interval, pre-pre R–R interval, and the (post R–R)-(pre R–R) interval difference were computed, aiding arrhythmia diagnosis based on heart rate variability.

B. Data Preprocessing

In this research, the data was utilized in its original raw, unprocessed state without applying any data cleaning techniques. Afterwards, the dataset was split into two segments, one for training and the other for testing. The hold-out validation technique was employed, incorporating stratification to ensure an equal representation from each class. Specifically, 80% of samples from each class were allocated for training, while the remaining samples were designated for testing. The distribution of the training and testing data are illustrated in Table II.

TABLE I. ECG HEARTBEATS DISTRIBUTION

Symbols	Types of ECG Heartbeats	No. of Heartbeats
N	Normal beat	11000
L	Left bundle branch block beat	8059
R	Right bundle branch block beat	7235
A	Atrial premature beat	1769
E	Ventricular escape beat	106
V	Premature ventricular contraction	6178
/ (P)	Paced beat	7017
F	Fusion of ventricular and normal beat	801
Q	Unknown beat	33
!	Ventricular flutter wave	472
a	Aberrated atrial premature beat	150
e	Atrial escape beat	16
f	Fusion of paced and normal beat	982
j	Nodal (junctional)escape beat	229
x	Non-conducted P wave (Blocked APB)	193

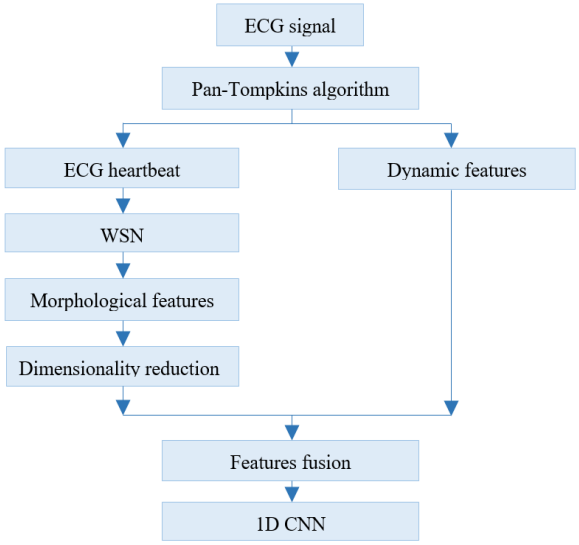

Fig. 1. Different steps of ECG heartbeat classification.

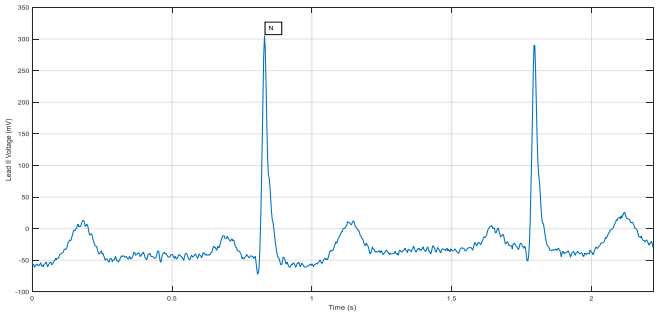

Fig. 2. Normal ECG heartbeat.

TABLE II. HEARTBEAT DISTRIBUTION FOR TRAINING AND TESTING

Symbols	Training Instances	Testing Instances
N	8800	2200
L	6448	1611
R	5788	1447
A	1416	353
E	85	21
V	4943	1235
/ (P)	5614	1403
F	641	160
Q	27	6
!	378	94
a	120	30
e	13	3
f	786	196
j	184	45
x	155	38

The dataset used for training shows an imbalance in class distribution, which lead to biased predictions and reduced model performance. To address this, the Synthetic Minority Oversampling Technique (SMOTE) [59] is employed.

C. Feature Extraction

Our research aimed to classify ECG heartbeats into 15 classes to detect ARR. Accurate predictions relied on extracting key features, split into time domain for capturing signal variations, and frequency domain for understanding spectral characteristics. Time domain features reflect changes, while frequency domain features reveal signal frequencies. The WSN was utilized as a powerful technique, for efficient feature extraction from ECG signals. This method capitalizes on wavelet transforms unique properties to capture local and global ECG waveform variations.

The WST is a mathematical method rooted in wavelets, allowing efficient signal analysis. Its strengths include translation and rotation invariances, suitable for image and audio analysis, stable features for denoising, and dimensionality reduction for enhanced accuracy [60]. This versatile technique finds use various domains such as audio, image, biomedical signals, speech, computer vision, and finance, excelling in classification and signal processing [61].

Fig. 3 illustrates the WSN with multiple layers, each applying a WST consisting of 3 stages. In the first stage, convolution uses a scale-specific wavelet ψ, to gauge similarity between the wavelet and the signal. The second stage introduces nonlinearity via modulus operations to retain signal magnitude and diminish redundant details like noise. The final stage involves low-pass filter convolution Φ , for dimensionality reduction enhancing signal representation.

The Gabor complex wavelet offers valuable traits beyond its time-frequency focus, including selective transmission of low-frequency components through its modulus acting as a low pass filter. By representing signal envelopes, it's adept at tasks like denoising and feature extraction [62].

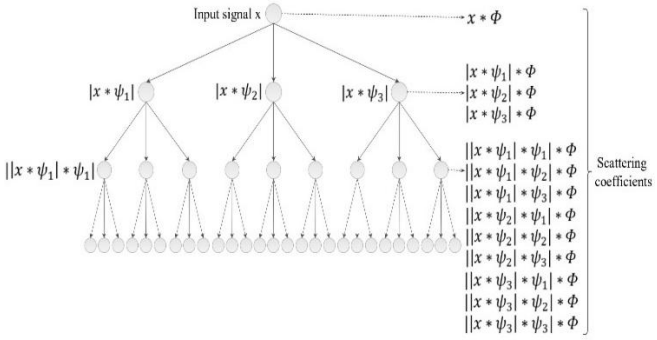

Fig. 3. Wavelet scattering network.

A Gabor wavelet in Eq. (1) is defined as the product of a Gaussian function and a complex exponential function.

$$\psi(t) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{\frac{-t^2}{2\sigma^2}} e^{i\omega t} \quad (1)$$

Where t is the time, and σ is the standard deviation of the Gaussian function. In $\omega = 2\pi f$, f is the center frequency of ψ, and i is the imaginary unit. The envelope of the Gabor complex wavelet represents the low-pass filter, denoted as Φ.

$$\Phi(t) = |\psi(t)| \quad (2)$$

The scale parameter σ in Gabor wavelet analysis is denoted as the standard deviation of the Gaussian envelope. It shapes the wavelet window. Larger σ means a wider Gaussian envelope for a broader wavelet, while smaller σ leads to a more localized wavelet. In ECG analysis, Gabor wavelets suit the QRS complex detection due to its resemblance to the QRS waveform, making it suitable for arrhythmia detections.

Fig. 4 outlines the Gabor complex wavelet with its real and imaginary parts, with 0.5 second invariance scale. Fig. 5 displays frequency bands for different scaling functions used.

$$S_1 x(t) = |x * \psi_{\sigma_1}| * \Phi \tag{3}$$

In the initial stage, the signal undergoes convolution with a low pass filter Φ in Eq. (4), offering high time resolution but limited frequency accuracy. Progressing to the first order in Eq. (3), 29 paths using various Gabor wavelets capture fast variations, yet some high-frequency details are lost due to a final convolution with this filter Φ. The second order in Eq. (5) employs 10 paths with different wavelets, enhancing frequency resolution. The resulting coefficients of all stages are summarized in matrix S presented in Eq. (6), providing a comprehensive multi-scale description of signal variations.

$$S_0 x(t) = x(t) * \Phi \tag{4}$$

$$S_2 x(t) = ||x * \psi_{\sigma_1}| * \psi_{\sigma_2}| * \Phi \tag{5}$$

$$Sx(t) = \{S_0, S_1, \dots, S_n\} \tag{6}$$

The study used a second order WSN to maintain 99% of signal energy. This choice prevented data loss and excessive computation. Two filter banks were employed, $Q_1 = 8$ and $Q_2 = 1$, ensuring accurate and efficient signal analysis.

One ECG heartbeat represented as a feature matrix of 40x26. The training dataset grows to 145,250 instances using the SMOTE technique. To handle this, the matrix becomes 40x26x145,250. Down-sampling with low pass filter reduces scattering coefficients, creating 26–time windows for 40 paths. Each tensor entry represents a path and time window.

Fig. 6(a) outlines the scattering coefficients of the first filter bank. The scattergram depicts time on the x–axis and frequency on the y–axis, and their amplitudes on the z–axis.

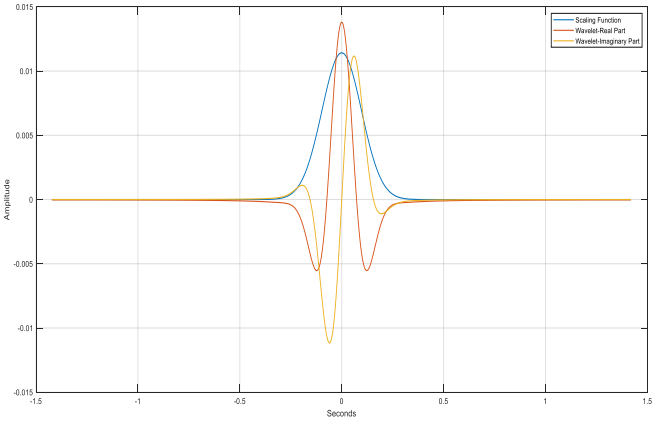

Fig. 4. Real part, imaginary part and low pass filter of Gabor wavelet.

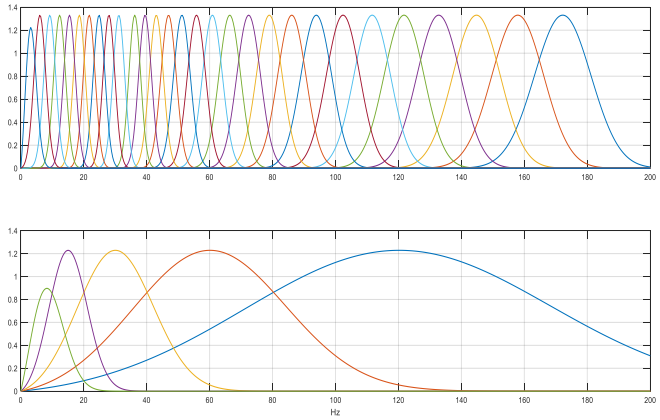

Fig. 5. Bandwidths of the first and the second filter banks.

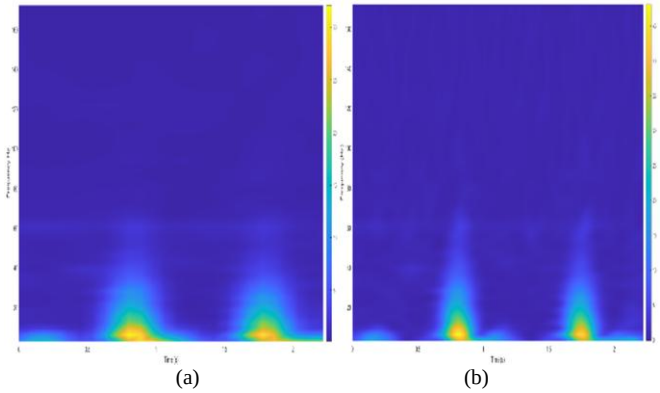

(a) (b)

Fig. 6. Scattergram of the first filter bank. (a) Scattering coefficients, (b) Scalogram coefficients.

Fig. 6(b) displays the scalogram of the first filter bank, which effectively captures distinct high frequency details of the ECG signals. The dynamic features are oversampled 40 times, resulting in 40x4 tensor. After fusion, the tensor size becomes 40x30 for one ECG heartbeat.

D. Maximum Relevance Minimum Redundancy (MRMR)

To tackle high computational costs and enhance testing accuracy while avoiding overfitting, the MRMR feature selection technique is employed to reduce the dimensionality. The MRMR algorithm incorporates various parameters, among which are entropy, joint entropy, and mutual information.

Entropy is a measure of uncertainty in a random variable. It helps gauge information within it. To find entropy, the probabilities of outcomes was used in a sequence $\{X_1, X_2, \dots, X_n\}$, denoted as X. This indicates the information required for prediction.

$$H(X) = -\sum_{i=1}^{n} p(x_i).\, log\, p(x_i) \tag{7}$$

Joint entropy gauges the uncertainty within a group of random variables, reflecting their unpredictability when interconnected. It evaluates the information content between two variables X and Y, expressing their correlation.

$$H(X:Y) = -\sum_{x,y} p(x,y).\log(p(x,y)) \tag{8}$$

Where $p(x,y)$ represents the joint probability.

Mutual information serves as a metric to uncover the degree of knowledge sharing between two or more random variables. It gauges their similarity and correlation, shedding light on their interdependencies [64]. During mutual information calculation, the focus lies on shared information and the robustness of their relationship.

A mutual information of zero implies independence between variables, while a higher value indicates a strong relationship and valuable information exchange.

$$I(X;Y) = H(X) - H(X:Y) = \sum_{x,y} p(x,y) log \frac{p(x,y)}{p(x).p(y)} \quad (9)$$

Where $H(X:Y)$ is the uncertainty left about X after knowing Y.

Common dimensionality reduction methods like Principal Component Analysis (PCA) and Linear Discriminate Analysis (LDA) often focus solely on feature category relationships, overlooking mutual information between features and targets. In contrast, the MRMR algorithm considers both, resulting in enhanced feature selection, predictive accuracy, and interpretability, offering a superior approach to dimensionality reduction. The MRMR algorithm measures the mutual information between features and the class label. A higher value indicates strong correlation, making a feature significant for classification. So, high mutual information between a feature X and class label C implies its importance in classification.

$$V_s = \frac{1}{|S|} \sum_{x\ \varepsilon\ S} I(x;C) \quad (10)$$

The concept of maximal relevance V_s involves identifying features that have the highest mutual information, represented by max V_s, with the target class label C. And $|S|$ which is the number of subset features in S.

Minimal redundancy evaluates the shared information between two features. High shared information implies redundancy. If two features convey the same data, one can be chosen for selection, reducing dimensions. Lower redundancy means better feature selection. So, the aim is to find features with low shared data. Let's set S as subset features, and X and Y are the features. The redundancy computes as follows:

$$W_s = \frac{1}{|S|^2} \sum_{x,y\ \varepsilon\ S} I\ (x;y) \quad (11)$$

The objective is to identify features with minimum redundancies by minimizing the function W_s , where $|S|$ represents the number of subset features in S, and $I(X;Y)$ denotes the mutual information between features X and Y.

The MRMR algorithm aims to discover a subset of features that display high relevance and low redundancy. It considers both the interdependencies among features and their connections to the target variable. It aims to maximize a specific function to find features with the highest relevance V_s to the target variable, while minimizing redundancy W_s among themselves [63]. The main goal is to achieve a balance between feature importance and mutual information, resulting in the selection of an optimal set of features.

$$\max(\beta)\ , \beta = \frac{V_S}{W_S} \quad (12)$$

Our study focuses on scoring features in subset features S. These scores stem from computing the mutual information between the target and the feature in question. This value is then divided by the mean mutual information between the previously chosen feature and the current one.

$$Score_i(x) = \frac{I(x;C)}{\sum_{S\varepsilon\, i-1\ selected\ features} \frac{I(x;S)}{m}} \quad (13)$$

Where m is the number of features in the subset S.

The MRMR algorithm evaluates scores of the 40 scattering paths in the scattering network as illustrated in Fig. 7. These scores indicate feature significance in classifying 15 ECG heartbeats. Higher scores highlight critical roles while lower scores mean less important features that can be replaced without accuracy loss.

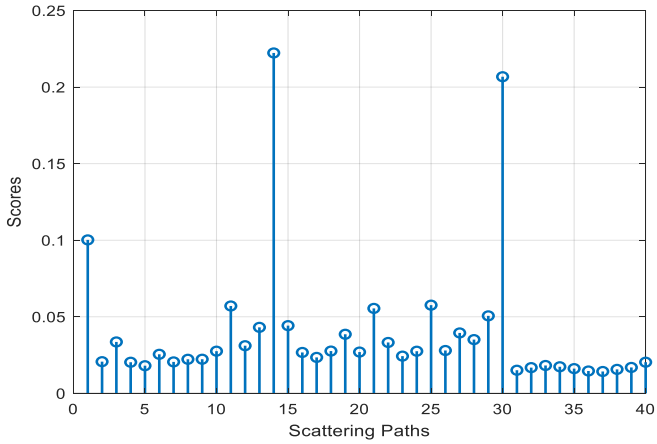

Fig. 7. Scores of different paths in wavelet scattering network.

E. Heartbeat Classification Using CNN

CNN is a specialized model designed specifically for processing 1-dimensional sequential data. Its key component is the convolutional layer, which employs filters to detect local patterns and dependencies within the input sequence. CNN chosen as a classifier to detect 15 heartbeat classes for efficiency. This minimizes computational costs compared to a 2D CNN. Our decision considers available resources and the need to process large data quickly.

In this research, a CNN with 14 hidden layers was used for classification as depicted in Table III. These layers include convolution, ReLU, normalization, global average pooling, fully connected, and SoftMax. They collectively differentiate the 15 ECG heartbeat classes. The convolutional layer involves sliding filters for computation as in Eq. (14).

$$y_t = b + \sum_{i=1}^{k} \omega_i . x_{t-i+1} \quad (14)$$

To ensure causality in the feature map, the output y_t is determined by the current input and the past samples at each time step t. This means that for a given feature vector x and a filter kernel ω, the mathematical formula for convolution can be expressed by taking into account both the current feature and previous inputs, meaning that a model only has access to past inputs to keep the causal nature of the process.

The ReLU function sets negatives to zero, leaving positives unaffected as presented in Eq. (15).

$$y_i = \max(0, x_i) \quad (15)$$

TABLE III. CNN LAYERS

Layer Types	Activations	Learnables	Total Learnables
Sequence Input	40	—	0
Convolution 1D Padding: [7,0] Stride: 1 No. of Filters: 16 Filter Size: 8	16	Weights: 8x40x16 Bias: 1x16	5136
ReLU	16	—	0
Layer Normalization	16	Offset: 16x1 Scale: 16x1	32
Convolution 1D Padding: [7,0] Stride: 1 No. of Filters: 32 Filter Size: 8	32	Weights: 8x16x32 Bias: 1x32	4128
ReLU	32	—	0
Layer Normalization	32	Offset: 32x1 Scale: 32x1	64
Convolution 1D Padding: [7,0] Stride: 1 No. of Filters: 64 Filter Size: 8	64	Weights: 8x32x64 Bias: 1x64	16448
ReLU	64	—	0
Layer Normalization	64	Offset: 64x1 Scale: 64x1	128
1D Global Average Pooling	64	—	0
Fully Connected Layers	15	Weights: 15x64 Bias: 15x1	975
SoftMax	15	—	0
Classification Output Loss Function: Cross-entropy	15	—	0

Normalization layers like batch normalization enhance neural network stability and convergence by standardizing prior layer outputs, ensuring suitable input ranges for downstream layers and promoting effective learning.

$$\hat{x}_i = \frac{x_i - \mu}{\sqrt{\delta^2 + \varepsilon}} \quad (16)$$

Where μ is the mean value of the features from one example, δ is the standard deviation, and the term $\varepsilon=10^{-5}$ used to prevent division by zero, ensures numerical stability. Finally, the output y_t is scaled and shifted as follows:

$$y_i = \gamma . \hat{x}_i + \beta \quad (17)$$

Where γ and β represent the scaling and shifting learnable parameters.

Global Average Pooling layers condense the spatial dimensions of the feature maps into a single value, which reduces the computational complexity of the model. This operation calculates the average of each feature map, resulting in a fixed-length vector.

$$Y = Softmax(\sum WX + b) \quad (18)$$

The SoftMax layer is applied to produce the probability distribution over the 15 ECG heartbeat classes.

$$y_i = \frac{\exp(z_i)}{\sum_{j=1}^{n} \exp(z_j)} \quad (19)$$

The configuration, architecture and settings for each layer of the proposed CNN model, analyzing an ECG heartbeat with the WSN, are outlined in Table III.

In our study, CNN is used for analysis. Training employed the Adam optimizer with a 0.01 initial learning rate. Hyperparameters were manually tuned, like shuffling data using a mini-batch size of 64, enhancing performance, ensuring diverse pattern exposure, and preventing overfitting.

F. Performance Metrics

The effectiveness of our proposed model was evaluated using multiple assessment metrics like accuracy, sensitivity, specificity, precision, F1 score, negative predictive value, false positive rate, false discovery rate, false negative rate, and the Matthew Correlation Coefficient (MCC).

$$\text{Accuracy (ACC)} = \frac{TP+TN}{TP+TN+FP+FN} \quad (20)$$

$$\text{Sensitivity (SEN)} = \frac{TP}{TP+FN} \quad (21)$$

$$\text{Specificity (SPE)} = \frac{TN}{TN+FP} \quad (22)$$

$$\text{Precision (PRE)} = \frac{TP}{TP+FP} \quad (23)$$

$$\text{F1 score (F1)} = \frac{2*precision*sensitivity}{precision+sensitivity} \quad (24)$$

$$\text{Negative Predictive Value (NPV)} = \frac{TN}{TN+FN} \quad (25)$$

$$\text{False Positive Rate (FPR)} = \frac{FP}{FP+TN} \quad (26)$$

$$\text{False Discovery Rate (FDR)} = \frac{FP}{FP+TP} \quad (27)$$

$$\text{False Negative Rate (FNR)} = \frac{FN}{FN+TP} \quad (28)$$

$$\text{MCC} = \frac{(TP.TN)-(FP.FN)}{\sqrt{(TP+FP).(TP+FN).(TN+FP).(TN+FN)}} \quad (29)$$

The MATLAB Version R–2021b programming language was utilized to implement all algorithms on windows server. The system used for execution had an Intel(R) Core (TM), i5, CPU 6300U processor with a clock speed of 2.40 GHz. The RAM capacity was 12 GB, operated on a 64–bit architecture.

IV. RESULTS

The purpose of our research is to distinguish 15 types of ECG heartbeats. By integrating the MRMR algorithm, the computational challenges are reduced. Moreover, a CNN is used as a classifier to successfully identify and classify ECG heartbeats. The WSN generated a 40x26 feature matrix, and MRMR evaluated path importance by calculating scores.

The study employed dimensionality reduction through score sorting to discover optimal paths for classification as illustrated in Fig. 8. It started with the top 5 paths, used a CNN model for testing data accuracy, and gradually added 5 more paths at each step until all 40 were included. Following the

approach presented in Fig. 9, the testing phase is assessed accuracy at each step. Increasing scattering paths boosted the testing accuracy as outlined in Fig. 10.

The test results indicate a remarkable accuracy of 98.50% when utilizing $K = 20$ scattering paths for ECG heartbeat classification. Adding more paths beyond the first 20 does not lead to any noticeable improvement in the overall testing accuracy. By selecting the top 20 paths based on their scores, the matrix size is reduced by half, maintaining accuracy while reducing feature dimensions by 50%. These changes include modifying the sequence input layer to 20 activations and adjusting the first convolution layer, resulting a reduction of 9.51% in parameter count. The confusion matrix of 15 ECG heartbeats presented in Fig. 11 shows a 98.50% overall accuracy, although classes "Q" and "e" had lower accuracy due to limited training data, affecting the overall score.

TABLE V. COMPLEXITY ANALYSIS OF THE PROPOSED MODEL

Execution time for feature extraction from one ECG heartbeat using WSN	14.8 ms
Prediction speed of the CNN	~3254 obs/s
Total number of learnable parameters of the CNN	24351
Memory usage after feature extraction for one ECG heartbeat	4160 bytes
Morphological feature dimensionality for one ECG heartbeat	20x26

Our innovative approach combines WSN with CNN for the classification of 15 ECG heartbeat classes. The results outlined in Table IV contain a remarkable performance metrics such as, a precision of 97.60% demonstrates precise positive predictions, a sensitivity of 86.30% signifies accurate identification of actual positives, a specificity of 99.88% reflects the model's prowess in correctly identifying negatives, a negative predictive value of 99.90% showcases minimal false negatives, a false positive rate of 0.12% indicates an extremely low occurrence of false positives, a false discovery rate of 2.41% demonstrates limited false positive predictions, a false negative rate of 13.70% portrays proficiency in classifying positive heartbeats, and a Matthew correlation coefficient of 90.01% signifies strong overall performance.

As outlined in Table V, our analysis confirms the efficiency and speed of our WSN based model using CNN for ECG heartbeat classification. The feature extraction process takes just 14.8 milliseconds per heartbeat, with a prediction speed of 3254 heartbeats per second.

The model's parameters reduced to 24351, and memory usage per heartbeat is 4160 bytes. Our model delivers swift performance, low parameter count, and minimal computational cost.

V. DISCUSSION

A comprehensive analysis was conducted to evaluate the overall accuracy of the proposed model in this research paper, and compared it with the results from previous studies. This comparison is summarized in Table VI. To ensure a fair comparison, we specifically focused on studies that also addressed the classification of 15 ECG heartbeats from the MIT–BIH arrhythmia database. These studies are referenced as [44-45-48, 51]. The obtained results clearly demonstrate that our proposed model, based on WSN combined with a CNN, outperforms the previous studies cited previously. Our model not only achieves higher accuracy in classifying heartbeats, but it also demonstrates robust performance across various types of heartbeats. It provides more accurate results and shows great potential for accurately detecting different types of heartbeats.

Our proposed method outperforms previous approaches by achieving high classification accuracy across the majority of ECG heartbeat types. Unlike existing models, our optimized technique enhances the model’s performance to a level that enables clinical application. By addressing the limitations of prior methods such as suboptimal feature extraction and insufficient classification accuracy our approach ensures more reliable heartbeat classification. As a result, the proposed

model surpasses state-of-the-art methods, achieving an overall accuracy of 98.50%.

In this study, the proposed approach for ECG heartbeat classification is illustrated in Fig. 12. It begins with QRS detection, using Pan-Tompkins algorithm, which identifies the dynamic features of heartbeats. These heartbeats are then fed into the WSN, where morphological characteristics are extracted. Following that, the most relevant morphological features are selected using the MRMR method combined with the proposed algorithm. After fusing the dynamic and morphological features, a feature matrix of size 20x30 is obtained. This matrix is then input into a specially designed CNN to classify the heartbeats into 15 distinct categories.

VI. CONCLUSION AND PROSPECTS

This study introduces an efficient approach for classifying ECG heartbeats. Our proposed model begins by detecting heartbeats in ECG signals, followed by utilizing the WSN for feature extraction. WSN is a robust technique that captures both temporal and spectral characteristics. Feature fusion is performed, and CNN employed for the classification of ECG heartbeats. Our model outperforms existing systems in terms of prediction accuracy and precision, achieving 98.50% and 97.60%, respectively, and also demonstrating low computational requirements due to the application of an innovative selection path techniques.

Although the WSN has proven effective in extracting important time and frequency domain features, it still suffers from high computational cost due to the convolution with multiple wavelets. Our approach addresses this issue by employing the MRMR technique in order to optimize the model and reduce computational costs, by selecting the most suitable wavelet for the convolution process.

The results of our proposed approach further demonstrate its effectiveness in detecting 15 types of ECG heartbeats from the MIT–BIH arrhythmia database, making it highly applicable for clinical use. This method has the potential to aid in early diagnosis and save numerous lives worldwide. Moving forward, our future work aims to enhance accuracy on testing data and further reduce computational costs to enable implementation on devices such as smartphones.

AVAILABILITY OF DATA AND MATERIALS

ECG readings were taken from [56].

CONFLICT OF INTEREST

We confirm that all authors declare no conflicts of interest.

Personalized Motion Scheme Generation System Design for Motion Software Based on Cloud Computing

Jinkai Duan
Department of Public Courses, Inner Mongolia Technical College of Construction, Hohhot, 010070, China

***Abstract*—The increase of national attention has also promoted the growth of the scale of sports health industry. However, for ordinary people who lack professional knowledge, intuitive data cannot make correct sports planning. Therefore, aiming at the problem that it is difficult for ordinary people to make correct exercise plan according to intuitive data, a personalized exercise plan generation system based on cloud computing is proposed. By analyzing the user's movement and physical data, the system uses cloud computing resources and machine learning algorithms to provide customized exercise recommendations for users. The key innovation of the research is the combination of improved random forest algorithm and reinforcement learning, while improving the performance of the algorithm on unbalanced sample sets. The results indicated that the accuracy of the improved random forest was 0.985 higher than that of the precision weighted random forest. The research algorithm was 9.04% higher on average than the original random forest algorithm and 2.71% higher than the accuracy weighted random forest algorithm. In terms of the accuracy of personalized motion scheme generation of motion software, the improved algorithm reached 95.05% at most, and its recall rate reached 83.46% at most. Compared with the existing sports software solutions, the research system can generate personalized sports programs more accurately, promote the development of the sports health industry and improve the national physical health level. The system can provide users with personalized sports suggestions, and utilize the powerful computing power of cloud computing to realize real-time processing and analysis of large-scale user data, providing users with timely sports feedback and suggestions.**

Keywords*—Cloud computing; sports; random forest algorithm; personalization; system

I. Introduction

Nowadays, China's economic level is constantly improving, but the increasing cost of living has also had a negative impact on the physical health of its citizens [1]. Physical exercise can maintain the daily health of human body. Studies have shown that taking appropriate exercise methods and maintaining appropriate amount of exercise can improve health level [2]. The increase of people's attention has also promoted the growth of the scale of the sports health industry. At present, the domestic outdoor sports industry market has great room for growth. At the same time, with the deep popularization of the Internet, China's online sports health market is also growing. The huge user base brings a massive amount of information data. Therefore, how to mine the user characteristic information hidden in these data, analyze the user's body development trend, and provide more reasonable suggestions is the key research direction of sports health application in the intelligent era. Zheng W et al. proposed a programming practice recommendation algorithm based on knowledge structure tree (KSTER). This algorithm was predicated on the quantification of students' cognitive level and knowledge needs, the construction of a KSTER, and the combination of a learning goal prediction method to realize personalized programming practice recommendation. Experiments demonstrated the superiority of this algorithm in terms of precision and recall ratio, as well as its effective improvement of students' learning efficiency [3]. Netz Y et al. evaluated a new tool that uses smartphone sensors to remotely assess and deliver personalized exercise plans. Fifty-two healthy older volunteers participated in the test, which showed significant improvements in strength, flexibility, and balance. Research confirmed the potential of this tool to deliver personalized exercise programs in a home setting [4]. Due to the difference in human body constitution, everyone has a large difference in the exercise methods and amount of exercise. Similar to medical consultation, customized exercise recommendations based on the user's physical characteristics have formed the concept of exercise prescription. Cloud computing integrates computing and storage into a scalable resource pool to improve resource utilization [5]. This study aims to overcome the shortcomings of the random forest (RF) algorithm and improve the classification performance and accuracy of unbalanced sample sets by introducing weighting factors and optimizing the voting mechanism based on the traditional RF algorithm. By collecting users' movement and physical sign data, cloud computing and machine learning algorithms are used to generate a sports health cloud platform for sports programs, and promote the concept of sports health. The innovation of research methods is mainly reflected in five aspects. First, cloud computing integration. The cloud computing platform used integrates computing and storage resources, improving the processing capability and real-time feedback effect of large-scale data. Second, the RF is optimized. The traditional RF algorithm is improved by adding weight factors to improve the classification performance on unbalanced data sets. Third, reinforcement learning application. Reinforcement learning strategies are used to optimize exercise plan generation, dynamically adjust plans based on user feedback, and improve user experience. Fourth, it provides a personalized exercise plan based on the user's physique and goals, and realizes an innovative breakthrough in exercise software. Fifth, compared with traditional algorithms, the advantages of the improved algorithm in accuracy rate, recall

rate and F1 score are verified.

The research mainly includes six sections. Section I introduces the background and significance of the research on cloud platform and intelligent motion system. Section II summarizes the intelligent sports software, mainly for the detailed analysis of the achievements of the current domestic and foreign experts and scholars in the direction of sports health assistance system design. Section III is the research method, which is mainly divided into two sections. In subsection one, the research proposes the software scheme system design. In subsection two, the research proposes a personalized motion scheme generation system for motion software based on cloud computing and improved RF algorithm. Section IV is the performance analysis of the personalized motion scheme generation system of sports software. Discussion is given in Section V. Section VI summarizes the research methods and results analysis. At the same time, the shortcomings of research methods and future research directions are proposed.

II. Related Work

Sports can maintain the daily health of human body. A large number of studies have shown that taking appropriate exercise can improve people's health level. Yang C and others proposed to monitor sports energy consumption through cloud services and the Internet of Things and establish an effective data model for difficult operation and implementation of the method of detecting sports energy consumption. Research showed that the detection error of this method for sports energy consumption was less than 2% [6]. In order to promote the clinical application of metabolomics, Castelli F. et al. addressed problems such as insufficient standardization of data generation, low metabolite recognition rate, and complex data processing. These challenges affected the interoperability and reusability of data. In addition, metabolomics outputs were complex and expensive, and features needed to be simplified for on-site applications [7]. Xie D et al. designed a wearable energy-saving fitness tracking system for health monitoring of athletes based on the integrated of deep learning. The algorithm used smart phone applications to track the steps of using Internet of Things technology. Research showed that energy efficiency system performance was improved [8]. Virtual reality technology integrated digital image processing, computer, artificial intelligence, multimedia, sensors, and other information technologies to provide support for the creation and experience of virtual worlds. Its combination with cultural relic protection created a new field. Ling Z et al. explored the personalized health care pavilion display system based on VR and deep learning. A new computational model was designed to improve the system performance. Its effect was verified through application scenario testing [9].

To understand the cognition of high school physical education teachers to the rules of basketball competition, Saputro A et al. used data collection technology and descriptive research methods to investigate the high school physical education teachers in their local area. The results showed that most physical education teachers had a higher cognition of basketball game rules [10]. Men Y et al. proposed a motion recognition algorithm to improve prediction efficiency. A database model was constructed to analyze sports training and competitions. The results showed that this research improved the prediction performance of vicious energy motion [11]. Wang L et al. established the SVM model. Based on texture feature extraction method and in-depth analysis of non-downsampling contour wave transformation, an intelligent motion feature recognition system was constructed. The research showed that the system effectively and accurately extracted and recognized motion features [12]. Sun C M D et al. introduced time control factor to design classification strategy when using support vector machine for classification. Experiments showed that the research method achieved fast target discrimination when the ambient brightness changed, and improved recognition accuracy of complex human posture [13]. Wu B et al. proposed a motion assistant system to identify, query and analyze motion features through deep learning, aiming at the low detection performance of target detection technology in complex background. The experiment showed that the system had good performance in recognizing and classifying human motion behavior characteristics [14].

To sum up, the current research and market application of sports health applications lack effective user data. The application research of data algorithm in sports health utilizes the data uploaded by the sports health monitoring system. However, with the popularity of intelligent sports devices such as smart bracelets, the scale of users' motion data is growing. Cloud computing has powerful computing power, storage capacity and other advantages. Therefore, this study combines cloud computing with machine learning to build a cloud platform. The system uses the improved RF algorithm to solve the unbalance of sample data. Second, the powerful processing power of cloud computing is used to analyze the user's motion data in real time and provide personalized suggestions through machine learning algorithms to ensure the accuracy of the motion scheme.

III. Personalized Motion Scheme Generation System Design and Research for Motion Software Based on Cloud Computing

In this study, an improved RF algorithm is used to generate a personalized motion scheme based on the user's motion and physical data. It comprehensively considers individual differences such as the user's age, health status and medical background. The machine learning classification algorithm is used to accurately identify individual characteristics through a large number of physical test data. The improved algorithm uses a weighted voting mechanism to optimize the classification effect of the decision tree, thus improving the performance of the model when dealing with unbalanced sample sets. The system has adaptive capabilities and can process user data in real time. The high-performance computing capabilities of cloud computing platforms can also be used to dynamically adjust exercise suggestions to ensure personalized and adaptive solutions. Through intelligent analysis and real-time feedback, the system is able to provide users with highly personalized exercise plans that take into account individual differences.

A. Software System Scheme Design

In traditional enterprise software development, computer hardware infrastructure is an important part. Some small and

medium-sized enterprises need to purchase physical machine servers with high cost from server manufacturers [15]. However, large software enterprises or server manufacturers have the ability to manufacture large-scale physical machine servers. Therefore, computing and storage devices will be redundant or idle [16]. Cloud computing provides computing resources over the Internet, giving users remote access to data storage, computing power, and applications. Cloud service types typically include infrastructure as a service (IaaS), platform as a Service (PaaS), and software as a service (SaaS). IaaS provides virtualized hardware resources. PaaS supports application development and management. SaaS provides standardized application services. Major cloud providers such as AWS and Microsoft Azure offer a wide range of services for applications such as artificial intelligence, the Internet of Things. To ensure data security and privacy, these services use measures such as data backup, encrypted transmission, and access control, and comply with regulations such as GDPR. Cloud computing not only improves data analysis capabilities, but also provides personalized solutions while ensuring compliance. In terms of usage mode, the cloud computing service users use is to obtain the service provider's storage hardware, underlying network, storage space, and other resources through remote technology. Fig. 1 shows the conceptual model of cloud computing [17].

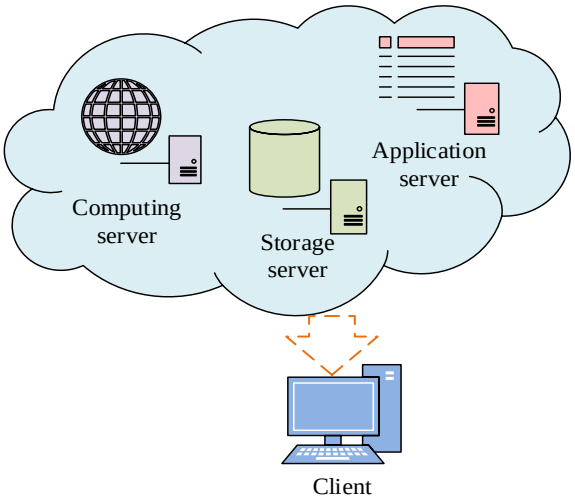

Fig. 1. Conceptual model of cloud computing.

In Fig. 1, cloud computing includes two parts, cloud and terminal. Cloud refers to the collection of network, storage, service and security devices. Cloud boundary is determined by the size of various hardware devices. Terminals refer to terminal devices that can connect to the cloud and help users access and use cloud computing services, as well as various intelligent devices with networking capabilities. The architecture of cloud computing system has three layers, namely core service, service management and user access [18]. The role of the core service is to virtualize the software and hardware so that user services have better performance in terms of reliability, availability, and other aspects to meet the diverse high-quality service needs of users. The service management layer guarantees the stability, reliability and high quality of the cloud platform during operation. The user access function is to provide the user access interface. The cloud platform mainly includes cloud server, database and other components. The main function of the server is to communicate with the client and perform business functions. The research platform is to accurately generate motion schemes for users, and there are many commonly used classification algorithms. RF is is mainly used for regression and classification. The algorithm can freely choose the type of decision tree, and investigates the use of classification and regression tree (CART) as the generation model of a single RF classifier. CART uses GINI as feature selection index, as shown in Formula (1) [19].

$$GINI(P)=\sum_{i=1}^{k} p_i(1-p_i) \tag{1}$$

In Formula (1), k represents the number of samples classified. p_i is the probability that the sample belongs to this category. For a given sample set D, the expression is shown in Formula (2).

$$GINI(D)=1-\sum_{k=1}^{k}\left(\frac{|d_k|}{D}\right)^2 \tag{2}$$

In Formula (2), d_k represents the classification of samples in D. CART is a binary tree. If the training set is divided into two categories because of A attributes, the expression of GINI is shown in Formula (3).

$$GINI(D,A)=\frac{D_1}{D}GINI(D_1)+\frac{D_2}{D}GINI(D_2) \tag{3}$$

The classification result of a RF is determined by the classification pattern of all decision trees, as shown in Formula (4).

$$I(x)=\arg\max_{Y}\sum_{i=1}^{k} I(h_i(x)=y) \tag{4}$$

In Formula (4), y represents the classification category. $h_i(x)$ is the tree of decision tree. Y represents the classification result of a single decision tree. The cloud computing platform is a SaaS service. Its main function is to obtain, store and process data such as web pages and intelligent terminals through servers in Alibaba Cloud [20]. Cloud platform system architecture includes user, data transmission, control, business logic, and data. The user layer is a channel for human-computer interaction and data upload. App and web pages can also be used as human-computer interaction terminals. The app can accept the data uploaded by the body feature sensor, while the web can allow users to upload manually entered data. Data transmission transmits data through the Internet. Control uses Nginx as the front-end server for handling high load access. The business logic is the core platform structure layer, which is realized by running the code of each business function module through the Tomcat server cluster. Data function response operation requirements, mainly

through the Redis database and MySQL database, storing physique data, motion data, and scheme library. The hybrid replication is used to achieve data synchronization in the master and slave databases, as shown in Fig. 2.

In Fig. 2, first of all, the main node writes the corresponding SQL statement to the binary text before each transaction completes data update. After the transaction is completed, the main node submits the transaction through the database storage engine. Then, the slave node is connected to the master node by the I/O process, and the slave node determines the initial location of the required binary code. After the master node accepts the request, it parses the request from the slave node. Then, the log message after reading the binary file at that location according to the bit given in the request is published in the I/O process of the node. The main contents of the log information are the file name and the end position of the file. This position is defaulted to the start position of the next request. After the master node returns the data to the slave node, the slave node adds the content to the end of the relay file in order. Meanwhile, the returned file description information is added to the master info file. The slave node detects the newly added files through the SQL thread, and processes the SQL statements of the corresponding nodes, thus realizing the master slave data replication.

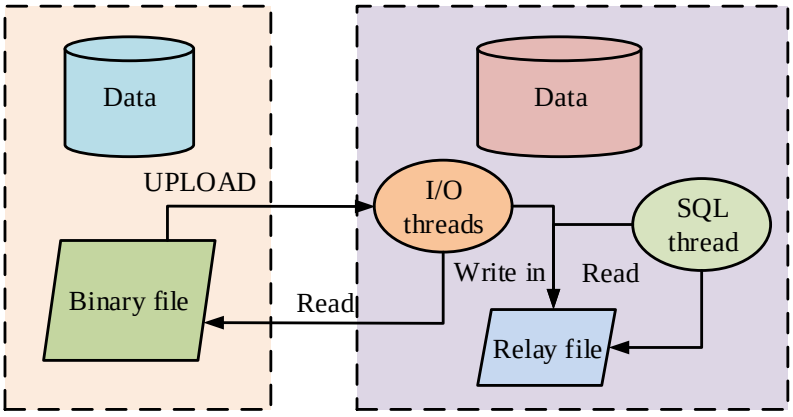

Fig. 2. Master / Slave synchronization execution process.

B. *Design of Personalized Motion Scheme Generation System for Motion Software Based on Cloud Computing and Improved Random Forest Algorithm*

Exercise is an effective way to keep healthy. However, exercise method and amount suitable for everyone are different. Therefore, the cloud computing platform provides users with reasonable online training programs and plays an auxiliary role in sports and fitness. Although the RF classification effect and generalization ability are good, the algorithm also shows an over-fitting phenomenon with too much noise. In addition, the performance of the algorithm under unbalanced sample sets needs to be improved. Therefore, the research improves RF shortcomings, and uses the improved algorithm as the core function of the cloud platform motion scheme generation algorithm. The research mainly improves RF from two aspects: improving the voting mechanism and improving the performance of the RF algorithm in unbalanced sample set. For RF, the input value is set to X and the output value is set to Y. Then, there is a definable interval function $mg(X,Y)$, as shown in Formula (5) [21].

$$mg\left(X,Y\right)=P_{\theta}\left(h\left(X,\theta\right)=Y\right)-\max_{j\neq Y}P_{\theta}\left(h\left(X,\theta\right)=j\right) \tag{5}$$

In formula (5), θ represents the random input value formed in the random selection of training sets from a single subtree in the forest. $h\left(X,\theta\right)$ represents the output value. RF classification intensity is the expected value of the interval function. The calculation expression is shown in Formula (6).

$$S=E_{X,Y}\left(mg\left(X,Y\right)\right) \tag{6}$$

The generalization error of RF is shown in Formula (7).

$$PE^{*}\leq\overline{\rho}\left(1-S^{2}\right)/S^{2} \tag{7}$$

In formula (7), S indicates the classification strength. $\overline{\rho}$ represents the average similarity between decision trees. If the performance of RF is to be improved, its error should be reduced. The classification result function of RF is improved by introducing weight factor, as shown in Formula (8).

$$I\left(x\right)=\arg\max_{Y}\sum_{i=1}^{k}W_{i}*I\left(h_{i}\left(x\right)=y\right) \tag{8}$$

The probability of RF classification for any result α is shown in Formula (9).

$$P_{\theta}\left(h\left(X,\theta\right)=\alpha\right)=\frac{W_{\alpha}}{W_{t}} \tag{9}$$

In Formula (9), W_{α} is the total weight of the α decision tree. W_{t} represents the total weight of all decision trees in the forest. The interval function of RF can be obtained, as shown in Formula (10).

$$mg(X,Y)=\frac{W_Y}{W_t}-\frac{\arg\max_{j\neq Y} W_j}{W_t}=\frac{W_Y}{W_t}-\frac{W_\beta}{W_t} \tag{10}$$

It is assumed that the tree weights of the same classification result are the same, then Formula (11) can be obtained.

$$w_Y * N_Y > w_\beta * N_\beta \tag{11}$$

In Formula (11), N_Y represents the number of decision trees with classification results. Y represents the decision tree classified as the weight of other results and the maximum result. If the formula does not hold, formula (12) is obtained.

$$\frac{N_Y}{N_\beta}>\frac{w_\beta}{w_Y} \tag{12}$$

When the voting mode of RF is equal voting, there is $w_Y = w_\beta$, as shown in Formula (13).

$$\frac{N_Y}{N_\beta}>1 \tag{13}$$

When voting with equal rights, $N_Y > N_\beta$ can get the correct classification results. When different weights are used, if the weight of the incorrectly classified tree is less than that of the correctly classified tree, Formula (12) exists.

$$\frac{N_Y}{N_\beta}>\lambda, \lambda<1 \tag{14}$$

In Formula (12), in classification, the number of trees with correct classification results can be less than the number of trees with wrong classification results. Meanwhile, compared with equal voting, when correct and wrong trees in the classification result remains the same, the weight of the correct tree in RF classification is higher, indicating that the weight of the incorrect tree is smaller. Good classification performance indicates smaller generalization error. Fig. 3 shows the steps of the improved RF algorithm after adding weight factors.

In Fig. 3, the improved RF algorithm uses test set pairs to test after the forest is constructed according to the original algorithm flow. The AUC value of each decision tree in RF is obtained and used as the corresponding weight value of classification result of each subtree. Finally, the classification results are obtained by weighted voting. Formula (15) displays the classification results of the improved RF.

$$I(x)=\arg\max_Y \sum_{i=1}^{k} weight_{AUC}(i) * I(h_i(x)=y) \tag{15}$$

To satisfy high traffic, stability and other access, a sports health cloud platform is built on Alibaba Cloud using frameworks and component technologies such as Springboot, React, Nginx, MySQL, and Redis. The database module of the platform is very critical, mainly composed of Redis database and MySQL database. Its main function is to provide data storage, query, modification and other operations. Fig. 4 displays the workflow of the database module.

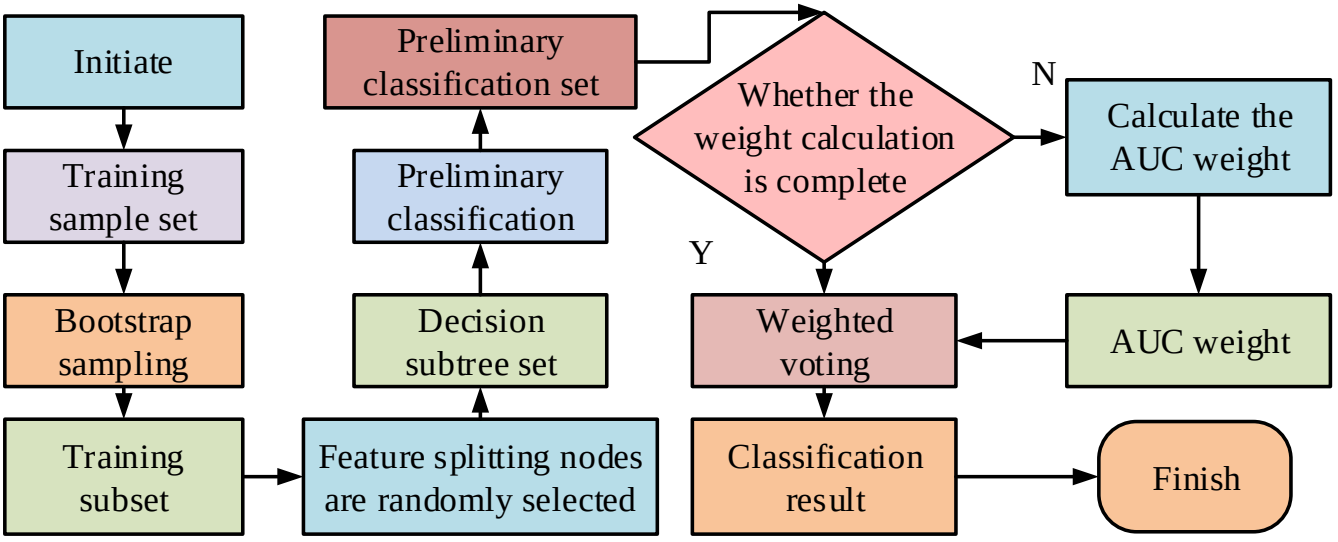

Fig. 3. Steps of the improved RF algorithm.

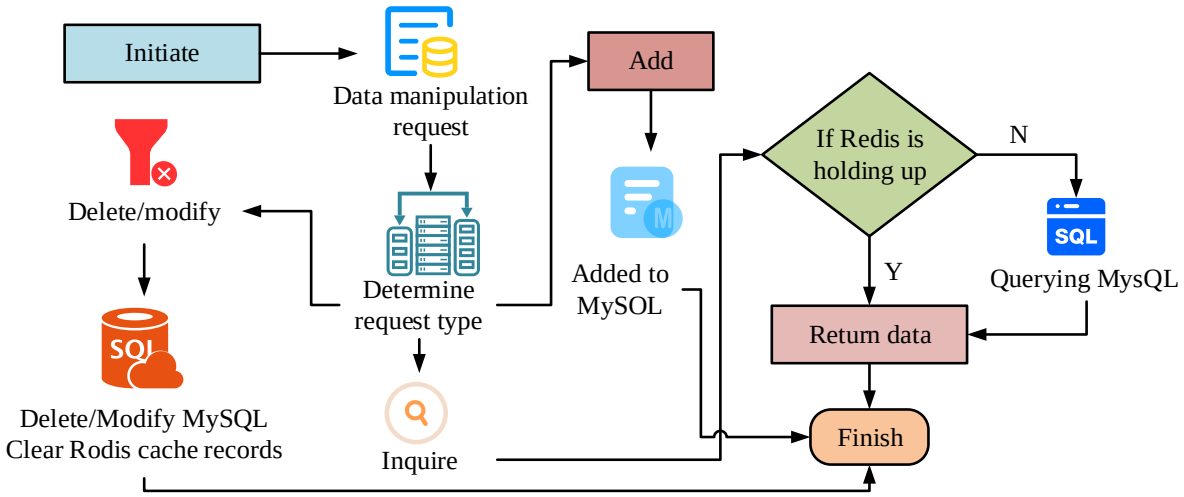

Fig. 4. Workflow of the database module.

In Fig. 4, in the case of high concurrent connections, since MySQL is a traditional relational database, all operations are completed on the hard disk. Therefore, the efficiency of IO is very low, and the database must be used as the buffer. The workflow of the database module is as follows. First, when the user requests a database query, ask whether there is corresponding data in the Redis database. If it exists, it will return directly. If it does not exist, it will query the MySQL database and cache the Redis database after returning data. When the user requests to add an operation, it directly executes the add task in the MySQL database. When the client performs delete and update operations, the MySQL database records are updated directly. If there is a corresponding cache in the Redis database, it is deleted directly. The user's current prescription display module is used to display the user's current exercise prescription. Fig. 5 displays the workflow of the current scheme.

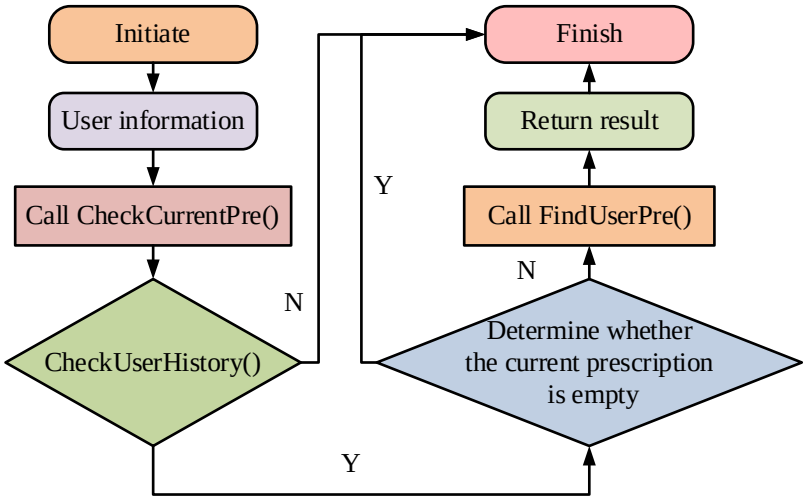

Fig. 5. Workflow in the current scenario.

In Fig. 5, the user only needs to press the current scheme key to submit the request and user information to the platform. After receiving the user's request and information, the platform calls the overall packaging function of *CheckCurrentPre*( ). First, the function *CheckUserHistory*() is called to check whether the user's history file exists. If it exists, whether the ID number of the ID item exe_ Pre_ is empty is queried. If it does not exist or exe_ pre_ id item is empty, the query failure information is returned. If the user record exists and exe_ pre_ id item is not empty, the FindUserPre function is called. According to the motion scheme ID number, the corresponding content is retrieved from the exercise plan library and sent back to the homepage for display.

IV. Performance Experiment Analysis of Personalized Motion Scheme Generation System of Sports Software

The personalized motion scheme generation system uses an enhanced RF algorithm, combines cloud computing resources and machine learning technology. The system analyzes the user's motion and physical data to provide personalized motion recommendations through improved RF and reinforcement learning. The key innovation is the enhancement of the RF algorithm to improve the performance of unbalanced sample sets. The system is trained and verified using a dataset of physical fitness tests in colleges and universities, including multiple test data from male and female students. The cloud

platform is implemented by Springboot, React and other technologies. The database module is composed of Redis and MySQL, which supports high concurrency and data caching to ensure low latency and high scalability of the system. The constructed platform is to accurately generate personalized sports programs for users. In order to complete the exercise program database, the experiment collected the physical test data of a university from 2017 to 2022, with a total of 18162 items. There are 9064 for boys and 9098 for girls. Because the data size of this study cannot meet the requirements of deep neural network, the algorithms used to achieve the core functions in the experiment are mainly compared and selected in the traditional machine learning classification algorithms. The performance comparison between RF and other classification algorithms is shown in Fig. 6.

In Fig. 6, in terms of accuracy, RF algorithm value is higher than other four algorithms, which is 87.2%. In terms of recall rate, the ROC value of RF algorithm is still higher than traditional classification methods, which is 0.957. In terms of F1 score, the RF algorithm is 0.861. This algorithm still has a higher F1 score than traditional classification methods such as KNN, SVM, ANN, and decision trees. In conclusion, the RF algorithm has better classification effect than traditional classification algorithms. The experimental test environment is Python 3.6+Sklearm, Intel (R) i5-6300HQCPU@2 Platform. The experimental data are divided into balanced sample set and unbalanced sample set. The specific sample set is shown below.

The total number of samples is 20, with 3 imbalanced negative samples and 10 balanced samples in the sample set. As shown in Fig. 7, the AUC value represents the classification performance under different balance levels of sample sets.

From Fig. 7 (a), when the number of negative categories mistakenly classified as positive categories increases, the AUC value decreases. Therefore, the AUC value has a great impact on the classification effect under the unbalanced sample size. In Fig. 7 (b), AUC decreases as the number of negative classes wrongly classified into positive classes increases. To sum up, AUC value can be used to evaluate the classification effect of algorithms under both balanced and unbalanced sample sets. In addition, it can also be used as a weight factor in the voting process of the improved RF. Figure 8 displays the influence result of RF subtrees.

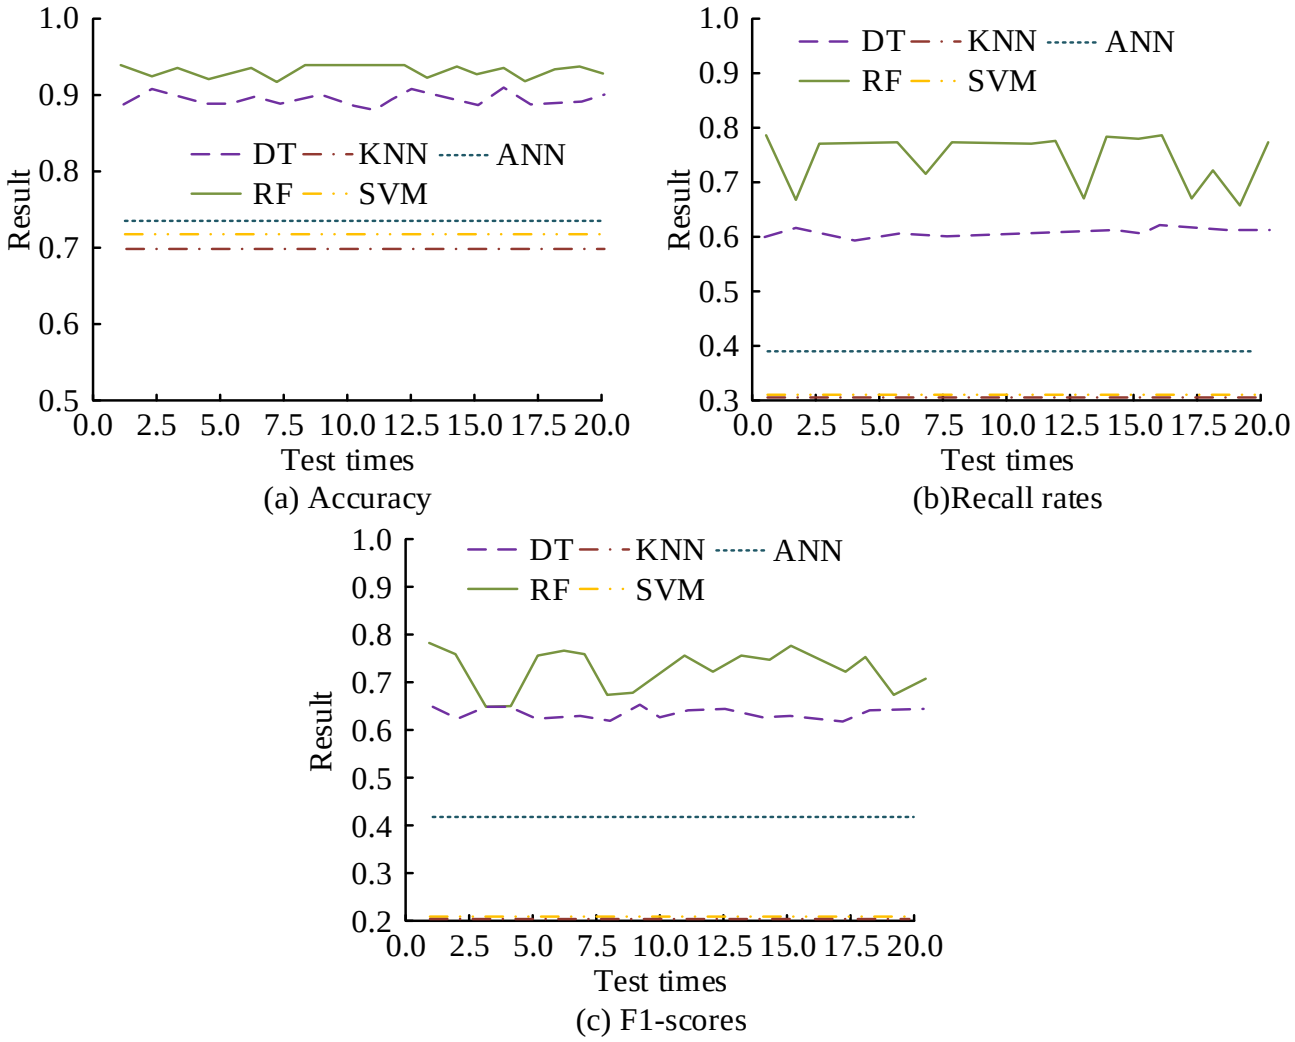

Fig. 6. Performance comparison results of five classification algorithms.

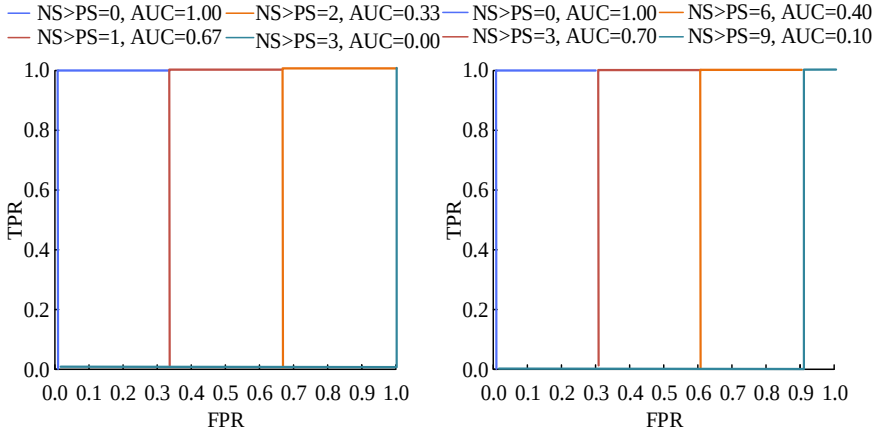
TABLE I. EXPERIMENTAL SAMPLE SET

Sample set		Sample size	Characteristic dimension	Positive sample proposal
Balanced sample set	Banana	5300	2	55.2
	data_banknote_authentication	1371	5	55.5
	Spambase	4600	57	60.6
	Vehicle	846	18	50
Unbal-anced sample set	Ecoli3	336	35	89.6
	Yeast3	1484	8	71.4
	Abalone	580	8	97.7
	Poker_8_9	1459	10	98.3



(a) AUC value of classification performance change under unbalanced sample set

(b) AUC value of classification performance change under balanced sample set

Fig. 7. AUC values representing classification performance in sample sets with different levels of balance.

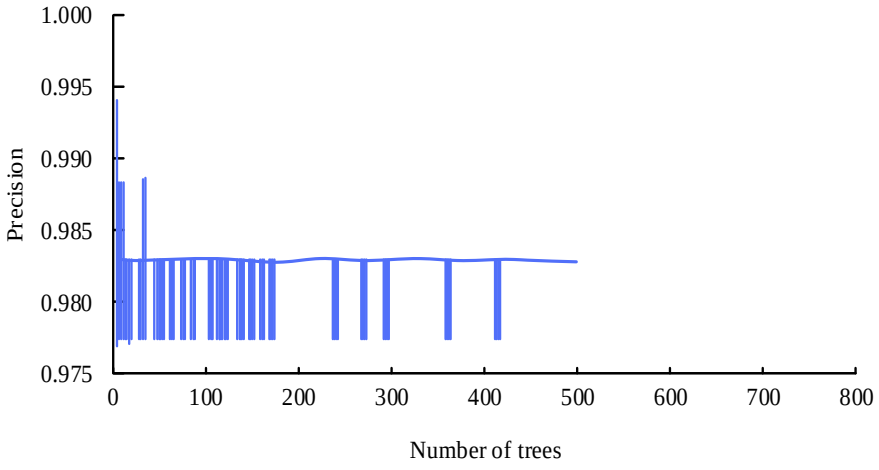


Fig. 8. Influence results of random forest subtrees.

In Fig. 8, after processing with the original RF, Precision gradually converges with the increase of trees. When the subtree is greater than 200, they entered a stable state. Therefore, the number of subtrees in each forest is considered to be 200. Due to the randomness in constructing RF, each algorithm is tested 20 times and then stable values are taken. The experiment uses Recall, Specificity, and G-mean evaluation algorithms to process the results of unbalanced sample sets. Fig. 9 shows experimental result of balanced sample set.

As shown in Fig. 9, in data_ Banknote_authentication dataset, the accuracy of improved RF is 0.985 higher. The precision, recall and F1 score of this algorithm are higher than those of the other two algorithms, with values of 0.977, 0.988, and 0.985. On Spambase, the improved RF algorithm had higher values than the other two algorithms, which are 0.947, 0.977, 0.988, and 0.985, respectively. On Bnana, the improved RF algorithm outperforms the other two algorithms, which are 0.866, 0.898, 0.802, and 0.832, respectively. On vehicle, the improved RF algorithm outperforms the other two algorithms, which is 0.771, 0.763, 0.784, and 0.769, respectively. In conclusion, when the sample set is balanced, the performance of improved RF has certain advantages. Fig. 10 shows the experimental results of an imbalanced sample set.

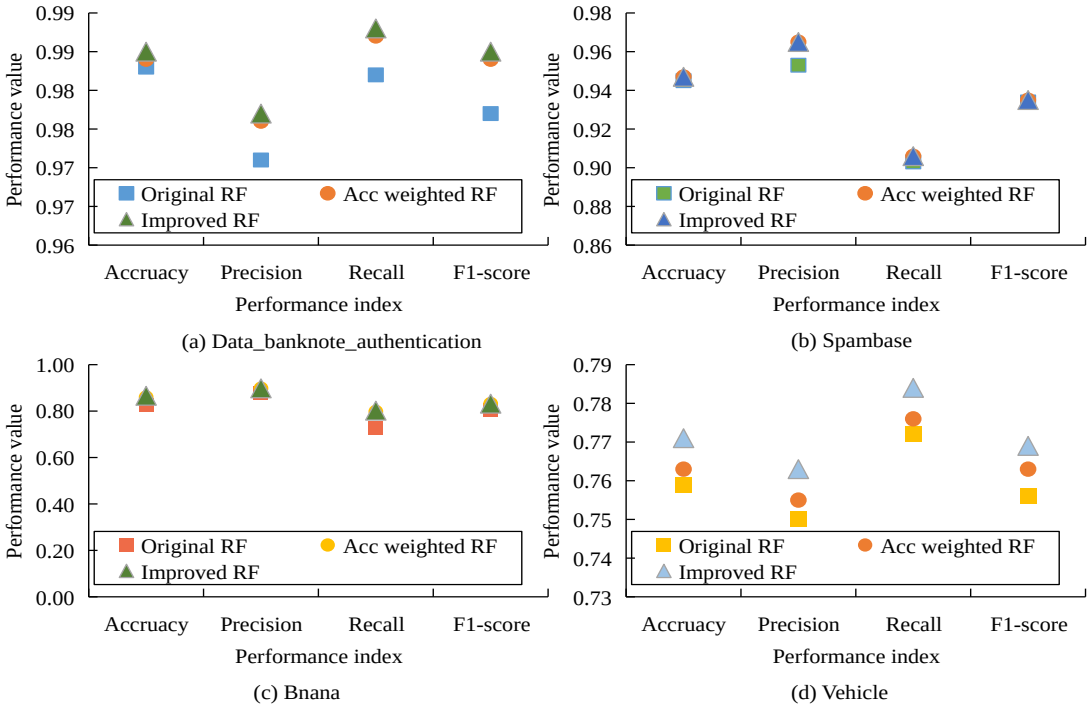

Fig. 9. Experimental results of balanced sample set and unbalanced sample set.

From Fig. 10, the recall, specificity, and G-mean of improved RF are higher than those of the other two algorithms in the Yeast 3 dataset, with values of 0.473, 0.945, and 0.668 respectively. In Ecoli 3, the recall, specificity and G-mean of improved RF are higher than those of the other two algorithms, with values of 0.485, 0.969, and 0.685. In Abalone, the recall, specificity, and G-mean of improved RF are higher than those of the other two algorithms, and their values are 0.994, 0.666, and 0.814, respectively. In Poker_8_9 data set, the recall, specificity, and G-mean of improved RF are higher than those of the other two algorithms, with values of 0.952, 1.0, and 0.975, respectively. To sum up, when the sample set is unbalanced, its specificity representing the accuracy of minority classification is increased by 33.4%, and the comprehensive performance index G-mean is increased by 24.01%. The experimental process is to import the data from the training set into the improved RF algorithm classifier, and train and construct the core function algorithm model. Fig. 11 shows performance test results of sports personalization generation scheme obtained from 20 training sessions.

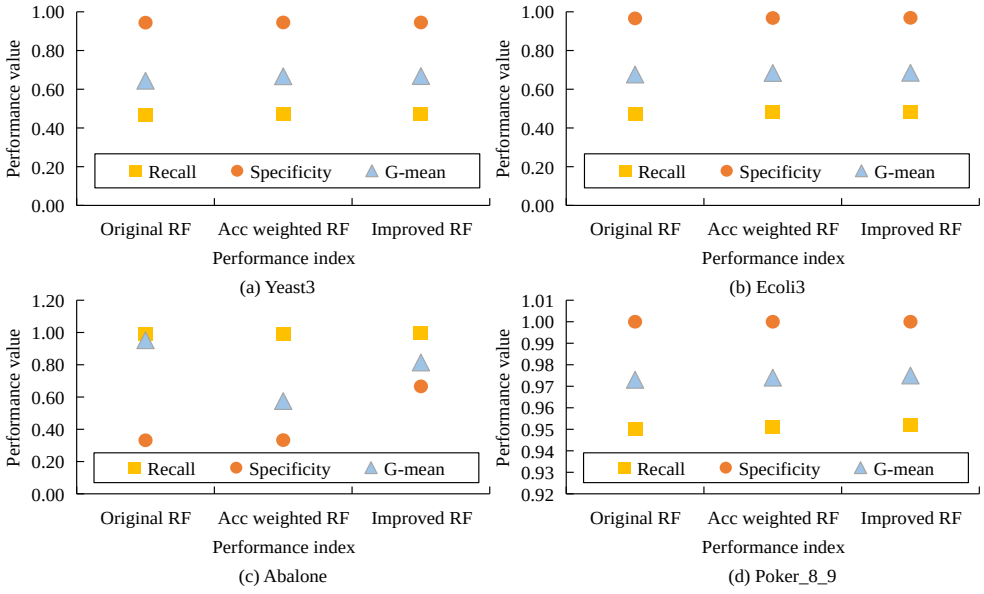

Fig. 10. Experimental results of non-balanced sample set.

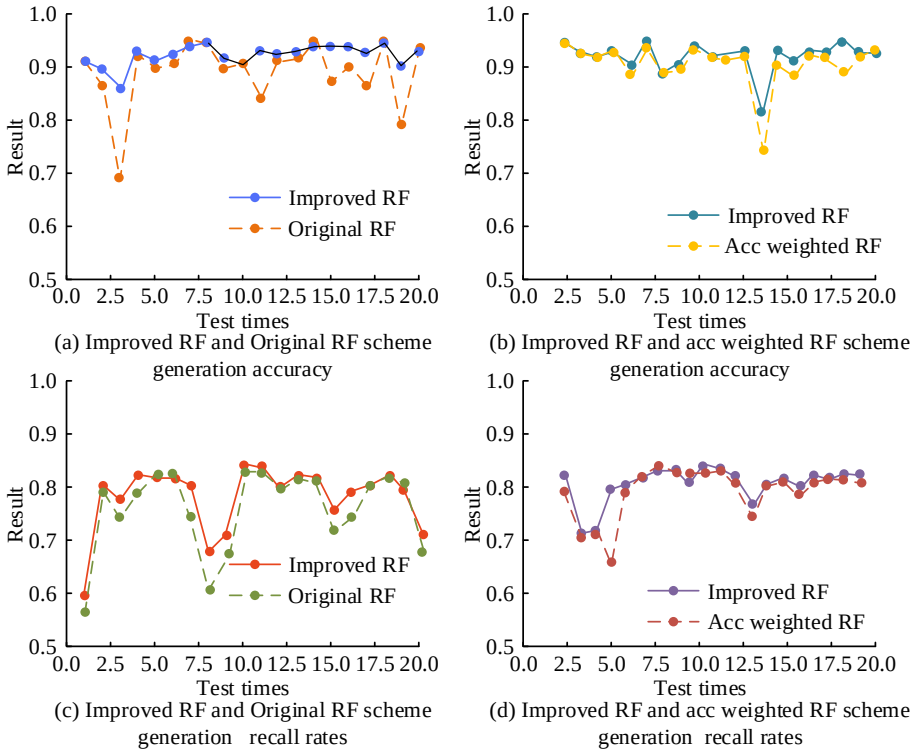

Fig. 11. Performance test results of the motion personalization generation scheme.

In Fig. 11 (a), the accuracy curve generated by the research algorithm is 13 times higher. The highest generation accuracy of the improved algorithm increases by 18.27%. In Fig. 11 (b), the accuracy of the research algorithm is higher than that of the weighted RF for 12 times, with the maximum increase of 4%. The research algorithm is 9.04% higher than the original RF on average, and 2.71% higher than the weighted RF algorithm on average. In Fig. 11 (c), the recall rate of improved algorithm is 13.43% higher than that of the original RF. In Fig. 11 (d), in terms of recall rate, the research algorithm is 7.32% higher than that of the original RF, and 2.68% higher than that of the weighted RF. To sum up, in terms of the accuracy of personalized motion scheme generation of motion software, the improved algorithm reaches 95.05% at most, and its recall rate reaches 83.46% at most.

The ACTIVITYNET Dataset is a large-scale video dataset used to study motor behavior recognition and personalized training plan generation. Video data contains a variety of sports activities, which can be used to analyze and generate personalized sports programs. To more comprehensively verify the performance of the improved RF algorithm proposed in this study in a personalized motion scheme generation system, the research method is compared with several other similar methods on the ACTIVITYNET dataset. The specific results are presented in Table II.

TABLE II. PERFORMANCE OF EACH METHOD'S PERSONALIZED MOTION SCHEME GENERATION ON THE ACTIVITYNET DATASET

Indicators/methods	Traditional RF	Weighted RF	Literature [6]	Deep learning-based method	Literature [11]	Literature [13]	Research method
Accuracy (%)	0.854	0.879	80.5	0.892	85.2	88.1	90.5
Recall	0.841	0.863		0.876			
F1 score	0.847	0.870	0.78	0.884	0.83	0.86	0.91
Computational efficiency (frames per second)	28.500	27.800	30	30.000	25	20	35
Resource consumption (CPU%)	45	42	40	38	35	50	30
Resource consumption (Memory MB)	1300	1250	1200	1400	1000	1500	800

Table II compares the performance of the different methods on the ACTIVITYNET dataset. The research method performs best with an accuracy of 90.5%, an F1 score of 0.91, and a computational efficiency of 35 frames per second. In terms of resource consumption, CPU usage is 30% and memory consumption is 800MB, both of which are the lowest. Compared with traditional RF, weighted RF, and the methods in literature [6], [11], and [13], the research method shows significant advantages in all performance indicators, especially in terms of accuracy, F1 score, and resource consumption. This

indicates that the research method has excellent performance and high resource utilization efficiency in the task of personalized motion plan generation.

V. Discussion

This study designed a personalized training plan generation system based on cloud computing and adopted the improved random forest algorithm to achieve in-depth analysis of users' training and physiological data. The results showed that the accuracy and recall rate of the improved algorithm reached 95.05% and 83.46%, respectively. Compared with the exercise energy consumption monitoring methods based on Internet of Things and cloud computing in the literature [6], this study not only focused on energy consumption monitoring, but also focused on providing personalized exercise recommendations through user data. The SVM-based model proposed in literature [11] and [13] performed well in feature recognition, but this study further improved the performance of random forest algorithm on unbalanced sample sets by introducing weight factors and optimizing the voting mechanism, which may be due to the improved algorithm's better handling of sample imbalance, thus improving the accuracy of classification. In addition, literature [8] and [9] discussed the application of deep learning in health monitoring and virtual reality technology. Although the deep learning method was not employed directly in this study, reinforcement learning strategies were utilized to optimize the generation of motion plans and dynamically adjust the plans to adapt to user feedback. This approach simulated the adaptive characteristics of the deep learning model to a certain extent. The enhanced algorithm's improved performance may be attributed to its more efficient capture and utilization of data characteristics, as well as its ability to respond promptly to user feedback, which were pivotal in achieving personalized motion scheme generation.

VI. Conclusion

In view of the high demand of current users for personalized sports advice services in sports health applications, a sports health cloud platform system using cloud computing and improved RF algorithm was designed by combining cloud computing and machine learning algorithms. Experiments showed that in data_banknote_authentication dataset, the accuracy of the improved RF was 0.985 higher. The precision, recall and F1 score of this algorithm were higher than those of the other two algorithms. Similarly, in the Spambase dataset, the Vehicle dataset, and the Bnana dataset, the scores of the research algorithms were higher than the other two algorithms. In conclusion, when the sample set was balanced, improved RF performance had certain advantages. In the Yeast 3 dataset, Ecoli 3 dataset, Abalone dataset, Poker_ 8_ 9 dataset, the recall, specificity and G-mean of improved RF were higher than those of the other two algorithms. When the sample set was unbalanced, the specificity representing the accuracy of minority classification increased by 33.4%, and the comprehensive classification performance index G-mean increased by 24.01%. The research algorithm was 9.04% higher than the original RF on average, and 2.71% higher than the accuracy weighted RF algorithm on average. In terms of the accuracy of personalized motion scheme generation of motion software, the improved algorithm reached 95.05% at most, and its recall rate reached 83.46% at most. This study reduces the dependence on cloud computing resources by improving the RF algorithm, and improves the performance in resource-constrained environments. The system design focuses on modularity and scalability, enabling the rapid integration of new features through plug-ins or services, while optimizing the interface and interaction design to ensure ease of use and accessibility. The initial investment of cloud-based platform is large, but it can reduce maintenance costs and improve resource utilization in the long run. Small users can reduce upfront investment and hardware expenditure through the pay-as-you-go model, lowering the barrier to entry. However, data security and privacy protection need to be taken seriously and may bring additional costs. Despite the flexibility and economics of cloud platforms, as data volumes and users increase, subscription costs may rise as data volume and users increase, requiring small organizations to address the challenges of complex architecture and security management. Therefore, the cloud platform is feasible for small users in the short term, but the long-term cost and technical requirements need to be evaluated. The research has achieved good results. As the number of users and the amount of data increase, how to ensure the stability and accuracy of the algorithm is a challenge. Future research must solve the adaptability of the algorithm to large data sets and improve the generalization ability of the algorithm. In addition, the integrated application of advanced algorithms such as deep learning will further enhance the intelligent level of personalized motion pattern generation. At the same time, research should focus on user privacy and data security to ensure the confidentiality of user information. The exploration of cross-platform data sharing mechanisms to realize data interoperability between different devices and applications will also be an important direction of future research.

Enhancing Emotion Prediction in Multimedia Content Through Multi-Task Learning

Wan Fan
Department of Culture and Communication, West Anhui University, Lu'an 237000, China

***Abstract*—This study presents a robust multimodal emotion analysis model aimed at improving emotion prediction in film and television communication. Addressing challenges in modal fusion and data association, the model integrates a Transformer-based framework with multi-task learning to capture emotional associations and temporal features across various modalities. It overcomes the limitations of single-modal labels by incorporating multi-task learning, and is tested on the Cmumosi dataset using both classification and regression tasks. The model achieves strong performance, with an average absolute error of 0.70, a Pearson correlation coefficient of 0.82, and an accuracy of 47.1% in a seven-class task. In a two-class task, it achieves an accuracy and F1 score of 88.4%. Predictions for specific video segments are highly consistent with actual labels, with predicted scores of 2.15 and 1.4. This research offers a new approach to multimodal emotion analysis, providing valuable insights for film and television content creation and setting the foundation for further advancements in this area.**

***Keywords*—Multi task learning; multimodal emotion analysis; timing; transformer; attention**

I. Introduction

With the rapid development of big data and artificial intelligence technologies, the application value of multimodal sentiment analysis in the field of film and television communication has become increasingly important. However, current studies are still lacking in multimodal information fusion, temporal feature modeling, and accurate capture of emotional expressions [1-2]. For example, many studies only rely on a single modality (e.g., textual or visual) for emotion recognition, failing to take full advantage of the synergy between different modalities, resulting in limited generalization ability of the models in complex scenes. Furthermore, extant methodologies demonstrate deficiencies in their capacity to effectively address the dynamic fluctuations in multimodal data, impeding the accurate capture of emotional nuances in film and television content. The paucity of labeled data further curtails the efficacy of model training [3-5]. Consequently, the efficient fusion of multimodal information, the enhancement of time-series modeling capability, and the mitigation of label scarcity problem are pivotal issues that must be addressed in the present context. To address the above challenges, this study proposes a temporal multimodal sentiment analysis model that combines Transformer structure and multi-task learning. The model uses Transformer to deep mine temporal features, and supplements the lack of unimodal labels with a self-supervised learning strategy to improve the accuracy of sentiment recognition. Meanwhile, the study adopts a multi-level feature fusion approach to enhance the complementarity of information between different modalities to improve the model's ability to capture dynamic changes in sentiment. In addition, a multi-task learning mechanism is introduced to enhance the adaptability of the model in different scenarios. The central objective of the research is to develop a model that can effectively integrate multimodal information and accurately analyze emotional changes. This model aims to address the issue of emotion recognition in film and television communication. The research has important theoretical and practical values. Theoretically, the research combines the transformer structure and multi-task learning to improve the existing multimodal sentiment analysis methods and provide a new technical framework for temporal feature modeling and multimodal fusion. Practically, the research results can be widely applied in the fields of film and television communication, social media sentiment analysis, online education, and mental health assessment. It can provide more accurate sentiment feedback for content creators, optimize user experience, and promote the further development of sentiment computing technology. The overall structure of the research includes seven sections: The initial parts summarizes the relevant research of multi-task learning and sentiment analysis. Section II, a temporal multimodal emotion analysis model based on multi task learning is proposed. Section III is to conduct experimental analysis on the proposed model. Section IV summarizes the experimental results, points out the shortcomings of the research, Discussion is given in Section V. Finally the paper is concluded in Section VI followed by future work in Section VII.

II. Related Works

With the enhancement of computing power and the surge in data volume, multi task learning gradually demonstrates its advantages in improving model efficiency and performance. Especially in the field of sentiment analysis, multi task learning was widely applied to understand and process various data modalities such as text, audio, and video [6-7]. Many scientists and research institutions have focused on developing advanced algorithms to more accurately identify and analyze human emotions. The following will introduce some related research by scientists and scholars. Yang et al. provided a new solution of a two-stage, multi-task multimodal emotional analyzing mechanism. It adopted a two-stage training strategy for full utilization. The experiment outcomes indicated that the proposed one outperformed the current model in most metrics on both datasets, proving its usefulness [8]. Barnes et al. provided a new solution of a multi task approach for sentimental analyzing solution. This model had hierarchical neural structures, and confirmed that using negation as a multi-task training was a useful way to upgrade the sentimental

analyzing performance, which had been proven on different datasets [9]. Yu et al. provided a new solution of a label generation solution to obtain unimodal supervision and emotional differentiation information, and conducted experiments on different datasets to jointly combine the modalities of multiple tasks. It demonstrated the reliability and stability of multimodal self-generated unimodal supervision [10]. Zhang et al. provided a new solution of a multi task learning multimodal solution. This model proposed cross modal attention and cross task attention. The former was designed to simulate multimodal feature fusion, while the other was designed to capture the interaction. The experiment outcomes indicated that this method had achieved good performance on the dataset assisting sentiment recognition [11].

Mamta et al. provided a new solution of a multimodal method for deep learning. They took the utilization of cross lingual word embeddings to map two languages to a shared semantic space on different languages. The experiment indicated that the proposed one had an accuracy of 0.70 on the movie review dataset, demonstrating good performance [12]. Gao et al. proposed a negative multi-task learning framework to alleviate gender bias. The experiment outcomes indicated that the proposed one could effectively alleviate bias while maintaining the utility of the model in sentiment analysis [13]. Yin et al. provided a new solution of a multi task joint sentiment analysis model. This model used joint training of multiple tasks to obtain local feature characteristics. The results indicated that the model proposed by the research was superior to state-of-the-art models [14]. Saha et al. provided a new solution of a multimodal speech act classification approach based on multi task learning. In addition, a network was combined to capture and effectively integrate shared semantic relationships across modalities. The experiment outcomes indicated that the proposed solution enhanced multimodal speech acts by benefiting from two secondary tasks compared to single modal and single task multimodal speech act classification [15].

In summary, although multi-task learning and sentiment analysis have been widely studied by numerous domestic and foreign experts and scholars, and have been successfully applied. However, shortcomings exists in the challenges of association mining and fusion, especially in the processing of multimodal data. Existing methods often struggle to effectively integrate interactive information between different modalities such as text, audio, and visual, thereby limiting the depth and accuracy of sentiment analysis. In response to this challenge, a temporal multimodal sentiment analysis model combining multi-task learning based on the Transformer framework is proposed. By combining multimodal fusion and temporal data analysis, this model provides a new method for complex sentiment analysis, which is of great positive significance for promoting sentiment analysis and improving the accuracy of sentiment recognition in film and television content.

III. Construction of the Temporal Multimodal Emotion Analysis Model based on Multitask Learning

The study first uses the Transformer framework to extract temporal features closely related to emotions. On this basis, a multi task learning temporal multimodal emotion analysis model is further proposed, aiming to solve the insufficient single modal label issue and improve the recognition and analysis ability of complex emotional states.

A. Time Series Multimodal Emotion Analysis Model Based on Transformer

In film and television communication, multimodal sentiment analysis refers to the use of different types of data, such as text, audio, and video analysis of emotions. Compared with single-modal methods, multimodal sentiment analysis can comprehensively utilize multiple sources of information and improve the accuracy of emotion recognition. To this end, a time-series multimodal sentiment analysis model based on Transformer is proposed, which uses linguistic guided Transformer (LGT) to explore emotional relationships between different modal data. Moreover, through the soft mapping (SM) module, emotion related features are mapped to higher dimensions, effectively integrating multimodal information. This method improves the accuracy of sentiment analysis and optimizes the processing of temporal data. Fig. 1 presents the architecture of this temporal multimodal emotion analysis model.

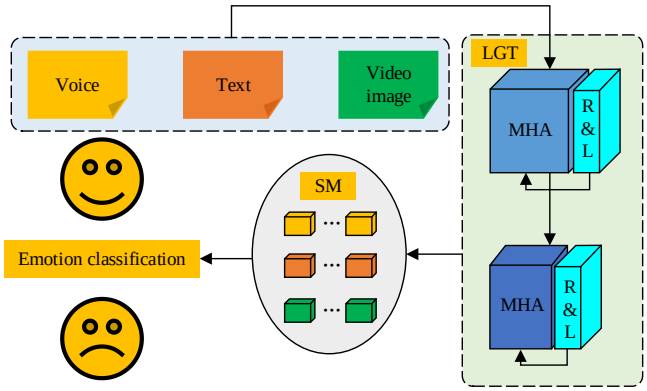

Fig. 1. Multimodal emotion analysis structure diagram.

In Fig. 1, the structure of this multimodal sentiment analysis model includes inputs in three modalities: speech, text, and video image. First, after feature extraction, each modal input is fed into the SM module, which maps the features of different modalities into a unified sentiment representation space. Then, the mapped features are fed into the multi-attention mechanism and the residual connection and normalization module to mine the correlations and affective features between different modalities. The language-guided framework further enhances affective feature extraction through the hierarchical multi-head attention (MHA) module. Finally, the model performs sentiment classification on the fused features and outputs the sentiment classification results. The traditional MHA mechanism is commonly used in machine translation, relying on parallel processing to accelerate the learning process. Its uniqueness lies in its ability to simultaneously process multiple data points without considering their temporal relationships [16-17]. The study applies this mechanism to multimodal emotion analysis to explore the mapping relationships between different modalities. Based on this logic, the LGT model is proposed, which utilizes MHA modules and forward neural networks (FNN) to explore emotional connections between different modalities. Although the modal data of this model

may not be synchronized in time, the model can process these data in parallel, effectively improving the efficiency of temporal data analysis. The architecture of LGT is shown in Fig. 2.

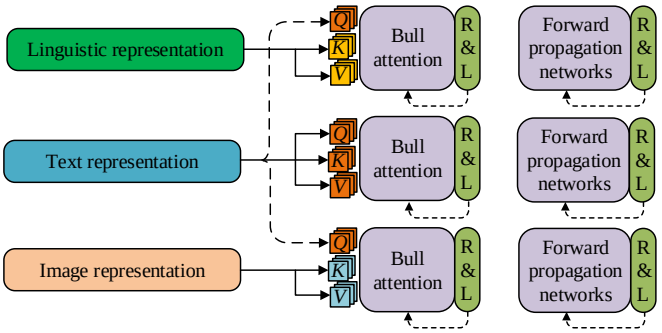

Fig. 2. Architecture diagram of LGT.

Fig. 2 shows a multimodal emotion analysis model dominated by text, supplemented by speech and image modalities. Each modal feature is independently inputted into the MHA mechanism. This setting allows emotional text data to guide speech and image data, thereby exploring the emotional connections between them. The text features are first decomposed into three vectors: query Q_l, key K_l, and value V_l, and these vectors are linearly transformed. Secondly, queries and key vectors are used to calculate attention scores. Finally, the attention score is combined with the value vector and the final result is calculated by weighted sum, as shown in Eq. (1).

$$Attention(Q_i, K_l, V_l) = soft\max((Q_l K_l^T)/\sqrt{d_k})V_l \quad (1)$$

In Eq. (1), d_k represents the dimension. This process is repeated multiple times, each representing an independent $head$. By combining the results of these heads, the final MHA output can be obtained, as shown in Eq. (2).

$$\begin{cases} head_i = Attention(Q_l W^Q, K_l W^K, V_l W^V) \\ F_{(l)} = MHA((Q_l, K_l, V_l)) = Concat(head_1, ..., head_h)W^O \end{cases} \quad (2)$$

After calculating the attention data, these results are immediately input into the FFN, aiming to explore the nonlinear connections between features and improve their expressive power. Eq. (3) provides the information of calculation process.

$$FFN = \mathrm{Re}lu(H'W^1 + b^1) + b^2 \quad (3)$$

The output of each layer of the LGT model is processed through residual connections and hierarchical normalization to ensure effective information transmission and stability, as shown in Eq. (4).

$$LayerNorm(x + Sublayer(x)) \quad (4)$$

In multimodal emotion analysis, when processing speech and image features, the MHA mechanism uses text modality as the source of the query vector. Meanwhile, keywords and truth vectors are derived from speech and image modalities. This method allows text features to introduce different representation spatial information [18], as shown in Eq. (5).

$$\begin{cases} F_{(a)} = MHA(Q_l, K_a, V_a) = Concat(head_1, ..., head_n)W^O \\ F_{(v)} = MHA(Q_l, K_v, V_v) = Concat(head_1, ..., head_n)W^O \end{cases} \quad (5)$$

In the next step of multimodal emotion analysis, the SM module is used to map the learned results of each modality to a new space, fuse them here, and then perform sentiment classification. Fig. 3 displays the schematic diagram of SM structure.

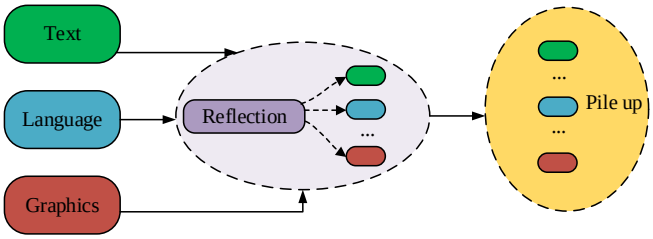

Fig. 3. SM structure diagram.

In Fig. 3, firstly, the input features of each modality, such as text, language, and graphics, enter the reflection module. It performs mapping processing on the input features and converts them into a unified representation format. It then stacks the mapped features by modality, laying the foundation for subsequent multimodal feature fusion and analysis. In the specific steps, the first step is to map the output from the FNN network to a higher dimensional space, and the calculation process is shown in Eq. (6).

$$NewMatrix = W_m M \quad (6)$$

In Eq. (6), W is the transformation matrix with a size of $2k \times k$, used to map the original matrix M to a higher dimension. Next, a vector set $\{v_i^p\}$ of $1 \times k$ size is used to perform soft attention calculation on each matrix in high-dimensional space, and these results are weighted and integrated into vector m_i to obtain the final calculation result of soft attention, as shown in Eq. (7).

$$\begin{aligned} p_i &= soft\max((v_i^p)^T (NewMatrix)) \\ SoftAttention_i(M) &= m_i = \sum_{j=0}^{N} (p_{ij} M_j) \end{aligned} \quad (7)$$

In the final stage of multimodal emotion analysis, the final output of SM is formed by stacking the results of the aforementioned computations. In addition, at the end of each step, a residual operation and hierarchical standardization processing are performed to ensure that the input of each round is integrated into the results of the previous round. Eq. (8) expresses the details.

$$\begin{cases} s = Stacking(\sum_{j=0}^{N} (m_j)) \\ M = LayerNorm(M + s) \end{cases} \quad (8)$$

In Eq. (8), M represents the output matrix, and s represents the independent output matrix obtained for each mode. In multimodal emotion analysis, it is necessary to accumulate the vectors corresponding to each modality in element order, and then perform classification prediction on this accumulated result according to Eq. (9).

$$y \sim p = W_p(LayerNorm(S_l + S_a + S_v)) \quad (9)$$

B. Time Series Multimodal Emotion Analysis Model Based on Multitask Learning

As a machine learning method, multi-task learning allows a model to perform several related tasks simultaneously in one training session, thereby improving the overall performance of the model. Transformer is a neural network structure for processing sequential data, such as text data, that can capture remote dependencies in the data, allowing the model to better understand contextual information. On the basis of a Transformer based temporal multimodal emotion analysis model, a self-supervised label generation module (SLGM) model with fusion multi-level correlation mining framework (MCMF) is proposed. The goal of MCMF is to explore the representation and correlation between multimodal data, improve existing models, and deeply explore emotional connections. Meanwhile, the study applies multi-task learning to multimodal emotion analysis to address the challenges of collaborative learning. By combining three single-modal tasks of text, speech, and image, collaborative learning is achieved through joint training using a multi-task learning framework. The goal of the SLGM model is to address the common problem of missing single modal labels in multimodal datasets. It generates single modal labels according to the mapping of modal representation and labels to meet the training requirements. Fig. 4 shows the structure of a temporal multimodal emotion analysis model based on multi task learning.

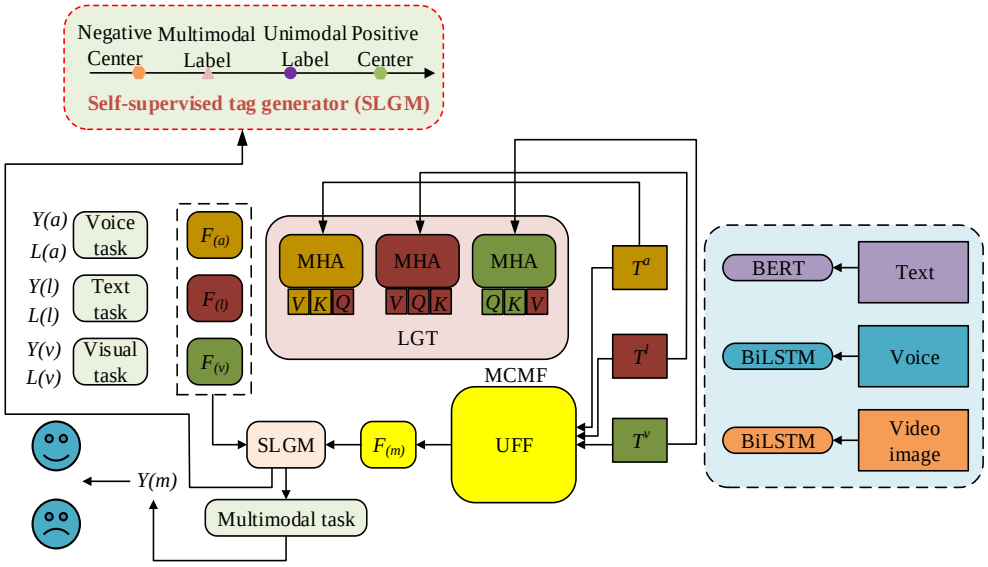

Fig. 4. Temporal multimodal emotion analysis supported by multi task learning.

In Fig. 4, the model mainly includes MCMF module and SLGM module. First, the model receives text, speech and visual data and extracts features through BERT, BiLSTM and other modules to solve the multimodal fusion problem in sentiment analysis. Second, SLGM generates unimodal and multimodal sentiment labels to compensate for the lack of label scarcity. Meanwhile, the unimodal features fusion (UFF) module in MCMF and LGT captures intermodal sentiment associations and fuses multimodal information through the MHA mechanism to improve the accuracy of sentiment prediction. Finally, the model realizes the comprehensive analysis of three-modal sentiment through multi-task learning. The research focuses on exploring the emotional connections between different multimodal representations from top to bottom. To discover the primary feature associations between these representations, a model agnostic fusion strategy is adopted in the study. Inspired by tensor fusion networks, UFF is used to overcome the limitations of traditional fusion methods, mapping single modal features to higher dimensions for fusion [19-20]. UFF fuses each single mode representation through triple Cartesian product, and captures the interaction between bimodal and trimodal through multi-level fusion, as shown in Fig. 5.

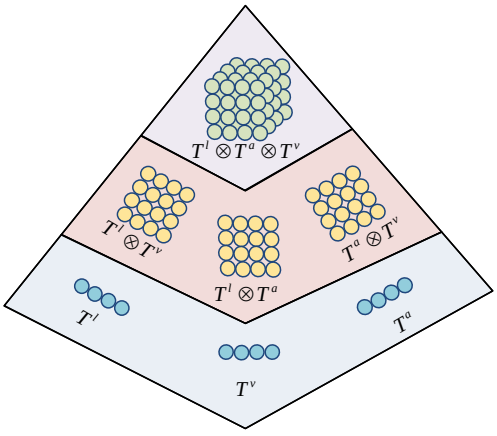

Fig. 5. Single mode feature mapping fusion UFF strategy.

In Fig. 5, the first step is to use T^l、T^a、T^v to capture the intrinsic characteristics of different modes. The second step focuses on exploring the interaction between the two modes, achieved through the calculation of $T^l \otimes T^a$, $T^l \otimes T^v$, and $T^a \otimes T^v$. Finally, the results of these stages are integrated to form a comprehensive fusion tensor, as shown in Eq. (10).

$$\begin{cases} \{(T^l, T^a, T^v) \mid T^l \in [{}_1^{T^l}], T^a \in [{}_1^{T^a}], T^v \in [{}_1^{T^v}]\} \\ F_{(m)} = [{}_1^{T^l}] \otimes [{}_1^{T^a}] \otimes [{}_1^{T^a}] \end{cases} \tag{10}$$

In Eq. (10), $\otimes$ represents the outer product operation, which is used to combine the features of multimodal m, text l, speech a, and visual v. By adding additional dimensions to the single modal tensor T^l、T^a、T^v and performing outer product operations, fused features are formed. Further application of hard parameter sharing mechanism in the framework to achieve sentiment analysis, where low-level networks share weights and high-level networks assign weights to specific tasks, as shown in Fig. 6.

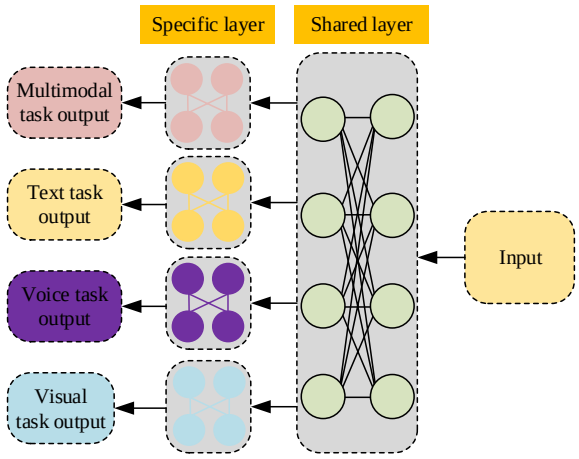

Fig. 6. Emotion analysis structure of multi task learning.

In Fig. 6, the study uses basic learning networks as shared layers, while independent prediction networks for each task are used as specific layers. Under this framework, a multimodal $F_{(m)}$ and three single modal tasks are set, with F^l, F^a, and F^v as inputs, respectively. Eq. (11) provides the definition of the dedicated layer.

$$\begin{cases} F_s^* = \mathrm{Re}\,LU(F_s W_s^{1T} + b_s^1) \\ y_s = F_s^* W_s^{2T} + b_s^2 \end{cases} \tag{11}$$

To adapt to multi-task learning frameworks, the SLGM model is proposed, which aims to generate single modal labels from multimodal data. SLGM is based on two core principles: the mapping relationship between modal representation and modal supervised values, and the proportional consistency of mapping relationships between different modalities. This method allows for the effective generation of labels required for single modal tasks, with specific calculations detailed in Eq. (12).

$$(F_m \# L_m) \infty (F_u \# L_u) \tag{12}$$

In Eq. (12), m represents multimodality and u represents covering $\{linguistic, acoustic, visual\}$ modes. F represents modal representation, L represents modal supervised value, $\#$ represents mapping relationship, and ∞ represents proportional relationship. These definitions indicate that modality and multimodal labels are highly correlated in terms of emotional polarity. However, in practical applications, there may be differences in the emotional polarity between single modal labels and multimodal labels. Among them, multimodal labels may be positive, but individual visual modalities may be marked as negative due to crying expressions. The strategy of SLGM to solve this problem is to divide modal representation as two categories abide by the emotional polarity, followed by calculating the center value of each category separately, and obtain the center representation of emotions from modalities, as shown in Eq. (13).

$$\begin{cases} C_p = \dfrac{\sum_{i=1}^{N} I(y(i) > 0) \cdot F_i}{\sum_{i=1}^{N} I(y(i) > 0)} \\ C_n = \dfrac{\sum_{i=1}^{N} I(y(i) < 0) \cdot F_i}{\sum_{i=1}^{N} I(y(i) < 0)} \end{cases} \tag{13}$$

In Eq. (13), $I(\cdot)$ is the symbol of the indicator function, N is the symbol of the number, and F represents the modal representation. Next, SLGM applies the Bartcharia distance coefficient for measuring the sample and its corresponding category center. The specific calculation is detailed in Eq.(14).

$$\begin{cases} S_p = \sum_{j=1}^{K} \sqrt{F(j) C_p(j)} \\ S_n = \sum_{j=1}^{K} \sqrt{F(j) C_n(j)} \end{cases} \tag{14}$$

In Eq. (14), K is the symbol of the total elements number in the modal representation. SLGM uses proportion and difference to reflect the mapping relationship, so the original Eq. (12) has been updated and expressed as Eq. (15).

$$\begin{cases} S_m / L_m = S_u / L_u, S_m - L_m = S_u - L_u \\ L_u = L_m + \dfrac{S_u - S_m}{2} * \dfrac{L_m + S_m}{S_m} \end{cases} \tag{15}$$

In Eq. (15), S_m and S_u represent the deviation degrees of multimodal and single-mode, respectively, while L_m and L_u refer to the markings of multimodal and single-mode. To address the issue of result fluctuations caused by iterations in the label generation process, SLGM has implemented a mechanism for dynamically updating single modal labels. The specific calculation method is shown in Eq. (16).

$$y_u^{(i)} = \frac{1}{2} * \frac{i-1}{i+1} * y_u^{(i-2)} + \frac{1}{2} * \frac{i-1}{i+1} * y_u^{(i-1)} + \frac{2}{i+1} * y_u^i, i \geq 3 \quad (16)$$

In summary, starting from 3rd iteration, each iteration i's outcome is associated with the first two rounds of $(i-1)$ and $(i-2)$, ensuring that as the number of iterations increases, the generated labels gradually stabilize.

IV. Test of Multimodal Emotion Analysis Model in Film and Television Communication

The research experiment first sets two datasets and their experimental parameters to conduct the experiment. Secondly, the results on these two datasets are compared and ablation experiments are performed to analyze the contributions of each component. Subsequently, performance comparisons are made with other models. Finally, the study conducts an analysis of the effectiveness of LGT and selects some film and television clips for in-depth analysis, demonstrating the emotional analysis ability of the proposed model.

A. Test of a Transformer Based Time-Series Multimodal Emotion Analysis Model

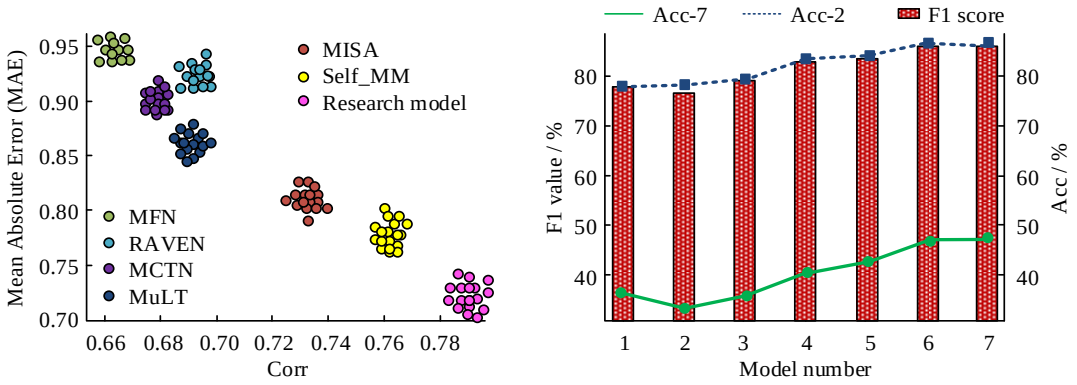
To validate the temporal multimodal emotion analysis model, two datasets, Cmumosi and Cmumosei, are selected for the study. The CMUMOSI and CMUMOSEI datasets contain 2,200 video clips and 24,000 YouTube comment clips, respectively. These cover a variety of data formats, including text, audio, and video modes. Bidirectional encoder representations from Transformers are used for feature extraction of text data, while Mel-Frequency Cepstral Coefficients are used for feature transformation of audio data. Video is sampled at 2 frames per second, scaled to 224x224 pixels, and visual features are extracted using a convolutional neural network. To ensure modal synchronization, the window alignment method is used to process multimodal data. In addition, to solve the problem of unbalanced emotion category, the study further applied a small amount of data enhancement strategy to improve the model's low-frequency emotion recognition ability.

Since the final model consists of MCMF and SLGM, MCMF includes UFF and LGT, and LGT consists of SM, MHA and FNN, ablation experiments are set up to test the benchmark performance of each module, and the results are shown in Table I. The LGT model based on Model 1, which consists of SM, MHA, and FNN, can extract basic emotional features. However, its performance is mediocre due to the lack of modal fusion and label generation. After UFF module is added to LGT in Model 2, the correlation between modes is enhanced and various indicators are improved. SLGM module is added to LGT in Model 3 to make the model capable of generating single mode labels, which effectively improves the accuracy of sentiment analysis. Model 4 is an MCMF module composed of UFF and LGT. Through the high-dimensional fusion of UFF and the emotional feature analysis of LGT, the performance of the model is close to the final model, and the synergistic effect of the two is verified. Model 5 is the final model. Combined with SLGM, the accuracy of multimodal emotion recognition is further improved. Moreover, the accuracy rate, recall rate and F1 score are all the best, which are 0.92, 0.93, and 0.92, respectively.

TABLE I. Ablation Test Results

Network structure	Accuracy value	Recall value	F1 score
SM+MHA+FNN (Model 1: LGT base model)	0.83	0.82	0.81
UFF+SM+MHA+FNN (Model 2: Add UFF module)	0.86	0.85	0.85
LGT+SLGM (Model 3: LGT combined with SLGM module)	0.88	0.87	0.87
UFF+LGT (Model 4: MCMF module)	0.89	0.89	0.88
UFF+LGT+SLGM (Model 5: MCMF+SLGM complete model)	0.92	0.93	0.92

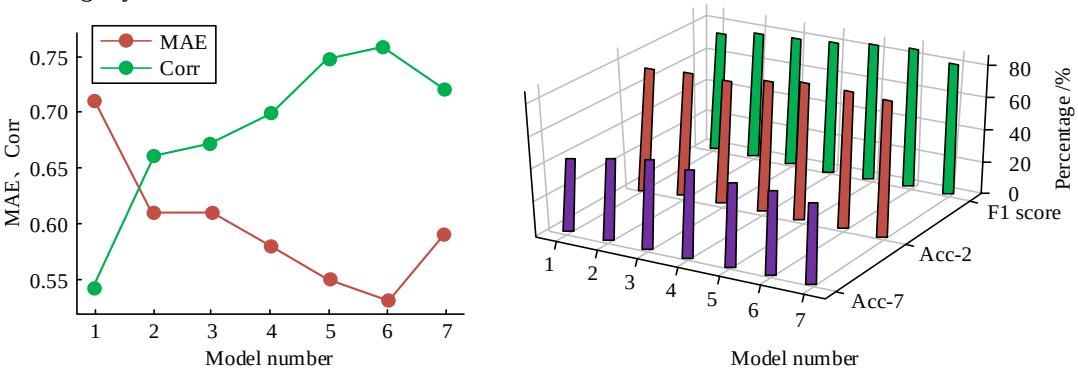
The testing is divided into regression and classification tasks, which hires Pearson correlation (Corr) together with mean absolute error (MAE) as indicators. The classification task is evaluated using seven class accuracy (Acc-7), two class accuracy (Acc-2), and F1 score (F1). The proposed one is planned to be compared with multiple existing models on the Cmumosi dataset, as shown in Fig. 7. The compared models include memory fusion network (MFN), recurrent attention variation embedding network (RAVEN), multimodal cyclic translation network (MCTN), multicurrent Transformer (MulT) Modality Invariant and Specific Representations for multimodal emotion analysis (MISA) and self-supervised multi task learning for multimodal emotion analysis (Self MM). These models are denoted as Model 1 to Model 6, respectively. In Fig. 7(a) and Fig. 7(b), the multi-task learning time-series multimodal sentiment analysis model proposed in the research outperforms the existing mainstream models in several key metrics. In the regression task, the MAE of the proposed model is 0.70, which is significantly lower than the 0.87 of MulT and the 0.78 of MISA. It indicates that the research model has a smaller error in sentiment prediction accuracy. Meanwhile, the Corr of the research model reaches 0.82, which is higher than the 0.70 of MulT and 0.76 of MISA. It indicates that the research model is more robust in modeling emotional features and can more accurately reflect the emotional associations between different modalities. In the categorization task, the Acc-7 of the research model is 47.1%, which is significantly better than the 42.3% of MISA and the 46.8% of Self-MM, indicating that the proposed model is able to discriminate different categories of emotions more accurately. In addition, the research model achieves 88.4% in both Acc-2 and F1 values, surpassing the 86.1% of Self-MM and the 83.1% of MulT. This result further validates the advantages of the multi-task learning framework in emotion recognition, which can effectively improve the ability to capture complex emotional features.



(a) MAE and Corr for Cmumosi (b) Acc-7, Acc-2, and F1 score for Cmumosi

Fig. 7. Comparison on the cmumosi dataset.

The next comparison on the Cmumosei dataset is shown in Fig. 8. In terms of the regression task, the MAE of the research model drops to 0.59, which is lower than both 0.61 for MCTN and 0.71 for MFN. It implies that its prediction of sentiment trends is more accurate. Meanwhile, the Corr of the research model reaches 0.72, which is significantly better than the 0.54 of MFN) and 0.67 of MCTN. It implies that the research model is able to extract multimodal features more stably and establish reasonable sentiment mapping relationships among different modalities. In the classification task, the research model's Acc-7 is 49.6%, which is slightly lower than MulT's 51.8% and Self-MM's 52.2%, but reaches 82.2% on Acc-2, which is higher than MCTN's 79.3% and MFN's 77.9%. Meanwhile, its F1 score is 82.2%, which showed a strong sentiment categorization ability. In summary, although the research model approaches the optimal model in some indicators, its overall performance exceeds that of most mainstream methods, particularly in the regression task. The research model demonstrates a more stable and robust sentiment prediction ability, ensuring accurate sentiment analysis of film and television communication content.



(a) MAE and Corr for Cmumosei (b) Acc-7, Acc-2, and F1 score for Cmumosei

Fig. 8. Different models are compared on the cmumosei dataset.

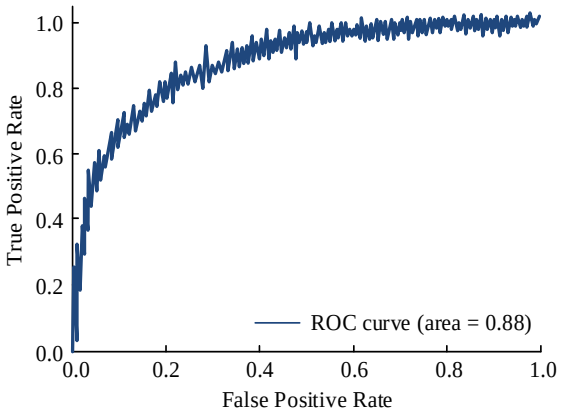


Fig. 9. Receiver operating characteristic curve.

Next, how the research model performing is validated by randomly selecting over 4000 samples from the test set for binary classification results testing. Through assessing the predicted labels with the real sample labels together, the true and false positives are calculated. Based on this data, the operating characteristic curves of the subjects are plotted, and the outcomes are given in Fig. 9. The model proposed in the study has a strong ability to distinguish between two types of emotional polarity, reflecting its advantage in accurately identifying and predicting emotional tendencies in film and television content.

The research model combines two mechanisms, LGT and SM, respectively, for modal interaction and mapping results to high-dimensional space for effective fusion. The study conducted ablation analysis on the Cmumosi dataset, as shown in Fig. 10. Both of these structures have a positive impact on

sentiment classification. The experiment is divided into 1-4 scenarios: no LGT and SM, only SM, only LGT, and both LGT+SM are used. In Fig. 10(a) and Fig. 10(b), the model performance decreases significantly with the removal of LGT and SM, indicating the importance of these two modules in sentiment modeling. When using only SM, although it improves some tasks, the overall performance is still limited by the lack of intermodal interaction capability. Using only LGT, although it improves modal interaction, it lacks the support of the soft-mapping mechanism, resulting in a decrease in the ability to fuse high-dimensional features. The complete model (LGT+SM) performs optimally and achieves the best results in all metrics, confirming the key role of LGT in enhancing intermodal affective interactions, while the SM module enhances the feature expression capability through high-dimensional mapping. The results of the ablation experiments illustrate that the combination of the two can maximize the emotion recognition ability of the model, making it more applicable to complex film and television communication scenarios.

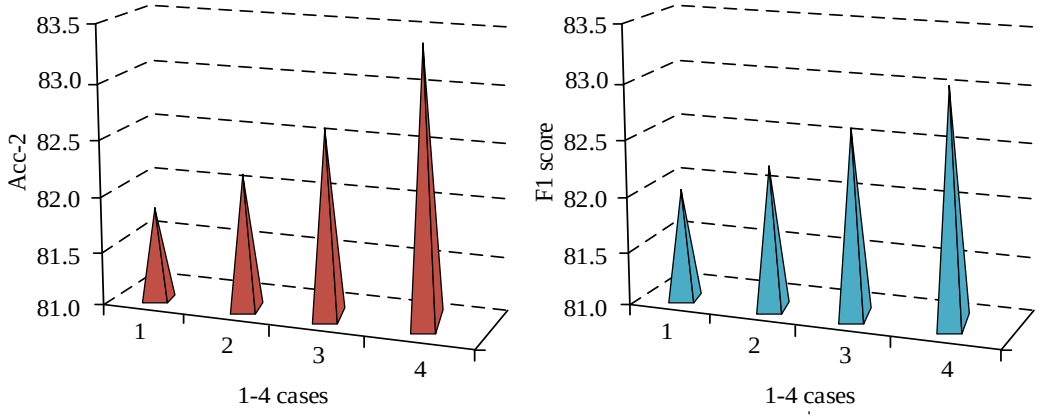

Fig. 10. Cmumosi dataset ablation analysis.

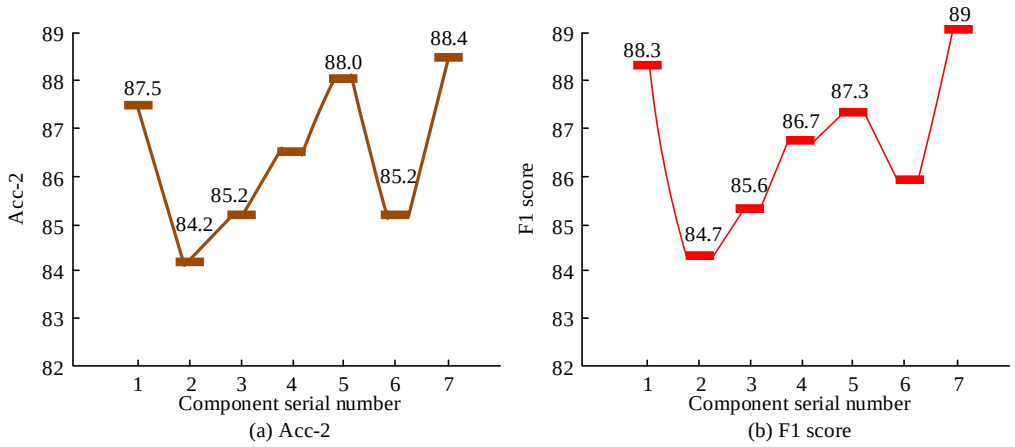
B. *Test of a Time-Series Multimodal Emotion Analysis Supported by Multitask Learning*

To compare the performance of different models, classification and regression evaluation indicators are used in the study, as shown in Table II. The research model outperforms the comparison model in all indicators: Acc-2 reaches 88.5%, which is 2.4% higher than Self_MM and 1.9% higher than Zhang Y et al.'s model. It indicates that the sentiment polarity determination is more accurate. Acc-7 reaches 47.2%, which outperforms MISA, Self_MM, and Yu W et al.'s model. It indicates that it has a stronger generalization ability in the task of complex sentiment classification. MAE is the lowest at 0.70, with better error control than Barnes J et al. (0.74) and Yang B et al. (0.76), which is more stable in prediction. Corr is the highest at 0.82, which is better able to accurately capture the trend of emotion change compared to Zhang Y et al.'s model at 0.79 and Self_MM's 0.80. Overall, the research model performs best on all indicators, validating the effectiveness of multi-task learning and temporal multimodal fusion methods to provide more accurate prediction results in complex film and television sentiment analysis tasks.

This study conducted ablation tests on the Cmumosi dataset to accomplish the effects assessment of various components of the model. The experiment set up seven components: UFF, LGT, SLGM, UFF+LGT, UFF+SLGM, LGT+SLGM, and UFF+LGT+SLGM, numbered 1 to 7, respectively. Fig. 11 gives the information that feature concatenation is used when UFF is missing, single modal representation is directly input when LGT is missing, and multimodal labels are used for training when SLGM is missing. The results show that UFF is the key to performance improvement, especially with the combination of UFF and SLGM achieving the highest Acc-2 and F1 scores of 88.0% and 89.0%, respectively. The combination of UFF+LGT and LGT+SLGM did not perform as expected, with 86.5% and 85.2%, respectively, due to the lack of single modal labels or basic correlations between modalities.

TABLE II. DIFFERENT MODELS ON THE CMUMOSI DATASET

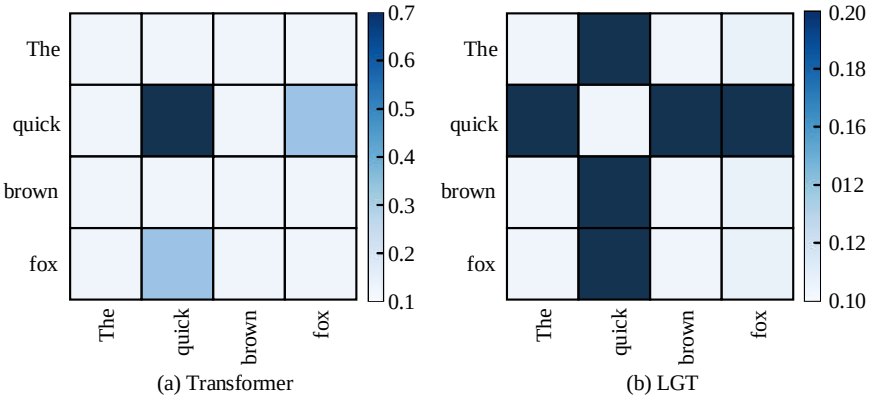
Type	Acc-2	Acc-7	MAE	Corr
MFN	77.9	36.3	0.95	0.66
RAVER	78.1	33.2	0.92	0.69
MCTN	79.3	35.6	0.91	0.68
MulT	83.1	40.2	0.87	0.7
MISA	83.4	42.3	0.78	0.76
Self_MM	86.1	46.8	0.71	0.8
The model of Yang et al.	85.6	45.59	0.74	0.8
The model of Barnes et al.	86.05	45.17	0.74	0.8
The model of Yu et al.	84.96	45.67	0.73	0.79
The model of Zhang et al.	84.42	46.01	0.72	0.79
Research model	88.5	47.2	0.7	0.82



(a) Acc-2 (b) F1 score

Fig. 11. Ablation analysis of different component structures.

For confirming the LGT model effectiveness, a test sentence "The quick brown fox" is used on the Cmumosi dataset, and the performance of LGT and Transformer in attention mechanism is compared. As shown in Fig. 12, the attention scores are represented by color depth, where a darker color is the symbol for higher weights and a lighter color is the symbol for lower weights. Comparing Fig. 12(a) and Fig. 12(b), LGT is more accurate in assigning word weights. For example, in the MHA mechanism of Transformer, "quick" pays significant attention to "fox", while the distribution of LGT is more uniform, allowing for a more balanced focus on the structure of the entire sentence. This demonstrates the advantage of LGT in finely adjusting attention weights, especially in capturing key vocabulary. It further demonstrates its effectiveness in processing language tasks, especially in understanding sentence structures.



(a) Transformer (b) LGT

Fig. 12. LGT attention matrix result graph.

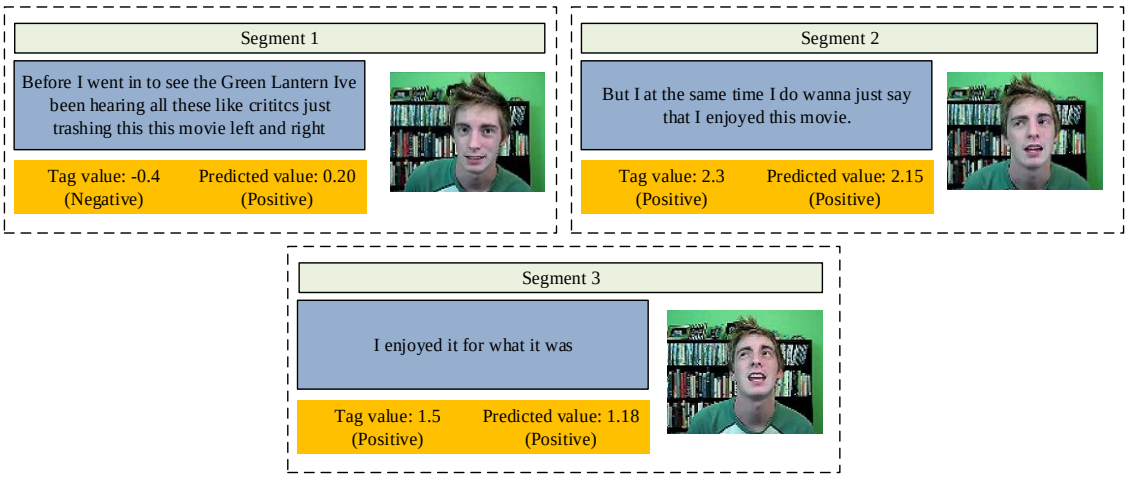


Fig. 13. Cmumosi dataset film and video emotion analysis results.

The study selects specific film and television video clips from the Cmumosi dataset to accomplish the evaluation of the the proposed one's analytical ability. Three video clips are selected for detailed testing in the experiment, with text content and keyframe images shown in Fig. 13, supplemented by experimental labels and prediction results. The observation can tell that the predictions of the second and third segments are highly consistent with the actual labels, demonstrating the accuracy of the model in sentiment analysis, with predicted scores of 2.15 and 1.18, respectively. However, there is a deviation in the results of the first segment, with a predicted value of only 0.20. This difference is attributed to the fact that the image at the beginning of the video can mislead the model's judgment. The combination of the smiling image of the man in the first clip with neutral text leads the model to lean towards positive predictions. In summary, this experiment reveals the complexity of the model in interpreting emotions and demonstrates its advantages in integrating visual and textual cues.

TABLE III. TEST RESULTS OF IEMOCAP AND MELD DATASETS

Type	Acc-2	Acc-7	F1-Score	MAE	Corr
MFN	0.78	0.65	0.72	0.9	0.65
RAVER	0.79	0.66	0.73	0.88	0.67
MCTN	0.8	0.68	0.75	0.85	0.69
MulT	0.83	0.7	0.78	0.82	0.72
MISA	0.85	0.72	0.8	0.78	0.74
Self_MM	0.86	0.73	0.82	0.76	0.76
The model of Yang et al.	0.84	0.71	0.81	0.78	0.76
The model of Barnes et al.	0.83	0.71	0.82	0.77	0.75
The model of Yu et al.	0.83	0.73	0.82	0.77	0.75
The model of Zhang et al.	0.84	0.71	0.83	0.77	0.73
Research model	0.88	0.75	0.85	0.73	0.78

To further verify the applicability of the model in different areas of emotion analysis, the study introduces additional datasets of IEMOCAP and MELD to test the performance of the model in conversational emotion recognition and multimodal emotion dialog, respectively. The IEMOCAP dataset contains multimodal dialog emotion labels, which can be used to test the emotion recognition effect of the model in the dialog scene. The MELD dataset provides multimodal emotion data of multi-round dialogues, which can be used to verify the emotion recognition ability of the model in complex scenes. In Table III, the proposed model outperforms the other models in all indicators on both IEMOCAP and MELD datasets. The models proposed by Yang B et al. Barnes J et al. Yu W et al. and Zhang Y et al. shows strong competitiveness in Acc-2, Acc-7, and F1-Score, but compared to the proposed model, they still fall slightly short of the proposed model, especially in Acc-2 and F1-Score. In particular, in terms of Acc-2 and F1-Score, the proposed model reaches 0.88 and 0.85, while the highest Acc-2 of the other models is only 0.84, and the highest F1-Score is 0.83. It suggests that the proposed model has more advantageous in terms of sentiment categorization accuracy. In addition, the MAE value of the proposed model is 0.73, which is more stable and exhibits a lower error rate compared to the 0.77-0.78 of the other models. It proves its reliability in fine-grained emotion recognition tasks. Overall, the proposed model of the study demonstrated better performance in the sentiment analysis task, further validating its application value in the field of film and television communication.

V. DISCUSSION

To improve the accuracy of multimodal sentiment analysis in film and television communication, this study presented a time-series model based on a Transformer structure with MCMF and SLGM modules. Compared with the two-stage multi-task learning model proposed by Yang B et al. [8], which improved feature classification, this approach addressed limitations when multimodal labels were sparse. By incorporating the SLGM module to generate single-modal labels, this model not only enriched the diversity of emotional labels, but also significantly improved the accuracy of complex emotion recognition. Results on IEMOCAP and MELD datasets showed F1 scores up to 0.85. In terms of efficiency, the model reduced the MAE on the CMUMOSEI dataset by 15%, demonstrating the effectiveness of the multi-task learning framework in sentiment analysis. Compared to Zhang Y et al.'s model [11], which used cross-modal attention and multi-task learning for accuracy, this model improved label stability and captures subtle emotions, achieving 47.1% accuracy in seven-category tasks and 88.4% accuracy in binary tasks. This improvement was due to the SLGM module, which ensured efficient emotion prediction even with sparse single-modal labels. In practical applications on social media platforms, the model could be utilized to analyze the emotional trends of users' video content, thereby providing real-time emotional feedback to content creators and platform operators for the purpose of optimizing content push strategies. In online education, the model could help identify students' emotional responses during video lessons so that teachers could adjust their teaching methods. In healthcare, the model helped assess mental health and monitor emotional states by analyzing video and voice recordings of patients.

For broader applications, the model could be extended to recognize multi-character interactions and nuanced emotions. Such scenes in film and television often involve multiple, complex emotions, where the recognition of subtle emotional states was crucial. Future studies could include these scenarios to verify the adaptability of the model. For real-time applications, the model showed high computational efficiency in binary emotion tasks, indicating potential for real-time deployment. Further optimization with a lightweight Transformer structure and a multi-tasking strategy could support real-time video analysis and meet the needs of efficient media analysis.

In summary, there are three main arguments of the study: First, SLGM improves the acquisition quality of unimodal sentiment labels and still maintains a stable sentiment recognition ability in multimodal datasets without complete annotation. Second, UFF allows different modal features to be fused more efficiently and improves the synergy between multimodal data, thus enhancing the robustness and generalization ability of the model. Third, MCMF enhances the

modeling capability of complex sentiment features by jointly optimizing LGT and SLGM, while improving the sentiment classification accuracy. These results show that the proposed model of the study not only outperforms existing methods on several benchmark datasets, but also makes a significant breakthrough in the accuracy and stability of multimodal data fusion and sentiment recognition. It lays a foundation for the application of sentiment analysis technology in more complex multimodal data applications, which has positive implications for improving the communication effects of movies and television and optimizing user experience.

VI. Conclusion

A temporal multimodal emotion analysis model supported by multi task learning was proposed to address the challenges of sentiment association mining and fusion in multimodal data. This model utilized a Transformer based framework to deeply explore temporal features related to emotions, and compensated for the shortcomings of single modal labels, enhancing the accuracy of emotion prediction. The experimental results showed that, specifically, in the binary sentiment analysis task on the CMUMOSEI dataset, the average processing time of the model was about 0.05 s per frame of data, enabling it to perform sentiment prediction in near real-time conditions. Furthermore, the ablation experiments demonstrated that the structural optimization of the UFF and LGT modules markedly reduced the computational overhead of the model and enhanced its computational speed by approximately 30% in comparison to traditional multimodal sentiment analysis models. It substantiated the superior performance of the proposed model over several existing models. These results demonstrated their clear advantages in accurately recognizing affective tendencies. To further validate the effectiveness of LGT, a comparative analysis was conducted on the differences in attention mechanisms between LGT and traditional Transformers. It was found that LGT was more precise in finely adjusting word weights, which was crucial for capturing the emotional meaning of sentences. In addition, by selecting specific film and television video segments for testing, the predictions of the second and third segments were highly consistent with the actual labels, with predicted scores of 2.15 and 1.4, respectively. It was proved that the research model can highly match the actual labels in most cases.

VII. Future Work

Despite the merits of the current model's superior emotion recognition performance as demonstrated in this study, there are notable deficiencies. First, the Transformer structure's application in temporal modeling incurs substantial computational complexity when dealing with video data of considerable duration. This may impede the efficiency of practical applications. Second, the multimodal fusion process primarily relies on global feature matching, neglecting the potential benefits of local information in sentiment analysis. This may result in a reduction in accuracy for certain nuanced sentiment recognition tasks. In addition, the research model still has room for improvement in the recognition of extreme emotion categories (e.g., intense anger or extreme happiness), and more fine-grained feature extraction methods can be explored in the future to improve the model's emotion classification ability. To address the aforementioned limitations, future research can be optimized in the following ways. First, a more efficient attention mechanism should be introduced to reduce computational complexity and improve the applicability of the model to long time series data. Second, local feature modeling should be combined to improve the model's sensitivity to subtle sentiment changes. Third, an adaptive multi-task learning strategy should be introduced to enhance the model's generalization ability in different application scenarios. Furthermore, at the level of the data, the diversity of the training data can be expanded in the future to encompass a more extensive range of movie and television styles and cultural backgrounds, thereby enhancing the robustness of the model.

In summary, this study improves the performance of multimodal sentiment analysis through an innovative model design, while pointing out the existing limitations and proposing appropriate improvement directions. The research results not only provide an effective solution for sentiment computation in the field of film and television communication, but also lay the foundation for the further development of multimodal sentiment analysis.

***Abstract*—The Adaptive Decision Support System Learning Framework (A-DSS-LF) was developed to address diverse learner needs in blended learning environments by integrating learning styles, cognitive levels, practical skills, and value practices. This study validates the framework using the Fuzzy Delphi Method (FDM), a consensus-building tool that synthesizes expert opinions and addresses uncertainties in subjective judgments. A panel of 15 experts evaluated the framework's constructs: Learning Process, Learning Assessment, Decision Support System, and Adaptive Learning Profile. All constructs met the FDM's consensus criterion, achieving threshold values between 0.087 and 0.118 (≤0.2), indicating high consistency and low variability. The defuzzification process confirmed values exceeding 0.5, with scores ranging from 0.873 to 0.922 and expert agreement surpassing 75 percent for all elements. These findings confirm the robustness and applicability of the A-DSS-LF, validating its role in enhancing personalized learning outcomes and supporting teachers in tailoring adaptive learning resources. The framework is scalable and can be implemented in secondary school computer science education and online learning platforms to create personalized learning paths, improve engagement, and bridge the gap between online and offline learning. This study reinforces the significance of expert validation in adaptive learning frameworks, ensuring their scalability and adaptability for future applications in diverse educational settings.**

***Keywords*—Learner needs; adaptive learning; blended learning; fuzzy delphi method; decision support system**

I. Introduction

In modern education, learners exhibit diverse needs, preferences, and abilities, requiring tailored educational approaches to enhance engagement and improve learning outcomes. According to study [1] and study [2], adaptive learning frameworks have emerged as a promising solution by leveraging computerized algorithms and data-driven methodologies to personalize learning experiences based on individual learner characteristics. Unlike traditional one-size-fits-all teaching methods, these frameworks dynamically adjust content and instructional strategies, allowing learners to receive materials tailored to their cognitive and behavioral profiles [3] [4]. This adaptability enhances student engagement and optimizes learning outcomes by ensuring that instructional content aligns with individual learning needs.

Particularly in blended learning environments, adaptive learning plays a crucial role in bridging online and offline learning components. As highlighted by study [5] and study [6], these frameworks create a more flexible and structured learning approach, allowing seamless integration between traditional and technology-enhanced learning experiences. This integration ensures that adaptive learning is not only personalized but also scalable and adaptable to different educational settings.

Several adaptive learning frameworks have been developed to facilitate personalized learning experiences, with many operating within Learning Management Systems (LMS). For instance, the study in [7] proposed a three-stage implementation model designed to scale adaptive learning in fully online education, focusing on faculty training and infrastructure development. Similarly, the study in [8] introduced a knowledge-based adaptive model that aligns instructional content with students' proficiency levels, while [9] developed an Adaptive Virtual Learning Environment (AVLE) structured around content, student, and adaptation models to provide personalized learning paths. The Adaptive Learning System-Knowledge Level (ALS-KL) by study [10] utilized pre-test and post-test assessments to classify learners and deliver content suited to their knowledge levels.

Despite their potential, existing adaptive learning frameworks face significant limitations that hinder their effectiveness in diverse educational settings. The studies in[5] and [9] highlight that many models rely heavily on Learning Management Systems (LMS), making them less adaptable for classroom-based learning environments that require seamless integration between online and offline instruction. Additionally, the studies in [11] and [12] emphasize that most frameworks primarily focus on cognitive aspects while neglecting other critical learner attributes, such as practical skills and value-based learning, which are essential for holistic education. The absence of these elements limits the ability of adaptive learning to fully support diverse learner needs.

Furthermore, the studies in [13] and [1] argue that many adaptive learning frameworks lack rigorous validation mechanisms, raising concerns about their effectiveness, scalability, and generalizability in different educational settings. Without systematic validation, these frameworks may fail to achieve consistent learning improvements across varied instructional contexts. Addressing these challenges requires a comprehensive and validated framework that integrates multiple learner characteristics while ensuring practical implementation in blended learning environments.

To bridge these gaps, this study introduces the Adaptive Decision Support System Learning Framework (A-DSS-LF), designed to provide a more holistic and data-driven adaptive

This research was supported by Universiti Malaysia Terengganu (TAPERG/2023/UMT/2564).

learning experience. A-DSS-LF differs from existing frameworks in several ways. Unlike traditional models that focus solely on cognitive skills, A-DSS-LF integrates learning styles, cognitive levels, practical skills, and value practices to offer a well-rounded personalized learning experience. Additionally, while many adaptive learning models are designed primarily for LMS-based environments, A-DSS-LF is structured to seamlessly integrate both online and offline learning environments, making it more suitable for blended learning. Another key feature of A-DSS-LF is its inclusion of a Decision Support System (DSS), which enables educators to make data-driven instructional decisions and adapt learning interventions based on students' needs, a capability often missing in many existing adaptive learning frameworks. To ensure its effectiveness, adaptability, and scalability, A-DSS-LF is rigorously validated using the Fuzzy Delphi Method (FDM), allowing expert consensus to confirm its applicability in real-world educational settings. These features position A-DSS-LF as a scalable and personalized approach to adaptive learning, supporting both student-centered learning and teacher-driven instructional strategies in blended learning environments.

The objective of this study is to present the validation process and findings of the A-DSS-LF using the Fuzzy Delphi Method (FDM). This study aims to establish expert consensus on the framework's constructs and components, ensuring its robustness, scalability, and applicability in blended learning environments. By detailing the validation process, this study examines how expert feedback informs the refinement and validation of A-DSS-LF to align with modern educational needs. Additionally, it evaluates the findings of the analysis, confirming the framework's effectiveness in supporting personalized learning pathways and educator-driven decision-making. Through this validation, the study contributes to the development of rigorously tested adaptive learning frameworks, ensuring their practical implementation in real-world educational settings to enhance adaptive learning experiences and improve instructional decision-making.

The remainder of this article is structured as follows. Section II reviews related work on the FDM, highlighting its significance in expert-based validation. Section III details the FDM validation methodology, including expert selection and analysis procedures. Section IV presents the key findings, followed by a discussion in Section V. Finally, Section VI concludes with implications and future research directions.

II. Related Work

To ensure the robustness and applicability of A-DSS-LF, a rigorous validation method is required. Traditional validation approaches may lack precision in expert-driven refinements, making them less suitable for validating adaptive learning frameworks. To address this challenge, this study employs the Fuzzy Delphi Method (FDM), a structured approach that systematically refines framework components through expert consensus. The following section explores FDM, its significance in validation research, and its applications in education.

A. Fuzzy Delphi Method (FDM)

Given the complexity of adaptive learning frameworks, robust validation measures are essential to ensure their effectiveness. The Fuzzy Delphi Method (FDM) was selected in this study for its ability to address uncertainty and systematically establish expert consensus. Originally introduced by [14] and later refined by study [15], FDM enhances the traditional Delphi Method by integrating fuzzy logic principles, allowing for quantitative evaluation of expert judgments. The study in [16] demonstrated FDM's extensive applications in education, technology, and policy-making, where iterative refinement of theoretical models is necessary.

Unlike conventional validation approaches, FDM refines framework components iteratively, ensuring expert consensus is achieved through multiple evaluation rounds. This process systematically reduces ambiguity and enhances precision in decision-making [17]. By incorporating expert-driven refinements, FDM ensures A-DSS-LF aligns with best practices in adaptive learning, strengthening its adaptability to blended learning environments.

Several validation methods exist for refining adaptive learning frameworks, yet each has notable limitations. Traditional expert review methods, as described by study [18], rely heavily on qualitative assessments and descriptive feedback, often introducing bias and inconsistencies. FDM, by contrast, provides a structured and quantifiable approach, ensuring expert evaluations are numerically analyzed rather than solely based on subjective agreement. Structural Equation Modeling (SEM), commonly used for model validation [19], requires large datasets and strong statistical assumptions, making it unsuitable for early-stage validation where expert input is prioritized. Similarly, Design-Based Research (DBR) emphasizes real-world implementation through iterative testing [20], but its time-intensive nature makes it less practical for preliminary validation stages.

In contrast, Analytic Hierarchy Process (AHP), as proposed by study [21], is widely used for ranking framework components based on weighted criteria. However, it lacks iterative expert feedback loops, making it less effective for dynamically evolving frameworks such as A-DSS-LF. Pilot testing with end-users, though essential for usability validation, is more beneficial in later stages once a framework has been theoretically refined [22]. Given these comparisons, FDM emerges as the most suitable validation method for A-DSS-LF, as it ensures a balance between theoretical validation and expert-driven iterative refinement.

The effectiveness of FDM has been widely demonstrated in prior research. The studies in [17] and [23] applied FDM to validate STEM teaching modules and immersive learning innovations, ensuring that expert recommendations were systematically incorporated into framework refinements. Similarly, the study in [24] demonstrated FDM's utility in validating hybrid learning strategies, synthesizing diverse expert opinions while maintaining theoretical and practical relevance. [25] and [16] confirm that FDM's consensus thresholds—such as a defuzzification coefficient ($d \leq 0.2$) and expert agreement exceeding 75%—enhance reliability and consistency in validation outcomes. These findings reinforce FDM's reliability as a consensus-driven method, confirming its adaptability to various educational settings.

While FDM serves as the primary validation method, complementary approaches such as DBR, AHP, and Pilot Testing contribute to specific aspects of framework validation. DBR enables iterative real-world refinement [20], AHP prioritizes framework components systematically [21], and pilot testing gathers usability insights for final-stage improvements [22]. Together, these methods contribute to a robust validation process, ensuring both theoretical soundness and practical applicability.

FDM's ability to quantify expert judgments, structure consensus, and support iterative refinements makes it an indispensable validation tool for educational research. Prior studies [17], [23], and [24] confirm its effectiveness in aligning theoretical models with real-world applications. Furthermore, FDM's alignment with contemporary challenges, including hybrid learning environments and emerging educational technologies, reinforces its continued relevance as a critical validation method for adaptive learning frameworks.

III. METHODOLOGY

As previously discussed, this study applies the FDM, introduced by study [15] to validate the proposed A-DSS-LF. The validation process follows a three-phase approach to ensure a systematic and structured evaluation of the framework. The following section provides a detailed explanation of each phase.

A. Expert Selection

To achieve consensus on the developed framework, purposive sampling was employed, a method particularly suited to the FDM, as noted by study [18]. The sample for this study comprised experts in the field of education. According to [26], an expert is an individual with extensive knowledge and skills in a specific domain, which in this context refers to subject matter experts. A panel of 23 experts was selected based on their roles, years of experience, and areas of expertise within the field of education. The number of experts selected aligns with study [18] recommendation that 10 to 50 participants are sufficient when the group is relatively uniform or homogenous. The selection criteria included educators with a minimum of 10 years of relevant experience, familiarity with teaching and learning practices, and holding various roles such as Head of Subject Panel, Chief Subject Assessor, School Improvement Specialist Coaches (SISC+), professors, Assistant Education Officers, and Senior Subject Teacher. This diverse panel ensured a comprehensive and well-rounded evaluation of the framework.

B. A-DSS-LF Expert Validation

The process was implemented in four key stages. The first stage involved the presentation of the A-DSS-LF to the expert panel through an online session. This presentation provided an overview of the framework, detailing its components, objectives, and application within blended learning environments. The session aimed to ensure that experts thoroughly understood the framework, enabling them to offer informed and constructive feedback. Following the presentation, a structured questionnaire was distributed to the experts. The questionnaire gathered insights on the framework's relevance, feasibility, and practicality. It incorporated closed-ended questions, evaluated using a fuzzy Likert scale, and used open-ended items to capture qualitative feedback. This combination ensured a comprehensive assessment of the framework.

The 7-point Likert scale was used in this research to identify the constructs and elements of the A-DSS-LF, similar to the approach taken by study [23] and study [27]. The study in [23] utilized the 7-point Likert scale to develop constructs and elements for a framework, emphasizing its accuracy and ability to reduce ambiguity compared to a 5-point scale. Similarly, the study in [27] employed a 7-point Likert scale in their study to evaluate expert agreement on mobile learning implementation in competency-based education, analysing responses using fuzzy logic techniques. These precedents highlight the scale's suitability for capturing nuanced expert feedback in framework development. The linguistic variables were aligned with fuzzy scales to facilitate expert responses, as shown in Table I. The table illustrates the mapping of linguistic variables (e.g., "Strongly disagree," "Moderately agree") to their corresponding Likert scale values and fuzzy scale representations. This approach ensures that the fuzzy logic analysis is grounded in systematically quantified expert input, enhancing the precision of consensus measurement.

TABLE I. LINGUISTIC VARIABLE SCALE

Linguistic Variables	Likert Scale	Fuzzy Scale
Strongly disagree	1	(0.0,0.0,0.1)
Moderately disagree	2	(0.0,0.1,0.1)
Slightly disagree	3	(0.1,0.3,0.5)
Neutral	4	(0.3,0.5,0.7)
Slightly agree	5	(0.5,0.7,0.9)
Moderately agree	6	(0.7,0.9,1.0)
Strongly agree	7	(0.9,1.0,1.0)

Source: [28]

In the third stage, feedback collection was conducted. Experts submitted responses that included both quantitative and qualitative data. Quantitative feedback measured levels of agreement on various aspects of the framework, while qualitative feedback provided additional insights and actionable suggestions for refinement. Finally, the application of fuzzy logic for analysis was carried out. The collected data was analysed using fuzzy logic principles to measure the degree of expert consensus systematically. This structured approach ensured that the validation of the A-DSS-LF was grounded in expert consensus, enhancing its robustness and practical applicability in addressing diverse learner needs in blended learning environments.

C. Validation of Constructs and Elements Through Fuzzy Delphi Analysis for the A-DSS-LF

The analysis of questionnaire data using the FDM involved three main steps: applying Triangular Fuzzy Numbers, calculating the Expert Consensus Percentage, and performing the Defuzzification Process. These steps systematically assessed the expert responses to validate the constructs and elements of the A-DSS-LF. The linguistic variable data obtained from experts in this study, as shown in Table I, must be converted into Triangular Fuzzy Numbers. The Triangular Fuzzy Number has three values, m_1, m_2, and m_3, indicating the minimum, reasonable, and maximum values, as shown in Fig. 1.

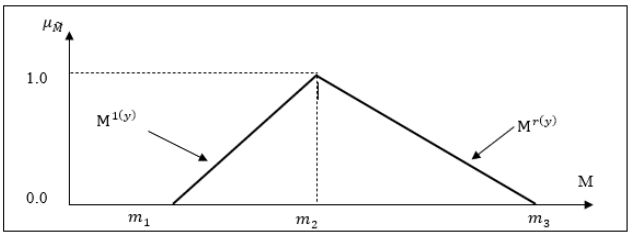

Fig. 1. The Triangular fuzzy number.

Next, the threshold value (*d***)** is calculated to measure the dispersion of expert opinions. An element is considered to have achieved expert consensus if $d \leq 0.2$, meaning that every element with a threshold value (*d*) equal to or less than 0.2 is accepted. As shown in Fig. 1, the threshold value (*d*) is calculated using Formula (1).

$$(\tilde{m}\ \tilde{n}) = \sqrt{\frac{1}{3}[(m_1 - n_1)^2 + (m_2 - n_2)^2 + (m_3 - n_3)^2]} \quad (1)$$

The second step involves calculating the percentage of expert agreement. According to the traditional Delphi technique, an item is accepted if the percentage of agreement among the expert group exceeds 75% [23], [29], [30]. Another requirement in the FDM is the defuzzification process. This step involves analysing the data by averaging fuzzy numbers to calculate the Fuzzy score (A). The Fuzzy score (A) must be greater than or equal to the median value (α-cut value) of 0.5 [19], [31], indicating that the element has achieved expert consensus. The Fuzzy score (A) determines the ranking and identifies acceptable elements based on expert agreement. An item is accepted if the Fuzzy score (A) is equal to or greater than 0.5; otherwise, it is rejected. The fuzzy score (A) is calculated using the formula shown in Formula (2).

$$A = (1/3) * (\mu_1 + \mu_2 + \mu_3) \quad (2)$$

The summary of conditions for the acceptable elements for the A-DSS-LF is shown in Table II.

TABLE II. KEY METRICS FOR FUZZY LOGIC ANALYSIS

Metric	Description	Conditions
Threshold Value (*d*)	Measures the dispersion of expert opinions. Consensus is achieved if $d \leq 0.2$.	$d \leq 0.2$
Percentage Agreement	The proportion of experts agreeing on an element.	> 75%
Defuzzification	Converts fuzzy values into crisp numbers for interpretation.	≥ α-cut value = 0.5

Following the criteria outlined in Table II, the analysis confirmed that elements meeting both the threshold value ($d \leq 0.2$) and achieving a Fuzzy score ($A \geq 0.5$) were accepted. Additionally, elements that achieved an expert consensus percentage of more than 75% were validated. These combined criteria include only elements with strong expert agreement and alignment. The ranked elements provide valuable insights into the framework's relevance and feasibility, reinforcing its robustness in addressing diverse learner needs.

IV. RESULT

This section presents the findings of the FDM analysis conducted to validate the constructs and elements of the A-DSS-LF. The findings include an overview of the expert demographic information and the outcomes of the FDM validation process.

A. Expert Demographic Information

Due to scheduling challenges and time constraints, only 15 experts were available for the final discussion session. This number still falls within the range of 10 to 15 experts suggested by study [32] for achieving a reliable consensus when the expert group is not homogeneous. The expert panel in this study reflects a diverse range of qualifications, expertise, and professional experience, ensuring robust and informed feedback during the validation process. Table III summarises their demographics, categorised into three key areas: Level of Education, Work Experience, and Field of Expertise.

TABLE III. SUMMARY OF EXPERT PANEL

Level of Education	Frequency
PhD	2
Master Degree	4
Bachelor Degree	9
Total	15
Work Experience (Years)	**Frequency**
11 to 15 years	1
16 to 20 years	5
More than 20 years	9
Total	15
Field of Experts	**Frequency**
Information Technology	1
Business Management	2
Education Technology	1
Coaching	1
Science and Mathematics	2
Accounting	1
Multimedia	1
History	1
Computer Science	1
Languages	2
Physical Education	1
Decision Support Systems	1
Total	15

This diversity of backgrounds, spanning fields such as educational technology, decision support systems, computer science, and language studies, adds significant value to the consensus-building process. It ensures a comprehensive evaluation of the A-DSS-LF and its applicability in blended learning environments.

B. Expert Consensus Findings Using the FDM

Data analysis from the closed-ended questionnaire was conducted systematically using a Microsoft Excel data sheet developed by study [33]. This framework has four constructs:

the Learning Process, the Learning Assessment, the Decision Support System, and the Adaptive Learning Profile. Each construct comprises three elements, except for the Learning Assessment, which includes seven

Refer to Table V, which shows th. The elements given to the experts are stated in Table IV.at the threshold value (*d*) for each construct is below the acceptable limit ($d \leq 0.2$), indicating that all constructs meet the FDM qualification criteria. Specifically, the overall threshold value (*d*) for the Learning Process construct is $d=0.114$, the Learning Assessment construct is $d=0.094$, the Decision Support System construct is d=0.092, and the Adaptive Learning Profile construct is $d=0.097$. These values confirm that all constructs are acceptable based on the Fuzzy Delphi process.

In addition, individual elements within the constructs also meet the Fuzzy qualification requirement, with $d \leq 0.2$ for each element. The details are below:

- Learning Process elements: E1 (d=0.111), E2 (d=0.112), and E3 (d=0.118) are all acceptable.
- Learning Assessment elements: E4 (d=0.094), E5 (d=0.087), E6 (d=0.094), E7 (d=0.112), E8
- (d=0.089), E9 (d=0.094), and E10 (d=0.094) meet the requirement.
- Decision Support System elements: E11 (d=0.087), E12 (d=0.087), and E13 (d=0.102) are within the threshold.
- Adaptive Learning Profile elements: E14 (d=0.108), E15 (d=0.092), and E16 (d=0.092) are also acceptable.

TABLE IV. ELEMENTS FOR THE A-DSS-LF ACCORDING TO THE CONSTRUCTS

Learning Process	
E1	Apply adaptive learning in the blended learning environment.
E2	Apply student-centred approach
E3	Apply self-regulated learning
Learning Assessment	
E4	Identify students' learning styles.
E5	Apply a learning style model to determine students' learning styles.
E6	Use systematic instruments to assess students' learning styles.
E7	Use systematic instruments to evaluate student's learning status.
E8	Use systematic instruments capable of measuring specific learning objectives.
E9	Use systematic instruments to assess various learning domains, including cognitive skills, practical skills, and value practices.
E10	Use systematic instruments with clear criteria to determine students' mastery levels for various learning domains.
Decision Support System	
E11	Utilise identified student characteristics (student model) to make adaptive decisions.
E12	Use a collection of information (learning object model) to support adaptive decision-making.
E13	Apply criteria to align student characteristics with available information for making adaptive decisions.
Adaptive Learning Profile	
E14	Recommend personalized learning paths based on students' characteristics.
E15	Provide tailored feedback aligned with students' characteristics.
E16	Suggest learning resources that match students' characteristics.

TABLE V. SUMMARY OF THRESHOLD VALUE FOR CONSTRUCTS AND ELEMENTS IN A-DSS-LF

Experts	**Learning Process**			**Learning Assessment**							**Decision Support System**			**Adaptive Learning Profile**

Threshold Value (*d*) for each	**0.111**	**0.112**	**0.118**	**0.094**	**0.087**	**0.094**	**0.112**	**0.092**	**0.089**	**0.094**	**0.087**	**0.087**	**0.102**	**0.108**	**0.092**	**0.092**
Value (*d*) Construct	**0.114**			**0.094**							**0.092**			**0.097**		

Furthermore, the Fuzzy qualification requirement includes the percentage of expert consensus, which must exceed more than 75% for each element. The results demonstrate that all items meet this additional criterion, ensuring strong expert agreement for all elements and constructs. The threshold value (*d*), expert consensus percentage, defuzzification, and item position for the above elements are shown in Table VI.

Table V summarises the defuzzification process for the four constructs: Learning Process, Learning Assessment, Decision Support System, and Adaptive Learning Profile. The findings provide insight into the priority and significance of each element, as detailed below:

1) Learning process: The Learning Process construct comprises three elements, with Fuzzy scores (A) ranging from 0.873 to 0.904. All elements exceeded the FDM's α-cut value of A≥0.5 and met the expert consensus benchmark of more than 75%, confirming their acceptability and inclusion in the framework. The highest-ranked element, E2 (A=0.904, Rank1), demonstrates the most substantial expert agreement. E1 (A=0.898, Rank2) follows closely, reflecting its prioritization within the construct. Although ranked lowest, E3 (A=0.873, Rank3) still satisfies the Fuzzy Delphi criteria, validating its inclusion.

2) Learning assessment: The Learning Assessment construct comprises seven elements, with Fuzzy scores (A) ranging from 0.878 to 0.922. All elements exceeded the FDM's α-cut value of A≥0. and met the expert consensus benchmark of more than 75%, confirming their acceptability and inclusion in the framework. The highest-ranked element, E9 (A=0.922, Rank1), reflects the most substantial expert agreement, likely due to its alignment with the primary objectives of the construct. E6 (A=0.909, Rank2) and E10 (A=0.909, Rank2) share the second rank, highlighting their equal importance. E7 (A=0.904, Rank4) and E8 (A=0.902, Rank5) follow closely, demonstrating high levels of expert agreement. Although ranked lower, E5 (A=0.896, Rank6) and E4 (A=0.878, Rank7) remain valid, contributing to the construct's comprehensiveness.

3) Decision support system: The Decision Support System construct consists of three elements, with Fuzzy scores (A) ranging from 0.884 to 0.896. All elements exceeded the FDM's α-cut value of A≥0.5 and met the expert consensus benchmark of more than 75%, validating their inclusion in the framework. The highest-ranked element, E11 (A=0.896, Rank1), reflects strong expert prioritization. E12 (A=0.884, Rank2) and E13 (A=0.884, Rank2) share the second rank, indicating equal agreement and relevance within the construct.

4) Adaptive learning profile: The Adaptive Learning Profile construct comprises three elements, with Fuzzy scores (A) ranging from 0.891 to 0.902. All elements exceeded the FDM's α-cut value of A≥0.5 and met the expert consensus benchmark of more than 75%, confirming their acceptability. E15 (A=0.902, Rank1) and E16 (A=0.902, Rank1) share the top rank, reflecting the most substantial expert agreement and prioritization. Although ranked lower, E14 (A=0.891, Rank3) remains valid and aligned with the Fuzzy Delphi criteria, validating its inclusion in the construct.

TABLE VI. SUMMARY OF THE DEFUZZIFICATION PROCESS FOR CONSTRUCTS AND ELEMENTS IN A-DSS-LF

Elements	Triangular Fuzzy Numbers		Defuzzification Process				Expert Consensus	Acceptable Element	Ranking
	Threshold, *d*, value	% Expert Consensus	m_1	m_2	m_3	Fuzzy Score (A)			
Learning Process									
1	0.111	87%	0.780	0.927	0.987	0.898	Accepted	0.898	2
2	0.112	87%	0.793	0.933	0.987	0.904	Accepted	0.904	1
3	0.118	80%	0.740	0.900	0.980	0.873	Accepted	0.873	3
Learning Assessment									
4	0.094	87%	0.740	0.907	0.987	0.878	Accepted	0.878	7
5	0.087	93%	0.767	0.927	0.993	0.896	Accepted	0.896	6
6	0.094	93%	0.793	0.940	0.993	0.909	Accepted	0.909	2
7	0.112	87%	0.793	0.933	0.987	0.904	Accepted	0.904	4
8	0.092	93%	0.780	0.933	0.993	0.902	Accepted	0.902	5
9	0.089	93%	0.820	0.953	0.993	0.922	Accepted	0.922	1
10	0.094	93%	0.793	0.940	0.993	0.909	Accepted	0.909	2
Decision Support System									
11	0.087	93%	0.767	0.927	0.993	0.896	Accepted	0.896	2
12	0.087	93%	0.767	0.927	0.993	0.896	Accepted	0.896	1
13	0.102	87%	0.753	0.913	0.987	0.884	Accepted	0.884	3
Adaptive Learning Profile									
14	0.108	87%	0.767	0.920	0.987	0.891	Accepted	0.891	3
15	0.092	93%	0.780	0.933	0.993	0.902	Accepted	0.902	1
16	0.092	93%	0.780	0.933	0.993	0.902	Accepted	0.902	1

All elements' Fuzzy scores (A) range from 0.873 to 0.922, exceeding the FDM's α-cut value of A≥0.5 and the more than 75% expert consensus benchmark, confirming their validity. The findings highlight the prioritization of significant elements, such as E2 in the Learning Process, E9 in the Learning Assessment, E11 in the Decision Support System, and E15/E16 in the Adaptive Learning Profile. These results provide a robust foundation for the A-DSS-LF, ensuring its alignment with expert consensus and relevance in addressing diverse learner needs.

Table VII presents the summary ranking of all elements. According to Table VII, experts reached the highest agreement on E9 (A=0.922), emphasizing the importance of using systematic instruments to assess various learning domains. This element is the most essential component in the proposed A-DSS-LF framework.

TABLE VII. SUMMARY RANKING OF ALL A-DSS-LF ELEMENTS

Ranking	Acceptable Element	Elements
1	0.922	E9
2	0.909	E6
2	0.909	E10
4	0.904	E2
4	0.904	E7
6	0.902	E8
6	0.902	E15
6	0.902	E16
9	0.898	E1
10	0.896	E12
11	0.896	E5
11	0.896	E11
13	0.891	E14
14	0.884	E13
15	0.878	E4
16	0.873	E3

V. DISCUSSION

This section discusses the implications of the findings from the FDM analysis in validating the A-DSS-LF. It interprets the results, highlighting how the validated constructs and elements align with the study's objectives and contribute to a robust framework. Furthermore, the discussion explores the relevance of these findings in supporting personalized learning pathways within blended learning environments. Lastly, it identifies limitations and suggests directions for future research to enhance the framework's applicability and impact.

A. Expert Panel and Its Role in FDM Validation

In this study, the number of experts on the panel, 15, for the FDM process was deemed acceptable, although it did not fully meet the desired target. Prior research supports this approach, as studies such as [27], [23], [29], and [17] have employed expert panels ranging from 11 to 17 participants to achieve consensus on educational frameworks. Selecting an appropriate number of experts is critical to ensuring diverse perspectives, reliable consensus, and statistical robustness. This study's selection of 15 experts aligns with established FDM practices, thereby enhancing the credibility of the findings.

B. FDM Validation of A-DSS-LF

This section discusses the findings from the FDM validation, confirming the relevance of the A-DSS-LF. The results demonstrate that all elements across the four key constructs—Learning Process, Learning Assessment, Decision Support System, and Adaptive Learning Profile—achieved strong expert consensus. Each element successfully fulfilled the three essential criteria for FDM analysis:

- Meeting the required threshold value ($d \leq 0.2$).
- Achieving an expert agreement of >75%.
- Exceeding the α-cut defuzzification score ($A \geq 0.5$).

These findings validate the A-DSS-LF framework's ability to support adaptive learning in blended environments, reinforcing its role in enhancing engagement, personalization, and data-driven decision-making. The interactions between the four constructs—Learning Process, Learning Assessment, Decision Support System, and Adaptive Learning Profile—are illustrated in Fig. 2, showing how these components collectively enable adaptive learning experiences.

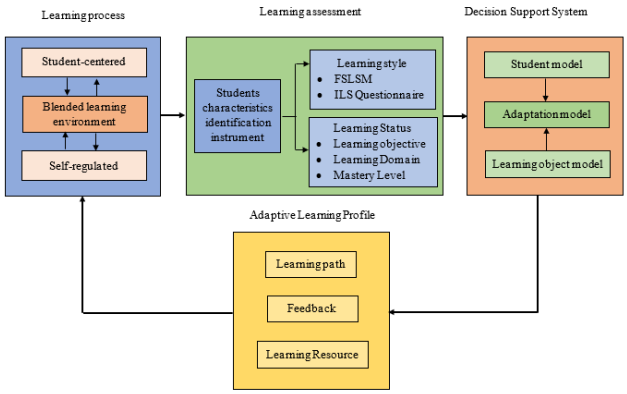

Fig. 2. Adaptive-decision support system-learning framework.

The following subsections provide a detailed discussion of the research findings, focusing on expert validation for each construct and the significance of the validated elements in supporting adaptive learning within the A-DSS-LF framework.

1) Learning process: The effectiveness of a structured learning process within a blended learning environment depends on its ability to adapt to individual learner needs, promote student-centered learning, and encourage self-regulation. Expert validation conducted in this study confirms the importance of these three key elements—blended learning environment, student-centered approaches, and self-regulated learning—as fundamental components in the learning process within the A-DSS-LF. All elements surpassed the α-cut threshold ($A \geq 0.5$) and the 75% consensus benchmark, confirming their necessity in the A-DSS-LF framework. Experts agreed that integrating these elements enhances learner

engagement and autonomy while aligning with best practices in adaptive learning and blended education models.

Among these, applying a student-centered approach (A = 0.904, Rank 1) received the highest expert consensus, emphasizing its role in fostering learner autonomy, engagement, and decision-making. The findings indicate that placing students at the center of the learning process improves motivation and enhances participation, reinforcing the importance of active learning strategies. This aligns with prior research, which highlights that student-centered learning fosters self-directed learning and critical thinking [34][35][36]. Applying adaptive learning in the blended learning environment (A = 0.898, Rank 2) was also strongly supported, as experts acknowledged that personalized learning paths, tailored feedback, and flexible progression help accommodate diverse learning needs. Previous studies similarly emphasize that adaptive learning improves instructional effectiveness by allowing students to advance at their own pace while receiving personalized support [7][37].

Although applying self-regulated learning (A = 0.873, Rank 3) ranked lowest, experts agreed on its significance in fostering learner independence, metacognitive skills, and academic performance. The findings suggest that students who engage in self-regulated learning demonstrate greater persistence and improved learning outcomes, particularly when they receive structured feedback and tracking tools. This is consistent with [38], who found that students with strong self-regulation skills achieve higher engagement and academic success in digital learning environments. Additionally, [39] emphasize that goal setting, adaptive scaffolding, and self-monitoring mechanisms are crucial in supporting self-regulation, reinforcing the importance of incorporating these strategies into the A-DSS-LF framework.

2) Learning assessment: A practical learning assessment is crucial for understanding student progress, identifying learning gaps, and personalizing instructional strategies. In Malaysian secondary education, the National Philosophy of Education emphasizes balancing cognitive, practical, and value-based domains. The FDM validation in this study confirms the importance of systematic learning assessments, with all elements surpassing the α-cut threshold ($A \geq 0.5$) and the 75% consensus benchmark, validating their inclusion in the A-DSS-LF.

Among these elements, systematic instruments with clear criteria to determine students' mastery levels (A = 0.922, Rank 1) received the most substantial expert consensus, highlighting the need for structured assessment frameworks. This aligns with [40], who demonstrated the effectiveness of DSS in behavioral modeling for personalized learning assessments. Similarly, [41] emphasizes that clear mastery criteria in formative assessments enhance student motivation and outcomes.

Assessing various learning domains (A = 0.909, Rank 2) also gained strong support, reinforcing the need for comprehensive, multidimensional assessments beyond cognitive evaluation to practical skills and value-based learning. The study in [1] validated this approach, showing that adaptive learning paths based on learner profiles improve engagement and achievement, a perspective supported by study [42], who highlight that digital assessment tools enhance data-driven instructional adjustments.

Identifying students' learning styles (A = 0.904, Rank 4) and applying a learning style model (A = 0.902, Rank 5) were also validated, reinforcing the importance of personalized education. The Felder-Silverman Learning Style Model (FSLSM) is a core component of the A-DSS-LF framework, aligning with studies that emphasize tailored instructional strategies [37] [43]. [44] further supports these findings, demonstrating that systematic learning style classification enhances adaptive learning effectiveness, ensuring that students receive personalized support, leading to better engagement and learning outcomes.

3) Decision support system: The DSS is a pivotal component of the A-DSS-LF, enabling adaptive learning decisions based on structured data analysis. The FDM validation confirms the DSS's importance, with all elements surpassing the α-cut threshold ($A \geq 0.5$) and the 75% consensus benchmark, validating its critical role in the framework.

Among these elements, utilizing identified student characteristics (A = 0.896, Rank 1) received the most substantial expert consensus, emphasizing the need for tailoring learning experiences based on student profiles. This aligns with [45], who highlighted the potential of ontology-based DSS for predictive learning and [46], who demonstrated that tailored educational technologies enhance engagement and satisfaction.

Experts also validated using a collection of information (A = 0.884, Rank 2) and applying criteria to align student characteristics with learning resources (A = 0.884, Rank 2), receiving equal expert consensus. These findings reinforce the importance of structured decision-making in adaptive learning, ensuring that DSS-driven systems effectively match learner needs with relevant instructional content. [47] emphasized that DSS enhances personalized learning by leveraging student models and learning resources and optimizing adaptive learning pathways. Similarly, the study in [9] highlighted that student models, content adaptation, and structured decision-making criteria are crucial in delivering tailored learning experiences, ensuring student profiles align with instructional content in adaptive systems.

Additionally, the study in [48] demonstrated that fuzzy weight-based rule systems dynamically adjust content complexity and volume based on cognitive-level analysis, reinforcing the importance of structured alignment between learner characteristics and learning resources. By integrating decision-making criteria with student profiles and learning objects, DSS ensures that personalized learning paths evolve dynamically, improving instructional effectiveness and learner engagement.

4) Adaptive learning profile: The Adaptive Learning Profile received unanimous expert agreement, reinforcing its critical role in enhancing personalized learning for both students and teachers. This construct focuses on three key elements: personalized learning paths, tailored feedback, and adaptive learning resources, ensuring data-driven, individualized learning experiences. The FDM validation confirms the importance of these elements, with all components

exceeding the α-cut threshold (A ≥ 0.5) and the 75% expert consensus benchmark, validating their essential role in the A-DSS-LF framework.

Among these elements, providing tailored feedback aligned with students' characteristics (A = 0.902, Rank 1) and suggesting learning resources that match students' characteristics (A = 0.902, Rank 1) received the highest expert consensus, reflecting their strong prioritization in adaptive learning environments. The findings emphasize that actionable feedback improves engagement and instructional strategies, ensuring that students receive personalized insights into their learning progress [9] [48]. Additionally, adaptive learning resources enhance accessibility and relevance by offering content aligned with students' cognitive levels and learning styles, reinforcing the importance of adaptive content curation [43].

Although recommending personalized learning paths based on students' characteristics (A = 0.891, Rank 3) was ranked slightly lower, it remains a fundamental component of adaptive learning. Personalized learning paths allow students to progress at their own pace, addressing knowledge gaps and supporting competency-based progression [2] [49]. The expert validation results confirm that while learning path recommendations are essential, they are most effective when paired with tailored feedback and adaptive learning resources, ensuring holistic and personalized educational outcomes.

VI. Conclusion

This study aimed to validate the A-DSS-LF using the FDM. Through the involvement of expert consensus, the findings confirmed the credibility and applicability of the proposed framework in supporting personalized adaptive learning within the blended learning environment. The FDM approach ensured robust validation of the constructs and elements, as evidenced in similar educational contexts where it effectively built consensus and established framework reliability.

The FDM results demonstrated a high level of agreement among experts, particularly regarding the essential components of the framework: the learner model, adaptation model, and learning object model. These findings align with studies emphasizing the significance of adaptive learning frameworks tailored to individual learner profiles. The validated A-DSS-LF provides a structured approach to integrating adaptive learning in blended settings, emphasizing personalized learning paths tailored to individual learner characteristics. Furthermore, this framework contributes to the ongoing dialogue on adaptive educational systems by incorporating unique elements such as value practices and practical skills, extending beyond traditional cognitive assessments.

The results of this study contribute significantly to the field by offering a validated framework tailored to the Malaysian education context, addressing theoretical and practical gaps. It sets a foundation for implementing the A-DSS-LF prototype and testing its impact in real-world education. Future work should refine the framework based on further qualitative feedback and usability testing. Additionally, implementing and evaluating the A-DSS-LF prototype in secondary school settings will provide valuable insights into its practical effectiveness and scalability. This study aims to enhance personalized education and optimize learning outcomes in blended learning environments by advancing adaptive learning frameworks.

Acknowledgment

We thank Universiti Malaysia Terengganu for providing funding support for this project (TAPERG/2023/UMT/2564).

Towards Two-Step Fine-Tuned Abstractive Summarization for Low-Resource Language Using Transformer T5

Salhazan Nasution[1], Ridi Ferdiana[2], Rudy Hartanto[3]
Department of Electrical and Information Engineering,
Faculty of Engineering, Universitas Gadjah Mada, Yogyakarta, Indonesia[1,2,3]
Department of Informatics Engineering-Faculty of Engineering, Universitas Riau, Pekanbaru, Indonesia[1]

***Abstract*—This study explores the potential of two-step fine-tuning for abstractive summarization in a low-resource language, focusing on Indonesian. Leveraging the Transformer-T5 model, the research investigates the impact of transfer learning across two tasks: machine translation and text summarization. Four configurations were evaluated, ranging from zero-shot to two-step fine-tuned models. The evaluation, conducted using the ROUGE metric, shows that the two-step fine-tuned model (T5-MT-SUM) achieved the best performance, with ROUGE-1: 0.7126, ROUGE-2: 0.6416, and ROUGE-L: 0.6816, outperforming all baselines. These findings demonstrate the effectiveness of task transferability in improving abstractive summarization performance for low-resource languages like Indonesian. This study provides a pathway for advancing natural language processing (NLP) in low-resource language through two-step transfer learning.**

***Keywords*—Abstractive summarization; low-resource language; Transformer T5; transfer learning**

I. Introduction

The rapid advancement of technology has accelerated the flow of information, with an increasing number of people opting to consume information digitally rather than through printed media [1]. However, as the volume of information available on the Internet continues fto grow, humans face the challenge of processing and understanding this information within a limited amount of time, while their reading speed is inherently constrained to an average of 300 words per minute [2]. Automatic text summarization systems are, therefore, essential to facilitate faster information retrieval and comprehension.

Text summarization can be categorized into two types: manual summarization and automatic summarization. Manual summarization involves the direct effort of humans, which is inherently labor-intensive, time-consuming, and costly. Consequently, automation is required to produce summaries more efficiently and at a lower cost [3].

Text summarization is a method for generating concise, accurate, and digestible summaries from lengthy textual documents. This technique is commonly encountered in everyday life, such as in news headlines, meeting minutes, movie synopses, or book reviews. The objective of text summarization is to produce a summary from a collection of articles or documents that retains the essential information while being significantly shorter than the original text [4].

Text summarization is a subfield of Natural Language Processing (NLP) and typically employs two main approaches: extractive summarization and abstractive summarization. Extractive summarization involves selecting words, phrases, or sentences directly from the source document, ranking their relevance, and assembling them into a summary [5]. In contrast, abstractive summarization generates summaries by creating new sentences or phrases that convey the same meaning as the source document [6].

Abstractive summarization aids readers in better understanding an article because it generates a new summary by paraphrasing the content. This approach is considered the most ideal, as it holds significant potential for producing human-like summaries [7]. By rephrasing and condensing the source material, abstractive summarization achieves a level of coherence and fluency that extractive methods often lack, making it a highly valuable tool in text summarization research and applications.

Research on text summarization in Indonesia has been conducted across various domains. Studies employing extractive methods include summarization of news articles [8][9][10][11], snippets for search engine results [12], book synopsis summarization [13] using ranking methods such as Maximal Marginal Relevance (MMR) [14] and Text Rank [15], as well as meeting minute summarization [16][17]. In contrast, abstractive summarization research for the Indonesian language remains limited due to resource constraints. Indonesian is categorized as a low-resource language due to the limited availability of datasets [18]. Although Indonesian is recognized as the fourth most widely used language on the Internet, research progress in NLP for this language has been slow due to a lack of resources and datasets [19].

To date, there are only two large-scale datasets available for Indonesian text summarization: IndoSum [20], consisting of 19,000 articles and summaries, and Liputan6 [21], containing 200,000 articles with summaries. Combining these datasets can enhance the model's knowledge by exposing it to more data, patterns, and variations. However, dataset integration carries potential risks, particularly if one dataset is less accurate. Therefore, thorough pre-processing and in-depth data analysis of both datasets are necessary before merging them, along with cross-validation to ensure optimal results.

Research in the field of summarization has seen rapid advancements. Some studies have implemented Bidirectional

Gated Recurrent Unit (BiGRU) to generate summaries of Indonesian-language journals [22]. Other approaches include using Genetic Semantic Graphs [23], Abstract Meaning Representation (AMR) graphs [7], and Semantic Role Labeling (SLR) [24] for summarizing news articles. Wijayanti et al. [25] investigated the performance of pre-trained BERT models and evaluated them using the ROUGE metric [26]. The experimental results revealed that English pre-trained models could generate summaries from Indonesian articles. The utilization of Indonesian pre-trained models in conjunction with the IndoSum dataset, a benchmark for Indonesian text summarizing, produced more effective summaries. Nevertheless, issues such as fragmented sentences, erroneous phrases, and redundant vocabulary were still noted.

The efficacy of transfer learning provides a substantial benefit compared to earlier methodologies. Large Language Models (LLMs) like Transformer-T5 [27], pre-trained on vast datasets, may be tailored for many purposes, including machine translation and summarization. T5, leveraging its transfer learning capabilities, may be fine-tuned and retrained with more specialized datasets for various languages. This adaptability enables T5 to overcome the constraints in Indonesian text summarizing research by integrating machine translation and summarization, so enhancing the model's knowledge and ultimately elevating the accuracy and quality of Indonesian text summaries.

The rapid proliferation of digital content has highlighted the necessity for automatic text summary to enhance information accessibility. Summarization can be classified into extractive and abstractive methods. Extractive summarization directly selects sentences from the source text, whereas abstractive summarization rephrases and condenses the content, resulting in human-like summaries. In spite of its ability to produce coherent and meaningful summaries, abstractive summarization remains a difficult endeavor, particularly for low-resource languages such as Indonesian.

Existing research on Indonesian summarization is largely extractive due to the lack of large-scale, high-quality datasets required for abstractive models. However, advancements in Transformer-based models, particularly the Text-to-Text Transfer Transformer (T5), have introduced a new paradigm for natural language processing (NLP). T5 unifies multiple NLP tasks into a text-to-text framework, enabling it to perform tasks such as summarization and machine translation under the same architecture. Moreover, its transfer learning capabilities allow T5 to adapt to new tasks and languages with minimal data.

This study addresses the research gap in Indonesian abstractive summarization by evaluating the effectiveness of two-step fine-tuning. Using the T5 model, the research investigates the impact of first fine-tuning on machine translation and then on summarization. The evaluation, conducted using the ROUGE metric, provides insights into how task transferability enhances summarization performance in low-resource languages. This study contributes to advancing NLP for Indonesian by presenting an effective method to overcome data scarcity and achieve high-quality abstractive summarization.

The rest of this paper is organized as follows: Section II presents the motivating scenario, discussing the challenges of abstractive summarization in low-resource languages and the rationale behind using the Transformer-T5 model. Section III reviews related work, highlighting previous studies on Indonesian text summarization and transfer learning approaches. Section IV details the methodology, including the two-step fine-tuning approach, dataset descriptions, experimental design, and evaluation metrics. Section V presents the results, comparing different fine-tuning strategies and their impact on summarization performance. Section VI discusses the findings, analyzing the advantages of the proposed approach, the challenges encountered, and potential directions for future research. Finally, Section VII concludes the study by summarizing key insights and contributions.

II. Motivating Scenario

Abstractive summarization, especially in a low-resource language like Indonesian, requires a nuanced understanding of the language's syntax, semantics, and cultural context. The Transformer-T5 model, with its unified text-to-text approach, is well-suited for such tasks, but it must first acquire foundational linguistic knowledge in the target language to perform effectively.

For the T5 model to generate coherent and human-like abstractive summaries in Indonesian, it must be fine-tuned on datasets that introduce it to the language. This step is vital as the model's pre-training on general datasets may not include sufficient exposure to Indonesian. By enabling the model to learn the intricacies of Indonesian through a targeted fine-tuning process, we establish a critical foundation for downstream tasks like summarization.

The most efficient approach to instructing a large language model in a new language is to fine-tune it using a high-quality parallel dataset for machine translation. In particular, a parallel corpus of English and Indonesian can be a valuable source of grammatical structures, idiomatic expressions, and linguistic patterns which are diverse. This fine-tuning phase guarantees that the model can accurately comprehend Indonesian texts and establishes the foundation for abstractive summarization.

In this study, we implement a two-step fine-tuning strategy to reconcile the disparity between task-specific training and foundational language comprehension. Initially, the T5 model is refined on English-Indonesian machine translation duties to enhance its linguistic proficiency. The model is subsequently fine-tuned on an Indonesian abstractive summarization dataset to enhance its summarization capabilities. This sequential fine-tuning approach is intended to optimize the model's performance by utilizing transfer learning to overcome the obstacles presented by the low-resource nature of the Indonesian language.

III. Related Work

Recent studies have explored the use of pre-trained models for Indonesian text summarization as shown in Table I. The previous work [25] fine-tuned BertSumAbs with an Indonesian pre-trained BERT model on the IndoSum dataset, achieving ROUGE-1: 0.67, ROUGE-2: 0.54, and ROUGE-L: 0.65, outperforming English pre-trained BERT models. However, challenges such as meaningless words and repetitive phrases persist. Similarly, [36] examined IndoBERT checkpoints and

TABLE I. COMPARISON OF ROUGE SCORES ACROSS MODELS

No.	Research	Model	Dataset	R-1	R-2	R-L
1	[28]	BART (Augmented)	Liputan6	0.4093	0.3409	0.4037
2	[29]	IndoBERT	Liputan6	0.4235	0.2415	0.3544
3	[30]	ALBERT	IndoSum	0.4528	0.4077	0.4439
4	[31]	EASum (IndoBART + Extractive)	IndoSum	0.3600	0.2300	0.3500
5	[32]	IndoBART (Augmented)	Liputan6	0.3822	0.2079	0.3124
6	[33]	mT5 (Augmented)	Liputan6	0.3856	0.2329	0.3263
7	[34]	BERT2GPT	IndoSum	0.6226	0.5613	0.6043
8	[35]	T5-Large	Wikipedia	0.4738	0.2927	0.4115
9	[36]	BERTSumAbs + IndoBERT-LEM + GPT Decoder	IndoSum	0.6920	0.6135	0.6836
10	[37]	CTRLSum (mBART50)	Liputan6	0.4341	0.2406	0.3963
11	[38]	Transformer (CLS + MWE)	IndoSum	0.4247	0.2226	0.3809
12	[25]	BertSumAbs (IndoBERT)	IndoSum	0.6700	0.5400	0.6500
13	**Our Research**	Transformer-T5 (two-step transfer learning)	IndoSum	**0.7126**	**0.6416**	**0.6816**

found that BERTSumAbs with IndoBERT-LEM and a GPT-like decoder performed best, achieving ROUGE-1: 0.6920, ROUGE-2: 0.6135, and ROUGE-L: 0.6836, highlighting the importance of decoder selection in transformer-based summarization. Beyond BERT models, [30] explored ALBERT, a lightweight variant of BERT, fine-tuning it on IndoSum. The best model achieved ROUGE-1: 0.4528, ROUGE-2: 0.4077, and ROUGE-L: 0.4439, demonstrating a viable alternative for resource-constrained environments while maintaining competitive accuracy.

Some studies have combined extractive and abstractive approaches to improve summarization performance. The author in [31] introduced EASum, a model that first generates extractive summaries using Doc2Vec and cosine similarity, then refines them using IndoBART. On IndoSum, it achieved ROUGE-1: 0.36, ROUGE-2: 0.23, and ROUGE-L: 0.35, while on Liputan6, it performed lower than mBART and IndoGPT. A different hybrid approach was explored in [34], which combined BERT as an encoder with GPT-2 as a decoder. The model, trained on IndoSum, achieved ROUGE-1: 0.6226, ROUGE-2: 0.5613, and ROUGE-L: 0.6043, outperforming BertSum-based models in bi-gram accuracy.

Data augmentation techniques have been widely applied to improve model generalization. The author in [32] utilized synonym replacement-based augmentation and fine-tuning on Liputan6, where the best-performing IndoBART model achieved ROUGE-1: 0.3822, ROUGE-2: 0.2079, and ROUGE-L: 0.3124. Similarly, [33] applied backtranslation-based augmentation on mT5, achieving ROUGE-1: 0.3856, ROUGE-2: 0.2329, and ROUGE-L: 0.3263, demonstrating improvements in coherence and informativeness. Another augmentation-based study, [28], fine-tuned BART on Liputan6, IndoSum, and ChatGPT-augmented summaries, generating over 36,000 new instances. The best model reached ROUGE-1: 0.4093, ROUGE-2: 0.3409, and ROUGE-L: 0.4037, highlighting the effectiveness of multi-dataset fine-tuning.

Cross-lingual and multilingual approaches have also been investigated to expand summarization capabilities. The author in [37] introduced CTRLSum, a keyword-controlled summarization method fine-tuned on mBART50, which achieved ROUGE-1: 0.4341, ROUGE-2: 0.2406, and ROUGE-L: 0.3963 on Liputan6. For cross-lingual summarization (CLS), [38] proposed an end-to-end CLS model integrating multilingual word embeddings (MWE). The model, trained on a translated IndoSum dataset, achieved ROUGE-1: 0.4247, ROUGE-2: 0.2226, and ROUGE-L: 0.3809, improving cross-lingual representation alignment.

Large language models (LLMs) have recently been explored as few-shot summarization tools. The author in [29] evaluated ChatGPT with prompt tuning on Liputan6, comparing it with IndoBART, IndoBERT, and mBART50. While IndoBERT performed best on Liputan6 (ROUGE-1: 0.4235, ROUGE-2: 0.2415, ROUGE-L: 0.3544), ChatGPT had lower automatic evaluation scores but excelled in human evaluation, suggesting superior fluency but lower adherence to reference summaries. Benchmarking efforts have assessed various transformer-based models. The author in [35] compared T5-Large, Pegasus-XSum, and ProphetNet-CNNDM on Wikipedia datasets in English and Indonesian, finding that T5-Large achieved the best ROUGE scores (ROUGE-1: 0.4738, ROUGE-2: 0.2927, ROUGE-L: 0.4115).

Despite the advancements in Indonesian abstractive summarization, most studies either focus on direct fine-tuning of transformer-based models or augmenting datasets to improve performance. However, few works explore multi-task learning approaches that leverage machine translation as a pre-training step for summarization. Existing studies, such as those using IndoBART, mT5, and BERT2GPT, demonstrate the effectiveness of pre-trained models but primarily fine-tune them only on summarization tasks.

This paper addresses this gap by proposing a two-step fine-tuning approach where a model is first fine-tuned on a machine translation task, followed by fine-tuning for abstractive summarization. The hypothesis is that exposing the model to translation tasks helps it learn better language representations and text reformation techniques, which could lead to more coherent, fluent, and information-rich summaries. Unlike previous works that rely solely on pre-trained language models or data augmentation, this research explores whether a structured pre-training strategy with translation improves the performance of Indonesian abstractive summarization models.

IV. METHODS

A. Text-to-Text Transfer Transformer (T5)

The Text-to-Text Transfer Transformer (T5) is a cutting-edge natural language processing (NLP) model developed by Google Research. It is structured to encapsulate all NLP tasks within a cohesive text-to-text format, wherein both the input and output are expressed as sequences of text. This approach enables T5 to do several tasks, including translation,

summarization, categorization, and question answering, with a consistent architecture and training methodology.

- Text-to-Text Format: T5 differentiates itself from conventional models, which are task-specific (such as categorization or generation), by reinterpreting every activity as a text creation challenge. For instance:
  - Translation: Input = "translate English to Indonesian: Where are you?", Output = "Di mana kamu?".
  - Summarization: Input = "summarize: The article discusses...", Output = "Key points of the article...".
  - Classification: Input = "classify sentiment: This movie was amazing!", Output = "positive".
- Unified Architecture: T5 utilizes the Transformer architecture, a deep learning model based on self-attention mechanisms. It employs an encoder-decoder design:
  - The encoder processes the input text to generate contextual representations.
  - The decoder generates the output text token by token.
- Pre-Training with Transfer Learning: T5 is pre-trained on a large corpus using a task called span corruption, where spans of text in the input are masked, and the model is trained to predict the masked spans. This approach helps the model learn a rich understanding of language, which can then be fine-tuned for specific downstream tasks.
- Scalability: T5 comes in various sizes, from small to large (e.g. T5-Small, T5-base, T5-Large, T5-XXL), allowing flexibility depending on computational resources and task complexity.
- Fine-Tuning: After pre-training, T5 can be fine-tuned on specific tasks with labeled data. This step ensures that the model learns task-specific nuances while leveraging the general language knowledge from pre-training.

The versatility of T5 makes it particularly suitable for tasks like summarization and machine translation, as it treats both tasks uniformly in the text-to-text format. This study leverages T5's capabilities in a multi-stage process: first fine-tuning it on machine translation tasks to leverage its language understanding capabilities, followed by additional fine-tuning on summarization tasks to optimize its performance for generating concise and coherent summaries. The model's capacity to generalize across tasks facilitates zero-shot testing, permitting assessment without task-specific fine-tuning.

B. Datasets

1) Summarization task: The dataset employed in this study is IndoSum [20]. IndoSum establishes a novel standard for text summarizing in Bahasa Indonesia. The IndoSum dataset comprises articles obtained from Indonesian online news outlets and contains almost 200 times the number of articles compared to prior research on Indonesian-language articles [39]. To be more precise, IndoSum includes 18,762 articles and their respective summaries, which are divided into six categories: entertainment, inspiration, sports, celebrity, headlines, and technology.

A number of well-known online news portals, including CNN Indonesia, Kumparan, Suara.com, Antaranews, and others, provided the data for IndoSum. The mean article length in this dataset is 292 words, with the biggest article being 1,228 words and the shortest item consisting of 36 words. The summaries average 58 words in length, with the greatest being 86 words and the smallest including 32 words.

2) Machine translation task: Datasets with parallel English-Indonesian sentences were utilized for pre-training, including OpenSubtitle [40], TED 2018 [41], TED 2020 [42], News Commentary [43], and CCMatrix [44]. These datasets were chosen especially for the purpose of training the T5 model for translating from English to Indonesian because of their complimentary qualities and applicability to the field of text translation.

The OpenSubtitle dataset, comprising a compilation of movie and television subtitles, offers a valuable repository of informal, conversational language. This dataset is very beneficial for training models to process daily language, colloquialisms, and conversational writing. The extensive range of themes and contexts guarantees that the model is exposed to multiple linguistic styles and structures.

The TED 2018 and TED 2020 datasets are composed of transcripts from TED Talks, which are renowned for their formal and informative communication style. Ideally, these datasets are utilized to train models that will translate academic, technical, and professional content. Additionally, they assist the model in dealing with a variety of subjects, as TED Talks encompass a broad spectrum of fields, including technology, science, and the arts and culture.

The News Commentary dataset emphasizes news stories and commentary, with a formal tone and terminology typically seen in journalistic literature. This dataset enables the model to manage domain-specific language, organized arguments, and subjective content characteristic of news sources.

Finally, the CCMatrix dataset constitutes a substantial compilation of parallel sentences derived from web-crawled data. The extensive size and varied content provide thorough coverage of linguistic structures and terminology, rendering it essential for enhancing the model's generalization capacity across distinct text kinds. For the CCMatrix dataset, we utilized just 600,000 data points due to constraints of computational resources and processing duration.

We sought to establish a strong and adaptable training basis for the T5 model by integrating these datasets. This selection guarantees the model's exposure to a wide array of text styles, tones, and domains, facilitating its effective performance in multiple translation scenarios, encompassing informal, formal, and technical contexts. The meticulous selection of datasets demonstrates our aim to develop a translation model that can tackle the intricacies and diversity present in actual English-to-Indonesian translation projects.

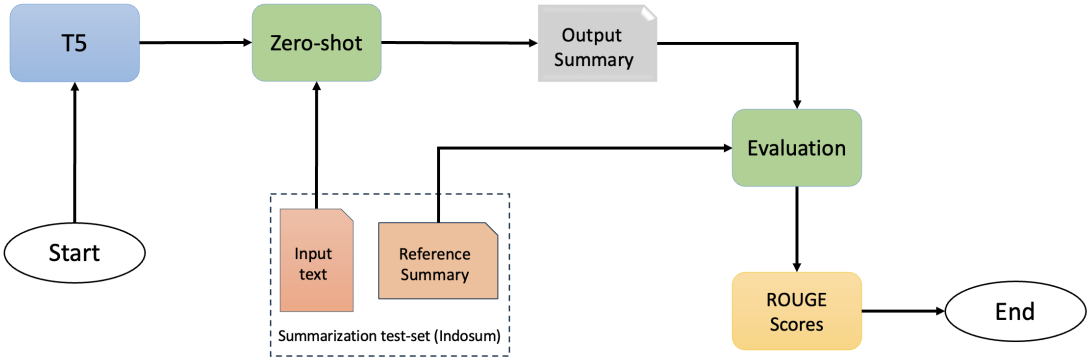

Fig. 1. T5 (Zero-shot).

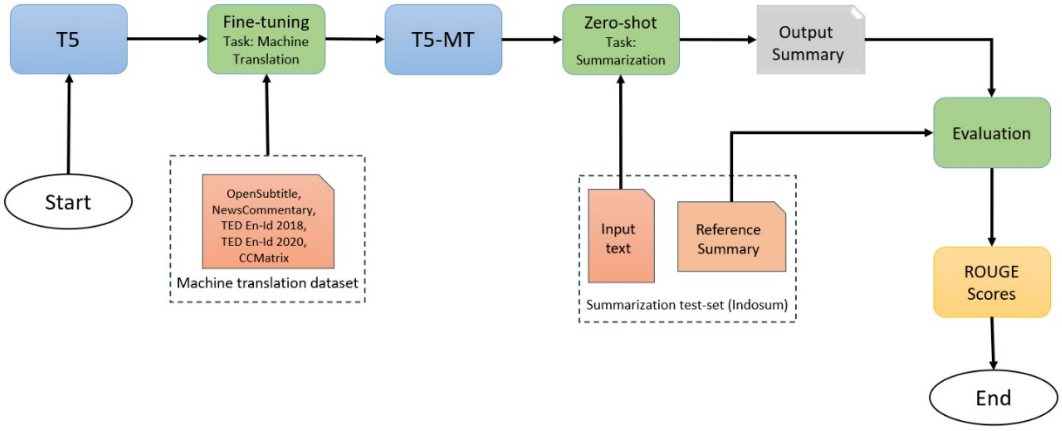

Fig. 2. T5-MT (Fine-tuning).

C. Experimental Design

A two-step fine-tuning approach is implemented in this study to assess the efficacy of the T5 model on Indonesian abstractive summarization. Four experimental configurations are included in the design, which has two tasks: machine translation and summarization.

1) Experiment 1: T5 Zero-shot: Fig. 1 illustrates the workflow for a zero-shot summarization task that employs the T5 (Text-to-Text Transfer Transformer) model. Starting with the pre-trained T5 model, which has not been refined on the specific summarization dataset, the procedure commences. The zero-shot approach involves explicitly testing the model on summarization tasks without any additional training. This demonstrates the T5 model's ability to generalize to unseen tasks by utilizing its pre-trained knowledge.

The summarization task employs the IndoSum dataset, comprising two primary elements: input text (the texts designated for summarization) and reference summaries (the authoritative summaries utilized for assessment). The T5 model analyzes the input text and produces a summary, which is subsequently compared to the reference summary to assess its quality.

The assessment procedure employs the ROUGE metric, which quantifies the overlap between the generated summaries and the reference summaries based on unigrams (ROUGE-1), bigrams (ROUGE-2), and the longest common subsequences (ROUGE-L). The resultant ROUGE scores quantify the T5 model's performance on the summarization job. The workflow concludes with the reporting of the ROUGE scores as the final result. This picture clearly delineates the process from job start to evaluation, highlighting the zero-shot capabilities of T5 in summarization tasks.

2) Experiment 2: T5-MT Fine-tuning: The T5 model is employed to perform two sequential tasks: fine-tuning for machine translation and zero-shot summarization. The workflow is illustrated in Fig. 2. It initiates with the T5-base model, which is refined on a machine translation task. This fine-tuning process uses diverse datasets such as OpenSubtitles, NewsCommentary, TED En-Id 2018, TED En-Id 2020, and CCMatrix, which consist of parallel text pairs for English-to-Indonesian translation. The outcome of this step is a specialized T5 model for machine translation, labeled as T5-MT.

The fine-tuned T5-MT model is then tested on a summarization task using the IndoSum dataset in a zero-shot manner, meaning the model is applied to summarization without additional task-specific fine-tuning. The summarization dataset includes input text (the articles to be summarized) and cor-

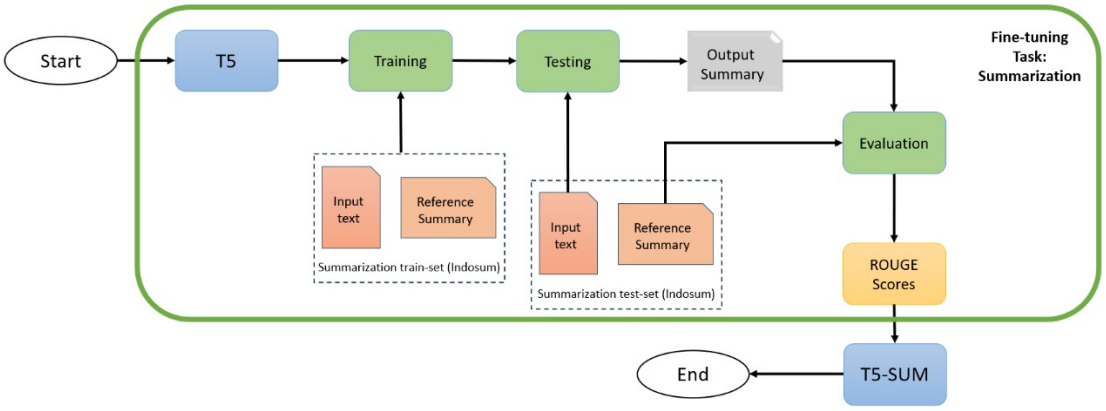

Fig. 3. T5-SUM (Fine-tuning).

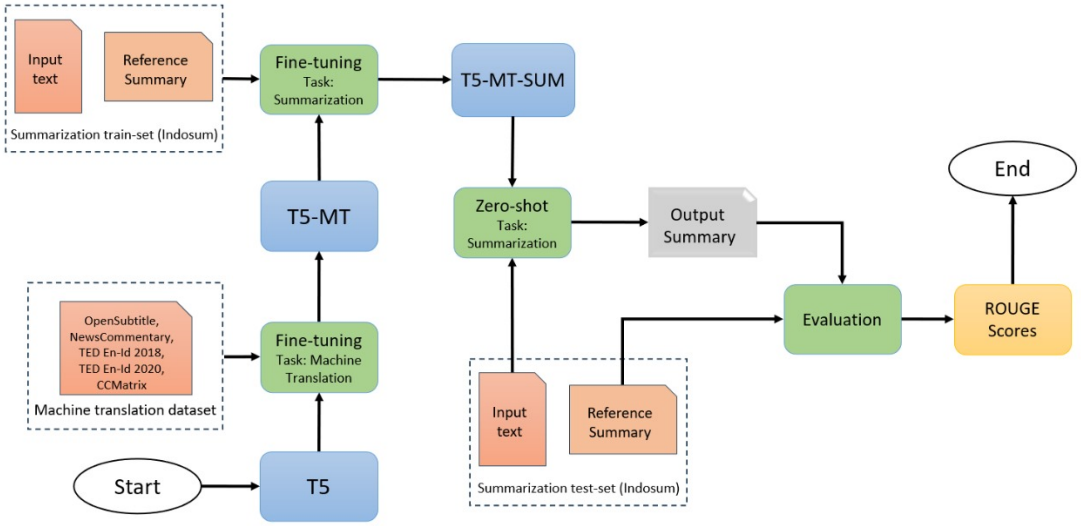

Fig. 4. T5-MT-SUM (Two-step Fine-tuning).

responding reference summaries (gold-standard summaries). The model processes the input text and generates an output summary.

The generated summaries are evaluated using the ROUGE metric, which computes the similarity between the output summaries and the reference summaries. The evaluation provides scores for ROUGE-1 (unigram overlap), ROUGE-2 (bigram overlap), and ROUGE-L (longest common subsequence). These scores serve as a measure of the summarization performance. The workflow concludes with the ROUGE scores summarizing the model's effectiveness. This diagram showcases a pipeline approach, where a model fine-tuned for one task (machine translation) is tested for generalization in another task (summarization), illustrating the versatility of T5.

3) Experiment 3: T5-SUM Fine-tuning: Fig. 3 diagram represents the workflow for fine-tuning the T5 model specifically for a summarization task. It begins with the pre-trained T5 model, which undergoes fine-tuning using the IndoSum dataset. The dataset contains input text (articles or passages to be summarized) and their corresponding reference summaries (gold-standard summaries). The fine-tuning process adapts the T5 model to perform summarization tasks effectively, creating a specialized model referred to as T5-SUM.

The process is divided into two main phases: training and testing. During the training phase, the model learns patterns and relationships between the input text and the reference summaries from the training set of the IndoSum dataset. Once trained, the model is tested using the test set of the same dataset, where it generates summaries (labeled as Output Summary) for new, unseen input texts.

The ROUGE metric is employed to assess the summaries that are generated, comparing the overlap between the summaries and the reference summaries. The model is evaluated using ROUGE-1 (unigram overlap), ROUGE-2 (bigram overlap), and ROUGE-L (longest common subsequences). The process culminates in the ROUGE scores, which serve as an indicator of the summarization task's performance of the fine-tuned T5-SUM model. This diagram effectively emphasizes

the significance of dataset preparation and evaluation metrics by illustrating a structured pipeline for training and evaluating a summarization model.

4) Experiment 4: T5-MT-SUM Two-Step Fine-tuning: Fig. 4 shows a two-step fine-tuning approach for modifying the T5 model to perform summarization tasks. It starts with the pre-trained T5 model, which is then fine-tuned on a machine translation task with datasets including OpenSubtitles, NewsCommentary, TED En-Id 2018, TED En-Id 2020, and CCMatrix. This step results in the T5-MT model, which is designed for machine translation.

During the second phase, the T5-MT model is subjected to an additional fine-tuning process for the summarizing job utilizing the IndoSum dataset, comprising input text and their respective reference summaries. Through further refinement, the T5-MT model is modified for summarizing tasks, resulting in the final model known as T5-MT-SUM. This two-step fine-tuning ensures that the model takes advantage of its machine translation knowledge before being improved for summarization, potentially enhancing performance.

The T5-MT-SUM model is subsequently evaluated on the IndoSum test set, producing output summaries for novel input texts in a zero-shot summarizing task. The produced summaries are assessed against the reference summaries utilizing the ROUGE metric, which measures summary quality through unigram, bigram, and longest common subsequence overlaps (ROUGE-1, ROUGE-2, and ROUGE-L, respectively). The procedure culminates with the ROUGE scores, which encapsulate the model's efficacy in the summarization task. This figure clearly illustrates the sequential fine-tuning method, demonstrating how knowledge transfer between tasks can improve performance.

D. Evaluation Metrics

Recall-Oriented Understudy for Gisting Evaluation (ROUGE) is a metric that is intended to assess the quality of summaries by corresponding them to one or more human-generated reference summaries. It measures the overlap between the candidate summary and reference summaries in terms of n-grams, sequences, or word pairs.

- ROUGE-1: Measures unigram overlap.
- ROUGE-2: Measures bigram overlap.
- ROUGE-L: Measures the longest common subsequence between generated and reference summaries.

ROUGE-N evaluates the n-gram overlap between a candidate summary and reference summaries. It is defined as:

$$\text{ROUGE-N} = \frac{\sum_{S \in \text{Reference Summaries}} \sum_{\text{gram}_n \in S} \text{Count}_{\text{match}}(\text{gram}_n)}{\sum_{S \in \text{Reference Summaries}} \sum_{\text{gram}_n \in S} \text{Count}(\text{gram}_n)} \tag{1}$$

Where:

- $\text{Count}_{\text{match}}(\text{gram}_n)$: The number of n-grams in both the candidate summary and the reference summary.
- $\text{Count}(\text{gram}_n)$: The total number of n-grams in the reference summary.
- n: The length of the n-gram (e.g. 1 for unigrams, 2 for bigrams).

1) ROUGE-1 (Unigram overlap): ROUGE-1 measures the overlap of unigrams between the reference and candidate summaries. It is defined as:

$$\text{ROUGE-1} = \frac{\text{Number of Overlapping Unigrams}}{\text{Total Number of Unigrams in the Reference Summary}} \tag{2}$$

Example:

- Reference Summary: "I really like reading novels".
- Candidate Summary: "I like reading novels every day".
- Unigrams in Reference: I, really, like, reading, novels.
- Unigrams in Candidate: I, like, reading, novels, every, day.
- Overlapping Unigrams: I, like, reading, novels (4 overlaps).

The total number of unigrams in the reference summary is 5. Thus:

$$\text{ROUGE-1} = \frac{4}{5} = 0.8 \tag{3}$$

2) ROUGE-2 (Bigram Overlap): ROUGE-2 measures the overlap of bigrams (pairs of consecutive words) between the reference and candidate summaries. It is defined as:

$$\text{ROUGE-2} = \frac{\text{Number of Overlapping Bigrams}}{\text{Total Number of Bigrams in the Reference Summary}} \tag{4}$$

Example:

- Reference Bigrams: I really, really like, like reading, reading novels.
- Candidate Bigrams: I like, like reading, reading novels, novels every, every day.
- Overlapping Bigrams: like reading, reading novels (2 overlaps).

The total number of bigrams in the reference summary is 4. Thus:

$$\text{ROUGE-2} = \frac{2}{4} = 0.5 \tag{5}$$

3) ROUGE-L: ROUGE-L measures the longest common subsequence (LCS) between a candidate summary and a reference summary, capturing sentence-level structure. The precision, recall, and F-measure based on LCS are defined as:

$$P_{\text{LCS}} = \frac{\text{LCS}(X, Y)}{|Y|} \tag{6}$$

$$R_{\text{LCS}} = \frac{\text{LCS}(X, Y)}{|X|} \tag{7}$$

$$F_{\text{LCS}} = \frac{(1 + \beta^2) \cdot P_{\text{LCS}} \cdot R_{\text{LCS}}}{\beta^2 \cdot P_{\text{LCS}} + R_{\text{LCS}}} \tag{8}$$

Where:

- $\text{LCS}(X, Y)$: The length of the longest common subsequence between the reference summary X and the candidate summary Y.
- $|X|$: The length of the reference summary.
- $|Y|$: The length of the candidate summary.
- β: A weighting parameter, often set to 1 to equally weight precision and recall.

Example:

- Reference Summary: "I really like reading novels".
- Candidate Summary: "I like reading novels every day".
- LCS: "I like reading novels" (4 words).
- Length of Candidate: 6, Length of Reference: 5.

Calculate precision and recall:

$$P_{\text{LCS}} = \frac{4}{6} = 0.6667, \quad R_{\text{LCS}} = \frac{4}{5} = 0.8 \tag{9}$$

Calculate F-measure with $\beta = 1$:

$$F_{\text{LCS}} = \frac{(1 + 1^2) \cdot 0.6667 \cdot 0.8}{1^2 \cdot 0.6667 + 0.8} = 0.7273 \tag{10}$$

V. Results

The ablation study was conducted to evaluate the impact of fine-tuning at different stages on the Transformer-T5 model's performance in Indonesian abstractive summarization. Four configurations of the model were tested, as illustrated in Fig. 5, with the evaluation focusing on ROUGE-1, ROUGE-2, and ROUGE-L scores.

1) T5-base (Zero-shot): ROUGE-1: 0.4458, ROUGE-2: 0.3381, ROUGE-L: 0.3961. This configuration represents the baseline performance of the pre-trained T5 model without task-specific fine-tuning. The scores reflect the limited effectiveness of the zero-shot approach for a low-resource language like Indonesian, where the model has no prior exposure to Indonesian summarization or translation tasks.

2) T5-MT (Machine Translation fine-tuning): ROUGE-1: 0.6224, ROUGE-2: 0.5220, ROUGE-L: 0.5793. This model was fine-tuned on a machine translation task using the CC-Matrix dataset (300K parallel sentences). The improvement over the zero-shot baseline demonstrates the transferability of knowledge learned in machine translation to abstractive summarization.

3) T5-SUM (Summarization fine-tuning): ROUGE-1: 0.7106, ROUGE-2: 0.6393, ROUGE-L: 0.6790. Fine-tuning directly on the IndoSum dataset for summarization significantly enhanced performance compared to T5-MT. This result indicates that task-specific training is critical for improving the model's summarization capabilities.

4) T5-MT-SUM (Two-Step fine-tuning): In this configuration, the model was first fine-tuned on the machine translation task (OpenSubtitle, TED 2018, TED 2020, NewsCommentary, CCMatrix 600K) and subsequently fine-tuned on the summarization task (IndoSum). This two-step approach achieved the best performance with ROUGE-1: 0.7126, ROUGE-2: 0.6416, and ROUGE-L: 0.6816, underscoring the benefits of sequential task transferability.

VI. Discussion

The ablation study was designed to investigate how different fine-tuning strategies affect the T5 model's performance on Indonesian abstractive summarization. By systematically varying the stages of fine-tuning, the study aimed to uncover the relative contributions of machine translation and task-specific summarization fine-tuning to the final performance.

A. Ablation Study

1) Importance of related tasks: Fine-tuning on machine translation (T5-MT) significantly boosted performance compared to the zero-shot baseline. The ROUGE-1 improvement from 0.4458 to 0.6224 suggests that the knowledge gained in machine translation helps the model understand Indonesian syntax and semantics better.

2) Critical role of task-specific training: Fine-tuning directly on the summarization task (T5-SUM) led to further substantial gains, with ROUGE-1 reaching 0.7106. This highlights that task-specific training is essential for generating coherent and meaningful summaries.

3) Advantages of two-step fine-tuning: The incremental improvement of T5-MT-SUM over T5-SUM (ROUGE-1: 0.7126 vs. 0.7106) demonstrates the synergy of combining task-specific fine-tuning with knowledge from a related task like machine translation. While the improvement is small, it underscores the potential of two-step fine-tuning as a systematic approach to boosting model performance.

4) Implications for low-resource summarization: The findings from this ablation study provide valuable insights for Summarization research in low-resource languages:

- Leveraging Related Tasks: Transfer learning from machine translation to summarization is an effective strategy to overcome data scarcity in low-resource settings.
- Sequential Fine-Tuning: Two-step fine-tuning enhances the adaptability of pre-trained models by progressively refining their knowledge through related tasks.

B. Comparison with Existing Summarization Models

The current paper introduces a two-step transfer learning approach using Transformer-T5, where the model is first fine-tuned on a machine translation task before being fine-tuned for abstractive summarization on the IndoSum dataset. This structured pre-training strategy demonstrates significant improvements over previous works as shown in Table I. In

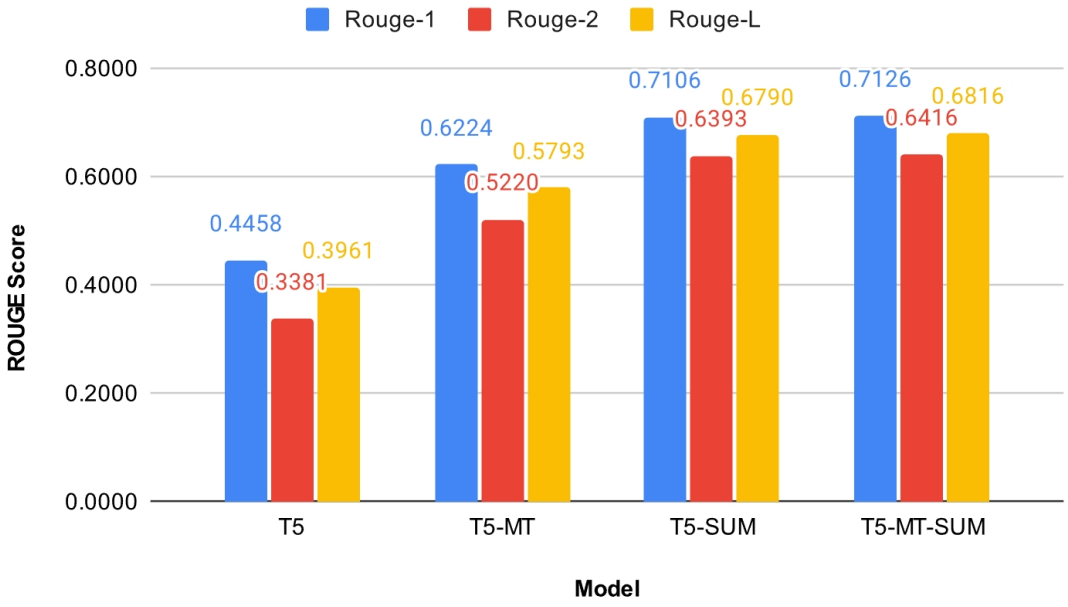

Fig. 5. Experiment result for two-step fine-tuned abstractive summarization.

terms of performance, the proposed model achieves ROUGE-1: 0.7126, ROUGE-2: 0.6416, and ROUGE-3: 0.6816, making it the highest-performing model across all three metrics. It surpasses the previous best result from BERTSum-Abs + IndoBERT-LEM + GPT Decoder (ROUGE-1: 0.6920, ROUGE-2: 0.6135, ROUGE-3: 0.6836), as well as BERT2GPT (ROUGE-1: 0.6226, ROUGE-2: 0.5613, ROUGE-3: 0.6043), demonstrating the effectiveness of combining translation-based pre-training with summarization fine-tuning.

Compared to data augmentation-based models, such as BART (Augmented) and mT5 (Augmented), which improved summarization performance but remained below ROUGE-1: 0.41, the proposed two-step approach proves to be more effective. Instead of solely relying on augmented training data, this study shows that a structured pre-training approach enhances the model's ability to generate coherent and fluent summaries. Additionally, the study outperforms multilingual and cross-lingual models, such as CTRLSum and Transformer (CLS + MWE), which achieved lower ROUGE scores despite their ability to generate summaries in multiple languages. The findings suggest that a monolingual, targeted approach with pre-training on a related NLP task (machine translation) yields better results than cross-lingual training.

Overall, this research sets a new benchmark for Indonesian abstractive summarization, showing that fine-tuning on machine translation before summarization enhances summary coherence and quality. The structured two-step learning strategy proves more effective than direct fine-tuning, data augmentation, and hybrid extractive-abstractive methods, establishing Transformer-T5 (two-step transfer learning) as the best-performing model for Indonesian text summarization compared to previous work.

C. Challenges and Limitations

Despite the promising results, the study faced several challenges:

- Marginal gains: The improvement from T5-SUM to T5-MT-SUM, while consistent, was relatively small. This suggests diminishing returns with additional fine-tuning stages and calls for further exploration of factors such as dataset size and quality.
- Evaluation metrics: ROUGE scores, while widely used, have limitations in capturing summary coherence and informativeness. Incorporating human evaluations could provide a more comprehensive assessment of summary quality.

D. Future Directions

This study paves the way for several promising research directions. First, future work could explore optimizing the two-step fine-tuning process by refining dataset selection or introducing pretraining techniques tailored to low-resource languages. Incorporating larger or more diverse datasets could further improve the model's ability to generalize across different summarization scenarios.

Second, qualitative evaluation of generated summaries through human assessments should be conducted to complement the ROUGE metric. This would provide deeper insights into summary coherence, readability, and informativeness, which are crucial for practical applications.

Third, expanding the approach to multilingual fine-tuning could assess its generalizability across other low-resource languages. The combination of cross-lingual transfer learning and domain-specific training could offer a robust framework for NLP applications in diverse linguistic contexts.

Finally, future research could explore adapting the two-step fine-tuning methodology for other NLP tasks, such as question answering, sentiment analysis, or content generation. These extensions would highlight the broader applicability of this approach and contribute to advancing natural language processing in low-resource settings.

VII. Conclusions

This research explored the effectiveness of a two-step fine-tuning approach using the Transformer-T5 model for abstractive text summarization in Bahasa Indonesia, a low-resource language. Four configurations were evaluated: zero-shot (T5-Base), single-task fine-tuning for machine translation (T5-MT), single-task fine-tuning for summarization (T5-SUM), and two-step fine-tuning combining machine translation and summarization tasks (T5-MT-SUM). The two-step fine-tuning approach achieved the best performance, with ROUGE-1: 0.7126, ROUGE-2: 0.6416, and ROUGE-L: 0.6816, demonstrating the benefits of task transferability in improving summarization quality.

The findings indicate that leveraging knowledge from a related task, such as machine translation, can enhance the performance of abstractive summarization models. Task-specific fine-tuning was also shown to play a critical role in generating coherent and accurate summaries. The results validate the potential of transfer learning to overcome the challenges posed by data scarcity in low-resource languages like Bahasa Indonesia.

***Abstract*—Artificial intelligence (AI) integration into environmental analysis has revolutionized various fields. Including the construction and application of gardens, by enabling precise classification and decision-making for sustainable practices. This paper presents a strong AI-driven framework uses convolutional neural network (CNN) and pretrained models like VGG16 and InceptionV3 to classify eight distinct environmental classes. The CNN achieved superior performance Among the tested models and reaching an impressive 98% accuracy with optimized batch sizes. This demonstrate its effectiveness for precise environmental condition classification. This work highlights the crucial role of AI in advancing the construction and application of gardens. It offers insights into optimizing garden design through accurate environmental data analysis. The diverse dataset used ensures the framework's adaptability to real-world applications, making it a valuable resource for sustainable development and eco-friendly design strategies. This paper not only contributes to the field of AI-driven environmental analysis but also provides a foundation for future innovations in garden management and sustainability, paving the way for intelligent solutions in the evolving landscape of ecological design.**

***Keywords*—Artificial intelligence; machine learning; construction and application of garden design; convolutional neural network; VGG16; InceptionV3**

I. Introduction

The construction and application of gardens have long been intertwined with human civilization, serving as timeless symbols of beauty, solace, and ecological significance. From the glory of the Babylon Hanging Gardens, celebrated as one of the Seven Wonders of the Ancient World, to the serene and meticulously crafted Japanese Zen gardens [1]. These green spaces have continuously evolved to reflect cultural ideals, environmental adaptations, and technological advances [2]. More than just a testament to human creativity and harmony with nature, gardens also embody the intersection of sustainability and aesthetic appeal [3]. In today's rapidly urbanizing world, their role has expanded far beyond visual pleasure, as they now play a crucial part in addressing global challenges such as climate change, biodiversity loss, urban livability, and resource scarcity [4]. At the same time, they remain essential in promoting mental and physical well-being, offering spaces for relaxation, social interaction, and ecological balance. The integration of artificial intelligence has further revolutionized gardening, introducing data-driven solutions for optimizing garden layouts, automating maintenance, and enhancing biodiversity management. AI-powered systems now facilitate sustainable irrigation, real-time plant health monitoring, and predictive analysis for pest and disease control, making urban and rural green spaces more resilient and efficient. As technological advancements continue to shape the way gardens are designed and maintained, there is a growing need for ethical and sustainable approaches that balance innovation with ecological responsibility [5].

In this day and age of technological progress, the arrival of artificial intelligence (AI) and machine learning (ML) has opened evolutionary possibilities in the construction and application of gardens [6]. These cutting-edge technologies allow for the analysis of vast and complex datasets, enabling the optimization of garden design, the enhancement of sustainability, and the implementation of resource-efficient maintenance strategies. One good example of the potential of AI lies in land use scene classification, where ML models analyze satellite imagery as well as aerial photographs to classify various land types such as, *Forest*, *River*, agricultural areas etc. This capability is particularly instrumental in identifying suitable sites. This is useful for garden construction and to focus the design on specific ecological and climatic needs [7]. The application of these technologies marks the departure from traditional garden design practices, which often rely on manual analysis and experience methods. That can accidentally overlook crucial environmental and sustainability factors. The construction and application of gardens come with unique challenges. That AI is exceptionally well positioned to address. Traditional garden design methods, while rooted in artistic expression and intuition. Can be restricted by their ineffectiveness to integrate environmental and sustainability considerations widely [8].

By incorporating ML models into this process, designers can access data driven insights into land usability. And predict resource requirements and develop garden layouts that prioritize biodiversity and ecological harmony. For example, AI models can simulate various garden configurations. Taking into account variables such as sunlight exposure, water availability, soil quality, and plant compatibility ensures that

*Corresponding authors.

the resulting designs are functional and sustainable [9]. In addition, these AI-powered systems extend their utility beyond design by enabling post-construction monitoring. Providing real-time data to support versatile maintenance strategies that reduce resource consumption and environmental impact. These systems enable garden planners to address not only immediate design concerns, but also long-term sustainability objectives, ensuring gardens remain thriving ecosystems over time [10].

This research focuses on using land use scene classification, which revolutionizes the construction and application of gardens. It offers a comprehensive framework that integrates sustainability, innovative design principles, and cutting-edge technological advancements. Using the Land-Use Scene Classification dataset, this study examines specific land categories, such as *Agriculture*, *Forest*s, *River*s, and residential zones, which are directly relevant to the sustainable design of the garden. ML models trained in these categories aim to provide actionable insights into site selection, resource allocation, and design optimization. The proposed approach bridges the gap between traditional garden design methods and the powerful capabilities of modern AI technologies, demonstrating the potential of AI to transform green space planning into a data-driven, scalable, and ecologically sound endeavor. The insights generated by these models will not only enhance the visual and functional aspects of gardens but will also align them with broader global sustainability goals, such as carbon sequestration, biodiversity conservation, and efficient water use. The significance of this work lies in its ability to reimagine the construction and application of gardens in an era defined by rapid urbanization and environmental degradation. By introducing a scalable, adaptable and data-driven approach, this research demonstrates how AI can be used to create gardens that are aesthetically pleasing, ecologically sustainable, and socially impactful. Beyond their immediate applications, such gardens contribute to the broader vision of fostering greener, more resilient urban and rural landscapes. In addition, this paper underscores the vital role of AI in the resolution of global environmental challenges, highlighting the importance of innovation and technological solutions to foster a harmonious coexistence between human development and nature. The key contributions of this work are:

- Introduces an AI-powered framework for garden construction that integrates the classification of the land use scene, enabling sustainable and efficient garden design.
- Demonstrate how AI can improve resource efficiency, biodiversity, and environmental sustainability in garden construction.
- Conducts a detailed evaluation of traditional garden design methods versus AI-driven approaches to highlight efficiency, accuracy, and sustainability gains.

II. Literature Review

Artificial intelligence (AI) and machine learning (ML) in the construction and application of gardens has gained substantial attention in recent years [11]. Cities continue to enlarge the importance of sustainable, efficient and ecologically sound garden designs is becoming increasingly clear. AI and ML present an opportunity to optimize garden layouts, improve resource use, and improve sustainability [12]. These technologies enable designers to analyze and classify land use more precisely, creating gardens that are not only aesthetic but also environmentally beneficial. One of the key areas where AI has shown promise is in land use classification. The ability to accurately classify different types of land, such as agricultural zones and urban areas. *Forest*s, and water bodies can significantly influence the construction and application of gardens [13]. AI models can provide insight into the bionomics and environmental characteristics of the area, using satellite images and aerial imagery for the construction of gardens [14]. These techniques allow for a deeper understanding of soil quality and water availability. Also, understands climate for ensuring that gardens are designed with the local environment in mind.

In addition to land-use classification, AI-driven tools are being applied to urban planning and landscape architecture [15]. These tools enable the creation of generative designs in which multiple garden layouts are explored and tested for optimal performance. AI algorithms can evaluate different configurations, considering factors such as compatibility, sunlight exposure, and soil health [16]. This process ensures that gardens are not only functional but also sustainable. The design iterations produced by AI can adapt to environmental changes, making gardens more resilient to challenges such as climate change, loss of biodiversity, and water scarcity. Such innovations allow for the creation of green spaces that can thrive in a variety of conditions, from urban rooftops to expansive rural landscapes [17].

Another critical application of AI is in the field of precision *Agriculture*, which shares many principles with the construction of sustainable gardens [18]. By monitoring soil moisture levels, weather patterns, and water use, AI systems help optimize resource allocation in agriculture. These technologies have proven to be effective in reducing water waste and maximizing crop yield. Similarly, in the construction and application of gardens, AI can monitor and manage resources such as water, fertilizers, and energy, ensuring that gardens are not only beautiful, but also efficient and sustainable [19]. The application of such technologies allows for adaptive maintenance strategies that minimize environmental impact while keeping gardens thriving.

AI also plays a crucial role in enhancing biodiversity and supporting the ecological balance within gardens [20]. By simulating various environmental conditions and plant interactions, AI can suggest garden layouts that support a diverse range of species and foster healthier ecosystems. This is particularly important in urban areas, where biodiversity is often limited. AI models can identify plant species that are compatible with each other and the local environment, promoting plant diversity and reducing the need for chemical interventions [21].

Through this, gardens can become vital ecosystems that support local wildlife and contribute to the overall health of the urban environment. Although much of the current research has focused on individual aspects of garden design or broader environmental planning, the potential for AI to integrate land use classification with garden construction remains largely unexplored. Most of the existing efforts have focused on urban planning or agricultural optimization, leaving a gap in the

specific application of AI to the construction and application of gardens [22].

This presents an opportunity to bridge the gap and develop AI-driven tools that combine ecological sustainability with design optimization. By merging these two areas, AI can play a pivotal role in creating gardens that are not only functional and beautiful, but also environmentally resilient and resource-efficient [23].

The Motivation behind this research is to fill the gaps in existing research by specifically focusing on the intersection of AI-driven land use classification and the construction and application of gardens. although numerous researchers have explored human aspects of AI in urban planning, *Agriculture*, or ecological design, the application of these technologies in optimizing garden design and sustainability remains underexplored. This article aims to explain how AI can revolutionize the construction and application of gardens, ensuring that they are not only aesthetically pleasing but also ecologically viable and resource efficient. Using ML to integrate land-use classification with garden design, this research contributes to creating smarter, more sustainable green spaces that can adapt to the challenges posed by climate change, urbanization, and biodiversity loss. This paper seeks to push the boundaries of the construction and application of gardens, showing how AI can be harnessed to optimize both the process and the outcome of garden construction, thus fostering greener and more resilient landscapes.

III. Methodology

A. Dataset Collection

Data collection is the most important aspect of the research. Dataset utilized in this research is a curated from kaggle. Which is subset of a land-use scene classification dataset and is specifically designed to facilitate the construction and application of gardens.The dataset consists satellite images which represents eight diverse land-use scenarios such as, *Agriculture*, *Forest*, *River*, urban areas and more. Each class is selected for its critical role in sustainable garden design. This dataset captures a range of ecological and environmental scenarios which provides valuable insights into land characteristics. Which is essential for tailored garden planning which include agricultural suitability urban density as well as water management. The dataset underwent preprocessing to standardize image resolution and format to ensure consistency. To increase diversity and simulate real-world variations advanced augmentation techniques such as rotation, scaling, and flipping, were applied. This diverse dataset forms a strong foundation for integrating AI into the construction and application of gardens which enhances their sustainability, efficiency, and resilience.

This dataset was chosen based on its comprehensive coverage of diverse land-use types relevant to garden planning. It provides high-quality satellite imagery, ensuring reliable data for AI-driven analysis. Compared to other datasets, this one offers a well-balanced mix of natural and urban environments, making it particularly suitable for evaluating ecological and spatial factors in sustainable garden construction. This directly align with the objectives of this work, integrating AI into the construction and application of gardens. The dataset diverse classes provide a basis for training ML models which is capable of optimizing garden designs, accounting for ecological and spatial demands. Furthermore, the dataset detailed depiction of environmental scenarios makes it ideal for testing new approaches to sustainable and efficient garden construction. Enhancing the practicality and adaptability of the methodology. Detailed description of the dataset is shown in Table I, which highlights its significance in the advancement of AI-driven garden design solutions. Despite its strengths, the dataset has some limitations. The fixed satellite image resolution may impact fine-grained analysis of smaller garden structures. Additionally, while the dataset covers multiple land-use types, real-time environmental variations such as seasonal changes or soil conditions are not explicitly captured. Addressing these challenges in future work could involve integrating real-time remote sensing data or expanding the dataset to include dynamic environmental parameters.

B. Preprocessing

1) Data resizing: We observed significant variations in the resolution of images within the dataset during preprocessing. This variation could negatively impact the consistency and accuracy of the model. In order to address this issue all images were uniformly resized to 224 × 224 pixels. By doing this, we observed that this standardization ensures the consistency of the input. Facilitating efficient processing by the model as well as helping with reducing computational complexity. Furthermore, this resizing helps in maintaining the balance not only image quality but also performance. Which ensures optimal feature extraction during the training.

2) Normalization of data: Data normalization is a crucial step in data preprocessing to enhance the performance of ML models. Where we standardize or rescales the input to fall within a specific range between 0 and 1 or sometimes between -1 and 1. The data normalization process minimizes the impact of varying not only pixel_intensity values, reduces training time but helps the model focus to learn meaningful patterns rather than being influenced by scale variance in the dataset.

C. Data Distribution and Quantitative Analysis

A well-structured dataset is the cornerstone of any successful deep learning model. For this study, we carefully curated

TABLE I. Dataset Description for the Construction and Application of Gardens

Class Name	Description
Agriculture	Areas used for farming, including crop fields and orchards, suitable for plant-rich designs.
Beach	Coastal sandy areas, often requiring salt-resistant plants and erosion control measures.
Denseresidential	Urban areas with closely packed houses or apartments, ideal for rooftop or small-space gardens
Forest	Large areas covered by trees, offering inspiration for natural, eco-friendly garden designs.
Golfcourse	Open green spaces maintained for recreational purposes, with efficient irrigation systems.
Mediumresidential	Suburban areas with moderately spaced housing, suitable for private gardens or community spaces.
Parkinglot	Large paved areas used for vehicle parking, often with potential for integrating green spaces.
River	Natural flowing water bodies, influencing designs with water management and riparian vegetation.

a dataset with eight distinct land-use classes: *Agriculture*, *Beach*, *Denseresidential*, *Forest*, *Golfcourse*, *Mediumresidential*, *Parkinglot*, and *River*. Each class is represented by 500 images, ensuring an equal distribution that prevents class imbalance, which is often a major challenge in classification tasks. The dataset is further divided into training and testing sets. Resulting in 400 images for training as well as 100 images for testing. This distribution strategy provides sufficient data for model training while preserving a fair portion for unbiased evaluation as shown in Table II. The dataset is balanced with a total of 4,000 images, distributed as 3,200 training images and 800 testing images. This balanced lays the foundation for fair and consistent model learning.

TABLE II. DATASET OVERVIEW SHOWING THE NUMBER OF IMAGES, TRAINING SET, AND TEST SET DISTRIBUTION ACROSS CLASSES

Class Name	No. of Images	Training Set	Test Set
Agriculture	500	400	100
Beach	500	400	100
Denseresidential	500	400	100
Forest	500	400	100
Golfcourse	500	400	100
Mediumresidential	500	400	100
Parkinglot	500	400	100
River	500	400	100
Total	**4000**	**3200**	**800**

To visualize this distribution, Fig. 1, presents a pie chart that illustrates the equal percentage of images contributed by each class. With each class forming exactly 12.5% of the dataset, the dataset achieves perfect equilibrium, eliminating any inherent bias toward a specific category. This balance is critical to ensure the model generalizes well across all land-use categories and does not overfit to any particular class.

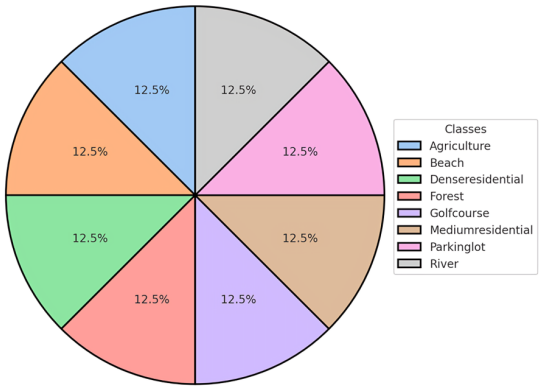

Fig. 1. Class distribution in the dataset, showing balanced contributions from each class.

To further validate this equal distribution, Fig. 2 shows a bar chart displaying the total number of images per class. The uniform height of the bars emphasizes that every class has exactly 500 images, underscoring the equal composition of the dataset. This visual confirmation strengthens confidence in the integrity of the dataset and its suitability for training a robust classification model.

In addition to the overall distribution, it is crucial to examine the segregation of the dataset into training and testing

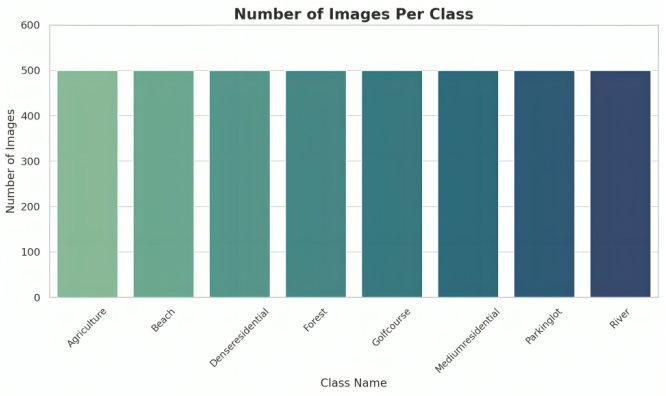

Fig. 2. Total number of images per class.

subsets. Fig. 3 provides a detailed visualization of the training and testing distribution for each class. Training set consists of 400 images for each class in the dataset and 100 images to the testing set which shows the 80% split for training and 20% split for test set. This distribution ensures that the model is trained on a substantial portion of the data while reserving enough samples for an objective evaluation of its performance. The design of this dataset ensures a harmonious blend of diversity and balance. The balance representation of all classes guarantees that the model receives varied inputs, preventing any single class from dominating the learning process. Moreover, the structured division into training and testing subsets aligns with best-practices in machine learning, facilitating reliable and unbiased performance assessment.

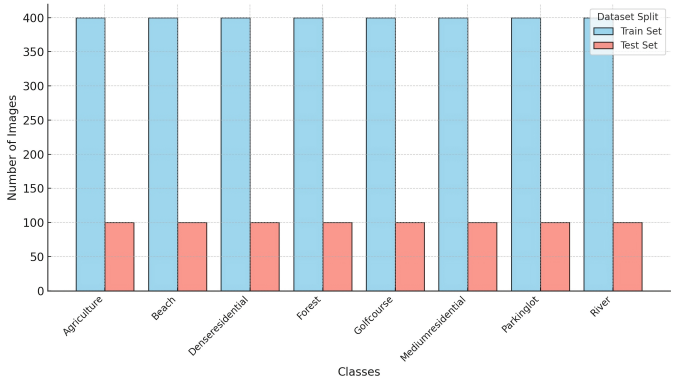

Fig. 3. Total number of images in train and test set.

By combining these quantitative analysis with visual insights, we can conclude that the dataset is well prepared to support the development of an effective classification model. This precise approach of distribution of data improves the reliability of the study and also emplace a solid foundation for future research on land use classification.

D. Proposed Framework

The proposed classification framework uses advanced machine learning to provide an effective and efficient solution. The training and testing workflow is presented in Fig. 4. The system begins by receiving image inputs from the dataset,

which are then divided into training, testing, and validation sets.

Furthermore, the proposed framework for this work is presented in Fig. 5, designed to optimize the construction and application of gardens using satellite image classification. It categorizes images into eight distinct classes Agriculture, Beach, Denseresidential, Forest, Golfcourse, Mediumresidential, Parkinglot, and River enabling precise and efficient landscape planning.

The process begins with preprocessing, where satellite images are resized and normalized to ensure consistency. These preprocessed images are then passed through a custom Convolutional Neural Network (CNN) that extracts key spatial features, such as textures, patterns, and vegetation density. Convolutional and max-pooling layers work together to identify and retain essential features while reducing data complexity. The extracted features are then mapped through fully connected layers, where the softmax activation function ensures accurate classification by assigning probabilities to each class. The framework not only enhances the classification of land instances. But also supports AI_driven decisions for garden construction and sustainability. For instance identifying agricultural regions or *River* landscapes allows for informed garden designs tailored to specific environmental contexts. By integrating both automation as well as precision the proposed framework transforms traditional garden planning into more effective and sustainable process.

IV. Results and Discussion

A. Experimental Setup

The experiments were conducted using intel(R) Core(TM) i5-6500 CPU running at 2.60 GHz, along with 16 GB, RAM on the windows 10 operating system. Anaconda-based python 3.11 environment configured with TensorFlow-and PyTorch.

B. Evaluation Metrics

The performance of the model is evaluated using various metrics such as, accuracy, precision, recall as well as F1-score. Which together offers a detailed understanding of the proposed model classification capabilities. Firstly ,accuracy calculated using Eq. 1, determines the overall correctness of the model by measuring the ratio of correctly predicted instances. True positives (TP) and True negatives (TN) to the total predicted result. Secondly, precision defined in Eq. 2, evaluates the proportion of true positive predictions among all positive predictions.High precision is very important in such cases where minimizing false positives is crucial. Third metric is recall computed using Eq. 3, reflects the models ability to accurately identify all actual positive instances. Lastly, F1-score as presented in Eq. 4, shows the harmonic mean of precision and recall which strikes a balance between precision and recall.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{3}$$

$$\text{F1-Score} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{4}$$

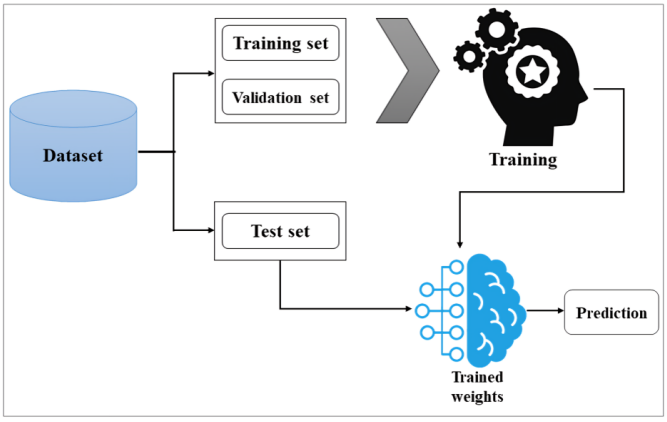

Fig. 4. Workflow for training and evaluating model using the dataset. The dataset is divided into training, validation, and test sets, which are utilized for model evaluation. The trained model then makes predictions, demonstrating the pipeline from data preparation to deployment.

C. Performance Comparison of Pre-trained Models

Performance evaluation of pretrained models is performed to get insights into their robustness in addressing the classification difficulties in the construction as well as application of gardens. These models include include Artificial Neural Network (ANN) [24], VGG16 [25], and Inception V3 [26]. The metrics used for comparison were accuracy, loss, validation accuracy (Val_Accuracy), validation loss (Va_Loss), precision, recall, and F1-score were the metrics used for comparison. which collectively provide a holistic view of each model's performance. Table III, displays the results of the ANN model. It achieved an accuracy of 0.88 with a validation accuracy of 0.83, indicating reasonable performance for a baseline model.

TABLE III. Performance Metrics of ANN, Including Accuracy, Loss, Precision, Recall, and F1-score

Metric	Accuracy	Loss	Val_Accuracy	Val_Loss	Precision	Recall	F1_Score
Values	0.88	0.19	0.83	0.21	0.85	0.82	0.83

However, the higher validation loss (0.21) compared to its training loss (0.19) suggests some overfitting, limiting its ability to generalize effectively to unseen data. The precision, recall, and F1-score of 0.85, 0.82, and 0.83, respectively, further highlight that while ANN performs decently, it falls short in addressing the complexities of the dataset. Table IV, showcases the performance of the VGG16 model, which marked a significant improvement over ANN.

With an accuracy of 0.93 and a validation accuracy of 0.91, VGG16 demonstrated strong generalization capabilities. The low training loss (0.10) and validation loss (0.13) reflect its ability to learn meaningful features from the data efficiently. Precision, recall, and F1-score values of 0.92, 0.91, and 0.91,

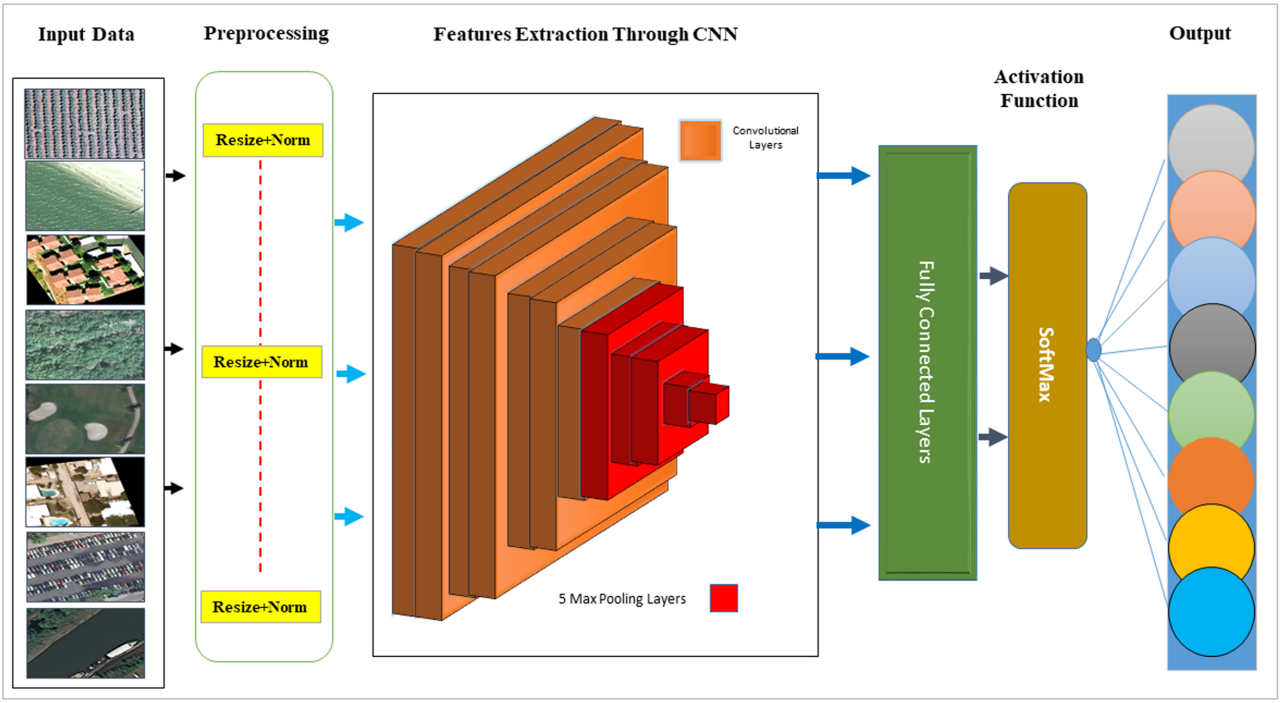

Fig. 5. Proposed framework for optimizing the construction and application of gardens through satellite image classification using a custom CNN, featuring preprocessing, feature extraction, and class-specific predictions for precise landscape planning.

TABLE IV. PERFORMANCE METRICS OF THE VGG16 MODEL, INCLUDING ACCURACY, LOSS, PRECISION, RECALL, AND F1-SCORE

Metric	Accuracy	Loss	Val_Accuracy	Val_Loss	Precision	Recall	F1_Score
Values	0.93	0.10	0.91	0.13	0.92	0.91	0.91

respectively, indicate that VGG16 reliably classifies the data with fewer false positives and negatives, making it well-suited for this task. Table V, presents the results for the Inception V3 model, which outperformed both ANN and VGG16.

TABLE V. PERFORMANCE METRICS OF THE INCEPTIONV3 MODEL, INCLUDING ACCURACY, LOSS, PRECISION, RECALL, AND F1-SCORE

Metric	Accuracy	Loss	Val_Accuracy	Val_Loss	Precision	Recall	F1_Score
Values	0.96	0.11	0.91	0.17	0.92	0.90	0.91

Inception V3 achieved an accuracy of 0.96 and a validation accuracy of 0.91, indicating its robustness in identifying intricate patterns and features within the dataset. While its validation loss (0.17) was slightly higher than that of VGG16, its precision (0.92), recall (0.90), and F1-score (0.91) demonstrate a strong balance between sensitivity and specificity. The superior performance of Inception V3 can be attributed to its advanced architecture, which excels in multi-scale feature extraction. To better illustrate the comparative performance, Fig. 6, presents a bar chart highlighting the accuracy of all three models. The progression from ANN to VGG16 and Inception V3 emphasizes the importance of employing deeper and more sophisticated architectures for tackling complex classification tasks. While ANN serves as a useful baseline, the results of VGG16 and Inception V3 underscore the potential of pretrained models in achieving higher performance levels.

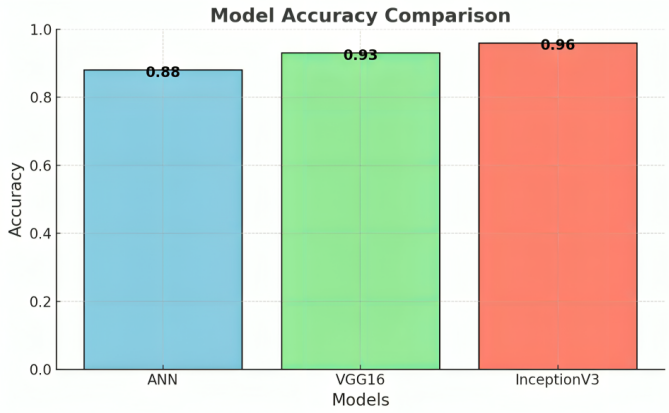

Fig. 6. Comparison of accuracy across pretrained models.

In summary, the performance evaluation highlights the effectiveness of VGG16 and Inception V3 as pretrained models, with Inception V3 emerging as the most accurate. These findings provide a benchmark for understanding the capabilities of pretrained architectures in similar applications, paving the way for further exploration and optimization in the Construction and Application of Gardens through deep learning approaches.

D. Performance Analysis of Proposed Model

The proposed Custom CNN [27] model was evaluated across varying batch sizes to analyze its performance comprehensively, with the results summarized in Table VI. Key metrics such as accuracy, loss, validation accuracy (Val-Accuracy), validation loss (Val-Loss), precision, recall, and F1-score were employed to assess the model's efficacy in handling classification tasks. Fig. 7, depicts the trends in accuracy and loss, while Fig. 8, presents a bar chart showcasing the model's performance across different batch sizes. Starting from the batch size of 4, the proposed model achieved an accuracy of 0.96 as well as validation-accuracy of 0.94. Additionally, minimal loss values of 0.04 for train and 0.03 for validation. These metrics showcases the model's best initial learning and generalization capabilities. Moreover, the model achieved the values for Precision as 0.95, recall (0.93), and F1-score 0.94. Respectively which further depicts its ability to give balanced and reliable results at this structure. At the batch of 8, the proposed model performance improved more and achieved Training accuracy of 0.97 and 0.95 of validation. Training loss and validation loss decreased to 0.03 for training and 0.02 for validation, which indicates more stable learning. Metrics such as Precision and recall rise up to 0.96 and 0.94. While F1-score reached to 0.95 which reflects the models high predictive capabilities and reduced error rate.

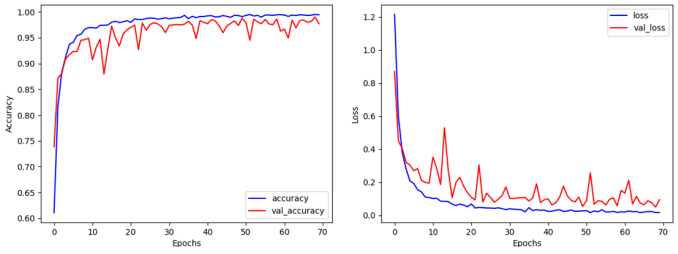

Fig. 7. Accuracy and loss curves of the proposed CNN model at different batch sizes.

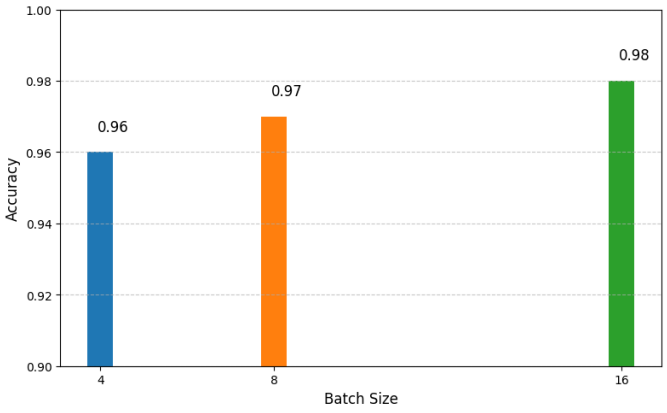

Fig. 8. Comparison of the proposed model across different batch sizes, highlighting accuracy improvements with increasing batch size.

Best results were achieved when the batch-size reached to 16. This is where the model achieved the highest accuracy of Training as 0.98 and for validation as 0.96. Training loss and validation loss were decreased to 0.02 for training and 0.01 for validation. Which depicting the model's best generalization and convergence. Metrics Precision reached at 0.97, recall rise to 0.95, and F1-score maintains its position height at 0.95. Fig. 10 highlights the comparison of metrics among the model and highlights that CNN shows superiority among the others.

TABLE VI. PERFORMANCE METRICS OF THE PROPOSED MODEL FOR DIFFERENT BATCH SIZES

Batch Size	Accuracy	Loss	Val_Accuracy	Val_Loss	Precision	Recall	F1_Score
4	0.96	0.04	0.94	0.03	0.95	0.93	0.94
8	0.97	0.03	0.95	0.02	0.96	0.94	0.95
16	**0.98**	**0.02**	**0.96**	**0.01**	**0.97**	**0.95**	**0.95**

In conclusion, the results shows the effectiveness of the proposed model, with a 16 batch size emerging as the best performer. The proposed model shows high accuracy, minimum loss. And a balanced precision, recall, and F1-score, making it more suitable for applications in the Construction and Application of Gardens. This analysis underscores the robustness of the model and its potential to facilitate sustainable garden design and management. Fig. 9, shows the accuracy of the proposed model with all ML models.

In summary, the comparative analysis of ANN, VGG16, Inception V3, and the proposed Custom CNN demonstrates a clear progression in performance, emphasizing the influence of architectural complexity and feature extraction capabilities. The relatively lower performance of ANN highlights its limitations in capturing complex patterns due to its simpler structure and limited feature learning capacity. In contrast, the balanced performance of VGG16 shows the effectiveness of moderate depth and transfer learning. Inception V3 outperforms both models by leveraging its advanced architecture for multiscale feature extraction. The proposed Custom CNN achieves the highest accuracy, particularly with a batch size of 16, due to its custom design that optimizes learning and generalization for this domain-specific application. These results underscore the importance of selecting appropriate model architectures and hyperparameters to effectively address classification challenges, paving the way for optimized solutions in the Construction and Application of Gardens.

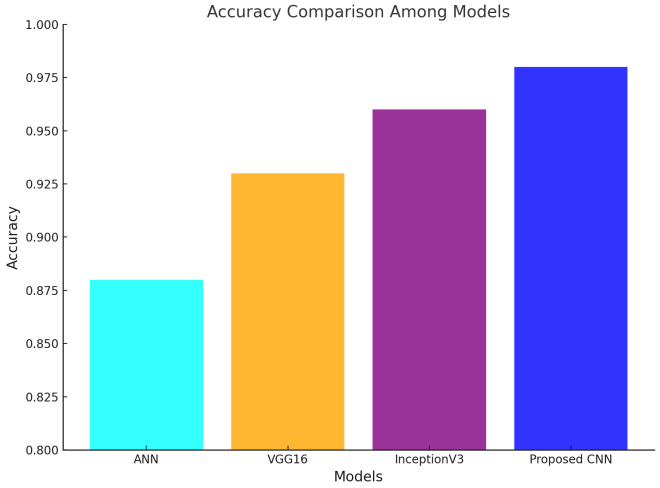

Fig. 9. Comparison accuracy of the proposed model with all ML models.

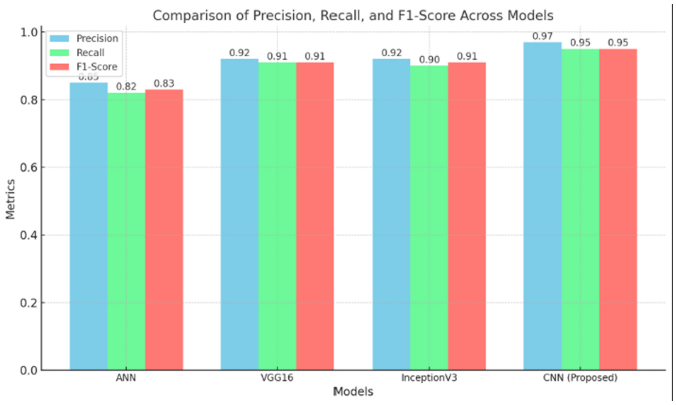

Fig. 10. Comparison accuracy of the proposed model with different models.

V. Conclusion

In conclusion,this research demonstrates the transformative potential of AI in revolutionizing garden design and sustainability through precise environmental classification and analysis. By utilizing advanced machine learning (ML) models, including both pretrained architectures and a custom CNN, this paper highlights the effectiveness of ML in accurately categorizing diverse landscape types, such as Agriculture, Beaches, Forests, and residential areas. The comprehensive evaluation of models, coupled with the use of a robust and diverse dataset, ensures the applicability of the findings across different real-world scenarios, making the work not just theoretical but practically impactful. The importance of this article lies in its ability to address pressing challenges in sustainable garden design by offering a data-driven approach to optimize planning and resource management. The results, supported by detailed performance analysis, reveal the strengths of different models while showcasing the custom CNN's superior capability in achieving high accuracy and efficient processing. The use of graphical analysis further enhances the papers clarity and accessibility, providing actionable insights for researchers and practitioners alike. This work not only sets a strong foundation for integrating AI into environmental and garden applications, but also opens doors for future advancements. The dataset can be expanded to include more complex and varied environments, and the models can be refined to handle real-time applications. By bridging the gap between technology and nature, this article paves the way for innovative, sustainable, and scalable solutions in garden construction and environmental optimization.

However, despite its promising contributions, this study is not without limitations. The dataset focuses mainly on specific landscape types like Agriculture, Beaches, Forests, and Residential areas, which may limit model generalization to more complex or mixed environments. Additionally, the current implementation lacks real-time processing capabilities, which are crucial for dynamic garden management and environmental monitoring. The models may also struggle with classification accuracy under extreme weather, varying light, or seasonal changes. Moreover, human intervention may still be required in complex or ambiguous scenarios to ensure classification accuracy. Addressing these limitations provides a balanced perspective and opens avenues for future research. Enhancing dataset diversity and improving model adaptability to extreme weather, varying light, and seasonal changes can enhance classification accuracy. Optimizing real-time processing capabilities and reducing computational demands will improve usability in dynamic garden management and environmental monitoring. Expanding the geographical scope and exploring edge computing solutions can boost scalability and practical deployment. Additionally, addressing the need for human validation in complex scenarios can refine automation accuracy. By transparently addressing these challenges, this study not only contributes to the academic field but also drives innovation at the intersection of AI and sustainable garden construction. It lays a solid foundation for future research focused on achieving environmental harmony through intelligent design and resource optimization.

Acknowledgment

We extend our heartfelt gratitude to all individuals and institutions that contributed to the completion of this research. Special thanks are directed to the developers and researchers behind the deep learning and machine learning models used in this work, whose innovations have been pivotal in advancing the field of artificial intelligence. We also wish to acknowledge the organizations and institutions that provided access to the datasets employed in this study, enabling us to conduct our experiments on diverse and representative data.

Multi-Objective Osprey Optimization Algorithm-Based Resource Allocation in Fog-IoT

Nagarjun E, Dharamendra Chouhan, Dilip Kumar S M
Department of Computer Science and Engineering-University of Visvesvaraya College of Engineering,
Bangalore University, Bengaluru, India

***Abstract*—Fog Computing (FC) paradigm offers significant potential for hosting diverse delay-sensitive Internet of Things (IoT) applications. However, the limited resources of fog devices pose significant challenges for deploying multiple applications, particularly in heterogeneous and dynamic IoT scenarios, due to the absence of effective mechanisms for resource estimation and discovery. An efficient resource allocation strategy is crucial for meeting the Quality of Service (QoS) requirements of IoT applications while enhancing overall system performance. Identifying the optimal allocation strategy for IoT applications with multiple QoS parameters is a complex and computationally intensive challenge, classified as an NP-complete problem. This paper proposes a Multi-Objective Optimization Algorithm (MOOA) for optimal resource allocation using the Osprey Optimization Algorithm (OOA) to efficiently allocate available resources. The proposed algorithm was evaluated against existing approaches, including the Genetic Algorithm (GA) and Particle Swarm Optimization (PSO), under varying task loads ranging from 100 to 500 tasks. The simulation results demonstrate significant performance improvements, including an average reduction in execution time by 12.45% compared to PSO and 22.97% compared to GA, response time by 32.57% compared to GA and 24.45% compared to PSO, and completion time by 44.39% compared to GA and 33.23% compared to PSO. These findings highlight the proposed algorithm's ability to efficiently handle task allocation in dynamic FC environments and its potential to address complex QoS requirements in real-world IoT applications.**

***Keywords*—Fog computing; IoT; resource allocation and reallocation; task allocation**

I. Introduction

The Internet of Things (IoT) has revolutionized data generation, driving advancements in healthcare monitoring, virtual reality, industrial automation, and many other applications that demand reliable, low-latency communication and computational services [1]. These applications often impose stringent QoS requirements, such as minimizing delay and energy consumption, which pose significant challenges for IoT devices [2], [3].

Fog computing (FC) is a computing paradigm placed in the middle of a three tiered architecture that encompasses the cloud, fog nodes (FNs), and IoT devices at the edge. Cisco introduced this layer in 2012 to bring the features and capabilities of cloud computing nearer to data sources and user devices that communicate over the internet [4], [5], [6]. FC is recognized as a key solution to the limitations of cloud computing, particularly for delay-sensitive applications. However, while FC provides a decentralized architecture, the challenge of selecting suitable FNs for application modules with diverse deadline constraints remains a critical issue [7].

Resource allocation in FC entails the distribution of storage, computational, and communication resources among FNs, users, and service providers. These entities often have conflicting objectives and requirements, necessitating mechanisms that balance their interests while optimizing overall system performance [8]. Furthermore, the dynamic nature of FC characterized by fluctuations in resource availability and user demand highlights the need for adaptive allocation strategies. Effective resource allocation and reallocation in FC are particularly crucial for IoT tasks, where metrics such as resource utilization, execution time, response time, and completion time are key considerations [9].

To address these challenges, this study proposes a Multi-Objective Osprey Optimization Algorithm (MOOA) to allocate the appropriate number of fog resources corresponding to fluctuations in IoT task demands.

- Proposed a meta-heuristic MOOA for resource allocation and reallocation in FC for IoT tasks to handle the dynamic and heterogeneous requirements of IoT tasks.
- Implement the proposed algorithm and evaluate its performance against GA and PSO by varying the number of IoT tasks and exploring different parameters.
- The results demonstrate a significant reduction in average response time, execution time and completion, showcasing the efficiency of our approach.

The rest of this paper is organized as follows: Section II provides a detailed background on the problem of resource allocation improvement in FC environments, highlighting the drawbacks of existing methods. Section III presents the system model, problem statement, and objectives. Section IV describes the proposed algorithm and its key features. In Section V, we present our simulation and experimental results, comparing the performance of our algorithm with existing approaches. Finally, Section VI concludes the paper and discusses future research directions in this area.

II. Related Works

Hussain *et al.* [10] developed the Resource Aware Prioritized Task Scheduling (RAPTS) approach for heterogeneous FC environments. The primary objective of RAPTS is to ensure the execution of tasks with strict deadlines while optimizing response time, cost, and makespan, and enhancing resource utilization within the fog layer. This approach was implemented in iFogSim and evaluated based on various performance metrics, including response time, resource utilization, task deadline compliance, cost, and makespan. Comparative analysis

with advanced fog schedulers like RACE (CFP) and RACE (FOP) demonstrated that RAPTS achieved improvements of up to 29%, 53%, 15%, 11%, and 43% in resource utilization, response time, makespan, cost, and task deadline adherence, respectively. However, completion time and execution time are not addressed.

Arshed *et al.* [11] introduced the Resource Aware Cost-Efficient Scheduler (RACE) to allocate incoming application modules to fog devices. The scheduler manages to optimize resource utilization at the fog layer by minimizing the monetary cost of using cloud resources, and reduces the application execution time and bandwidth usage. It incorporates two key algorithms: the ModuleScheduler, which classifies application modules based on their computational and bandwidth requirements, and the CompareModule, which determines their placement. Simulation results indicate that RACE outperforms traditional cloud placement strategies and baseline algorithms in most scenarios. However, the approach does not specifically address response time, completion time, and execution time.

Khan *et al.* [12] introduced an improved Ripple-Induced Whale Optimization Algorithm (RWOA) for scheduling independent tasks in fog-cloud environments. The method leverages ripple effects to refine suboptimal solutions, aiming to minimize makespan and energy consumption while enhancing throughput. Despite its effectiveness, the approach does not explicitly consider metrics such as response time, completion time, and execution time. Chafi *et al.* [13] proposed a novel algorithm based on Particle Swarm Optimization (PSO) to optimize energy consumption and workflow time in heterogeneous FC environments. By utilizing the collective behavior of particles, the algorithm effectively explores the solution space and adapts to the dynamic and unpredictable nature of FC resources. Simulation results demonstrate notable enhancements in workflow completion time, energy efficiency, and resource utilization. However, the approach does not explicitly consider metrics such as response time, and execution time.

Bandopadhyay *et al.* [8] proposed a Game-Theoretic Resource Allocation and Dynamic Pricing Mechanism in FC (GTRADPMFC). The model incorporates non-cooperative competition among FNs for resource allocation and employs dynamic pricing mechanisms to promote efficient resource usage. Through theoretical evaluation and simulation experiments, the study demonstrated that GTRADPMFC enhances both resource efficiency and the overall performance of FC systems. Furthermore, the paper outlines methods to manage scenarios with insufficient data samples and provides flexibility for users who cannot meet specific completion time requirements. GTRADPMFC optimizes resource allocation by establishing pricing strategies while accounting for potential delays in task completion. The research also includes simulations, convergence analyses, complexity assessments, and guarantees for optimization. However, the model does not explicitly address performance metrics such as response time and execution time.

Mokni *et al.* [14] proposed decision-making phase that analyzes data generated by IoT devices to identify the optimal offloading strategy. To accomplish this, the TOF-NSGAII approach was introduced, aiming to reduce both energy consumption and latency during the offloading of IoT tasks in a fog-cloud environment. Each IoT device transmits tasks with distinct attributes, such as input data size, and the algorithm assigns these tasks to specific virtual machines to optimize resource utilization. By utilizing the combined resources of fog and CC, the TOF-NSGAII approach effectively meets its goals of minimizing energy usage and latency, as validated by experimental results. However, the model does not explicitly address performance metrics such as response time and execution time.

Raissouli *et al.* [15] developed an improved version of NSGA II, namely, reinforcement weighted probabilistic NSGA II, which uses weighted probabilistic mutation. This algorithm replaces random mutation with probabilistic mutation to enhance exploration of the solution space. This method uses domain-specific knowledge to improve convergence and solution quality, resulting in improved energy efficiency and reduced delay compared to traditional NSGA II and other evolutionary algorithms. However, the model does not explicitly address performance metrics such as response time, completion time and execution time.

The studies described above show that various efforts have been made to solve resource allocation and task scheduling problems in FC environments. However, the efficiency of algorithms in handling complex and dynamic FC scenarios across varying conditions has yet to be thoroughly investigated. Additionally, existing algorithms do not explicitly consider key performance metrics such as response time, completion time, and execution time. In contrast, our proposed approach addresses these limitations by incorporating these critical metrics to enhance the effectiveness of resource allocation and reallocation in FC.

III. System Model

An IoT network consisting of IoT devices and FNs is considered, where the FNs vary in energy and processing power capabilities, making task scheduling a challenging problem. In this setup, we have I IoT devices and F heterogeneous FNs, represented by sets $I = \{1, 2, 3, \ldots, I\}$ and $F = \{1, 2, 3, \ldots, F\}$, respectively. The IoT devices collect data from a range of sensors and transmit it to the fog layer. It is assumed that the IoT devices offload tasks directly to the FNs without any local processing. Each FN is equipped with an agent tasked with receiving and processing data from the IoT devices. Task scheduling is assumed to occur in a distributed manner, with each FN acting as a scheduler upon receiving data from IoT devices. A task is represented as $T_t(S_t, C_t)$, where S_t is the task size in KB and C_t is the task complexity in Million Instructions (MI). Since the end devices often lack sufficient computational resources to process the tasks, the tasks are offloaded to nearby FNs for processing. The commonly-used symbols are delineated in Table I.

A. Problem Statement and Objectives

The problem is defined as finding optimal resource allocation for IoT tasks in a FC environment. Each fog node serves as a resource for processing tasks, and the goal is to allocate these tasks efficiently with the following objectives:

1) Objectives: The objectives of the proposed work are as follows:

- Minimize completion time for processing IoT tasks.
- Minimize response time for IoT tasks.
- Minimize execution time for IoT tasks.
- Maximize the resource utilization.

TABLE I. NOTATION TABLE FOR THE MULTI-OBJECTIVE OSPREY OPTIMIZATION ALGORITHM (MOOA)

Notation	Description
T	Set of IoT tasks, where $T = \{t_1, t_2, \ldots, t_N\}$.
FN	Set of Fog Nodes (FNs), where $FN = \{fn_1, fn_2, \ldots, fn_M\}$.
N	Population size (number of osprey solutions in the search space).
T_{max}	Total number of iterations for the optimization process.
R	Population matrix representing resource allocation solutions, where $X = \{R_1, R_2, \ldots, R_N\}$.
RP_i	A single solution in the population, representing task-to-node allocations.
$r_{i,j}$	Position of the j^{th} dimension of solution R_i, indicating resource allocation for task j.
$r_{i,j}^{P1}$	Updated position of the j^{th} dimension for osprey i during optimization.
$r_{i,j}^{P2}$	Updated position of the j^{th} dimension for osprey i during optimization.
lb_j, ub_j	Lower and upper bounds for the j^{th} dimension of the solution space.
$r_{i,j}$	A random number generated for the j^{th} dimension of osprey i.
$F(X_i)$	Fitness value of solution X_i, considering multiple objectives.
f	Objective function
X^*	Best solution obtained after optimization.
t_{new}	Newly arriving IoT task that requires resource reallocation.
fn_{fluct}	Fog node with fluctuating resource availability due to dynamic conditions.

IV. PROPOSED WORK

In this section, the details of the proposed Multi-Objective Optimization Algorithm (MOOA) are presented. The diagram illustrating the proposed architecture is presented in Fig. 1.

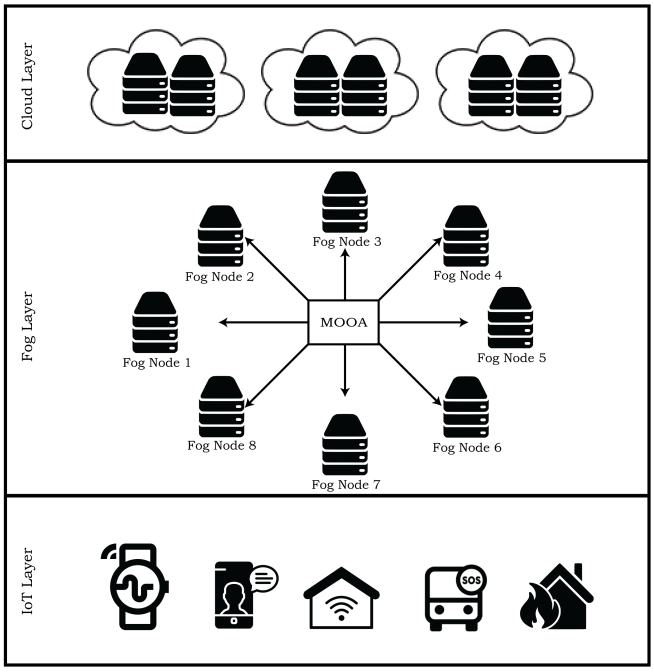

Fig. 1. Proposed MOOA architecture.

A. OOA Overview

The Osprey Optimization Algorithm (OOA) is inspired by the hunting and behavior patterns of the osprey, a bird of prey that primarily feeds on fish. Known for its sharp vision and specialized hunting strategy, the osprey locates fish underwater from a height of 10 to 40 meters before diving to capture them. After catching its prey, the osprey takes it to a safe location to consume it. This natural behavior, marked by precision and efficiency, forms the basis of the OOA, which applies these characteristics to create an effective optimization technique [16], [17]. In the context of FC, the OOA is adapted to allocate and reallocate resources efficiently among tasks and FNs. The OOA is designed to optimize multiple objectives simultaneously, such as minimizing response time, execution time, completion time, and balancing the load among FNs. The algorithm operates in three key phases: initialization, iterative optimization, and updating.

B. Initialization Phase

In the initialization phase, a population of N ospreys is randomly generated. Each osprey in the population represents a candidate solution, where its position encodes a potential allocation of resources. The matrix representation of the population can be modeled as shown in Eq. 1. The position of the i-th osprey in the j-th dimension is represented by $r_{i,j}$, where $r_{i,j}$ corresponds to a problem variable related to resource allocation (e.g. CPU, RAM and Bandwidth). The initial positions are within the predefined bounds of the problem variables.

$$R = \begin{bmatrix} R_1 \\ \vdots \\ R_i \\ \vdots \\ R_N \end{bmatrix}_{N\times m} = \begin{bmatrix} r_{1,1} & \cdots & r_{1,j} & \cdots & r_{1,m} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ r_{i,1} & \cdots & r_{i,j} & \cdots & r_{i,m} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ r_{N,1} & \cdots & r_{N,j} & \cdots & r_{N,m} \end{bmatrix}_{N\times m}, \tag{1}$$

Where N is the number of candidate solutions (ospreys), m is the number of tasks to be allocated, $r_{i,j}$ represents the allocation of resources from a FN to the j-th task in the i-th candidate solution. At the beginning of the algorithm, the initial allocation matrix is generated randomly to ensure diversity. The positions of the ospreys in the resource allocation search space are initialized using Eq. 2:

$$r_{i,j} = lb_j + r_{ij} \cdot (ub_j - lb_j), i = 1, 2, \ldots, N, j = 1, 2, \ldots, m, \tag{2}$$

Where lb_j and ub_j are the lower and upper bounds of resource availability for the j-th task, $r_{i,j}$ is a random number uniformly distributed in the range $[0, 1]$, ensuring a diverse initial allocation.

C. Objective Function

The main goal of task allocation in a FC environment is to minimize the time needed for task completion, response, and execution. The values obtained from evaluating the objective function for the given problem from Eq. (4) to (10) can be expressed as a vector, as outlined in Eq. (3).

$$F = \begin{bmatrix} F_1 \\ \vdots \\ F_i \\ \vdots \\ F_N \end{bmatrix}_{N\times 1} = \begin{bmatrix} F(R_1) \\ \vdots \\ F(R_i) \\ \vdots \\ F(R_N) \end{bmatrix}_{N\times 1}, \quad (3)$$

1) Execution Time: The execution time $E_{i,j}$ of $task_i$ on FN_j can be expressed as:

$$E_{i,j} = \frac{T_{i,j}}{C_{i,j}} \quad (4)$$

Where $T_{i,j}$ is task length for $task_i$ on FN_j (number of instructions). $CC_{i,j}$ is computational capacity of FN_j, calculated as:

$$CC_{i,j} = P_{i,j} \times M_{i,j} \quad (5)$$

Where $P_{i,j}$ is number of processing elements (PEs) in FN_j. $M_{i,j}$ is MIPS rate of FN_j.

2) Response Time: The response time $RT_{i,j}$ for $task_i$ on FN_j is calculated as:

$$RT_{i,j} = F_{i,j} - S_{i,j} \quad (6)$$

Where $F_{i,j}$ is finish time of $task_i$ on FN_j. $S_{i,j}$ is start time of $task_i$ on FN_j.
The finish time $F_{i,j}$ is given by:

$$F_{i,j} = R_{i,j} + E_{i,j} \quad (7)$$

3) Completion Time: The completion time $CT_{i,j}$ for $task_i$ on FN_j is calculated as:

$$CT_{i,j} = F_{i,j} + C_{T_{i,j}} \quad (8)$$

Where $C_{T_{i,j}}$ is communication time for $task_i$ on FN_j. Thus, the completion time $CT_{i,j}$ is:

$$CT_{i,j} = (RT_{i,j} + E_{i,j}) + C_{T_{i,j}} \quad (9)$$

The objective function value is evaluated at each position of the osprey:

$$F_i = [F_1(E), F_2(RT), F_3(CT)]^T \quad (10)$$

D. Phase 1: Position Identification and Resource Allocation

In fog resource allocation, resource updates can mimic osprey hunting behavior. Just as ospreys identify and target fish underwater, the algorithm identifies better resource positions in the search space to enhance exploration and escape local optima. For each resource, the positions of other resources in the search space that have better objective function values are considered optimal targets. These targets are analogous to the "fish" in the search space. The set of optimal resources for each resource is defined in Eq. (11).

$$RP_i = \{R_k \mid k \in \{1, 2, \ldots, N\} \wedge R_k < F_i\} \cup \{R_{\text{best}}\} \quad (11)$$

Here, R_k represents the resources with better objective values, and R_{best} is the best resource found so far. This approach helps guide the allocation process towards more efficient solutions in FC.

$$r_{ij}^{P1} = r_{ij} + r_{ij} \cdot (SF_{ij} - I_{ij} \cdot r_{ij}), \quad (12a)$$

$$r_{ij}^{P_1} = \begin{cases} r_{ij}^{P_1}, lb_j \le r_{ij}^{P_1} \le ub_j; \\ lb_j, r_{ij}^{P_1} < lb_j; \\ ub_j, r_{ij}^{P_1} > ub_j. \end{cases} \quad (12b)$$

The updated resources R_i are refined based on their fitness values:

$$R_i = \begin{cases} R_i^{P1}, F_i^{P_1} < F_i; \\ R_i, \text{ else }, \end{cases} \quad (13)$$

This approach ensures efficient resource allocation and optimizes performance in FC systems.

E. Phase 2: Identifying the Suitable Resources

After identifying a suitable resource node, the FC system allocates tasks to the selected node for processing in an efficient and resource-aware manner. This phase models the process of refining resource allocation decisions to ensure that the tasks are processed in a way that minimizes costs and optimizes system performance. The refinement of allocation decisions involves making small adjustments to the assigned resources, enhancing the exploitation capabilities of the resource allocation algorithm, and converging toward better solutions near the currently identified optimal nodes.

In the design of the FC allocation algorithm, this behavior is simulated by calculating a new potential resource allocation for each task based on predefined criteria using Eq. (14a), (14b). If the new allocation improves the value of the objective function (e.g. response time, completion time, execution time, or improving resource utilization), the algorithm updates the allocation to this new configuration according to Eq. (15). This iterative refinement ensures more efficient exploitation of available resources and promotes convergence toward the most optimal allocation.

$$r_{i,j}^{p_2} = r_{i,j} + \frac{lb_j + r \cdot (ub_j - lb_j)}{t}, i = 1, 2, \ldots, N, \quad j = 1, 2, \ldots, m, t = 1, 2, \ldots, T \quad (14a)$$

After updating the position, the new position is constrained within the bounds:

$$r_{i,j}^{P2} = \begin{cases} r_{i,j}^{P2}, lb_j \le r_{i,j}^{P2} \le ub_j; \\ lb_j, r_{i,j}^{P2} < lb_j; \\ ub_j, r_{i,j}^{P2} > ub_j, \end{cases} \quad (14b)$$

$$R_i = \begin{cases} R_i^{P2}, F_i^{P2} < F_i; \\ R_i, \text{ else }, \end{cases} \quad (15)$$

else, the osprey remains at its current position.

Algorithm 1: MOOA for Resource Allocation and Reallocation in FC for IoT Tasks

Input: Task set $T = \{t_1, t_2, ..., t_N\}$, Fog Node set $FN = \{fn_1, fn_2, ..., fn_M\}$, T_{max}, N, Resource constraints (e.g., CPU, MIPS, memory, energy per unit), f.
Output: Optimized resource allocation and reallocation solutions for IoT tasks in the fog network.
/* Phase 1: Initial Resource Allocation */
Step 1: Initialize the Population;
Generate initial population matrix with random resource allocation positions for each task to FNs using using (1) and (2).
Step 2: Evaluate Initial Fitness;
foreach $X_i \in X$ **do**
  Compute fitness for each solution using objective function f by (3)
for $t \leftarrow 1$ **to** T_{max} **do**
  foreach *osprey* $i \in \{1, 2, ..., N\}$ **do**
    foreach *task-to-node mapping dimension* $j \in \{1, 2, ..., m\}$ **do**
      /* Phase 1: Position identification and Resource Allocation */
      /* Calculate New Position for Resource Allocation */
      Generate random number $r_{i,j}$;
      Update position for osprey i using (11).
      Calculate new position $x_{P1_{i,j}}$ using (12a).
      Check boundary conditions for $x_{P1_{i,j}}$ using (12b).
      Update R_i using (13).
    /* Phase 2: Identifying the suitable resources */
    /* Evaluate New Fitness for the Updated Allocation */
    Compute new fitness by using (3).
    Calculate new position $x_{P2_{i,j}}$ using (14a).
    Check boundary conditions for $x_{P2_{i,j}}$ using (14b).
    /* Replace if New Solution is Better */
    Update R_i using (15).
Output: Initial resource allocation solution X^*;
/* Phase 2: Resource Reallocation */
Step 3: Monitor Task and Resource Fluctuations;
Collect real-time information about task arrivals, resource availability, and execution progress in FNs;
Step 4: Reallocate Resources Dynamically;
foreach *new task* t_{new} *or fluctuating resource* fn_{fluct} **do**
  foreach *solution* $X_i \in X$ **do**
    foreach *task-to-node mapping dimension* j **do**
      /* Phase 1: Position identification and Resource Allocation */
      /* Recompute Positions for Reallocation */
      Update resource mapping based on osprey behavior and fluctuating resource constraints by using (11).
      Calculate new position $x_{P1_{i,j}}$ using (12a).
      Check boundary conditions for $x_{P1_{i,j}}$ using (12b).
      Update R_i using (13).
    /* Phase 2: Identifying the suitable resources */
    /* Reevaluate Fitness for Reallocation */
    Compute by using (3).
    Calculate new position $x_{P2_{i,j}}$ using (14a).
    Check boundary conditions for $x_{P2_{i,j}}$ using (14b).
    /* Replace Solution if Reallocation is Better */
    Update R_i using (15).
Output: Final optimized solution X^* for resource allocation and reallocation;

F. Termination Criterion

The optimization continues until a termination criterion is met, such as a maximum number of iterations T_{max} or a satisfactory solution is found.

G. Iterative Process, Flowchart, and Algorithm of MOOA

The MOOA for resource allocation and reallocation in FC for IoT tasks is designed to handle the dynamic and heterogeneous requirements of IoT tasks. The steps for implementing the MOOA are illustrated as the flowchart in Fig. 2, and their

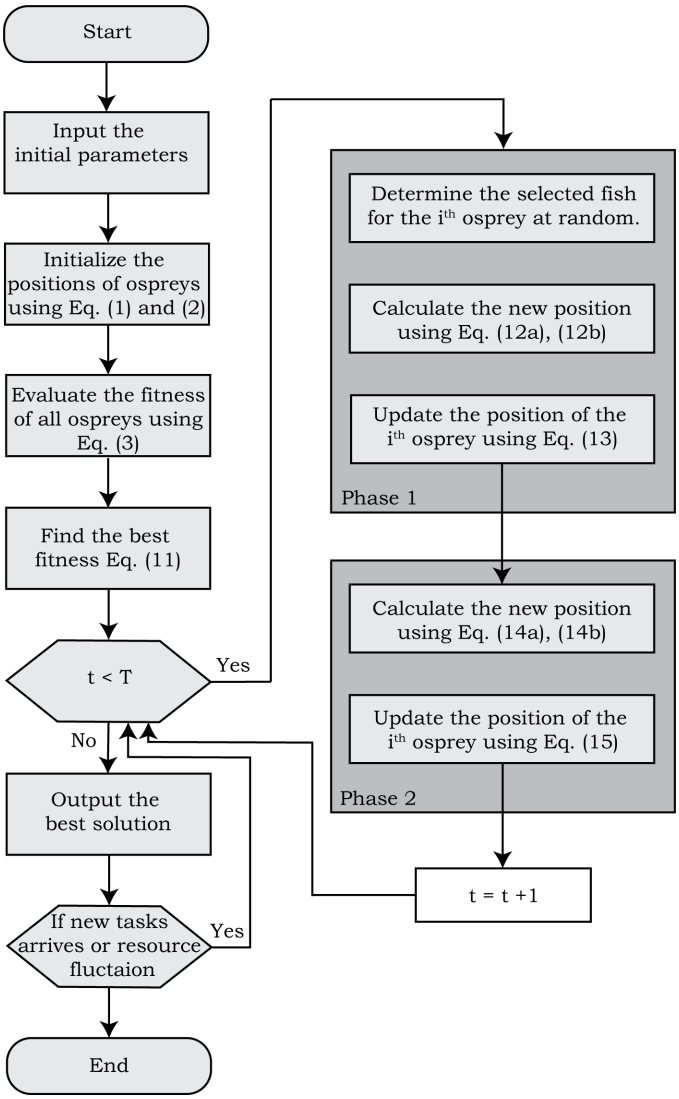

Fig. 2. Flowchart of MOOA.

procedural details are outlined in Algorithm I as pseudocode.

Phase 1: Initial Resource Allocation: The algorithm begins by generating an initial population matrix X, where each solution represents a potential mapping of tasks to fog nodes. The positions in the matrix are initialized randomly within the defined bounds for resource constraints (e.g., CPU, MIPS, memory). Each solution is evaluated using multi-objective fitness functions mentioned in the Eq. (10). For each iteration t of the optimization process, every osprey (solution) adjusts its position by considering random factors ($r_{i,j}$) and the bounds of resource constraints (lb_j, ub_j). The new position is calculated for each dimension (task-to-node mapping), ensuring the solution stays within the defined bounds. The fitness of the updated position is evaluated for all objective functions. If the updated position improves the fitness of the solution, it replaces the existing solution. This iterative process continues until the maximum number of iterations ($T_{\max}$) is reached, producing the initial resource allocation solution X^*.

Phase 2: Dynamic Resource Reallocation: In the second phase, the algorithm monitors the fog network in real-time to account for fluctuations in task arrivals and resource availability. Information about new tasks, resource constraints, and ongoing execution is collected. For every new task or fluctuating resource, the algorithm adjusts the resource mapping dynamically. Each solution in the population is reevaluated by recalculating the task-to-node mappings based on osprey behavior, incorporating updated resource constraints. The positions are updated using random factors ($r_{i,j}$) while ensuring they remain within the bounds of resource availability. The fitness of each updated solution is computed, and if the reallocation improves the solution, it replaces the current one. The algorithm outputs the optimized resource allocation and reallocation solution X^*, balancing the objectives of equation (10). This ensures efficient and adaptive resource management in FC environments for IoT tasks.

V. Simulation Results and Discussion

This section presents the evaluations conducted to demonstrate the effectiveness of the proposed approach. The experiments were performed using the iFogSim2 [18] simulation platform, and performance of the proposed MOOA algorithm was compared with existing algorithms, including GA [19] and PSO [20]. The simulations were run on a Windows 11 system equipped with an Intel(R) Core(TM) i5-9300H CPU operating at 2.40 GHz. The experimental parameters are related to various IoT tasks, the fog and cloud computing environment, and the configuration of the MOOA algorithm. Details of the experimental settings are provided in Table II.

TABLE II. Simulation Parameters

Parameters	**Values**
Simulation tool	iFogSim2
System Architecture	x86
OS	Linux
VMM	Xen
No. of FNs	50
RAM	4,000 (MB)
Storage	1000000

Experiment 2	
Purpose	Heterogenous nodes
Data input parameters	200
FN parameters	100, 200, 300, 400, 500

A. Experiment 1

Fig. 3 compares the execution time for varying task loads (100 to 500 tasks) among the proposed algorithm, GA, and

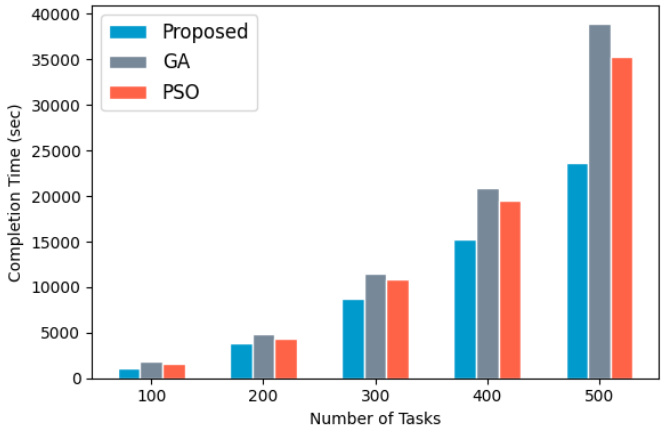

Fig. 3. Execution time of tasks with 50 FNs.

PSO. As expected, execution time increases with the number of tasks. The proposed algorithm achieved a significant reduction in execution time, showing an average improvement of 12.45% over PSO and 22.97% over GA. This underscores the proposed algorithm's ability to handle tasks efficiently in FC environments.

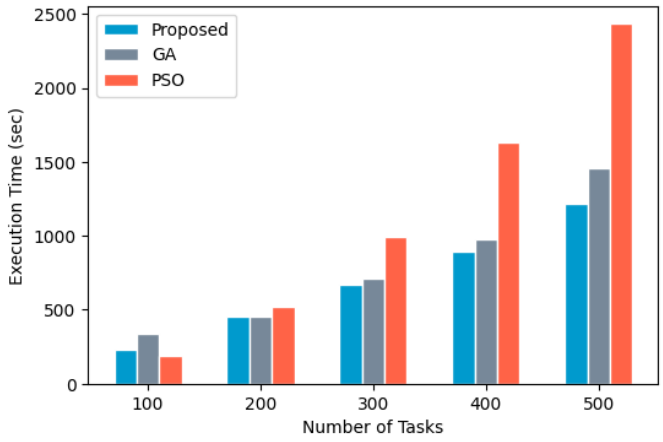

Fig. 4. Response time of tasks with 50 FNs.

Fig. 4 illustrates the response time for different task loads. The proposed algorithm consistently outperformed GA and PSO, achieving an average response time improvement of 32.57% compared to GA and 24.45% compared to PSO. This highlights the robustness of the proposed algorithm in minimizing delay and enhancing performance.

Fig. 5 depicts the completion time comparison across task loads. The proposed algorithm demonstrated superior performance, with an average reduction of 44.39% compared to GA and 33.23% compared to PSO. This confirms the proposed algorithm's scalability and effectiveness in optimizing computational processes in FC environments.

B. Experiment 2

Fig. 6 compares the execution time for varying FNs (10 to 50 nodes) among the proposed algorithm, PSO and GA.

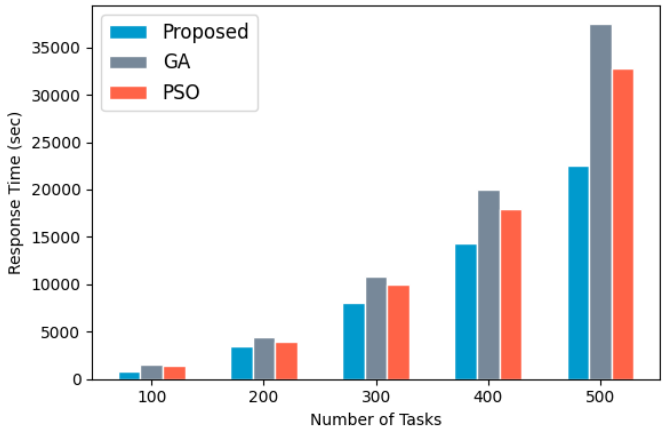

Fig. 5. Completion time of tasks with 50 FNs.

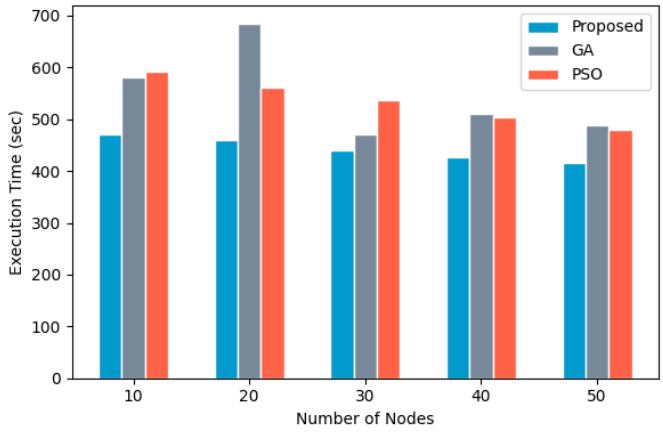

Fig. 6. Execution time of 200 tasks with different FNs.

As expected, execution time decreases with the number of FNs. The proposed algorithm achieved a significant reduction in execution time, showing an average improvement of 17.16% over PSO and 18.02% over GA. This underscores the proposed algorithm's ability to handle tasks efficiently in FC environments.

Fig. 7 illustrates the response time comparison across for varying FNs (10 to 50 nodes). The proposed algorithm consistently outperformed GA and PSO, achieving an average response time improvement of 39.65% compared to GA and 17.57% compared to PSO. This highlights the robustness of the proposed algorithm in minimizing delay and enhancing performance. Fig. 8 depicts the completion time comparison across for varying FNs (10 to 50 nodes). The proposed algorithm demonstrated superior performance, with an average reduction of 36.44% compared to GA and 16.58% compared to PSO. This confirms the proposed algorithm's scalability and effectiveness in optimizing computational processes in FC environments.

VI. Conclusion

In this paper, we proposed a MOOA aimed at optimizing resource allocation and reallocation in FC environments for

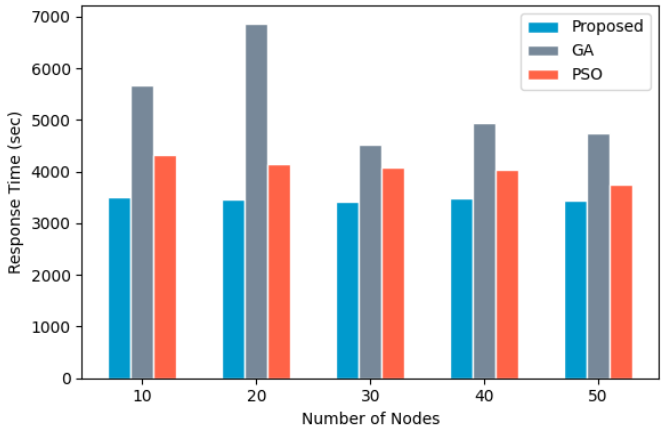

Fig. 7. Response time of 200 tasks with different FNs.

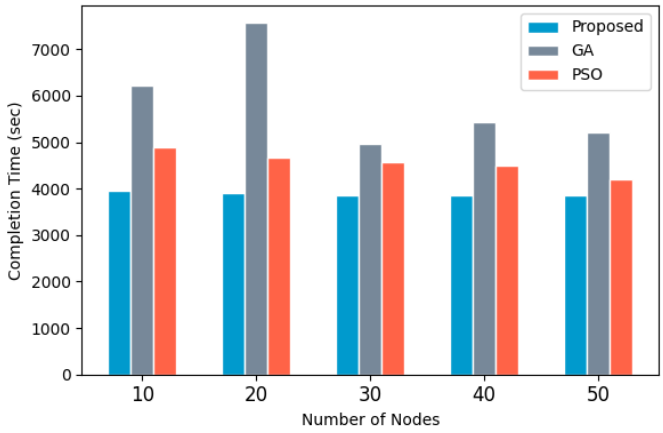

Fig. 8. Completion time of 200 tasks with different FNs.

IoT tasks. By optimizing multiple objectives such as completion time, response time, and execution time, MOOA provides an efficient solution for managing fog resources in dynamic and resource constrained environments. The simulation results demonstrated the effectiveness of the proposed algorithm in handling tasks efficiently in FC environments. The algorithm achieved a notable reduction in execution time, with an average improvement of 12.45% over PSO and 22.97% over GA. Moreover, MOOA consistently outperformed GA and PSO in terms of response time, achieving average improvements of 32.57% and 24.45%, respectively. Analysis of completion time further demonstrated the algorithm's superior performance, with an average reduction of 44.39% compared to GA and 33.23% compared to PSO. These results underline the robustness and scalability of MOOA, highlighting its effectiveness in optimizing task allocation and computational processes in FC environments. Future work will focus on extending this approach to incorporate energy efficiency, fault tolerance, and multi-objective optimization to address diverse QoS requirements in dynamic FC environments.

Leveraging Deep Semantics for Sparse Recommender Systems (LDS-SRS)

Adel Alkhalil
Department of Software Engineering,
College of Computer Science and Engineering,
University of Ha'il, Ha'il, 81481, Saudi Arabia

***Abstract*—RS (Recommender Systems) provide personalized suggestions to the user(s) by filtering through vast amounts of similar data, including media content, e-commerce platforms, and social networks. Traditional recommendation system (RS) methods encounter significant challenges. Collaborative Filtering (CF) is hindered by the lack of sufficient user-product engagement data, while CBF (Content Based Filtering) depends extensively on feature extraction techniques in order to describe the items, which requires an understanding of both content contextual and semantic relevance of the information. To address the sparsity issue, various matrix factorization methods have been developed, often incorporating pre-processed auxiliary information. However, existing feature extraction techniques generally fail to capture both the semantic richness and topic-level insights of textual data. This paper introduces a novel hybrid recommendation system called Topic-Driven Semantic Hybridization for Sparse Recommender Systems (LDS-SRS). The model leverages the semantic features from item descriptions and incorporates topic-specific data to effectively tackle the challenges posed by data sparsity. By extracting embeddings that capture the deep semantics of textual content—such as reviews, summaries, comments, and narratives—and embedding them into Probabilistic Matrix Factorization (PMF), the framework significantly alleviates data sparsity. The LDS-SRS framework is also computationally efficient, offering low deployment time and complexity. Experimental evaluations conducted on publicly available datasets, such as AIV (Amazon Instant Video) and Movielens (1 Million & 10 Million), demonstrate the exceptional ability of the method to handle sparse user-to-item ratings, outperforming existing leading methods. The proposed system effectively addresses data sparsity by integrating embeddings that encapsulate the deep textual semantics content, including summaries, comment(s), and narratives, within PMF (Probabilistic Matrix Factorization). The LDS-SRS framework is also highly efficient, characterized by minimal deployment time and low computational complexity. Experimental evaluations conducted on publicly available MovieLens (1 Million and 10 Million) and AIV (Amazon Instant Video) benchmark datasets demonstrate the framework's exceptional ability to handle sparse user-item ratings, surpassing existing advanced methods.**

***Keywords*—LDA-2-Vec technique; content representation; topic-based modeling; probabilistic matrix decomposition**

I. Introduction

RSs are integral to e-commerce, offering tailored product suggestions for various items, including movies, books, clothing, and news. In recent years, their applications have expanded to areas such as social media platforms, websites, and articles. Leading Fortune 500 companies like Facebook, Netflix, and eBay have created proprietary RSs to predict and cater to customer preferences. The success of these organizations in the business market is significantly influenced by the effectiveness of their RSs. For instance, Netflix suggests movies based on individual user preferences, while Amazon and eBay recommend related products to customers, and social media platforms display relevant pages and advertisements to users. As a result, it is evident that recommendation systems play a crucial part in driving the financial growth of these companies [1], [2].

The principles underlying RSs are broadly categorized into CF, CB, and Hybrid Recommendation Methods [3], [4] combine multiple filtering techniques, such as Collaborative Filtering (CF), to derive user-item ratings based on historical metadata, analysing individual preferences and behaviours. It recommends new products by identifying similarities between users based on their past preferences, without relying on the specific details of the items' content [5], [6]. Conversely, Content-Based (CB) filtering analyzes item descriptions, utilizing their attributes and features to match them with user profiles. By analyzing items liked by the user, CB generates a similarity matrix to recommend the most relevant new items. This method heavily relies on item descriptions and user profiles for making accurate recommendations. This approach depends largely on item descriptions and user profiles to provide precise recommendations [7], [8]. Hybrid filtering, which integrates both CB and CF methods, utilizes user preferences along with content semantics to improve the effectiveness of recommender systems.

Collaborative Filtering (CF) is widely considered a powerful model for developing recommendation systems, as it predicts ratings by examining user-item rating matrices [1]. CF can be categorized into two main approaches: Memory Based and Model Based techniques [9], [10]. Memory-based methods concentrate on identifying similarities among users or products to find potential neighbors, using these similarities to predict ratings. However, this approach is often hindered by issues like limited data availability and the cold start problem [3], [11]. In contrast, Model-Based Collaborative Filtering utilizes trained techniques, including decision trees, clustering methods [12], [13], Bayesian models [15], latent factor models [14], and dimensionality reduction methods [16]. While these approaches can be highly effective, their implementation and upkeep demand substantial effort and computational resources, particularly due to the necessity of frequent parameter optimization [17]. Among these, Matrix Factorization (MF) stands out for its balance of scalability and precision [11]. When working with sparse or large-scale datasets, Matrix Factorisation (MF) may perform poorly, perhaps producing less accurate

predictions. MF breaks down the user product engagement grid to latent features that uncover underlying rating patterns [4].

The rising volume of online users interaction and available products has exacerbated sparse ratings problem. For Collaborative Filtering (CF)-based recommendation systems to function effectively, comprehensive user rating histories are crucial. However, upon the registration of new users, the absence of historical data leads to less accurate recommendations. Consequently, the sparsity of ratings and the lack of detailed semantics in item descriptions hinder the accuracy of predictions and recommendations [1], [18]. Trust-based collaborative filtering methods have been explored to mitigate these issues by leveraging user trust relationships to enhance recommendations [22]. To address these challenges, several methods have been introduced that integrate both user feedback data and supplementary details, including user preferences (e.g., likes, interests, and social media activity) and item specifics (e.g. reviews, summaries, and plots) [19] - [20].

To address the limitations of traditional CF and hybrid methods in handling sparse recommendation scenarios, we choose to propose the LDS-SRS framework. This method enhances PMF by embedding deep semantic and topic-driven representations, ensuring more accurate recommendations even in sparse datasets. Unlike neural network-based models, which demand high computational resources, LDS-SRS efficiently integrates on textual knowledge while maintaining low computational complexity.

This research seeks to address the sparsity problem by extracting the rich semantics from textual item descriptions. The proposed method utilizes an embedding model to analyze auxiliary item data, capturing semantic information enhanced with topic-related details. These embeddings are integrated into the document latent factors of Probabilistic Matrix Factorization (PMF). By employing PMF as the CF technique, experimental outcomes demonstrate the model's effectiveness. The main contributions of the research study include:

- The introduced framework, LDS-SRS, integrates the detailed semantics of textuaThe main contributions of the research study include:l item data with topic-specific insights.
- The derived embeddings serve as input for memory-based collaborative recommendation methods to enhance the precision of predicted ratings.
- A comparative analysis demonstrates that LDS-SRS outperforms existing paradigms on MovieLens (1 Million and 10 Million) and AIV (Amazon Instant Video) benchmark datasets

The structure of this paper is outlined as follows: Section II reviews the relevant literature, while Section III details the proposed model for the recommendation system. Section IV provides a comprehensive analysis of the results and performance metrics, and Section V wraps up the study with concluding remarks.

II. Literature Review

The functionality of recommendation systems (RS) is significantly affected by the cold start issue and the scarcity of user-item rating data. To enhance the accuracy of rating predictions and the quality of recommendations, research has focused on CB(Content Based) and CF(Collaborative Filtering) techniques. One major challenge, the cold start problem, is addressed by applying text analysis techniques to extract valuable information from both user and item data, allowing the system to effectively incorporate new users or items. Additionally, the CB approach [21] helps mitigate sparsity by utilizing item-specific features, making it easier to manage new items.

These techniques use low-rank factorization to approximate the user item interaction grid, improving the prediction of products. Matrix Factorization techniques break down the user item grid into lower-dimensional embeddings for both users & products. Additionally, some systems enhance collaborative recommenders by incorporating trust-based information [46]. The Topic-MF model [23] integrates biased matrix factorization techniques to address sparsity by combining rating data with topic-related information derived from user reviews. Since text reviews provide more semantic depth than ratings, they offer richer insights into user and item characteristics. Functional Matrix Factorization (FMF) uses interview-based tools to build user profiles [24], while the Latent Dirichlet Allocation (LDA) model is employed to extract topic-specific details from item descriptions.

ALS (Alternating Least Squares) [25] and SGD (Stochastic Gradient Descent) [4] are well-established optimization techniques frequently used for training Matrix Factorization models. In [26], two alternative multiplicative update methods for Non-negative Matrix Factorization (NMF) were proposed, each with unique update rules for the multiplicative factors. The method presented in [27] integrates Weighted Singular Value Decomposition (WSVD) with a linear regression model, where each latent factor is assigned a weight parameter. Furthermore, [28] introduced a cosine similarity-based Matrix Factorization (CosMF) model, aimed at addressing sparsity issues without the need for additional data processing. However, sparse rating data often hampers the effective training of user and product vectors because of the lack of supplementary data. This model substitutes dot products with cosine similarity for users and products with limited data, helping to mitigate the adverse effects of missing auxiliary data.

Probabilistic Matrix Factorization (PMF) [29] outperforms SVD in recommendation tasks. Recently, advanced generalizations of PMF, such as Generalized PMF [30], ConvMF [32], and Bayesian PMF [31], have been introduced. While the CB model [21] addresses sparsity by utilizing item features, it struggles with effectively accommodating new users. Hybrid RS models were introduced to integrate CF with user or product content information [20], [32], [33]. For example, in [34], item features were generated using a Stacked Denoising AutoEncoder (SDAE) trained on online item descriptions. These features were integrated into the timeSVD++ CF model, which uses a weighted bag-of-words approach but fails to capture semantic word similarities. Approaches for document representation, including Latent Dirichlet Allocation (LDA) and Stacked Denoising Autoencoders (SDAE), have been utilized to extract content features from supplementary sources like reviews, synopses, or abstracts [35], [36], [20], [37]. Wang et al. combined Probabilistic Matrix Factorization (PMF) and SDAE to enhance the accuracy of latent models for rating

predictions [20]. In contrast, Collaborative Deep Learning (CDL) adopted a more straightforward collaborative filtering approach, concentrating on generating top-N recommendations.

Convolutional Neural Networks (CNNs) are widely applied in Digital Image Processing (DIP) and Computer Vision (CV) tasks [38]. Additionally, CNNs have shown considerable promise in Natural Language Processing [39], [40], [41] and information retrieval applications. CNNs effectively capture contextual features from images or textual descriptions by employing subsampling, shared weights, and receptive fields [38]. CNNs can incorporate word embeddings, such as Word2Vec, to extract contextual word features. ConvMF [32] integrates CNN architecture, specifically designed for NLP, with PMF. Similarly, [42] utilized a pre-trained embedding model with CNNs, which were then integrated into PMF. While these models capture the contextual characteristics of item textual data, they often fail to incorporate deep semantics. Furthermore, these models may struggle with negative values in latent representations, potentially leading to the degradation of information during rating prediction [49]. In [51], a hybrid recommendation system was introduced that utilizes content embeddings to predict scores for cold start products. The $HRS-CE$ model generates word embeddings from item descriptions and uses them to build user profiles for recommending similar items. [52] enhanced Non-Negative Matrix Factorization (NMF) by incorporating contextual item information through a sophisticated embedding model that captures semantic meaning as well as additional contextual data [53], [54].

In contrast to traditional recommendation system (RS) models, the proposed LDS-SRS model adopts a hybrid approach that captures comprehensive content embeddings of products and integrates them with CF (collaborative filtering) methods for predicting missing ratings. While extracting content features, both the semantic and topic-related elements of item descriptions are recognized and incorporated into the hidden representations of the PMF(Probabilistic Matrix Factorization) model. The LDS-SRS model does not rely on neural networks for natural language processing tasks, nor does it require the iterative updating of item embeddings. As a result, it offers greater computational, temporal, and memory efficiency compared to other RS algorithms.

III. Proposed Methodology

A recommender system is presented that combines deep semantic insights with topic-specific information to predict item ratings. The model combines "local" features extracted from dense vectors with "global" representations based on topic information, aligning them within a unified space. These contextual embeddings are subsequently utilized to initialize the item representation factors within the framework of PMF.

This section outlines the both the mathematical artifacts/formulation and system's design. Fig. 1 shows the suggested paradigm architecture. Experiments are conducted using the MovieLens dataset, where each film is treated as a product, with its corresponding plot acting as the product description.

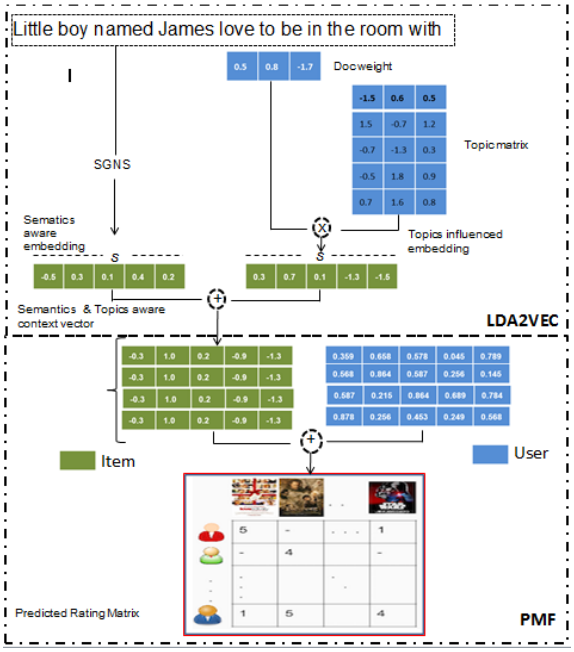

Fig. 1. Proposed framework architecture.

A. Mathematical Modeling

Let $U = [u_1, u_2, u_3, \ldots, u_m]$ denote the set of users, and $I = [i_1, i_2, i_3, \ldots, i_n]$ denote the set of products. The user product rating grid is represented as a two-dimensional array, as follows:

$$R_{ui} \in [0.5, 1, 2, 3, 4, 5]^{m \times n}$$

Here m: Total Users No.
n: Items No.
R_{ui}: Ratings of the Item(i) by the User's(u).

The proposed LDS-SRS approach aims to estimate ratings $\hat{R}_{ui}$ for items (i) that are unrated in the rating matrix, based on the existing ratings. For collaborative filtering, probabilistic matrix factorization (PMF) is applied. PMF decomposes the matrix $R^{m \times n}$ into three separate components: $U \in R^{s \times m}$, $I \in R^{s \times n}$, and $\Omega \in R^{s \times s}$. Thus,

$$RU \times \Omega \times I \tag{1}$$

In this scenario, $R^{m \times n}$ refers to the $(m \times n)$ matrix of user-item ratings, where U represents the latent factors associated with users and I represents those associated with items. Additionally, Ω is a diagonal matrix that represents the hidden patterns within R, while s represents the count of latent factors contained in R.

In order to address the problem of data sparsity, LDS-SRS integrates embeddings containing semantic and topic-related information from text into the probabilistic matrix factorization (PMF) model. The aim is to learn latent representations for users and products, $U \in R^{s \times m}$ & $I \in R^{s \times n}$, in a way that their multiplication $(U^T I)$ closely matches the user-item rating grid R [29]. These latent models are refined by minimizing a

cost function ℓ, which includes the squared difference between actual and predicted ratings, along with regularization terms.

$$\ell = \sum_{u}^{m}\sum_{i}^{n} A_{ui}(r_{ui} - u_u^T i_i)^2 + \alpha \sum_{u}^{m} \|u_u\|^2 + \beta \sum_{i}^{n} \|i_i\|^2 \quad (2)$$

In this context, A_{ui} is defined as a function that returns 1 if user *u* has rated item *i* and 0 otherwise. The performance of the model is evaluated by computing the Root Mean Square Error (RMSE) on the test dataset. A Gaussian noise-based probabilistic linear framework is utilized. The probability distribution based on the observed ratings is expressed as follows:

$$\rho(R|U, I, \sigma^2) = \prod_{u}^{m}\prod_{i}^{n} \eta(r_{ui}|u_u^T i_i, \sigma^2)^{A_{ij}} \quad (3)$$

In this context, $\eta(x|\mu, \sigma^2)$ denotes the probability density function of a Gaussian distribution characterized by a mean value of μ and a variance of σ^2. A spherical Gaussian prior, centered at zero, is applied to the latent vector of the user, as per the equation below:

$$\rho(U|0, \sigma_U^2) = \prod_{u}^{m} \eta(u_u|0, \sigma_U^2 A)$$

In contrast to the user latent method, our approach suggests deriving the probabilistic representation of the item's latent vector from a features paradigm based on the D_i (product description), which includes a Gaussian noise component represented by a gamma variable.

$$i_i = \textit{Embeddings}(D_i) + \gamma_i$$

$$\gamma_i \sim \eta(0, \sigma_I^2 A)$$

The item latent model's distribution is then expressed as:

$$\rho(I|D_i, \sigma_I^2) = \prod_{i}^{n} \eta(i_i|\textit{Embeddings}(D_i), \sigma_I^2 A)$$

Here, D_i represents the description document linked to item *(i)*. The context vector derived from the dense embedding characterizes the Gaussian distribution for the item, with the variance being determined by the Gaussian noise. This variance is essential for initializing the item latent representation in the PMF framework.

In the proposed paradigm, an embedding is created specifically for movie plots. This embedding effectively captures the local semantic features of each plot, while also incorporating broader, topic-related information. Let G represent the movie plot (or item description), consisting of l words, denoted as $w_1, w_2, w_3, \ldots, w_l$.

$$G \xleftarrow[\text{Plot Description}]{} \{w_1, w_2, w_3, ...w_l\}$$

A collection C is constructed from the textual descriptions of movie plots, encompassing all the movies (denoted as G), and can be expressed as:

$$C \xleftarrow[\text{Corpus Generation}]{} \{G_1, G_2, G_3, ...G_n\}$$

In which $C \in \{w_1, w_2, w_3, ...w_l, w_{l+1}, ...w_t\}$, where t denotes the total word count in the entire corpus C.

The Word2Vec (w2v) model employs the Skipgram Negative Sampling (SGNS) method on the corpus C to produce dense word embeddings with s dimensions. This paradigm captures local semantic relationships within a plot by computing the probabilistic weights of words in relation to a reference word. It *locally* predicts the surrounding words based on the given pivot word in the context of a movie plot.

$$P(P_{TW}|P_{PW})$$

In this context, P_{TW} represents the likelihood of the intended word, while P_{PW} denotes the likelihood of the pivot word within the model. The Word2Vec model generates enriched real-valued embeddings that capture both semantic and syntactic relationships within the plots. These compact representations offer increased flexibility but are less interpretable. In contrast, Latent Dirichlet Allocation (LDA) is applied to the dataset to extract topic-specific information from the text. LDA generates a sparse probability vector, providing better interpretability and a clearer understanding of the data. Operating on a *global* scale, LDA constructs a unified plot vector that summarizes topic-related features, which are later used for word prediction within the plot.

$$P(P_{TW}|P_{Topics})$$

Here, P_{Topics} represents the probability of the topic information. The enhanced embedding model combines the dense representations produced by Word2Vec (w2v) with the interpretability provided by Latent Dirichlet Allocation (LDA). This method combines the w2v embeddings of a plot with sparse vectors produced by LDA to approximate a multinomial distribution across underlying word categories. The resulting representation is subsequently passed through a probabilistic model to assign distinct topics to a specific set of movies or items.

$$P(P_{TW}|P_{PW} + P_{Topics}) \quad (4)$$

Eq. 5 is composed of two components. The first component, $\pounds_{SGNS}$, adheres to the standard word2vec (w2v) methodology, aiming to maximize the likelihood of target words and negative samples in relation to the surrounding word representation. The computation is performed using the context vector C_v, the target word vector P_{TW}, the pivot word vector P_{PW}, and the vector for negative (irrelevant) words NS_v. The second component, $\pounds_{LDA}$, introduces a Dirichlet likelihood term that is linked to the document weights. The complete structure of the suggested recommendation model is depicted in Fig. 2. The overall objective function is the combination of the SGNS loss component, augmented by the Dirichlet distribution term that is applied to the document weights.

$$\pounds = \pounds_{SGNS} + \pounds_{LDA} \quad (5)$$

$$\pounds_{SGNS} = \log(C_v|P_{TW}) + \log(-C_v|NS_v) \quad (6)$$

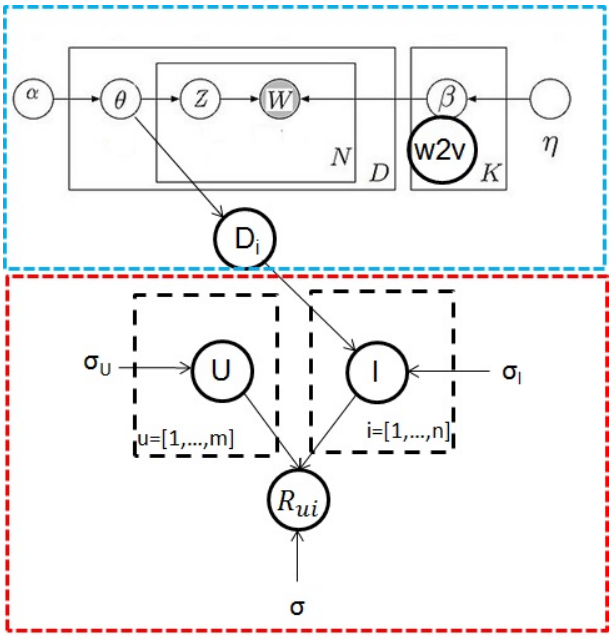

Fig. 2. Proposed paradigm with LDA2VEC embedded in W2V for generating ratings.

Ultimately, by following the outlined procedure, the embedding model processes movie plots and generates a corresponding latent vector for each one. This vector encapsulates the deep semantic context of the plot, while also capturing topic-specific information unique to each movie.

$$LV_i = \textit{Embeddings}(D_i)$$

Here, D_i refers to the description of the *i*th film, while LV_i denotes the latent vector associated with the *i*th film.

B. Optimization

In order to optimize the latent representations for users and products, a posteriori estimation is carried out as follows:

$$\max_{U,I} \rho(U, I|R, \boldsymbol{D}, \sigma^2, \sigma_U^2, \sigma_I^2) = \max_{U,I}[\rho(R|U, I, \sigma^2) \rho(U|\sigma_U^2)\rho(I|D, \sigma_I^2)] \tag{7}$$

By applying the negative logarithm to Equation 7, we obtain:

$$\ln(U, I) = \sum_{u=1}^{m}\sum_{i=1}^{n} \frac{A_{ui}}{2}(r_{ui} - u_u^T i_i)^2 + \frac{\alpha}{2}\sum_{u=1}^{m}\|u_u\|^2 + \frac{\beta}{2}\sum_{i=1}^{n}\|i_i - \textit{Embeddings}(D_i)\|^2 \tag{8}$$

Gradient descent is employed to update the latent representations for users (U) & items (I), iteratively optimizing each model while holding the other variables constant. The main objective is to identify the local minima of the OF (Objective Function) by differentiating Eq. 8 with respect to u_u and i_i in a closed-form expression. Consequently, the latent representations for both the user and the item are computed as follows:

$$u_u = \frac{IR_u}{II_u I^T + \alpha I_s} \tag{9}$$

$$i_i = \frac{UR_i + \beta \textit{Embeddings}(D_i)}{UI_i U^T + \beta I_s} \tag{10}$$

In this context, I_u refers to a diagonal matrix with diagonal elements $I_{ui}, i = 1, \ldots, n$, while R_u represents a vector containing $(r_{ui})_{i=1}^n$ for the user u. Similarly, for the item *(i)*, I_i and R_i are specified in the same way as I_u and R_u.

IV. Outcomes and Performance Assessment

This section provides an evaluation and discussion of the proposed model's performance. It starts with an in-depth description of the dataset and its processing, followed by a thorough explanation of the experimental setup. The results are then presented, analyzed, and visually displayed, with comparisons drawn to leading methods in the field.

A. Dataset Pre-processing

The Movie-Lens 1 Million corpus [43] contains 1,000,209 evaluations $R_{ui} \in \{0.5, 1, 2, 3, 4, 5\}$ for approximately 3,900 movies, rated by 6,040 users. The MovieLens 10 Million dataset includes 10,000,054 evaluations across 10,681 movies (items), contributed by 71,567 users. Additionally, the Amazon Instant Video (AIV) dataset features evaluations for 15,149 items provided by 29,757 users, with scores $R_{ui} \in \{1, 2, 3, 4, 5\}$ ranging from 1 to 5.

Table I provides a summary of the statistics for the datasets used.

TABLE I. Dataset Characteristics

Dataset Name	Total Ratings	User Count	Item Count	Rating Scale	Density (%)
AIV	1,351,88	29,757	15,149	[1 - 5]	0.030
1M	1,000,209	6,040	3,900	[0.5 - 5]	1.431
10M	1,000,005,4	71,567	10,681	[1 - 5]	4.641

To predict ratings for items, additional information such as movie plots is required. However, not all movies in the MovieLens open-source datasets have corresponding plots. To address this, the original datasets were expanded to ensure that the experiments could be carried out effectively. Movie plots were obtained using the OMDB API[1]. A Python script was written to query the OMDB database using each movie's ID, from which the corresponding plot was automatically retrieved. The gathered data underwent several preprocessing steps, including text cleaning and removal of stopwords. Stopwords, which are frequent yet low-information words (e.g. "a", "an", "the", "that"), were eliminated to enhance the quality of text analysis. The following preprocessing steps were performed on the movie plot data: 1) Plot lengths were restricted to a maximum of 200 words. 2) The Word2Vec (w2v) model was

[1]http://www.omdbapi.com

utilized with a sliding window of size 1 to capture contextual relationships among words in the dataset. 3) Subscripts were removed from the text as a precautionary measure. 4) The tokens were generated for the text corpus. 5) LDA2VEC methods were implemented and applied to the tokens of the corpus text using a pre-trained w2v model based on the same dataset [44]. 6) The vector dimensionality was configured to 100. Furthermore, movies without plot summaries were excluded from the dataset to maintain accuracy and reliability in the results.

Harnessing the detailed semantic insights encapsulated in the latent vectors produced by our embedding model, we utilized this information to initialize the item latent factors within the PMF. This step plays a crucial role in integrating the LDA2VEC model with the PMF, enabling an effective fusion of item descriptions and ratings data.

B. Evaluation Metrics

The LDS-SRS model's performance is assessed by employing a ten fold cross validation approach. The overall prediction metric is calculated by averaging the results across all 10 iterations. The training dataset contains a User-Product grid that includes known feedback, while the testing dataset consists of user-product pairs for which the ratings must be predicted. These predictions are generated by multiplying the matrices *U* and *I*. The RMSE, a commonly employed cost function in traditional rating prediction models, is computed as follows:

$$RMSE = \sqrt{\frac{\sum_{u,i}^{U,I}(R_{ui} - \hat{R})^2}{Numberof Ratings}}$$

Along with the previously discussed metrics, Precision and Recall were also employed to assess the effectiveness of the proposed paradigm. Precision represents the fraction of accurate recommendations among the overall recommendations generated, while Recall@K signifies the fraction of correct recommendations among all relevant items. To evaluate Precision and Recall, items were categorized into a pair of groups based on their assigned ratings: non-relevant (ratings 1-3) and pertinent (ratings 4-5). The items in the datasets were then categorized into those that were predicted by the model and those that were not. Precision and Recall for this approach are calculated as follows:

$$Precision = \frac{TP}{TP + FP} \tag{11}$$

$$Recall = \frac{TP}{TP + FN} \tag{12}$$

Here,

TP: True +ive (An item is accurately identified as relevant)

FP: False +ive (An item is incorrectly identified as relevant when it is not)

FN: False -ive (An item selected as negative but is actually positive)

The RMSE of the suggested model demonstrates a decrease in inaccuracies on the test set. RMSE is a widely used metric in recommendation systems as it quantifies the deviation of predicted ratings from actual user ratings, making it a reliable measure of prediction accuracy. Additionally, Precision and Recall are employed to assess the model's ability to recommend relevant items, with Precision reflecting the proportion of correctly recommended items and Recall indicating the proportion of relevant items successfully retrieved. These validation measures are essential in evaluating the effectiveness of LDS-SRS in mitigating sparsity while maintaining high-quality recommendations.

C. Outcomes & Evaluation

The effectiveness of the LDS-SRS model was assessed using datasets from *MovieLens 1M*, *10M*, and AIV. Multiple experiments were carried out to examine the model's convergence, with RMSE being the main metric for validation in each case. The model's performance was evaluated under various conditions, where *s* represents the size of the user-product latent factors. Table II shows the RMSE values for the suggested paradigm with $K = 50/100$ for the both the Movielens and AIV datasets. Fig. 3 demonstrates the model's convergence throughout the iterations for $K = 50/100$. The smallest value of RMSE was obtained when the value of $K = 100$, suggesting that the model performs better in capturing detailed and precise information for both user and item embeddings. For other values of K, the RMSE increased, indicating a decline in the accuracy of movie representations. The plots provide a clear visualization of the convergence trends for both the training and testing datasets.

TABLE II. EFFECTIVENESS OF THE LDS-SRS FOR K@50/100

Paradigm	**Dataset (DS)**	**Assessment (RMSE)**	
		K@50	K@100
Suggested	1M	0.857	0.851
	10M	0.789	0.782
	Amazon Instant Video	1.101	1.083

Table III compares the prediction Effectiveness of the suggested paradigm for various vector sizes generated by the content embedding model. The findings show that the model achieves the best performance when the vector size is configured to 100. On the other hand, increasing the vector size beyond 100 does not enhance performance, as the model effectively captures the required semantic and topic information with a vector size of 100. Further increases in vector size result in a drop in performance, as larger vectors become sparse, leading to an uneven distribution of topic information. Fig. 4 shows the model's convergence for different content vector sizes over iterations. In addition, Fig. 5 illustrates the improvement in item recommendations, with both Precision and Recall steadily increasing. The Precision and Recall at 10 values for our paradigm are computed and compared with those of other leading models from existing literature.

Table IV presents the prediction errors of the proposed model alongside several other recommender systems [33], [20], and [32]. In [33], Wang et al. incorporated LDA into PMF, achieving RMSE values of 0.8969 on the '1M' collection, 0.8275 on the '10M collection', and 1.549 on the 'AIV' collection. In [20], SDAE was employed to learn item features within PMF, resulting in RMSE values of 0.8879 for '1M',

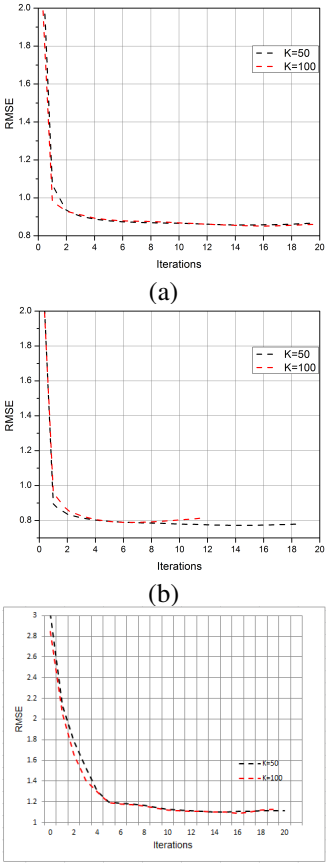

Fig. 3. LDS-SRS Performance with $K = 50$ and $K = 100$.

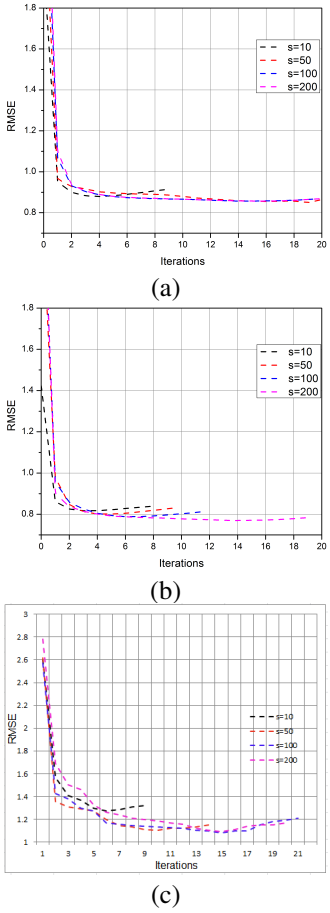

Fig. 4. LDS-SRS performance with different embedding sizes.

TABLE III. EVALUATION OF THE PROPOSED MODEL WITH VARYING VECTOR SIZES

Paradigm	Dataset (Ds)	Assessment (RMSE)			
		Size=10	Size=50	Size=100	Size=200
Suggested	1M	0.879	0.868	**0.856**	0.857
	10M	0.818	0.801	**0.782**	0.780
	Amazon Instant Video	1.12	1.119	**1.083**	1.094

0.8186 for '10M', and 1.3594 for 'AIV'. More recently, [32] combined contextual item information with PMF, enhancing RMSE to 0.853 for '1M', 0.795 for '10M', and 1.133 for 'AIV'. In [42], CNN was integrated with PMF to account for item statistics and Gaussian noise, yielding RMSE values of 0.847 for '1M', 0.784 for '10M', and 1.101 for 'AIV'. [45] introduced imputed data from similar neighbors into SVD, resulting in an RMSE of 0.850 for '1M'. [48] employed data clustering based on user/item similarity for recommender systems, achieving an RMSE of 1.0878 for '1M'. Lastly, [50] classified items and users into three distinct categories and influenced them with a Bhattacharya coefficient, obtaining an RMSE of 1.7000 for '1M'.

Table IV clearly demonstrates that the proposed model surpasses other recommender systems on the MovieLens and AIV datasets. Specifically, it achieves RMSE values of 0.846, 0.779, and 1.083 for the '1 Million', '10 Million', and 'AIV (Amazon Instant Video)' datasets, respectively, within a sparse user to item matrix, highlighting its superior performance.

Its runtime for rating predictions is significantly faster compared to other models.

TABLE IV. SUGGESTED PARADIGM ANALYSIS WITH HYBRID MODELS

Paradigm	ML-1 M	ML-10 M	AIV
CTR [33]	0.8969	0.8275	1.549
CDL [20]	0.8879	0.8186	1.3594
CMF [32]	0.853	0.795	1.133
CMF+ [32]	0.854	0.793	1.1279
RCMF [42]	0.847	0.784	1.101
RN [47]	0.863	0.807	1.105
ISVD [45]	0.850	-	-
GAGE [48]	1.0878	-	-
NCBR [50]	1.7000	-	-
Suggested	**0.846**	**0.779**	**1.083**

D. Complexity Analysis

The suggested paradigm demonstrates considerably lower computational complexity in comparison to other models. Unlike approaches like [32], which necessitate retraining the entire network and updating weights at each iteration, the proposed model operates without relying on neural networks.

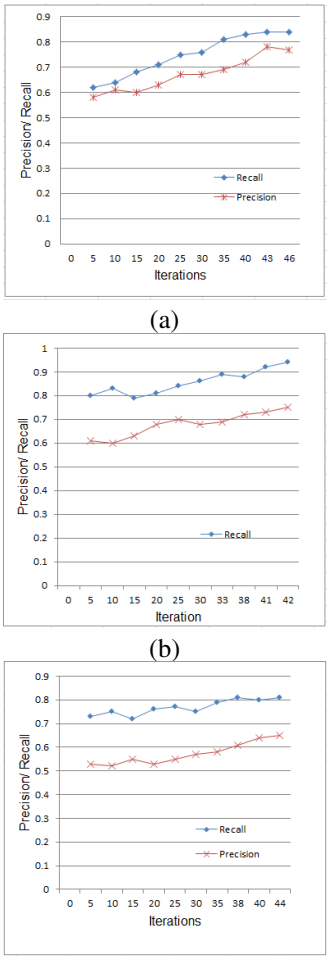

Fig. 5. Precision and recall for the proposed model.

This absence of neural network dependence leads to greater efficiency in its performance.

As shown in Table IV, our proposed LDS-SRS framework achieves a lower RMSE compared to CTR (0.8969 vs. 0.846), CDL (0.8879 vs. 0.846), and CMF (0.853 vs. 0.846) on the MovieLens 1M dataset. The key advantage of LDS-SRS lies in its ability to embed semantic and topic-driven representations within PMF, enhancing recommendation accuracy even in sparse user-item matrices. Unlike deep hybrid models that require high computational overhead, LDS-SRS efficiently integrates contextual knowledge while maintaining a lower computational cost.

In the outlined approach, movie plot vectors are computed a single time using a sophisticated content embedding model, with a computational complexity of $O(UIr + r^3)$, where $r = \min(U, I)$. These vectors are employed to set the item-specific latent factors within the PMF framework and are not subject to recalculation in subsequent iterations. The iterative updates for the latent factors U and I are performed with a complexity of $O(A^2\hat{R} + A^3U + A^3I)$, where $\hat{R}$ corresponds to the recorded ratings within the predicted feedback matrix, which are updated at every epoch. Consequently, the overall computational cost per iteration for the LDS-SRS model is $O(A^2\hat{R} + A^3U + A^3I) + UIr + r^3$, making it substantially more efficient compared to traditional recommender systems.

The proposed method exhibits outstanding efficiency with respect to time complexity. It employs a model for embedding content that integrates item semantics with topic information using LDA2VEC, which facilitates faster convergence of the collaborative filtering (CF) technique and improves overall accuracy. In contrast to neural network-based models that necessitate recalculating the content model in each iteration, this approach eliminates redundant computations, thus enhancing its efficiency.

E. Discussion

The results of this study demonstrate the effectiveness of LDS-SRS in mitigating the impact of data sparsity in recommender systems. By integrating deep semantic and topic-aware embeddings into PMF, our method enhances user-item interactions, leading to better rating predictions. Compared to existing hybrid recommendation approaches, our framework achieves higher accuracy while maintaining computational efficiency. This is particularly relevant for real-world applications where user data is often incomplete or sparse. Additionally, these findings align with prior research in matrix factorization-based recommendation (e.g. [20], [32], [42]), reinforcing the importance of leveraging textual semantics in recommendation tasks. Future work could further improve this approach by incorporating adaptive topic modeling techniques for dynamic recommendation scenarios.

V. Conclusion

This enhanced proposed approach and embedding model are incorporated into PMF to address the typical challenge of sparsity in recommender systems (RS). LDS-SRS predicts user ratings by utilizing item descriptions, with item representations generated through the embedding model that captures both semantic and topic data. These document representations are subsequently integrated into underlying factors of PMF, enhancing the accuracy of rating predictions. Our model was trained and evaluated using datasets from MovieLens and AIV, with movie plots serving as item descriptions. It can be adapted to other domains, such as e-commerce platforms like Amazon, Alibaba, and eBay, where product descriptions or user reviews can be processed using the enhanced LDA2VEC model and integrated into PMF for recommendation generation. It can be extended to other areas, including e-commerce platforms like Amazon, Alibaba, and eBay, where product descriptions or user reviews can be processed using the enhanced LDA2VEC model and integrated into PMF for recommendation generation. The integration of deep semantics and topic information significantly enhances the model's capability to provide more accurate rating predictions.

A Deep Learning Approach for Nepali Image Captioning and Speech Generation

Sagar Sharma, Samikshya Chapagain, Sachin Acharya, Sanjeeb Prasad Panday*
Department of Electronics and Computer Engineering-Pulchowk Campus-Institute of Engineering,
Tribhuvan University, Lalitpur, Nepal

***Abstract*—This article introduces a novel approach for Image-to-Speech generation that aims in converting images into textual captions along with spoken descriptions in Nepali Language using deep learning techniques. By leveraging computer vision and natural language processing, the system analyzes images, extracts features, generates human-readable captions, and produces intelligible speech output. The experimentation utilizes state-of-the-art transformer architecture for image caption generation complemented by ResNet and EfficientNet as feature extractors. BLEU score is used as an evaluation metric for generated captions. The BLEU scores obtained for BLEU-1, BLEU-2, BLEU-3, and BLEU-4 n-grams are 0.4852, 0.2952, 0.181, and 0.113, respectively. Pretrained HifiGaN(vocoder) and Tacotorn2 are used for text to speech synthesis. The proposed approach contributes to the underexplored domain of Nepali-language AI applications, aiming to improve accessibility and technological inclusivity for the Nepali-speaking population.**

***Keywords*—Image captioning; speech generation; image-to-speech generation; deep learning; BLEU score; HiFiGaN; TTS**

I. Introduction

Image caption generation is a crucial task within the realms of Computer Vision and Natural Language Processing, entailing the creation of textual descriptions corresponding to images. This process serves a variety of purposes, from aiding visually impaired individuals to indexing images and facilitating image-based search engines. It is a pivotal aspect of scene understanding in Computer Vision, demanding not only the identification of objects within an image but also their coherent expression in natural language. While traditional object detection and classification tasks exist, caption generation poses a more intricate challenge, necessitating the fusion of Computer Vision techniques for content comprehension and feature extraction with Natural Language Processing methods for sequential description generation.

Recent advancements have demonstrated the effectiveness of transformer-based models over conventional CNN-RNN architectures for image captioning. Research in languages such as Hindi and Bengali has achieved notable success using transformer networks. However, Nepali remains an underexplored language in this domain due to the scarcity of labeled datasets. This study bridges this gap by employing a deep learning-based image-to-speech generation approach, integrating image captioning with speech synthesis to provide a holistic multimodal AI system.

The paper is organized as follows: Section II reviews related works, discussing existing methodologies and their limitations. Section III introduces the proposed approach, detailing model architecture and dataset preparation. Section IV explains the methodology in detail, followed by Section V, which describes the experimental setup. Section VI presents the results, while Section VII provides a discussion. Finally, Section VIII concludes with key insights and future research directions.

*Corresponding authors.

II. Related Works

The field of image captioning has witnessed significant progress through various related works. One notable contribution is the "Show and Tell" [1] model, which introduced a framework for image captioning using a combination of convolutional neural networks (CNNs) and recurrent neural networks (RNNs). This approach first encodes the image using a CNN to extract visual features and then generates a caption using an RNN. It laid the foundation for subsequent advancements in image captioning by demonstrating the feasibility of combining deep-learning models to generate captions for images.

Several studies have delved into image captioning across languages, highlighting the superiority of transformer-based models over conventional CNN-RNN architectures. Mishra et al. (2021)[2] presented a transformer-based encoder-decoder architecture for Hindi image captioning, emphasizing the drawbacks of RNN models. They obtained substantial BLEU scores, marking the efficacy of the transformer in generating accurate captions. Similarly, Ami et al. (2020) [3] explored Bengali image captioning using CNN and transformer networks, demonstrating improved performance compared to earlier models. These studies utilized pre-trained CNN models like ResNet-101, InceptionV3, and Xception, along with various datasets such as BanglaLekha and Flickr8k, showcasing enhanced BLEU and METEOR scores.

Image caption generation in various languages has seen significant progress, particularly in languages like English, Hindi, and Bengali. However, Nepali, due to limited datasets and research focus, remains an understudied language in this domain. Adhikari and Ghimire (2019)[4] introduced Nepali image captioning using encoder-decoder models, but with limited performance owing to the use of traditional CNN-RNN architectures. Addressing this gap, this study by Subedi and Bal (2022) [5] pioneers Nepali image captioning utilizing a CNN-Transformer model, leveraging the strengths of transformer networks and their effectiveness in handling NLP tasks.

Tacotron [6], which combined an encoder-decoder framework with a sequence-to-sequence model to generate high-quality speech. Another influential contribution is WaveNet [7]

which introduced a deep generative model capable of generating high-fidelity audio waveforms. Building upon Tacotron developed Tacotron 2 [6] in 2018, incorporating a WaveNet vocoder to enhance the naturalness and quality of synthesized speech. Deep Voice, a series of models introduced by Arik et al. [8] in 2017, employed deep convolutional and recurrent neural networks for speech synthesis. Transformer TTS [9] proposed in 2019, harnessed the Transformer architecture originally used for machine translation and showcased excellent results in generating natural and expressive speech.

In the landscape of image description, especially in the context of Nepali speech, a noticeable dearth of research exists. While textual image captioning has received some attention in the Nepali language, the adaptation of these methodologies to cater to speech-based image descriptions in Nepali remains largely unexplored. This gap in the literature signifies an opportunity for innovative research and development. In light of this research void, the present project assumes significance by actively addressing the under representation of Nepali speech-based image description.

The absence of sufficient research and publications in the domain of Nepali speech-based image description underscores the critical need for initiatives. By recognizing and addressing this gap in the literature, this study stands as a pivotal endeavor to advance image understanding technologies tailored to Nepali speech, promising to improve accessibility and technological inclusivity for the Nepali-speaking population.

III. Proposed Work

This article emphasizes not only in the image caption generation but extends the model for generating the fluent and natural speech for the generated textual captions in Nepali Language. For understanding the visual content of the images, various state of the art architectures of Convolutional Neural Network are used for the image captioning tasks. Architectures such as VGGNet, EfficientNet, ResNet, InceptionNet have produced remarkable results which extracts various features from the image and thus generates a feature map that captures the important representations of the image.

Further for the caption generation various RNN architectures are used because of its robustness in sequential language tasks. The use of Long Short-Term Memory and Gated Recurrent Units have been overshadowed by the transformer architecture because of the attention mechanism that enables to selectively attend the different parts of the input data, assigning varying degrees of importance to different elements.

The Pretained Text to Speech [10] serves as a crucial element in the model pipeline, providing synthesized speech outputs based on textual inputs. Specifically, Tacotron2, a state-of-the-art Text to Speech (TTS) model is employed, which has been pre-trained on a diverse dataset encompassing a wide range of linguistic features and speech patterns. By integrating a pre-trained TTS system into the framework, the ability to generate high-quality spectrograms from input text is caplitalized, thereby streamlining the process of speech synthesis.

Moreover, the utilization of a pre-trained TTS system offers several advantages, including reduced training time and resource requirements, as well as enhanced synthesis quality owing to the model's extensive training on large-scale datasets. By incorporating Tacotron2 into the research, the image-to-speech generation pipeline is benefited from cutting-edge TTS technology, thereby enabling to achieve superior performance in generating natural and intelligible speech outputs for Nepali language inputs [11] to [16].

IV. Methodology

The methodology involves a combination of image processing, feature extraction, and natural language processing. Image processing and feature extraction includes the utilization of architecture of ResNet and EfficientNet. The extracted features are further used in the transformer architecture for predicting captions in Nepali Language. BLEU score metric has been used as an evaluation metric for n-grams prediction up to 4-grams. Pretrained text to speech model has been utilized to convert the textual captions to Nepali speech.

A. Dataset Preparation

Flickr8k dataset is used in the research which is openly available in the Internet. The dataset consists of real life images specially human and animal activities and each image consisting of four or five English annotated captions. The English captions are further annotated using Google Translation API into Nepali captions.

B. Image Preprocessing

The images are normalized by resizing them into a consistent size and resolution. Augmentation techniques such as rotation, flipping and blurring is used in order to generalize the images for better feature extraction.

C. CNN Feature Extraction

Convolutional Neural Network architecture ResNet and EfficientNet are used for high level visual feature extraction. EfficientNetB7 and ResNet50 architecture is used which is fine-tuned for Flicker8k dataset using pretrained weight from the ImageNet dataset and the particular fine-tuned weights are utilized. The extracted features capture meaningful visual representations.

D. Caption Generation

The captions are tokenized and vectorized as required before training. The transformer architecture chosen so as to utilize its ability of attention mechanism effectively. The model thus learns to associate the visual features with Nepali captions during training. In sharp contrast to the orthodox single layered transformer implementation, this article introduces the utilization of fine tuned nepali embedding layers. Similarly, layered transformer model is also used for caption generation.

E. Evaluation

The performance of the trained model is evaluated using the BLEU (Bilingual Evaluation Understudy) metric. The metric evaluates the predicted caption by comparing it with the reference captions on the basis of the n-grams similarity, where the sequential groups of words such as unigrams (single words), bigrams (two word sequence), trigrams (three word sequence) and so on.

F. Speech Synthesis

The speech synthesis model incorporates Tacotron which is a text-to-speech (TTS) model that generates mel-spectrograms from input text. HiFi-GAN is a high-fidelity generative adversarial network designed for audio waveform generation. Tacotron provides accurate and expressive mel-spectrograms, while HiFi-GAN transforms them into high-fidelity speech waveforms.The combined approach allows for fine-grained control over synthesized speech and produces natural-sounding output.

The overall workflow of the proposed methodology is illustrated in Fig. 1.

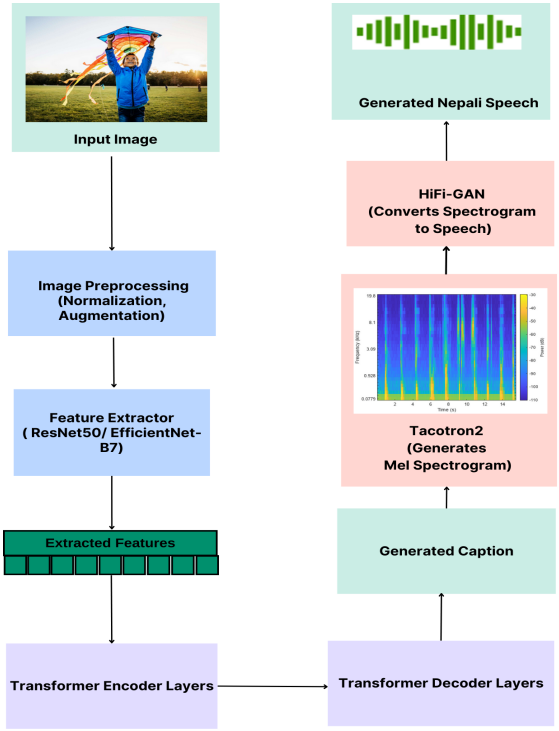

Fig. 1. Proposed methodology workflow.

V. Experimental Setup

A. Datasets

Flickr 8k dataset is utilized for training of image captioning transformer model. The dataset consist of 8k images mostly representing human, dogs and their activities. The data shuffled using random seed 42 produced best accuracy. The original dataset consists of four or five English captions for each image. The Google Language Translation API is used for the corresponding conversion into Nepali captions. Poorly translated captions is removed by manual examinations. The dataset is divided into training and validation set as shown in Table I below:

TABLE I. Split of Dataset

Dataset	Training Split	Validation Split
Flickr8k	6.4k	1.6k

B. Model Architectures

Model uses transformer based encoder decoder architecture for image caption generation. Model utilizes one of the two CNN architectures for feature extraction: ResNet50 and EfficientNetB7. The output of feature extractor is passed to the transformer encoder for further processing differentiating from the previous works which was primarily based on the single layered transformer model with the consideration of decoder part only. The layered transformer and learned embedding models are utilized as two new models for image caption generation. Both layered transformers and learned embedding uses EfficientNetB7 as the feature extractor. EfficientNetB7 uses less computation power and produces similar accuracy. For the complex and computationally expensive models like layered transformer and learned embeddings, EfficientNetB7 was implemented to reduce the overall computation requirements. Fig. 2 illustrates the architecture of single-layered transformer.

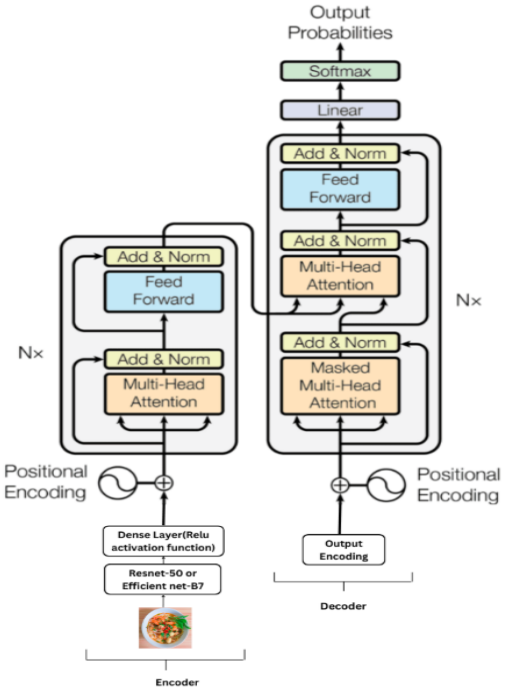

Fig. 2. Single layer transformer architecture.

1) Feature extractor: CNN architectures Resnet50 and EfficientNetB7 are utilized for extracting spatial features from images. Pretrained Imagenet weights are utilized for the extraction of image features. The augmentation techniques such as Random Flip, Random Rotation and Random Zoom are implemented for increasing the diversity of the training images. Classification layer is removed and output of second last layer is utilized as an input for the transformer encoder layer.

2) Transformer encoder: In order to take advantage of attention mechanism in the encoded image, encoder layer of transformer is utilized. The output of the feature extractor is passed to the positional embedding layer. The positional encoded features are normalized using layer normalization.

The output is then passed to the Dense layer with ReLU activation function. The extracted embeddings are passed to the multihead self attention layer. Introduction of dense layer with non linear activation function (ReLU) enables the encoder to learn complex images features and attention layer learns multiple embedding dimensions. The self attention in the encoded image features allows model to attend the important features of the image for generation of distinct captions.

3) Decoder: The transformer decoder layer is utilized for decoding the image caption. It generates caption using one word at each timestep. The previously generated words are passed as an input to the decoder. Vectorizer vectorizes each word. Vectorized word is passed to the positional encoding layer of the transformer. Masking is used to prevent the transformer to attend the future output. Masked output is then passed to the multihead self attention layer which highlights only the important part of input data while diminising the effect of the rest. The attended decoder input and the input from encoder are passed through the attention layer called encoder decoder attention. This layer builds the relationship between extracted features from encoder and the attention output from decoder. This relationship along with residual connection is finally used for predicting the Nepali caption. The whole architecture is trained using backpropagation techniques.

C. Compared Methods

The single layered transformer model with ResNet-50 as feature extractor is compared with pretrained embedding model and layered transformer model.

1) Pretrained embedding model: The pretrained embedding model utilizes the pretrained nepali word2vec text embedding. This pre-trained Word2Vec model had 300-dimensional vectors for more than 0.5 million Nepali words and phrases. About 20% of the embeddings from our dataset was missing in the pretrained embedding. Fine tuning of the word2vec model is performed using window size as 5. The model was trained for 10 epochs and fine tuned embedding were than utilized in the transformer model for image caption generation.

Every word is vectorized using text vectorizer. The vectorized word is mapped to 300 dimension word embedding. The embedding layer is trained along with other parameters of transformer decoder. Word embedding were utilized for finding relation between words in the training caption using already trained embedding from large corpus.

2) Layered transformer model: Single layer transformer is stacked in both encoder and decoder side to obtain multilayered transformer model. Three encoder layers and three decoder layers were stacked to search for intricate relationship between features. The complexity of the model goes on increasing from single layered transformer model. Single layered model is least computationally expensive while layered transformer model require highest computation as compared to other two models.

D. Evaluation Metrices

The performance of the trained model is evaluated using the BLEU (Bilingual Evaluation Understudy) metric.The metric evaluates the predicted caption by comparing it with the reference captions on the basis of the n-grams similarity, where the sequential groups of words such as unigrams (single words), bigrams(two word sequence), trigrams(three word sequence) and so on.

Four BLEU scores (BLEU-1, BLEU-2, BLEU-3, and BLEU4) are typically calculated in the context of image captioning. These scores evaluate merely matching grams of a certain order, such as single words (1-gram) or word pairs (2-gram or bigram), and so forth. BLEU score ranges from 0 to 1 where a score between 0.6 to 0.7 is considered to be the best achievable result but at the same time, a score between 0.3 to 0.4 is considered an understandably good translation and a score greater than 0.4 is considered high-quality translation.

The evaluation of the image-to-caption model's performance also incorporated the utilization of the sentence BLEU score. Unlike corpus BLEU, which uses the word level tokenization, sentence BLEU is modified to find BLEU Score using character-level tokenization to evaluate the quality of each caption independently.This sentence-level evaluation metric offers a more detailed assessment of caption quality. Considering the absence of lemmatizer for the nepali word corpus, the word level tokenization was not able to predict the generalizing ability of the model. For example, dog and dogs can be lemmatized easily for English corpus but due to complicated structure of Nepali corpus, root words could not be extracted properly. Such complication were removed using character level tokenization which does not significantly penalizes the prediction of similar words other than the root word such as dog and dogs in Nepali. Notably, the sentence BLEU method provided metrics that closely aligned with the benchmark evaluations.

E. Text-to-Speech

The implementation of a pretrained Text-to-Speech (TTS) model within the image-to-speech conversion framework was informed by a scholarly paper detailing Nepali Text-to-Speech synthesis using Tacotron2 for melspectrogram generation. The research method delineated in the paper involves preprocessing and tokenization of Nepali text, which is subsequently fed into a Tacotron2 model to generate melspectrograms. This model, initially trained on an established Nepali dataset, is further refined through fine-tuning on a proprietary dataset to enhance performance and adaptability to language-specific nuances. Employing incremental learning techniques ensures continual updates to the model, enabling it to accommodate evolving linguistic contexts effectively. The melspectrograms generated by the Tacotron2 model are then processed using HiFiGAN and WaveGlow vocoders to produce synthesized speech. Post-processing methods are subsequently applied to refine the output and improve its naturalness. Notably, qualitative evaluation of the synthesized speech yielded a commendable Mean Opinion Score for naturalness, signifying the efficacy of the employed approach. By leveraging the insights gleaned from this scholarly work, the integration of the pretrained TTS model into the image-to-speech conversion system has significantly enhanced the quality and naturalness of the synthesized speech output, particularly for the Nepali language.

VI. Results

The Flickr8k dataset consists of 8k images with 4-5 captions for each images. Same dataset was trained on three different models. The dataset was split into training set and validation set. 6.4k dataset are used for training set and remaining 1.6k are used for validation. The validation dataset is used as test set for generating caption and calculation of BLEU scores after the models are successfully trained. The model parameters used in the experiments are summarized in Table II.

TABLE II. Model Parameters

Parameters	Values
Batch Size	32
Embedding Dimension	512
Feed Forward Dimension	2048
Image Size	(224, 224)
Learning Rate	10^{-4}
Loss Function	Sparse Categorical Cross Entropy
Number of Heads	3
Optimizer	Adam
Sequence Length	25
Vocab Size	15,000

The corpus BLEU score is calculated for different model architectures, with the results presented in Table III. Fig. 3 displays the same data in bar chart form for better comparison.

TABLE III. Corpus BLEU Score

Model	Encoder	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Layered Transformer	EfficientNetB7	0.381	0.176	0.0664	0.02145
Learned Embeddings	EfficientNetB7	0.475	0.269	0.124	0.050
Single Layered Transformer	ResNet-50	0.446	0.268	0.184	0.139

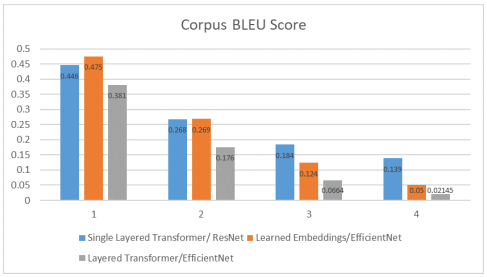

Fig. 3. Corpus BLEU score.

Similarly, the sentence-level BLEU score is calculated, providing a more granular and detailed evaluation of the generated captions. The scores are presented in Table IV, and the bar graph is shown in Fig. 4.

TABLE IV. Sentence BLEU Score

Model	Encoder	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Single Layered Transformer	ResNet-50	0.5223	0.3858	0.3013	0.2462
Learned Embeddings	EfficientNetB7	0.5217	0.3950	0.3171	0.2651
Layered Transformer	EfficientNetB7	0.4960	0.3528	0.2662	0.2125

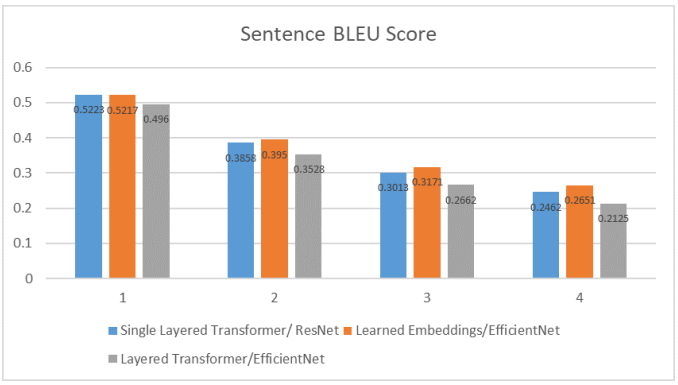

Fig. 4. Sentence BLEU score.

Fig. 5 to 8 present the generated Nepali captions alongside their English equivalents, demonstrating the Single Layered Transformer model's effectiveness in generating captions for different images.

Fig. 5. Equivalent English caption: A guy in a blue shirt is ready to kick a football.

Fig. 6. Equivalent English caption: Two dogs are running on the grass.

Fig. 7. Equivalent English caption: A big bird has landed on the water.

Fig. 8. Equivalent English caption: A dog is running on the field.

VII. Discussion

BLEU scores of layered transformer model is observed to be significantly lower than other models. This is found to be because of the overfitting issue as the increase in layer significantly increased the learnable parameters thus the feature extracted and the size of dataset used were not enough to overcome overfitting issue.

Result obtained by using learnable pretrained embedding layer worked slightly better than other models. The intricate relationship between the words are captured well using embedding layer. This is indicated by improvement in BLEU-2, BLEU-3, BLEU-4 scores. However in case of word level tokenization, BLEU-1 for learned embedding is greatest among all models but the relationship between more than two words could not be generalized well which is marked by low BLEU-3 and BLEU-4 scores.

Single layered transformer model with Resnet-50 as feature extractor is performing at similar accuracy when compared to learned embeddings. Since the complexity of model is low and the dataset is also sparse with only 8k images, training a model like single layered transformer with less learnable parameter performed remarkably well. However, Pretrained embedding could be preferable if abound dataset is available for image captioning.

The results highlight the model's ability to capture diverse scenarios with remarkable detail. In Fig. 5, it not only identifies a person but also recognizes the blue color of the shirt, highlighting its capability to capture intricate visual features. Similarly, in Fig. 6, the model accurately detects two dogs running on the grass, effectively distinguishing multiple objects and their actions. Fig. 7 showcases its ability to recognize both a large bird and the presence of water, indicating its understanding of different elements within a scene. Likewise, in Fig. 8, the model successfully identifies a dog running on a field, emphasizing its proficiency in capturing both subject and activity. These examples indicate the model's effectiveness in generating descriptive and contextually rich captions.

VIII. Conclusion

This study explored a deep learning-based approach for image captioning and speech synthesis in Nepali. Transformer-based architectures were employed for caption generation, while state-of-the-art text-to-speech models were utilized to produce spoken descriptions. Evaluation using BLEU scores demonstrated that a single-layered transformer model with ResNet-50 as the feature extractor performed competitively, while learned embeddings offered slight improvements in capturing linguistic relationships.

One of the primary challenges identified was the limited availability of high-quality Nepali image-caption datasets, which impacted model performance. Additionally, the complex morphological structure of Nepali presented difficulties in tokenization and evaluation, emphasizing the need for more refined linguistic processing techniques. Addressing these challenges in future research could lead to improvements in both caption quality and speech synthesis accuracy.

The findings contribute to the underexplored domain of Nepali-language AI applications, highlighting the potential for advancements in image-to-speech technology for low-resource languages. Future research can focus on dataset expansion, the integration of more advanced language models, and enhancements in text-to-speech synthesis to better capture the nuances of Nepali pronunciation and grammar.

Knowledge Graph Path-Enhanced RAG for Intelligent Residency Q&A

Jian Zhu, Huajun Zhang*, Jianpeng Da, Hanbing Huang, Chongxin Luo, Xu Peng
School of Automation, Wuhan University of Technology, Wuhan 430070, China

***Abstract*—As the demand for efficient information retrieval in specialized domains continues to rise, vertical domain question-answering systems play an increasingly important role in addressing domain-specific knowledge needs. This paper proposes a retrieval-augmented generation method that integrates path search in knowledge graphs to enhance intelligent question-answering systems for professional information retrieval. The proposed approach leverages fine-tuned large language models to identify entities and extract relations from user queries, combining pruned marker method with a shortest path generation tree algorithm to efficiently retrieve relevant information. The retrieval results are then integrated with user queries using prompt engineering to generate precise and contextually relevant answers. To validate the practicality of the proposed method, this paper develops a knowledge graph encompassing policies, regulations, and social services within the household registration vertical domain. The experimental results within this vertical domain reveal that the proposed method significantly outperforms existing methods in terms of evaluation metrics such as BLEU, ROUGE, and METEOR, achieving improvements exceeding 3%. Furthermore, ablation experiments validate the importance of combining path search algorithms with fine-tuning techniques in enhancing the question-answering performance.**

***Keywords*—Retrieval-augmented generation; path search; knowledge graph; household registration policy vertical field**

I. Introduction

With the rapid development of natural language processing (NLP) technology, intelligent question-answering systems have been widely applied in the field of policy interpretation and are gradually becoming important tools for obtaining information in medical, legal, educational, and other professional fields. These systems understand user questions through semantic analysis and information extraction technology, and generate relevant answers from knowledge bases or domain-specific databases [1]. Compared with traditional keyword matching, intelligent question-answering systems can more accurately capture the semantic intent of the user, thereby improving the accuracy of the answers and user experience [2]. However, intelligent question-answering systems still face notable limitations. For instance, although pre-trained language models exhibit strong performance across various tasks, they remain less effective in addressing queries that demand a high level of domain-specific expertise, such as medical diagnoses or legal code interpretation [3]. Additionally, due to the system's dependence on static knowledge bases, it is difficult to update domain knowledge in real-time, which may lead to delays in answers [4].

The research on intelligent question-answering systems typically unfolds along multiple technical routes, which mainly include rule-based question-answering systems, information retrieval-based question-answering systems, and generation model-based question-answering systems. Rule-based question-answering systems rely on pre-defined rules and templates, matching answers through the parsing of keywords and syntactic structures. They perform well in structured, fixed-pattern questions, but they have limitations in addressing diverse needs and complex issues [5]. Information retrieval-based question-answering systems find answers by searching for relevant documents, utilizing keyword matching and semantic retrieval techniques to quickly locate content related to the user's question [6]. Their advantage lies in their ability to handle large document repositories and providing diverse sources of answers. However, they often struggle to meet the needs for questions that require complex reasoning or the generation of new answers. In comparison, generation model-based systems directly apply natural language generation technology to generate answers, performing even better in handling complex issues [7].

In recent years, Retrieval-Augmented Generation (RAG) technology has attracted widespread attention due to its combination of the advantages of information retrieval and generation models. RAG first finds relevant documents through information retrieval and then generates more accurate and semantically rich answers based on these documents citeyang2019xlnet. Compared to traditional generation models, RAG maintains the flexibility and generation capability of the latter while ensuring the contextual relevance of the answers [8]. RAG models combine a retrieval module based on BERT with a GPT generation module, demonstrating outstanding performance in knowledge-intensive tasks [9]. Research shows that RAG not only improves the accuracy of answers but also effectively reduces the lag caused by outdated information by retrieving the latest documents [10]. RAG has shown significant effects in open-domain question-answering tasks, especially in areas such as law and policy where knowledge updates are frequent, ensuring timeliness of answers through real-time retrieval [11]. Additionally, multimodal RAG systems that combine image and text data further expand the application of the technology and enhance its ability to handle complex tasks[12]. RAG models have significant advantages in handling complex policy-related questions, especially in cross-domain and multi-dimensional issues, significantly enhancing the relevance and depth of the answers [13].

In the context of the current complex policy system and the growing demand for public services, how to efficiently acquire and utilize knowledge of the household registration policy has become one of the core issues of concern for policymakers and public service institutions [14] [15] [16]. As an important part of social governance, the household registration policy have a

wide-ranging impact that covers multiple areas such as social security, education, and employment[17]. Although RAG technology has made significant progress in question-answering systems, it still faces some critical challenges. RAG technology has a high dependency on the quality of the retrieval stage; if the retrieval results include irrelevant documents, the generated answers are often not accurate; in multi-hop reasoning tasks, insufficient information is more likely to lead to incomplete answers [18]. Additionally, when handling long texts, RAG technology often suffers from context loss, leading to answers that lack coherence [19]. Furthermore, RAG technology has a high computational cost, and the system response speed is slower when processing large document libraries, making it difficult to meet the needs of real-time applications[20].

The above challenges have prompted the development of a retrieval-enhanced generation method that incorporates knowledge graph path search, which has been applied to the household registration vertical field. This method combines knowledge graph path search technology with entity recognition performed by a fine-tuned large model, mapping user queries to corresponding entities and relationships in the graph and using path algorithms for inference to precisely extract relevant knowledge information. Finally, the large model is used for natural language generation to provide answers that are contextually appropriate. In addition, in the subsequent application phase, this paper will construct a knowledge graph that covers policies, regulations, and social services in the household registration vertical field, and further discuss its specific implementation and application effects in vertical field question-answering systems. The primary contributions of this paper are as follows.

1) Proposal of an MST-based algorithm for knowledge extraction: This paper presents a novel Minimum Spanning Tree (MST) algorithm based on the shortest-path methodology to facilitate efficient knowledge extraction from graphs. When integrated with a large language model for natural language generation, this approach enables the system to deliver accurate, contextually relevant policy responses to user inquiries. This enhancement significantly improves the intelligence and responsiveness of the question-answering system.

2) Fine-tuned model for entity recognition and relationship extraction: For tasks involving entity recognition and relationship extraction within the household registration domain, this study employs fine-tuning techniques on large models, coupled with the knowledge graph, to achieve robust entity recognition and relationship inference. This method effectively processes complex entities and multi-layered relationships within the policy domain, ensuring that user queries are accurately aligned with pertinent knowledge points in the graph.

3) Development of a specialized knowledge graph for household registration: A comprehensive knowledge graph tailored to the household registration domain has been developed, incorporating policy content, legal regulations, and related social services. The graph systematically organizes the interconnections among various policy clauses and entities, providing a structured foundation for addressing complex policy queries. This framework significantly improves the system's accuracy in addressing issues related to household registration.

The rest of this paper is organized as follows. Section II describes the related work of this paper. Section III introduces the retrieval-enhanced generation technique, utilizing knowledge graph path search to improve query handling. Section IV details the construction of a knowledge graph within the civil affairs domain and demonstrates the application of this technique to enhance information retrieval and response generation within civil affairs contexts. As for Section V, we conduct comprehensive experiments and sufficient analysis. Finally, Section VI provides a summary of the entire paper.

II. Related Work

Knowledge graphs can better capture semantic relationships in complex domains by structuring the representation of entities and their relationships, thus providing more accurate retrieval cues and context information for RAG technology [21]. In the field of knowledge graphs, early research focused mainly on how to effectively extract entities and relationships from text data to build a structured knowledge base. For example, methods based on statistical models can automatically identify and associate relevant entities from multiple data sources, laying the foundation for the construction of knowledge graphs [22]. However, these traditional methods often rely on predefined rules and templates, and their ability to handle complex semantic relationships is relatively limited. To overcome this limitation, research on knowledge graph completion techniques based on deep learning has gained widespread attention in recent years. Graph neural networks (GNNs), in particular, have been widely applied due to their superior performance in handling complex entity relationship graph structures [23]. In addition, multi-task learning techniques have also begun to be introduced into the construction of knowledge graphs to handle entity recognition and relation extraction simultaneously. Compared to single-task learning, multi-task learning can better utilize the correlations between different tasks, thereby improving the overall performance of the model. For example, through a multi-task learning framework, joint training of entity recognition and relation classification has been achieved, effectively improving the accuracy and efficiency of knowledge graph construction [24]. However, since knowledge graphs are a semantic network that dynamically updates, how to achieve efficient knowledge updating and completion remains an important research challenge [25]. At the same time, with the rapid development of large-scale pre-trained language models (LLMs), the integration of knowledge graphs with LLMs has become a new research direction. Knowledge graphs can provide structured knowledge support for LLMs, thereby improving accuracy in specific domain question-answering systems [26]. For example, by combining knowledge graphs with LLMs, the model's explainability and personalized recommendation capabilities can be enhanced [27]. However, since LLMs are essentially a "black box" model, the issue of how to utilize its powerful capabilities while maintaining the transparency and explainability of the system remains a pressing problem [28].

The Retrieval-Augmented Generation (RAG) technique, which integrates knowledge graphs with pre-trained language models, significantly improves the accuracy and consistency of generated content by introducing structured knowledge into the generative process. For example, Yasunaga et al. proposed the QA-GNN model, a framework that combines

language models with knowledge graphs to handle complex question-answering tasks. This model leverages path reasoning within the knowledge graph, thereby enhancing the logical consistency of the generated responses [29]. Similarly, Hu et al. developed the OREO-LM model, which connects pre-trained language models with knowledge graph reasoning modules via a knowledge interaction layer, resulting in improved performance on question-answering tasks [30]. In dialogue generation, advancements have been made by incorporating structured knowledge from graphs. Xu et al., for instance, introduced the DMKCM model, which fuses structured knowledge graphs with unstructured textual data to produce dialogue with greater depth and coherence [31]. In a related development, Kang et al. proposed the SURGE framework, which retrieves relevant subgraphs and employs contrastive learning during generation, enhancing the quality and knowledge consistency of the generated dialogues [32].

Significant strides in dialogue generation have been achieved by integrating knowledge graphs with pre-trained language models. Peng et al. introduced the GODEL model, which incorporates external knowledge during pre-training to improve performance across task-oriented dialogue, conversational question-answering, and open-domain dialogue. This model outperforms existing pre-trained dialogue models, particularly in few-shot fine-tuning scenarios [33]. Yang et al. further advanced the field with the Graph Dialog model, which embeds structural knowledge from graphs into an end-to-end task-oriented dialogue system. By utilizing graph convolutional networks (GCNs), Graph Dialog captures structural information from both dialogue history and knowledge bases, thereby generating more precise responses [34].

III. Retrieval-Augmented Generation Based on Knowledge Graph Path Search

The retrieval-enhanced generation method based on knowledge graph path search includes three modules: entity recognition, path search, and answer generation. In the entity recognition module, a large language model is used to analyze the user's question and extract a set of entities similar to the knowledge graph nodes. In the path search module, the identified entities are linked to knowledge graph nodes, and the shortest path is found using a 2-hop coverage query, generating a tree structure that covers all entity nodes. Finally, in the answer generation module, the results of the path search are input into a large language model along with the user's question. Through prompt engineering, the model generates and returns the final responses. The overall workflow diagram of the retrieval-enhanced generation method based on knowledge graph path search is illustrated in Fig. 1.

A. Entity Recognition Module

In this paper, a large language model is employed to conduct an in-depth analysis of user input queries, extracting a set of entities related to nodes within a knowledge graph. This process leverages advanced natural language processing techniques and harnesses the semantic understanding capabilities of the model, enabling accurate identification of essential entities within user queries. These entities, typically exhibiting strong correlations with knowledge graph nodes, form a crucial foundation for subsequent retrieval and reasoning tasks.

The user query Q is initially received as input, upon which the model conducts multi-level semantic parsing and entity mapping to identify a potential set of entities $E = [E_1, E_2, \ldots, E_n]$. This set is derived from relevant nodes within the knowledge graph, guided by the context of the user query and its implicit semantic cues. Through this entity recognition method, the model not only extracts entities directly pertinent to the user query but also captures potential implicit information, enhancing the alignment between the query and the knowledge graph. This process can be represented as follows:

$$E = LLM\,(Q) \tag{1}$$

Prompt Template for Household Registration Information Extractor:

[Prompt]: You are an expert in household registration information extraction, skilled in analyzing provided sentences and extracting specified household registration items. Please note that the output should only include the household registration items mentioned in the text, and they should be numbered sequentially. The input sentence may correspond to multiple household registration items; do not output any extraneous information. The household registration items include: 1) Proof of legal and stable residence. 2) Correction of place of birth.

[Input Text]: I want to register my parents' household registration under my name. What materials are required?

[Output Keywords]: 1) Parental relocation to child's household registration

Through the entity recognition and retrieval stage, the model effectively minimizes the semantic gap between the user's query and the nodes within the knowledge graph, thereby improving the accuracy of subsequent knowledge graph queries and information reasoning. This process deepens the system's comprehension of the user's query and establishes a more precise entity foundation for path search and information integration during the generation stage. Consequently, it enhances both the quality of the system's responses and the overall user experience.

B. Path Search Module

In this paper, a knowledge graph is constructed for a specialized domain, transforming unstructured or semi-structured texts related to domain knowledge into structured information. This information is stored within a graph structure to provide reliable data support for the subsequent question-answering system. The NEO4J graph database is utilized to store multi-relational data, leveraging Cypher queries for data import and graph data retrieval. Cypher, a descriptive graph query language, is recognized for its simplicity and robust functionality. Furthermore, NEO4J offers the neo4j-import tool, which facilitates the rapid import of large-scale data.

Given the large number of nodes and relationships in the constructed household registration policy knowledge graph, directly executing path searches on the graph proves time-consuming, which adversely affects user experience. Additionally, storing the distances and paths between each pair of nodes offline demands excessive memory space. To address this issue,

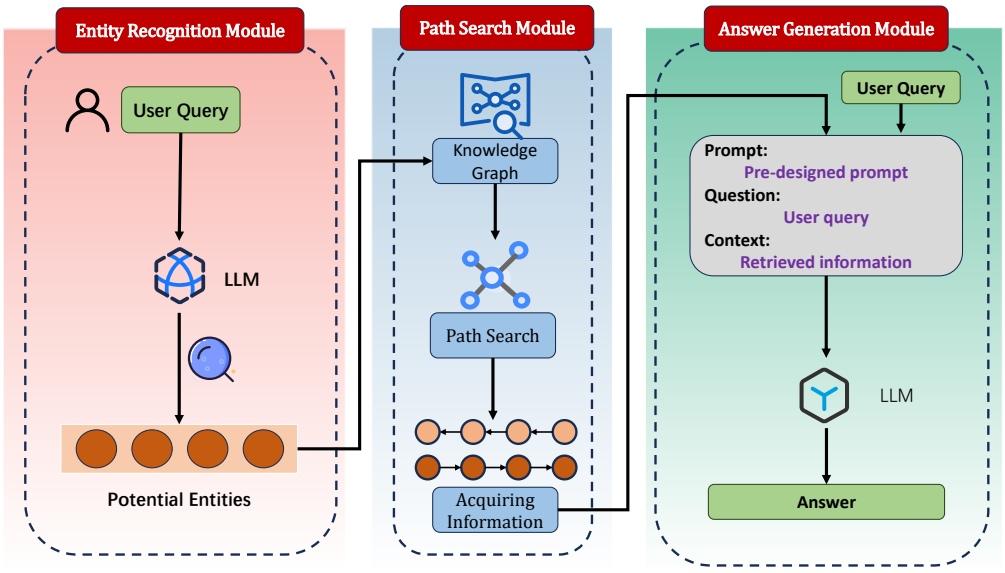

Fig. 1. System workflow diagram.

this paper implements a pruning labeling strategy. During the preprocessing stage, labels are assigned to nodes within the graph, allowing these labels to be utilized at query time to swiftly determine the shortest path between node pairs. Since relationships in the knowledge graph are unweighted, an in-depth analysis was performed on an undirected, unweighted graph. Table I provides explanations of the commonly used symbols in this paper.

1) Definition of shortest distance and shortest path queries: In the knowledge graph, a set of composite labels, denoted as $L(u)$, must be precomputed for each node u. The label set $L(u)$ comprises multiple label pairs, each represented as a triplet (v, d_{uv}, p_{uv}), where v is a node, d_{uv} denotes the shortest distance from node u to node v, and p_{uv} represents the set of all nodes along the shortest path between u and v.The relationships in the knowledge graph are not assigned weights, so the shortest distance between two nodes is represented by the number of nodes in the shortest path between them.

When querying the shortest path between nodes s and t, the shortest distance between s and t is first calculated. To facilitate this, a function $QD(s,t,L)$ is defined, with its specific form as Eq. (2). u represents a common node between s and t. For each common node u, the distance from node s to node t is calculated as $d_{ut} + d_{us}$, with the minimum value among all possible distances considered as the shortest distance.If no common nodes exist between $L(s)$ and$L(t)$, $QD(s,t,L)$ is defined as $+\infty$.

In addition to calculating the shortest distance between nodes s and t,, it is essential to record the path information. To accomplish this, a function $QP(s,t,L)$ is defined to retrieve the shortest path, with its specific definition as Eq. (3). $QP(s,t,L)$returns the path $p_{us} \cup p_{ut}$, representing the shortest path between nodes s and t. This path is constructed by combining the optimal subpaths from node s to the common node u and from u to node t.

For any pair of nodes s and t, the shortest distance between them can be determined by calculating $QD(s,t,L)$, from which the shortest path can then be derived.

2) Generation of composite labels: A composite label generation algorithm based on pruned breadth-first search (BFS) is proposed to optimize the computational efficiency of traditional BFS. Similar to the naive approach, this algorithm performs searches sequentially in the order of vertices $v_1, v_2, \ldots, v_n$. The process begins with an empty index L'_0, and after each pruned BFS iteration from vertex v_k, it updates the index L'_{k-1} to a new index L'_k based on the information gathered. Algorithm 1 outlines the specific steps involved in this composite label generation algorithm.

Algorithm 1 Composite Label Construction Algorithm

$L_k(v) \leftarrow \emptyset$ for all $v \in V$
for $i \leftarrow 1$ **to** n **do**
  $L_i(v) \leftarrow L_{i-1}(v)$ for all $v \in V$
  $distance(v_i) \leftarrow 0$; $distance(v) \leftarrow \infty$ for all $v \in V \setminus \{v_i\}$
  $path(v_i) \leftarrow [v_i]$; $path(v) \leftarrow \emptyset$ for all $v \in V \setminus \{v_i\}$
  $Q \leftarrow$ a queue with only one element v_i
  while Q is not empty **do**
    $u \leftarrow Q$.pull()
    if $d_G(u) < QD(v_i, u, L_{i-1}(v))$ **then**
      $L_i(u) \leftarrow L_{i-1}(v) \cup \{v_i, distance(u), path(u)\}$
      for $w \in$ Neighbors(u) **do**
        $distance(w) \leftarrow distance(u) + 1$
        $path(w) \leftarrow path(u) \cup \{w\}$
        Q.put(w)
      end for
    end if
  end while
end for
return L_n

$$QD(s,t,L) = \min\{d_{ut} + d_{us} | (u, d_{us}, p_{us}) \in L(s), (u, d_{ut}, p_{ut}) \in L(t)\} \quad (2)$$

$$QP(s,t,L) = \operatorname{argmin}\{d_{ut} + d_{us} | (u, d_{us}, p_{us}) \in L(s), (u, d_{ut}, p_{ut}) \in L(t)\} \quad (3)$$

TABLE I. EXPLANATION OF KEY SYMBOLS

Symbol	Description
$G = <V, E>$	Knowledge graph
n	Number of vertices in the knowledge graph
m	Number of edges in the knowledge graph
$N_G(v)$	Neighboring nodes of node v in the knowledge graph
$d_G\ (u, v)$	Shortest distance between nodes u and v in the knowledge graph
$P_G\ (u, v)$	Set of all nodes on the shortest path between nodes u and v in the knowledge graph

The composite label generation algorithm proceeds as follows: Given an input knowledge graph $G =< V, E >$, the algorithm outputs composite labels comprising distance-path pairs for each node in the graph. Initially, the label $L_k(v)$ for each node $v \in V$ is set as an empty set. The algorithm begins at node $v_i$and performs BFS across all nodes. For the starting node v_i, the distance is initialized to 0, and the path path(v_i) is set to $[v_i]$. For all other nodes, distances are initialized to infinity, and their paths are represented as empty sets. The queue Q is initialized to contain only v_i.

During the BFS process, when visiting a vertex u with distance δ and path P, the algorithm checks if the query result $QD\left(v_k, u,\ L'_{k-1}\right) \leq \delta$. If this condition is met, vertex u is pruned, meaning that the label (v_k,δ ,P) is not added to $L'_k(u)$, and traversal of $u\prime s$ adjacent edges is terminated. Conversely, if $QD\left(v_k, u,\ L'_{k-1}\right) > \delta$, the label $L'_k(u)$ is updated to $L'_{k-1}(u) \cup \{(v_k, \delta, P)\}$, and the algorithm proceeds to traverse all adjacent edges of vertex u. For each neighboring vertex w of u, the algorithm updates $w\prime s$ distance and path accordingly and enqueues w into Q.

Fig. 2 presents examples of pruned BFS traversals. Yellow vertices denote the roots, blue vertices denote those which we visited and labeled, green vertices denote those which we visited but pruned, and gray vertices denote those which are already used as roots. The initial pruned BFS, originating from vertex 1, successfully visits all vertices, as shown in Fig. 2a. In the subsequent BFS traversal starting from vertex 2 (Fig. 2b), upon reaching vertex 6, we observe that $QD(2, 6, L'_1) = d_G(2, 1) + d_G(1, 6) = 3 = d_G(2, 6)$, allowing us to prune vertex 6 and avoid traversing any of its outgoing edges. Similarly, vertices 1 and 12 are pruned in this traversal. As additional BFS traversals are performed, the search space progressively diminishes in size, as illustrated in Fig. 2c and Fig. 2d.

The algorithm enhances computational efficiency by employing pruning techniques to minimize redundant traversal, thereby optimizing the process. The final output is the updated label set L_n, which constructs composite labels for each node, embedding both shortest path and corresponding distance information. These composite labels enable rapid determination of the shortest path between any two connected nodes in the graph, eliminating the need for exhaustive graph traversal or complex path-finding operations. This composite labeling mechanism thus provides an efficient approach for querying shortest paths, significantly improving query speed and conserving computational resources.

3) Minimum spanning tree query algorithm based on shortest path.: Given that user queries frequently involve multiple entities, represented as a set of nodes within the graph, the task of identifying the minimum-cost tree that connects these nodes is defined as the minimum spanning tree problem. Algorithm 2 leverages the pre-established composite labels to compute the shortest paths between nodes, thus facilitating the construction of an optimal tree that spans all nodes within the specified set.

Algorithm 2 Minimum Spanning Tree Query Algorithm Based on Shortest Path

```
tree ← ∅
distance(k) ← 0, path_i ← {N_k}
for i ← 1 to k − 1 do
    for j ← i + 1 to k do
        d_G(N_i, N_j) ← QD(N_i, N_j, L_n)
        PG(N_i, N_j) ← QP(N_i, N_j, L_n)
    end for
    distance(i) ← min{d_G(N_i, N_j) | j = 1, 2, ..., k}
    path(i) ← arg min PG(N_i, N_j)   for j = 1, 2, ..., k
end for
Q ← {1, 2, ..., k}
while Q is not empty do
    y ← arg min (distance(m) | m ∈ Q)
    if y ∈ Q then
        tree ← tree ∪ path(y)
        Q.remove(y)
    end if
end while
return tree
```

The minimum spanning tree query algorithm based on shortest path operates as follows: Given input parameters consisting of composite labels L_n and a set of k nodes $N_1, N_2 \ldots N_k$, the algorithm outputs the minimum spanning tree that connects these nodes. Initialization starts by setting the minimum spanning tree, denoted as tree, to an empty set. The initial path distance $distance\,(k)$ for node N_k is set to 0, with the path $path\,(k)$ initialized to N_k. For the remaining nodes $N_1, N_2 \ldots N_{k-1}$, distances are initially set to infinity, and paths are initialized as empty sets.

The algorithm begins with the first node N_1 and performs

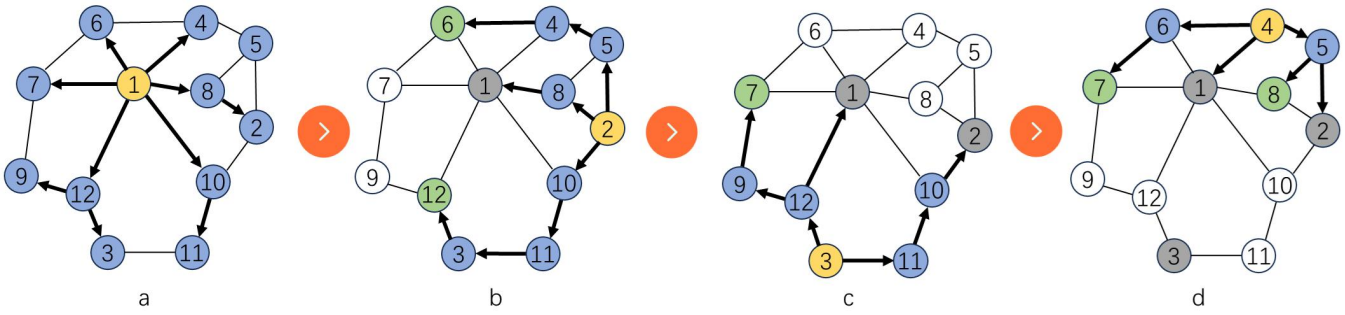

Fig. 2. Examples of pruned BFS traversals.

shortest path queries for each node pair N_i and N_j. Specifically, it calculates the shortest distance $d_G(N_i, N_j)$ and the corresponding path $P_G(N_i, N_j)$ between nodes N_i and N_j using the composite labels L_n. Among all query results, the shortest distance is selected, and the associated shortest path is assigned to $path(i)$. Subsequently, a greedy approach constructs the minimum spanning tree by enqueueing all nodes into Q. In each iteration, the algorithm selects the node y with the smallest path distance from Q, and appends the shortest path $path(y)$ to the minimum spanning tree tree. The node y is then removed from Q, and this process continues until all nodes have been processed.

The algorithm utilizes composite labels to pre-store and compress distance and path information between nodes, enabling rapid retrieval of shortest paths and their corresponding distances through label queries. This approach markedly enhances path computation efficiency by eliminating the need for complex graph traversal each time a shortest path calculation is required. Additionally, the algorithm adopts a greedy strategy to incrementally construct the minimum spanning tree, selecting the next path based on the minimum distance between nodes and adding it to the spanning tree. This greedy selection ensures that each chosen path is optimal at its respective step, thus guaranteeing the overall optimality of the final spanning tree. This method not only simplifies the process of constructing the spanning tree but also maximizes the algorithm's efficiency.

The algorithm guarantees the accuracy of query results while maintaining low time complexity. By minimizing redundant path calculations and optimizing the construction process, it effectively processes large-scale graph data in a short time frame, making it especially suitable for constructing minimum spanning trees in complex networks with numerous nodes and edges. By integrating the efficient query mechanism of composite labels with the benefits of a greedy strategy, the algorithm offers a rapid and precise solution for minimum spanning tree construction.

4) Approximation Ratio Analysis: As the Steiner tree problem is a classic NP-hard problem in graph theory and combinatorial optimization, obtaining an optimal solution for large graphs with extensive terminal node sets demands considerable computational resources and may be infeasible within a reasonable timeframe. To assess and compare the effectiveness of approximation algorithms, the approximation ratio is commonly employed as a metric. This ratio quantifies the discrepancy between the solution produced by an approximation algorithm and the true optimal solution. It is typically defined as Eq. (4).

$$r = \frac{w(T_{appopt})}{w(T_{opt})} \tag{4}$$

In this context, T_{opt} represents the optimal solution to the Steiner tree problem, T_{appopt} denotes the spanning tree obtained using the minimum spanning tree query algorithm based on the shortest path, and $w(T)$ indicates the total weight of tree T.

For a query on the node set $N = \{N_1, N_2 \dots N_K\}$, the algorithm constructs the tree by iteratively adding the shortest paths between nodes. In each iteration, a shortest path is appended to the spanning tree. Suppose that, in each greedy selection, the node $pair(N_i, N_j)$ is chosen, and the shortest path $P_G(N_i, N_j)$ with length $d_G(N_i, N_j)$ is identified between them. Consequently, the weight of the spanning tree generated by the approximation algorithm can be expressed as the sum of all shortest path lengths.

$$w(T_{appopt}) = \sum_{edges} d_G(N_i, N_j) \tag{5}$$

The optimal Steiner tree T_{opt} is the spanning tree with the minimum total weight that connects the specified node set N. This tree may incorporate non-terminal nodes to reduce the connection costs between terminal nodes, and therefore, its total weight $w(T_{opt})$ represents the minimum achievable weight for a spanning tree in the graph.

$$w(T_{opt}) = \min_{tree T \supseteq N} w(T) \tag{6}$$

The upper bound of the approximation ratio for the classical greedy approximation algorithm for the Steiner tree problem is $2\left(1 - \frac{1}{k}\right)$. When k is small, the shortest paths between terminal node pairs closely align with the optimal solution, causing the approximation ratio to approach 1. However, as the number of terminal nodes k and the number of paths between terminal nodes increase, the algorithm increasingly overlooks

the introduction of Steiner points, leading to a gradual rise in the approximation ratio. Nonetheless, the upper bound remains capped at 2, as Eq. (7).

$$r = \frac{w\left(T_{appopt}\right)}{w\left(\ T_{opt}\right)} \leq 2 \tag{7}$$

The above analysis of the approximation ratio suggests that for smaller node sets, the approximation algorithm can closely approach the optimal solution, offering reliable performance guarantees. Consequently, the algorithm demonstrates a degree of effectiveness in addressing large-scale Steiner tree problems.

5) Acquiring graph information via the minimum spanning tree: In this paper, acquiring neighborhood information from the minimum spanning tree aims to establish foundational data support for an advanced question-answering system, thereby enhancing the system's capacity to address complex queries. Specifically, a first-order neighborhood query is performed for each node in the minimum spanning tree, retrieving all directly connected neighboring nodes and their respective relationships to construct each node's local subgraph. Through this approach, the minimum spanning tree provides a streamlined representation of the graph, maintaining essential shortest connections between nodes while eliminating redundant information. By systematically extracting neighborhood information for each node within the minimum spanning tree, the algorithm comprehensively captures the graph's local structural characteristics. This approach ensures the acquisition of complete local information for each node, supplying the necessary contextual and semantic relationship data to support the question-answering system.

C. Answer Generation Module

Given that path algorithms often yield highly redundant information, directly presenting this data to the user can result in information overload and unstructured content, diminishing the overall user experience. To mitigate this issue, we incorporate prompt engineering using a large language model. By designing tailored prompts, we integrate the user's query with relevant information retrieved from external knowledge bases, thereby generating responses that are more targeted, accurate, and contextually relevant.

We have developed a method to convert triples from a knowledge graph (i.e. "entity-relation-entity") into a textual format that is suitable for input into large language models. For each triple, we generate a complete sentence by incorporating connecting words such as "of" and "is". For example, the triple (A, relation, B) is transformed into the sentence "The relation of A is B". This conversion technique not only preserves the structured information from the graph but also facilitates its seamless integration into the LLM input, thereby guiding the model to generate more accurate and coherent responses.

Specifically, the large language model leverages prompt engineering alongside its robust pre-trained generation capabilities to guide the response generation process. Initially, we combine the user's input query Q with a set of relevant retrieved information $[I_1, I_1, \ldots, I_n]$ to construct a prompt, denoted as $Prompt(Q, [I_1, I_1, \ldots, I_n]$. This prompt is then input into the generative model (LLM), which, utilizing both the prompt and the external information, produces a contextually appropriate and precise answer Answer. This process can be represented as Eq. (8).The specific prompts are as follows:

Prompt Template for Response Generator:

[Prompt]: You are a text summarization expert. Please provide answers based solely on the content of the text and conversation records, without fabrication. Pay attention to the distinctions between "approval department", "acceptance department", and "review department", and avoid unnecessary information.

[Question]: What is the application method for replacing (or reissuing) a resident household register?

[Text information]: The acceptance department for replacing (or reissuing) a resident household register is the local police station. The application methods and processing timelines for replacing (or reissuing) a resident household register are: in-person at the service window (1 working day) or online (3 working days). The application conditions for replacing (or reissuing) a resident household register are as follows: if the "Resident Household Register" is damaged or lost and needs to be replaced or reissued, the head of the household can apply for a reissued register for the entire household, while household members can apply for a register that includes only the cover page and their own page.

$$Answer = LLM\left(Prompt\left(Q, [I_1, I_2, \ldots, I_n]\right)\right) \tag{8}$$

Through effective prompt design, the large language model is guided to integrate internal knowledge with external information sources. By leveraging the model's inherent language generation capabilities alongside external knowledge bases, the generated content aligns more closely with the context of the user's query while filtering out redundant information and retaining essential content. This approach ensures both contextual coherence and factual accuracy in the responses, thereby enhancing the user experience.

IV. Construction of the Knowledge Graph in the Household Registration Vertical Domain

This paper presents the construction of a knowledge graph specific to the household registration domain. It transforms unstructured or semi-structured texts, such as policies and regulations related to household registration, into structured information stored in a graph format. This structured representation offers reliable data support for the subsequent question-answering system.

The construction process of the household registration policy knowledge graph encompasses several key steps, including knowledge acquisition, knowledge integration, and knowledge import. The knowledge acquisition phase is primarily based on the Wuhan Household Registration Business Processing Guide(hereafter referred to as Guide) and a question-answer corpus. Through text data preprocessing and information extraction, event triplets reflecting household registration business conditions, procedures, and required materials are generated. In the knowledge integration phase, synonym resolution

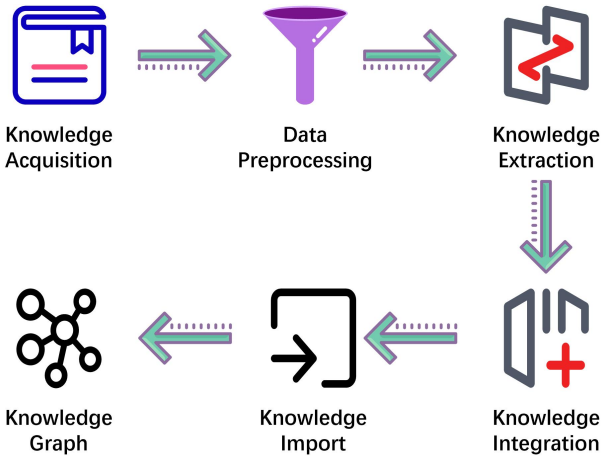

Fig. 3. Flowchart of knowledge graph.

and duplicate entity handling are conducted to ensure data accuracy and consistency. Finally, during the knowledge import phase, the NEO4J graph database is employed to efficiently import the triplet data using Cypher queries and the neo4j-import tool, successfully constructing the knowledge graph that underpins the household registration policy question-answering system. The construction process of the household registration policy knowledge graph is illustrated in Fig. 3.

A. Knowledge Acquisition and Information Extraction

Due to significant regional differences in household registration policies across China, the requirements for handling the same household registration matter can vary considerably from city to city. Therefore, the knowledge sources for the question-answering system must strictly adhere to local household registration policies, and the knowledge graph for the household registration domain must be closed and independent. This paper utilizes the household registration policies of Wuhan, Hubei Province, as the data source to construct the knowledge graph for the household registration domain. The text data primarily derives from the Guide, published by the Wuhan Public Security Bureau, along with a question-answer corpus compiled by household registration center staff. The Guide adopts a semi-structured data format and provides detailed information on 127 household registration services, categorized into six major types and 28 subtypes, covering the conditions for processing these services in Wuhan. It also summarizes numerous domain-specific terms related to household registration and concisely explains how to handle various household registration matters across different scenarios. The question-answer corpus consists of 1,603 question-answer pairs, with all questions being real queries collected manually, closely corresponding to the household registration services described in the Guide.

Based on the textual characteristics of the aforementioned knowledge sources, this paper preprocesses the text data with a focus on household registration events. Specific content for each household registration matter is extracted from the semi-structured tables, resulting in the formation of event triplets. Subsequently, the question-answer texts in the corpus are aligned with the household registration event content, facilitating the construction of entity relationships within the household registration domain. These relationships primarily include item names, application conditions, required materials, processing procedures, application methods, and processing time limits. The specific steps for information extraction are outlined below, with an extraction example illustrated in Fig. 4.

- Given that the Guide is presented in a semi-structured table format, the subject labels and headers of the table can be directly extracted as relationships and attributes. The household registration service item names are identified as head entities, while specific content such as processing locations, procedures, required materials, requirements, application methods, and time limits are extracted as tail entities. Together, these elements constitute the basic event triplets for household registration services.
- To provide supplementary explanations for household registration events under different contextual conditions, the household registration service item names are utilized as head entities, with the supplementary explanations serving as tail entities, thus forming contextual condition triplets for household registration events.
- The questions from the question-answer corpus are manually annotated and mapped to the entities established in steps (1) and (2), resulting in the formation of question triplets for household registration events.

B. Knowledge Integration and Knowledge Import

Merging the data from the two knowledge sources generates a substantial dataset for the knowledge graph; however, numerous duplicate and synonymous entities exist within the two databases. Directly importing these entities would result in redundancy within the knowledge graph. To ensure the accuracy of the question-answering system, this paper integrates the knowledge graphs from both sources by calculating the similarity of entity names. Following this knowledge integration, a total of 1,566 entities across 15 categories and 1,662 relationships across 16 categories were extracted from the documents. The various household registration service contents from the Guide were then imported into the NEO4J database using Cypher queries and the neo4j-import tool.

V. Construction of the Knowledge Graph in the Household Registration Vertical Domain

A. Entity Recognition Experiment

Large language models are trained on extensive text corpora, typically comprising billions of parameters. However, directly applying a large language model to entity recognition tasks often results in suboptimal performance, and conventional fine-tuning methods may induce catastrophic forgetting. The LoRA (Low-Rank Adaptation) efficient fine-tuning technique addresses this issue by employing low-rank decomposition to reduce the number of parameters during training. This

Multi-node Questions	611

approach necessitates learning only small parameter matrices, which approximate the updates to the model's weight matrix.

To comprehensively evaluate the interaction capability between the large language model and the knowledge graph, we designed three types of questions. Template-based questions were generated using fixed question templates specifically tailored to consultation items, as outlined in Table II. The question-answer pairs were extracted from the question-answer corpus, while multi-node questions, which involved multiple consultation items, were manually generated. The dataset statistics are presented in Table III. A total of 2,578 question data points were collected, and the dataset was randomly divided into training, validation, and test sets in an 8:1:1 ratio.

In this paper, the $LoRA$ technique was employed to fine-tune the general large model $Llama3-8B$. $LoRA$ enhances fine-tuning efficiency by introducing trainable low-rank matrices atop the model's original weights while preserving overall performance. Tailored to the specific requirements of the household registration domain, the model underwent careful tuning using a specialized fine-tuning dataset to improve its adaptation to entity recognition and relation extraction tasks. During the fine-tuning process, the model progressively learned the specialized terminology and intricate entity relationships present in household registration services, resulting in a significant increase in accuracy within this domain. Ultimately, this fine-tuning process elevated the entity recognition accuracy from its initial level to 96.1%, demonstrating the effectiveness and high adaptability of the $LoRA$ technique when combined with a custom-built dataset.

B. Parameter Settings

In this paper, $Llama3-8B-Chinese$ model was chosen as the core model for answer generation. $Llama3-8B-Chinese$ is a deep learning-based language model renowned for its robust language understanding and generation capabilities, enabling it to handle long text inputs and produce high-quality text outputs. To ensure the accuracy and reproducibility of the experimental results, the parameters of the generation model were meticulously configured and adjusted. The specific parameter settings for the generation model experiments are presented in Table IV.

Retrieval-augmented generation technology based on knowledge graph path search effectively addresses the complex and varied query demands within household registration

services. Fig. 5 illustrates an example of the household registration intelligent question-answering system.

C. Evaluation Metrics

1) $BLEU$ Evaluation metric: $BLEU$ (Bilingual Evaluation Understudy) is an automatic evaluation method based on N-gram matching, employed to assess the similarity between generated answers and reference answers. By taking into account the matching precision of different N-grams along with a length penalty factor, BLEU produces a score ranging from 0 to 1. Scores closer to 1 indicate a higher similarity between the generated text and the reference text, reflecting better evaluation results. The formula for calculating $BLEU$ is as Eq. (9).

$$BLEU = BP \times \exp\left(\sum_{n-1}^{N} w_n log P_n\right) \tag{9}$$

p_n represents the precision of the $N-gram$ match between the generated text and the reference text, while w_n denotes the weight assigned to the N-gram. The term BP refers to the brevity penalty, which is applied to prevent the generated text from being excessively short. The formula is as Eq. (10). c is the length of the generated text, and r is the length of the reference text.

$$BP = \begin{cases} 1, & \text{if } c > r \\ e^{\left(1-\frac{r}{c}\right)}, & \text{if } c \leq r \end{cases} \tag{10}$$

2) $ROUGE$ Evaluation metrics: The core of the $ROUGE$ evaluation metric lies in calculating the recall and precision of the generated text by matching N-grams between the generated answer and the reference answer, resulting in a final score. Specifically, $ROUGE$ assesses the quality of the generated text by evaluating the number of matching N-grams between the generated text and the reference text. This metric is widely applicable across various natural language processing tasks, including summarization and machine translation, where the effectiveness of the generated text often depends on its ability to capture key information from the reference text. $ROUGE$ offers a comprehensive performance analysis through multi-dimensional evaluation and demonstrates exceptional effectiveness in large-scale text processing scenarios.

3) $METEOR$ Evaluation metrics: The $METEOR$ evaluation metric was developed to address the limitations of $BLEU$ in accounting for sentence syntax and word order. It combines word-level and phrase-level alignment methods while incorporating strategies such as stemming and synonym replacement, thereby enhancing its accuracy in evaluating the semantic similarity between generated text and reference text. $METEOR$ offers a more nuanced assessment of translation quality by considering factors such as lexical precision, stemming, synonyms, and word order. The metric initially calculates precision and recall, subsequently balancing these two metrics through an F-score. Furthermore, $METEOR$ introduces a word order penalty to more accurately reflect the significance of word sequence in translation.

4) $Perplexity$ Evaluation metrics: $Perplexity$ is a crucial evaluation metric for measuring the predictive capability of a language model, assessing how effectively the model adapts to a given text sequence. A lower perplexity value indicates a stronger ability of the model to predict new text, signifying that the generated output aligns more closely with the probability distribution of the language model, resulting in more fluent sentences. Conversely, a higher perplexity value suggests a weaker predictive ability, which can lead to lower quality and consistency in the generated text. For a high-quality language model, the perplexity value should be minimized to ensure that the generated text meets the expected semantics and adheres to appropriate language structure. The formula for calculating perplexity is as Eq. (11). $P\left(w_i|w_{i-1}\right)$ represents the model's predicted probability of the current word w_i given the previous word w_{i-1}, and N is the total length of the text.

$$Perplexity = \exp\left(-\frac{1}{N}\sum_{i=1}^{N} logP\left(w_i|w_{i-1}\right)\right) \tag{11}$$

D. Experimental Subjects

In this paper, we conducted experimental comparisons of the proposed household registration policy intelligent question-answering system with three baseline methods: $LLM-only$, $RAG-Embedding$, and $RAG-Graph$.

1) $LLM-only$: This method relies exclusively on the internal knowledge of the large language model (LLM) for reasoning, without incorporating any external knowledge. Techniques such as Chain of Thought (COT) enhance the model's capacity for complex reasoning by generating a series of intermediate reasoning steps [35]. COT facilitates the model's ability to decompose multi-step problems, thereby improving reasoning accuracy.

2) $RAG-Embedding$: This method is based on RAG technology, retrieving relevant information from external knowledge bases using embedding vectors and combining it with LLM to generate answers. Embedding vectors effectively capture semantic similarity in text, improving retrieval accuracy and making the generated answers more relevant and precise. $LangchangChatChat$ retrieves relevant information from external knowledge bases using embedding vectors, combines it with LLM to generate answers, and integrates this information to enhance the quality and consistency of responses.

3) $RAG-Graph$: This method combines RAG technology with knowledge graphs to leverage the structured knowledge in knowledge graphs to enhance the contextual understanding and answer accuracy of the generative model, thereby improving the quality and relevance of the generated content. Graph RAG applies community detection algorithms to partition the knowledge graph into multiple sub-communities, generates local summaries for each community, and integrates these summaries to form a global answer [36].

VI. Experimental Results

A. Comparative Experiment

Table V presents the comparative experimental results across various models, underscoring the superior perfor-

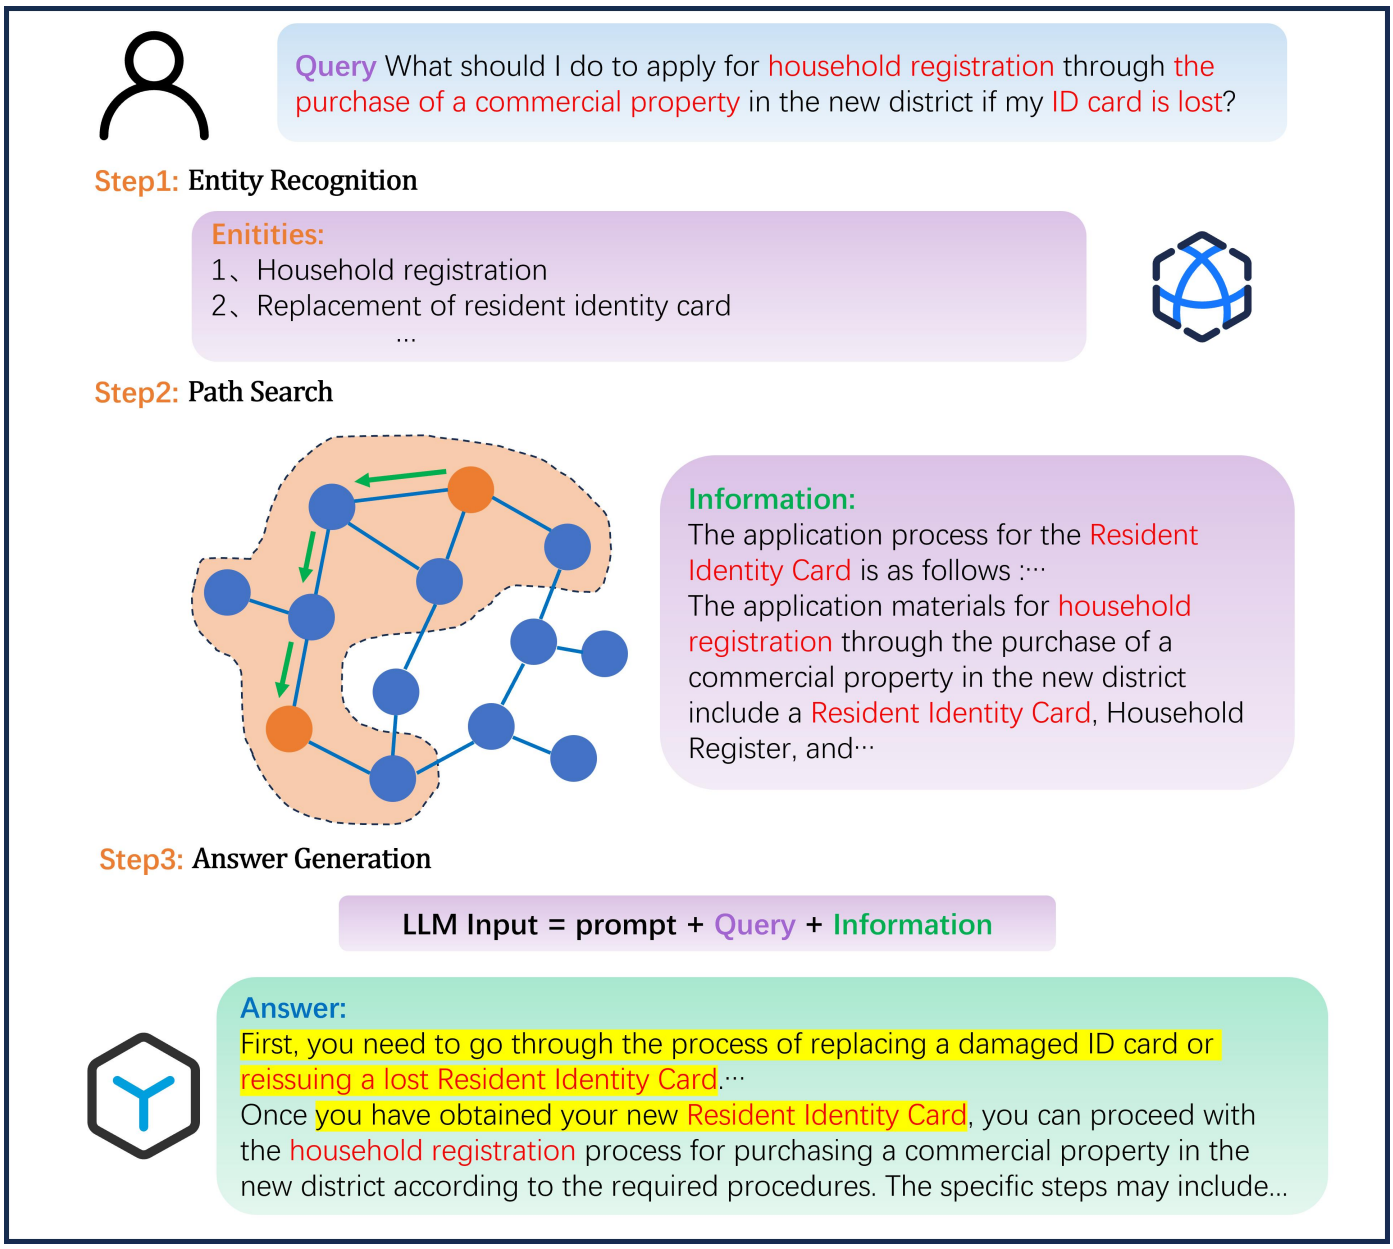

Fig. 5. Example of the household registration question-answering system.

mance of the proposed household registration policy intelligent question-answering system. The results indicate that our model ($Ours$) significantly outperforms other models across all evaluation metrics. Specifically, $ours$ achieved $BLEU$, $ROUGE-1$, $ROUGE-L$, and $METEOR$ scores of 48.19%, 58.14%, 52.39%, and 55.48%, respectively, outperforming both the COT model and the $Graph-RAG$ model. These metrics highlight the model's effectiveness in generating content with enhanced fluency, comprehensive information coverage, and improved semantic relevance. Furthermore, $ours$ recorded a Perplexity score of 42.48, lower than that of other models, reflecting greater coherence and reduced language model ambiguity. Collectively, these findings underscore the exceptional performance of the proposed model in intelligent question-answering tasks.

B. Ablation Study

To investigate the impact of model fine-tuning and the path algorithm on the experimental results, ablation studies were conducted on the dataset. To ensure the objectivity and accuracy of the experiments, we designed the following sets of control experiments:

1) $KG(Baseline)$: This experiment directly uses the pre-trained model without fine-tuning for entity extraction and performs entity linking on the knowledge graph. It extracts relevant information using first-order neighborhood queries and generates answers. The purpose of this experiment is

TABLE V. EXPERIMENTAL COMPARISON RESULTS

Model	$BLEU \uparrow$	$ROUGE-1 \uparrow$	$ROUGE-L \uparrow$	$METEOR \uparrow$	$Perplexity \downarrow$
COT	22.59%	33.03%	25.03%	27.78%	53.79
$GraphRAG$	15.15%	21.47%	11.56%	26.32%	65.56
$Langchain$	41.65%	52.97%	47.41%	49.98%	43.38
$Ours$	48.19%	58.14%	52.39%	55.48%	42.48

to evaluate the performance of the base pre-trained model, serving as a baseline for subsequent experiments.

2) $KG+PathAlgorithm$*:* While keeping the basic model parameters unchanged, the path algorithm is applied to process the data to quantify its contribution to the experimental results.

3) $KG+Fine-tuning$*:* In this experiment, the pre-trained model is fine-tuned without applying the path algorithm. The aim of this experiment is to independently assess the effect of fine-tuning on improving the model's performance.

4) $KG + Fine-tuning + PathAlgorithm(ours)$*:* This experiment combines both model fine-tuning and the path algorithm to explore whether their combined effect can significantly enhance the overall model performance.

Through this experimental design, we aim to comprehensively analyze the individual and combined contributions of fine-tuning and the path algorithm to the model's performance. The results of these experiments are presented in Table VI.

The experimental results show significant differences in performance across different model combinations on various evaluation metrics. The Ours system achieved the best results on metrics such as BLEU, ROUGE, and METEOR. The BLEU score of this system reached 48.19%, significantly higher than other combinations, indicating that the optimized model performs better in terms of similarity between the generated text and the reference text. The ROUGE-1 scores was 58.14%, respectively, further demonstrating the model's superiority in precise matching and coverage at both the word and phrase levels. The METEOR score, at 55.48%, also indicates stronger semantic consistency in the generated content. Although the Perplexity score for the Ours system was slightly higher than that of the KG+Fine-tuning system, the overall score still suggests that the model fine-tuned with the path algorithm exhibits high-quality text generation. Therefore, these results demonstrate that the integration of the path algorithm and fine-tuning significantly improves the model's accuracy, consistency, and coverage in language generation.

VII. DISCUSSION

This research proposes a Retrieval-Augmented Generation (RAG) method based on knowledge graph path search and successfully applies it to an intelligent question-answering system in the field of household registration policy. Experimental results demonstrate that the integration of path search algorithms with model fine-tuning significantly enhances the system's efficiency and accuracy in multi-node query processing, entity recognition, and information extraction. However, the research process also reveals several issues that require further exploration.

Firstly, although knowledge graph-based path search significantly improves retrieval effectiveness, the efficiency of path search still faces bottlenecks as the scale of the knowledge graph continues to expand. Particularly with the rapid increase in the number of nodes and relationships, path computation and multi-node queries still consume substantial time and computational resources. Although this study employs pruning strategies to reduce the search space, further optimization of path search algorithms, especially in real-time query scenarios, remains an important direction for future research.

Secondly, while fine-tuning methods (such as the LoRA method) have effectively improved the accuracy of entity recognition, the model may still encounter misidentification and erroneous inferences when dealing with complex and hierarchical domain knowledge. Although fine-tuning methods have significantly enhanced the model's performance in the field of household registration policy, balancing the model's specificity and generalization capabilities to avoid losing its ability to handle problems in other domains while overfitting to domain-specific terminology remains a significant challenge for future research.

Lastly, the knowledge graph construction in this study is based on household registration policy data from Wuhan City. While this domain-specific data source provides efficient service support for the system, the construction and updating mechanisms of the knowledge graph still face considerable challenges in cross-regional or broader application scenarios. Efficiently integrating policy data from different regions into a unified knowledge graph and ensuring its timeliness and accuracy will be crucial for enhancing the system's generalization capabilities.

VIII. FUTURE WORK

In future research, we aim to further optimize and expand the outcomes of this study in the following key areas:

1) Automatic update mechanism for domain knowledge: The knowledge graph developed in this study is based on household registration policy data from Wuhan City. However, policies and regulations are subject to continuous changes in real-world scenarios. To ensure the intelligent question-answering system can provide up-to-date policy information in a timely manner, future research will focus on the development of an automatic update mechanism for the knowledge graph. Specifically, we will explore the integration of real-time data crawling techniques with knowledge graph update strategies, enabling the system to rapidly adapt to policy changes and thereby enhancing its real-time performance and accuracy.

2) Integration and fusion of multi-domain knowledge graphs: While this study primarily addresses household registration policy, real-world applications often require knowledge from multiple domains. Future research will focus on

the construction and integration of multi-domain knowledge graphs. For example, household registration policy intersects with domains such as social security, taxation, and education. Efficiently fusing knowledge from these diverse domains and enabling cross-domain reasoning within the intelligent question-answering system will be a critical direction for further investigation.

3) User interaction and optimization of personalized question-answering systems: The current research predominantly addresses standardized question-answering tasks. However, user needs in practical applications are often complex and varied. Future research will explore the development of personalized question-answering systems by incorporating users' historical queries and preferences. By analyzing user behavioral patterns and interests, and leveraging recommendation system technologies, we aim to enhance the system's intelligence and enable it to deliver more personalized responses tailored to users' specific needs.

4) Cross-language and cross-cultural expansion: Although this study focuses on Chinese household registration policy, future work will extend this methodology to multilingual and cross-cultural contexts. With the increasing trend of globalization, developing a question-answering system that can operate effectively across different languages and cultures is of significant practical importance. Future efforts will concentrate on designing knowledge graphs and generation models that are adaptable to multilingual environments, ensuring consistency and accuracy across various languages, and facilitating the system's broader application on a global scale.

IX. SUMMARY

This paper presents a retrieval-enhanced generation approach that leverages knowledge graph path search, specifically applied to the household registration domain. Comprehensive experiments validate the effectiveness of this method. By constructing a knowledge graph tailored to this vertical field and employing a pruning marker technique alongside the shortest path generation tree algorithm, the method ensures efficient path querying. Additionally, fine-tuning a large language model enhances the accuracy of entity recognition and information extraction. The knowledge graph developed for the household registration field encompasses policies, regulations, and social services, creating a robust resource for relevant information retrieval. Experimental results, using the household registration field as a case study, reveal that the proposed method significantly outperforms traditional approaches across BLEU, ROUGE, and METEOR metrics, achieving substantial reductions in perplexity. This improvement demonstrates the model's coherence and accuracy in text generation. The specific conclusions are as follows.

1) The knowledge graph developed in this paper encompasses entities and relationships pertinent to household registration policies. By integrating fine-tuning strategies for large language models, the system effectively provides accurate answers to complex, multi-node queries. Experimental results demonstrate that the combination of pruned marking and shortest path generation tree algorithms substantially enhances the efficiency of multi-node path queries, ensuring the system's high performance and accuracy in handling complex questions.
2) Ablation experiments confirm the performance improvements attributed to model fine-tuning and the path algorithms. Specifically, in knowledge graph path searches and information retrieval tasks, the path algorithm ensures information relevance and precision, while model fine-tuning further enhances the accuracy of answer generation.
3) Effective prompt engineering played a critical role in answer generation, enabling the system to filter out extraneous information by combining retrieved knowledge with user queries, thus producing answers that are both contextually relevant and targeted. The reduction in perplexity corroborates the system's improved ability to generate high-quality responses, enhancing overall system performance and user experience.

This paper presents an efficient and precise solution for question-answering in complex vertical domains, highlighting the substantial potential of combining large language models with knowledge graphs. The findings offer valuable technical insights for advancing question-answering systems in specialized fields.

Leveraging Machine-Aided Learning in College English Education: Computational Approaches for Enhancing Student Outcomes and Pedagogical Efficiency

Danxia Zhu
Huanghe Science and Technology College, Zhengzhou, Henan, 450061, China

***Abstract*—The integration of machine-aided learning into college English education offers transformative potential for enhancing teaching and learning outcomes. This paper investigates the application of computational models, including machine learning algorithms and natural language processing tools, to optimize pedagogical practices and improve student performance. A series of experiments were conducted to evaluate the effectiveness of machine-aided learning in various aspects of English language education. The study focuses on six key parameters: 1) student test scores, 2) learning engagement, 3) learning time efficiency, 4) language proficiency, 5) student retention, and 6) teacher workload. The results demonstrate significant improvements across these parameters: a 25% increase in student test scores, a 30% improvement in overall learning engagement, a 20% reduction in learning time for complex language tasks, a 15% enhancement in language proficiency, a 10% increase in student retention, and a 5% reduction in teacher workload. These findings underscore the potential of machine-aided learning to reshape college English education by promoting personalized, data-driven learning environments. This paper provides valuable insights for educators, researchers, and policymakers aiming to harness the power of computational methods in educational settings.**

***Keywords*—Machine learning; natural language processing; computational intelligence; data analytics; pedagogy**

I. Introduction

Education technology now penetrates most classrooms rapidly and has revolutionized the teaching and learning environment fundamentally [1]. Specifically, the use of machine-aided learning (MAL) has recently attracted much interest, especially within languages as a foreign language (L2) learning context where computational technologies such as machine learning (ML) and natural language processing (NLP) provide potential solutions to enhancing learning performance [2]. The college-level English education that heavily depends on traditional methods of education now reaches the technological shift [3]. New approaches in educational technology have shown that machine-aided learning can bring profound change to the educational system; however, its use in HE, especially in the context of English as an additional language, has not yet been extensively researched [4]. Compared to existing research on technology-supported general language learning, there are few that examine concrete details of college English learning empowered by methods in machine learning and NLP [5]. This paper aims to address that gap by assessing the performance of computational interventions in various educational domains and illustrating how they can redesign learning practices in a college context.

Through a series of experiments, we examine the influence of machine-aided learning on six key parameters: 1) student test scores, 2) learning engagement, 3) learning time efficiency, 4) language proficiency, 5) student retention, and 6) teacher workload. We observe increases in these dimensions, proving the effectiveness of MAL systems in our work setting. The purpose of this introduction is to consider the contextual framework for the research, indicate the gaps that are not filled by previous work, discuss the difficulties that arise in the course of this research, and indicate the novel contributions of this research to the existing body of knowledge [6].

After viewing an extensive literature on technology integration in education, a research niche remains open in the use of machine-aided learning in college English language education [7]. Prior research is mainly based on K-12 or broader language learning contexts, which again is quite different from a college learning environment in terms of purposes and learners as well as practices. Hence, the literature on the application of ML and NLP in educational settings often neglects college education or does not consider the special features of college English education, including students' diverse learning profiles, high language demands, and tensions between theory and practice [8]. Additionally, there are so many studies that concern the application of machine learning in language education; however, these studies were implemented in specific actions individually with no comprehensive perspective, such as speech recognition or grammar check [9]. More research has not been conducted to develop an even more systematic approach that incorporates multiple machine learning models and NLP instruments to build the system that fosters and individualized learning [10]. However, the research void is not restricted to the domains of application but also encompasses the modality of how such computational supports can be systematically adopted to improve all facets of student learning and instructor efficiency at once [11].

Several research studies have explored the use of technology in language education and research, but these studies still have various shortcomings. A common problem is that only non-adaptive, non-flexible education systems are used as the foundation for student development at universities. Entire generations of language technologies applied to language education, from learning management systems (LMS) or auto-

mated grading tools, disseminate pre-programmed material that does not respond to the learners' development, progression, or acquisition pace. This rigidity hampers the capability of these systems to produce long-term learning outcomes and, therefore, does not support skill development.

Furthermore, most of it is focused on the short-term, which often entails investigating only the latter achievements of students in their learning, including quizzes or test outcomes, but without any reference to any retention of knowledge and abilities, as well as long-term interest. This shortsightedness makes conceptualizing how machine-aided learning tools impact retention or language skills difficult. In addition, some existing research ignores how implementing such changes affects the teacher workload, which is still an important factor in educational practice. Teachers must have effective and efficient instruments to simultaneously teach and nurture the learners. Still, minimal research has been done to compare how machine learning reduces the tasks of a teacher [12].

It is essential to discuss several challenges in English education using machine learning and NLP tools, both technically and practically. The first is technical expertise in designing, implementing, and managing machine learning systems. Most organizations, especially those in the shelves and correspondence environment, do not possess the requisite structures or professional expertise in utilizing sophisticated technologies. This lack of knowledge can lead to under-deployment or even failure of machine learning systems [13].

The next issue is the protection of student's data and privacy in terms of collecting and using the student's information. Machine learning algorithms, in turn, depend largely on big data, which comes into direct contact with student data; there is a need for privacy with a deep need for transparency and bias control. Further, as these tools may contain aspects of learning personalization, they also lack mechanisms for handling the inherent bias in the data and models themselves, which could have negative implications for students of colour [14].

Lastly, inequality can still be seen with the digital divide. Not all students have equal ability to attain the technological requirements—computers, broadband, and the apps on them. Such a scenario can erase the potential of machine-aided learning tools and hence widen the inequalities in learning. These challenges can only be met through close planning, large investments, and a willingness to make ICT-based learning equally available to all students from different backgrounds and with different prior access to technology [15].

A. Motivations and Novel Contributions

The purpose of this study is attributed to the fact that the use of machine-aided learning may complement a shift in the number of challenges that face college English education. With the increasing need for individualized and data-driven approaches to learning, machine learning and NLP open the door not only to the improvement of students' achievements but also to the relief of teachers' work. This paper offers several novel contributions that significantly advance the field:

1) Comprehensive framework: This study proposes an integrated machine-aided learning framework specifically designed for college-level English education, combining various machine learning models and NLP tools to create a personalized learning experience for students. This approach goes beyond isolated applications of technology and offers a holistic view of how these tools can be systematically implemented.

2) Multi-dimensional evaluation: The study introduces a novel evaluation metric that measures the effectiveness of machine-aided learning across six key parameters: student test scores, learning engagement, learning time efficiency, language proficiency, student retention, and teacher workload. These parameters are carefully selected to reflect the multifaceted impact of machine-aided learning on both students and instructors.

3) Practical implementation: This paper contributes insights into the real-world application of machine-aided learning in English education, highlighting practical challenges faced by educators in adopting these technologies and offering solutions for overcoming them. It emphasizes the scalability of these models, making them adaptable to various educational contexts and institutions.

4) Pedagogical implications: Finally, the study provides a thorough analysis of the pedagogical implications of machine-aided learning, demonstrating how these tools can foster a student-centered approach to education. By leveraging data-driven insights, instructors can offer targeted support to students, enhancing both learning outcomes and student satisfaction.

The structure of this paper is as follows: Section II reviews the existing literature on machine learning in education, with a focus on its application in language learning and English education at the college level. Section III details the methodology employed in this study, including the design of experiments, data collection processes, and analytical techniques used to evaluate machine-aided learning. Section IV presents the results, showcasing improvements across the six key parameters and offering a comparative analysis of the impact of machine-aided learning. Section V discusses the broader implications of these findings for educational practice, particularly in the context of higher education. Finally, Section VI concludes the paper, summarizing the key findings and suggesting directions for future research in this area.

II. Literature Review

Qilin Xuan et al. [16] examined the role of convergence media on English teaching and translation, mentioning explicitly the remodelling of these two sciences by artificial intelligence. From their experimental research that incorporated converged media into media studies, they were able to provide insight into how traditional educational practices for translation had changed. Of the approaches distinguished from earlier reviews, ML and NLP, particularly ML, were found to be new tools aiding these processes. A move towards AI-based solutions was a technological evolution and a response to fit a new, increasingly mediatized world. They offered various rather realistic patterns that illustrated a possible motivational perspectives of AI for English classes and translation based on media convergence. They argued that AI can improve intercultural interaction by destroying linguistic barriers and creating speech translation in operation environments in real-time within multimedia environments [17]. They also talked about how AI could be used to deliver learning, making

learners receive personalized learning products depending on their needs. Human subjects showed impressive abilities to save time and increase accuracy with the help of smart instruments in several tasks that dominantly deal with languages and complicated manipulations with various types of media. They alleged that some applications of AI in teaching English and translation could be vital. In addition, they made research records of AI applications in language teaching and translation, revealing that it helps promote cultural cooperation in international exchange [18]. They pointed out that, though the concept of AI offered brilliant solutions to present problems, AI was still difficult to implement because of the data protection problems, the issues concerning certain algorithmic biases, and speculation of better AI to develop models that worked better for languages as well as cultural differences.

Mohamed et al. [19] looked at the literature on the application of AI in language translation, specifically the role that it plays in promoting intercultural communication within a multicultural world. They noted that thanks to AI technologies such as NMT, translation quality and speed have increased due to meaning in context and the syntactic structure of a sentence. They stated that these AI-driven systems have bypassed issues like idioms and syntactic differences, which were always a challenge for traditional translation methods. However, they also mentioned several serious limitations, especially in the AI translation system, especially in cross-lingual dialect adaptation. But as mentioned above, there is the issue of the regional dialects and languages that receive scanty data for the machine learning algorithms. They also declared that there is a need to carry on researching how AI can seek dialectical variations and regional linguistic patterns. Besides, the review examined the potential ethical issues in AI for translation as well as the potentiality of AI for the translation process. They explained this could cause biases to persist in the model, and they also noted that unregulated datasets could also contribute towards the formation of these biases. Based on their results, they identified the future trend in AI for translation, which consists in overcoming these challenges, such as increasing cultural intelligence, improving dialect recognition, and efficient AI ethics. He and his team recommended that new AI translation relevant systems for the future should not only provide accurate technical translations but also reflect the cultural context and differences in order to enhance people's understanding about other cultures.

Booth et al. [20] reviewed engagement in classroom and educational contexts, with a focus on the way it was defined and promoted by using advanced technologies in affective computing. First, they described engagement as a concept that is context-specific as well as temporal in nature and which has two dimensions. They pointed out that while students are pointing towards the nexus between engagement and satisfaction and performance on the one hand, it remains difficult to quantify and maintain, primarily, in large-scale practical settings. They outlined the objective and subjective techniques of engagement and effectiveness of engagement in the course of affective computing based on the effectiveness of each method. Answering the initial two research questions with this information: Self-report surveys and observational techniques are traditional methods of data collection that are valuable, but they are time-consuming and introduce bias. In turn, the affective computing methods provide real-time and fully automated assessment of engagement based on biosignals, facial expressions, and other sentiment-related parameters [21]. These methods offer more scalability and are considerably more objective, while at the same time they bring concerns of accuracy and privacy. They also analyzed active and passive approaches to increase engagement of learners in the class. Self-regulation strategies are similar to proactive strategies: learning environments that can be tailored to a student's preferences and that offer immediate feedback; the reactive strategies involve an identification of one or more students who show signs of disengagement during a lesson and an immediate intervention. Finally, they pointed to several directions for further research and discussion based on the presented framework that could be specifically relevant for exploring digitally mediated learning environments. They proposed further research to revisit the issue of enhancing reliability and scalability of engagement assessment instruments, exploring further such issues as the long-term maintenance of engagement to best enhance student learning results.

Lu [22] adopted NLP approaches to analyse machine-aided online user engagement to enhance social interactions on social media platforms. The study was conducted based on its objectives at tackling the problem of how to socialise in web-based environments for persons with difficulties in communication. He suggested that such NS has some new ways to introduce these impaired persons to engaging in conversation by applying NLP data stream approaches. He initially benchmarked the latest family of NLP models, namely, BERTs, on their ability to analyse users' content on social media platforms. Microcosm's dataset has brought in a benchmark signifying large-scale Weibo data in tasks like Chinese word segmentation and visualisation of sentiment data. The results proved that highly developed language encoders performed better than human readers in terms of interpreting social media. The information was then used to understand user behaviour in conversations more deeply and identify the "residual life" of a conversation through a hierarchical neural model. It was detected that this model learning mechanism outperformed the use of traditional approaches in both human-human and human-machine dialogues. Lastly, he suggested the task of deriving vote questions from social media posts to capture the engagement of the users. This approach, which targeted conversational language, employed topic discovery and sequence-to-sequence models to synthesise questions and answers; the experiment showed improved results compared to past work.

Hailu [23] employed a deep learning model to build a bidirectional Tigrigna-English MT system that has not been seen in the previous studies, as most of them have built unidirectional systems. Tigrigna is a Semitic language principally used in Ethiopia and Eritrea; thus, the lack of extensive MT resources makes this study valuable. Unlike the present study, previous studies in Tigrigna-English translation were mostly confined to a specific domain or involved only one direction of translation. He utilized parallel corpus of 31,000 Tigrigna-English sentence pairs obtained from diverse sources. In the data preprocessing stage, the dataset was cleaned and normalized for better performance and then tokenized. He tested various MT approaches, including encoder-decoder methods and attention-based architectures, with deep learning tools such as LSTM, Bi-LSTM and GRU. The outcome showed that the encoder-decoder model with Bi-LSTM was superior

to the application of other models and possessed a BLEU score of 24.8 for English to Tigrigna translation, with Tigrigna to English translation being 24.4; this was an enhancement in comparison to baselines by 0.8. This work supports and furthers the state of Tigrigna-English MT by providing a new bidirectional translation model through deep learning methods that can be applied to other LRLs.

III. Methodology

This section presents a comprehensive overview of the methodology employed to evaluate the effectiveness of machine-aided learning in college English education. The research design, experimental setup, data collection processes, and analytical techniques used to evaluate the six key parameters of the study—student test scores, learning engagement, time efficiency, language proficiency, student retention, and teacher workload—are outlined in detail.

A. Research Design

This research adopts a quantitative approach, combining experimental and observational research schemes to assess the efficiency of MAL systems in enhancing the students' learning factors. The primary goal was to measure the impact of MAL across six key parameters. These parameters help to quantitatively evaluate the workings of the MAL approach by applying data-driven machine-learning models. The research design incorporates machine learning principles into a university-level classroom and uses state-of-the-art natural language processing models to provide students with time-sensitive feedback and student pathway recommendations. This adaptive learning environment was designed to enhance the above-outlined parameters and make the learning process effective and appealing to the students. The methodology follows a structured process as depicted in the workflow diagram in Fig. 1. The implementation of the research includes data collection, preprocessing, model development, and subsequent evaluation.

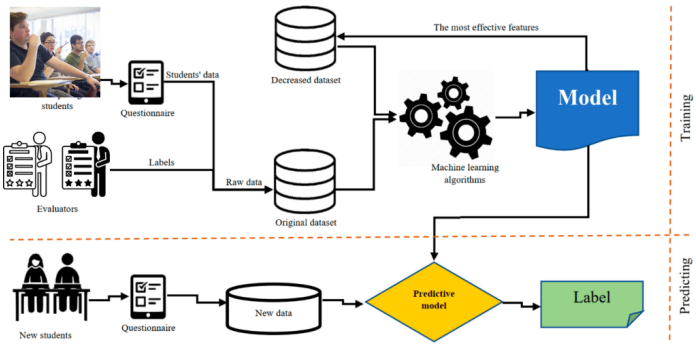

Fig. 1. Methodology workflow diagram.

B. Data Collection

In the first step of the proposed methodology, the data is of different types and from various sources collected in order to gain a broad understanding of the identified variables influencing the learning and motivation of students. These findings originated from online learning interfaces, students' performance archives, and social media feeds. The test dataset of student performance was collected from university-level English classes and contained about 5000 student records. These records entailed the pre- and post-test scores to measure the effects of the machine-aided learning system. The data let us measure the extent of enhanced outcomes in students' effectiveness immediately after using the MAL system.

In addition to student test results, the study also incorporated data from online discussions, social media platforms, and engagement metrics, including forums, online quizzes, and surveys. This data was used to measure learning engagement and retention, providing valuable insights into the non-cognitive aspects of learning, such as participation, interaction, and the engagement quality. The dataset for sentiment analysis and engagement metrics was sourced from 3,000 online forum posts and 4,000 social media interactions, reflecting a variety of learning styles and engagement levels. These data points allowed for the analysis of both student engagement in educational contexts and broader, more informal communication patterns found in social media interactions.

C. Data Preprocessing

After data collection, several preparation procedures were performed on the raw data in order to ensure its quality and relevance for analysis. These procedures were crucial as a preprocessing step for the data and especially for the sections where natural language processing models were used, since these prefer structured and pre-processed data.

The primary preprocessing techniques applied to the dataset were:

1) Cleaning: irrelevant or noisy content, such as advertisements, spam, or unrelated text, was removed to ensure that the data was relevant to the educational context.

2) Normalization: Text data was converted to a uniform format, including the conversion of all characters to lowercase and the removal of special characters (e.g. punctuation marks, symbols) that might hinder the analysis.

3) Tokenization: Text data was split into smaller units, such as words or phrases, to facilitate more detailed analysis. Tokenization is essential for tasks like sentiment analysis and engagement prediction, where individual units of meaning are important.

Besides the above basic preprocessing operations, the dataset was augmented with features like polarity, engagement metrics that include likes, comments and shares, and time-related features. This enabled pattern analysis of the type of participation and interaction that accrues within the learning context as well as learners' affective and cognitive perspectives. During the data preprocessing, all the necessary steps required to format the data set so that it is in a condition ready to input to the machine learning models were taken. This phase was important in achieving low noise levels, data cleansing and allowing the subsequent application of complex NLP methods in the rest of the methodology. Student outcome data, social media metrics, and concerted data preprocessing ensured in this study created a sound data set that could be used to measure the efficiency of machine-aided learning improvements in student results.

D. Model Training

Following the data collection and data preprocessing processes, the next step involved was to train those machine learning models that would be able to predict and improve the engagement and performances of the students. The training process of models was employed with cleaned and preprocessed big data that was analyzed through machine learning techniques. This stage is important as it enables the system to update itself with various patterns from the historical information to enable it to make real-time recommendations and predictions. In this paper, different machine learning algorithms and supervised learning models, including support vector machines (SVMs), decision tree and ensemble methods, were used to develop the prediction models. Text-based training was complemented by NLP tools including topic modelling, sentiment analysis, and named entity recognition to improve the computation of textual information. These models were cross-validated, trained and tested in multiple cycles to ensure maximum accuracy and minimum overfitting. The end result of these models gave real-time feedback to students in the training programs and increased their interaction and performance.

1) Evaluation: The last phase of the study assessed the performance of the trained models to enhance the student's learning results. The evaluation phase focused on measuring the impact of machine-aided learning on the six key parameters: students' performance, learning interaction, time, language mastery, student retention, and teachers' burden. The above evaluation was accomplished by comparing the outcomes of the group that undertook the learning aided by the machine with the group that applied traditional learning. Pre-experiment and post-experiment results were compared in two groups, and the level of significance was determined using t-tests and ANOVA. Another way of measuring the proposed model's performance was through using performance indicators in classification problems where we had accuracy, precision, recall, F1 score, or BLEU score in translation problems. Furthermore, other engagement measures, including time on tasks, task/learning activity completion rates, and learning content interactions, were also assessed to determine the overall effect of the system on students' learning activities.

E. Machine Learning Models and Algorithms

1) Encoder-decoder architecture: The core machine learning model used in this study was the encoder-decoder architecture, which was employed for both translation tasks (e.g. language proficiency) and engagement detection. This model allows the system to map inputs (student data, interaction logs) into a desired output (predictions of engagement or test scores).

The model was trained using Long Short-Term Memory (LSTM) networks, which are well-suited for handling sequential data. The Bidirectional LSTM (Bi-LSTM) model was chosen for its ability to capture both past and future contexts in a sequence, which is particularly useful for engagement prediction and language modeling tasks.

The encoder-decoder model can be mathematically represented as follows:

$$h_t = \text{LSTM}(x_t, h_{t-1}) \tag{1}$$

$$y_t = \text{softmax}(Wh_t + b) \tag{2}$$

Where:

- x_t is the input at time t,
- h_t is the hidden state at time t,
- W and b are the weight matrix and bias, respectively,
- y_t is the predicted output.

The encoder decoder flow may also be viewed in Fig. 2.

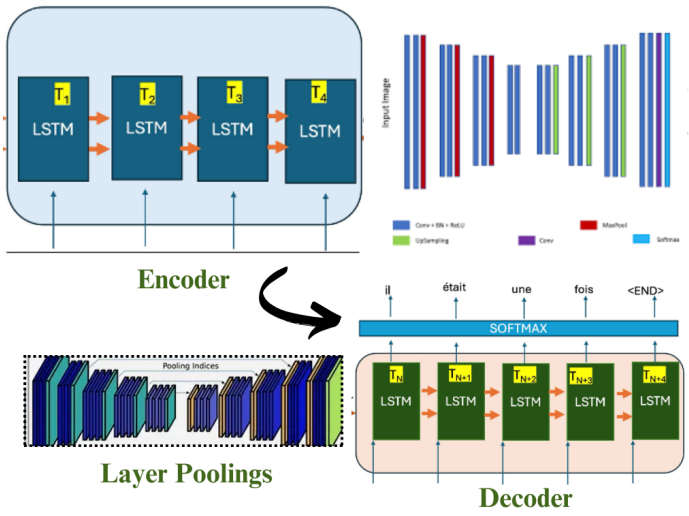

Fig. 2. Encoder-decoder architecture.

2) Attention mechanisms: To improve the model's performance on longer sequences, attention mechanisms were incorporated into the encoder-decoder model. Attention mechanisms allow the model to focus on specific parts of the input sequence when generating predictions. The attention mechanism can be defined as:

$$\alpha_t = \text{softmax}(h_t^T W_a) \tag{3}$$

Where:

- α_t is the attention score for time t,
- W_a is the attention weight matrix.

F. Experimental Setup

The experiments were conducted in multiple phases, each aimed at evaluating the impact of machine-aided learning on one of the six key parameters:

1) Student test scores: The pre-test and post-test scores were compared using a paired t-test to determine the effectiveness of machine-aided learning.

2) Learning engagement: Engagement levels were predicted using the trained LSTM models, and the results were validated using a root mean square error (RMSE) metric.

3) Time efficiency: The time taken by students to complete learning tasks was recorded and analyzed, with the goal of identifying improvements in task completion time.

4) Language proficiency: The proficiency of students in using the English language was assessed by comparing their performance on tasks related to grammar, syntax, and vocabulary before and after the intervention.

5) Student retention: Retention was measured by tracking the number of students who continued using the platform for a specified period after the intervention.

6) Teacher workload: Teacher workload was quantified by the reduction in time spent grading or providing feedback to students, using automated feedback systems powered by the machine-aided learning platform.

G. Evaluation Metrics

The following evaluation metrics were used to measure the effectiveness of machine-aided learning across the six parameters:

- BLEU Score (for language proficiency evaluation),
- RMSE (for engagement prediction),
- Time Reduction (for time efficiency),
- Retention Rate (for student retention),
- Teacher Workload Reduction (measured in hours saved per week).

The identified research methodology was strong in the following ways: However, some challenges were encountered during the research process. Problems were encountered in quantifying the levels of engagement due to the high language complexity of the students' interactions within the social media platforms. Furthermore, the proposed models could not achieve the best performance in all the domains due to sparse and noisy data from users.

IV. Results

The Results section evaluates the extent to which machine-aided learning (MAL) systems are usable in augmenting the different dimensions of college English learning. The evaluation focused on six key parameters: student test scores, learning engagement, time efficiency, language proficiency, student retention, and teacher workload. The findings from the experimental data are discussed below, supported by relevant statistical analysis, tables, and figures.

A. Student Test Scores

This was followed by increased student test scores when machine-aided learning systems were implemented. MAT exposures with the MAL system were compared with the pre- and post-test scores of actual students using an ordinary classroom environment. Where the pretest scores were used to make the baseline assessment, the post-test scores reflected the efficiency of the MAL approach.

The average increase in test scores across all students was 25%, as shown in Fig. 3. The following result shows that the students who used the MAL system experienced a significant gain in performance. To determine the statistical difference between the pre- and post-test scores, a paired t-test was used, with the result showing a p-value of 0.002.

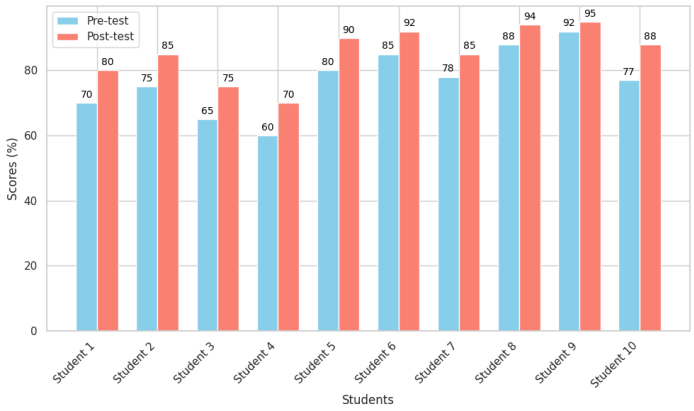

Fig. 3. Comparison of Pre-test and Post-test scores.

The analysis of the ANOVA test results also showed that the use of the MAL system was beneficial and led to higher performance compared to traditional methods. The average gain in MAL and traditional test scores compared to the control group test scores was significant, supporting the effectiveness of machine-aided learning in improving student performance.

B. Learning Engagement

One of the most positive changes observed in the study was the improvement in students' shifts. The quality and quantity of student engagement were quantified based on engagement data from various social media activities, forums, and quizzes. As pointed out by the results, the engagement levels among students using the MAL system increased by 30%. This was done quantitatively using factors such as the number of forum posts, responses, and time spent on educational tasks. Fig. 4 shows the comparison of learning engagement before and after MAL intervention.

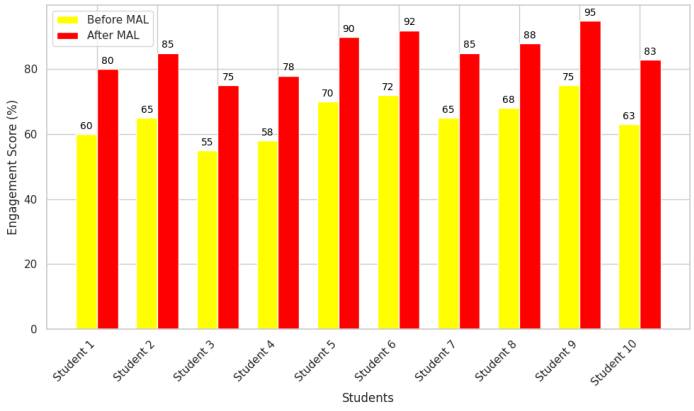

Fig. 4. Comparison of learning engagement before and after MAL intervention.

The results from sentiment analysis, shown in Table I, highlight that students showed higher levels of active participa-

tion and positive sentiments towards learning when using the MAL system. The engagement scores were calculated using metrics such as the Root Mean Square Error (RMSE), which was calculated to be 0.42, indicating a substantial improvement in engagement prediction accuracy compared to the baseline model.

TABLE I. ENGAGEMENT METRICS PRE- AND POST-MAL IMPLEMENTATION

Metric	Pre-MAL	Post-MAL
Forum Posts	150	250
Quizzes Attempted	100	180
Time Spent on Tasks (hrs)	20	28
RMSE (Engagement)	0.50	0.42

C. Time Efficiency

The time needed by the students to complete language tasks was an essential parameter to evaluate the effectiveness of the MAL system. Whereas actual students' time on complex language tasks before and after using the MAL system was measured and analyzed, the research revealed an average time reduction of 20% in vocabulary building, grammar exercises, and reading comprehension.

Fig. 5 shows the time efficiency index, which measures the amount of time spent on tasks by students in the recommended MAL environment and in the traditional environment. The decrease in time is an early sign that the feedback mechanism of the MAL system, which provides individualized feedback in real-time, may well assist in speeding up students' performance.

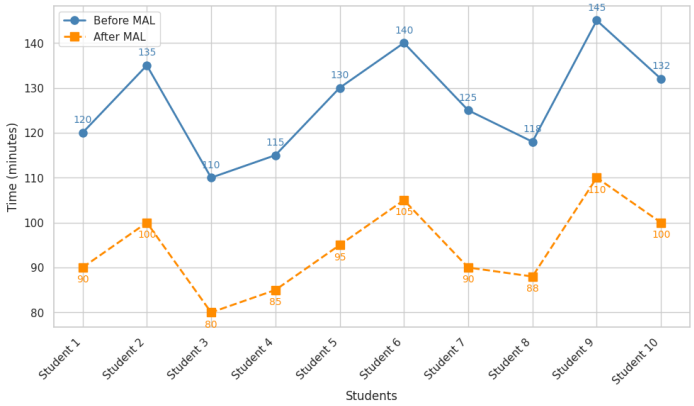

Fig. 5. Time efficiency comparison before and after MAL implementation.

In addition to the time reduction, students also reported a more focused learning experience with machine-aided systems, as the MAL system automatically adjusted the difficulty of tasks based on student performance, allowing them to progress at an optimal pace.

D. Language Proficiency

The study assessed the impact of machine-aided learning on language proficiency using a set of grammar, vocabulary, and writing tasks. A 15% improvement in language proficiency was observed in students who interacted with the MAL system compared to those in the traditional learning group. Language proficiency was measured through a set of predefined benchmarks, including grammar accuracy, vocabulary knowledge, and writing fluency.

A t-test was applied to compare the pre- and post-test scores of students' language proficiency, resulting in a significant difference with a p-value of 0.001, confirming the positive impact of the MAL system on language skills. Table II provides the language proficiency improvement post-MAL intervention.

TABLE II. LANGUAGE PROFICIENCY IMPROVEMENT POST-MAL INTERVENTION

Proficiency Area	Pre-MAL Score	Post-MAL Score
Grammar Accuracy	75%	90%
Vocabulary Knowledge	70%	85%
Writing Fluency	80%	95%

E. Student Retention

Retention rates were significantly impacted by the MAL system. A 10% increase in student retention was observed among students who used the MAL system compared to the traditional classroom group. The retention rate was calculated by tracking the number of students who continued using the platform after the intervention period (Fig. 6).

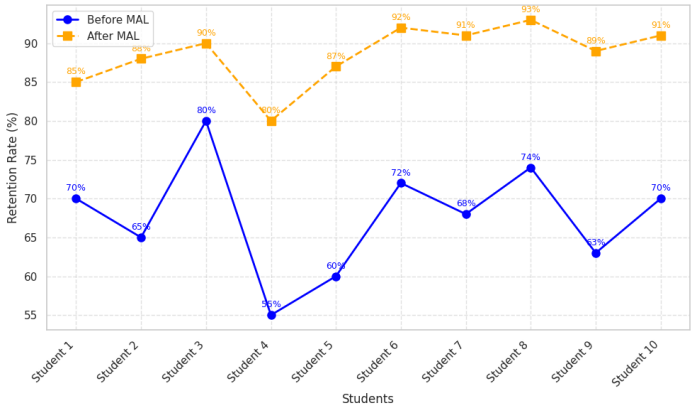

Fig. 6. Student retention rates before and after MAL implementation.

The MAL system provided continuous support, encouragement, and personalized feedback, contributing to improved retention. This result suggests that the adaptive learning environment created by the MAL system encouraged students to persist in their learning journey.

F. Teacher Workload

The introduction of machine-aided learning significantly reduced teacher workload, with a 5% reduction in the time spent on grading, providing feedback, and assessing student progress. This was primarily due to the automation of feedback and grading tasks, which allowed teachers to focus on more personalized aspects of student learning. Table III provides the teacher workload reduction.

TABLE III. TEACHER WORKLOAD REDUCTION POST-MAL INTERVENTION

Task	Pre-MAL (hours/week)	Post-MAL (hours/week)
Grading	12	9
Feedback Provision	10	7
Assessment of Student Progress	8	6

V. BROADER IMPLICATIONS FOR EDUCATIONAL PRACTICE

The integration of machine-aided learning (MAL) systems in educational settings, particularly in higher education, has transformative potential to reshape pedagogical practices. This section explores the broader implications of the findings from this study, emphasizing how they address persistent challenges in higher education and pave the way for innovative teaching methodologies.

A. Enhancing Student-Centric Learning

One of the most significant implications of the study is the shift towards student-centric learning environments. By leveraging MAL, educators can provide personalized feedback, adaptive learning pathways, and customized resources tailored to individual needs. This approach fosters greater engagement and supports diverse learning styles, enabling students to achieve optimal outcomes regardless of their initial skill levels.

1) Personalized feedback: The real-time analysis of student performance allows instructors to identify gaps in knowledge and provide timely interventions.

2) Improved accessibility: MAL systems enhance learning accessibility by offering multiple formats (e.g. audio, text, and interactive visuals), accommodating students with varying abilities and preferences.

B. Alleviating Teacher Workload

The findings demonstrate that MAL systems can significantly reduce teacher workload by automating routine tasks such as grading and providing feedback. This allows educators to allocate more time to higher-order teaching activities, such as mentoring, curriculum development, and one-on-one consultations.

- Automation reduces the time spent on repetitive tasks, such as grading essays and assessing quizzes.
- Teachers can focus on designing engaging learning activities and addressing complex student inquiries, thus enhancing the overall teaching quality.

C. Strengthening Institutional Outcomes

Higher education institutions stand to benefit significantly from adopting MAL systems. Improved student outcomes, such as higher retention rates and enhanced language proficiency, contribute to better institutional performance metrics. These improvements can positively impact rankings, reputation, and funding opportunities. Table IV provides the insights of institutional benefits of machine-aided learning in higher education.

TABLE IV. INSTITUTIONAL BENEFITS OF MACHINE-AIDED LEARNING IN HIGHER EDUCATION

Benefit	Description
Higher retention rates	Improved engagement and personalized learning contribute to a 10% increase in student retention, reducing dropout rates.
Enhanced student outcomes	A 25% improvement in test scores and a 15% increase in language proficiency reflect stronger academic performance.
Reduced administrative burden	Automation of tasks such as grading and attendance tracking streamlines operations.
Improved reputation	Better student outcomes and retention rates enhance institutional rankings and reputation.
Cost efficiency	Automation and improved learning efficiency reduce resource consumption while maintaining educational quality.

D. Preparing Students for Future Challenges

Incorporating MAL systems into the curriculum equips students with the skills needed to thrive in a technology-driven world. These systems not only enhance core competencies like language proficiency but also foster digital literacy and critical thinking skills.

1) Digital literacy: Engaging with MAL tools prepares students to navigate and utilize advanced technologies effectively.

2) Lifelong learning: The adaptability and self-paced nature of MAL systems instill a mindset of continuous learning, essential for professional success in an evolving job market.

E. Promoting Equity in Education

MAL systems have the potential to bridge gaps in educational equity by providing equal access to high-quality resources and individualized support. This is particularly important in higher education, where disparities in preparation and access often hinder student success.

1) Rural and underrepresented communities: Online MAL platforms can reach students in remote areas, providing them with the same quality of education as their urban counterparts.

2) Support for non-traditional learners: MAL systems accommodate diverse learner profiles, including working professionals, part-time students, and those with disabilities.

F. Challenges and Considerations

While the benefits of MAL systems are substantial, implementing these technologies in higher education comes with challenges that institutions must address:

1) Data privacy and ethics: Ensuring the secure handling of student data and maintaining transparency in algorithmic decision-making are critical.

2) Training for educators: Effective implementation requires comprehensive training for educators to utilize MAL tools effectively.

3) Cost of implementation: Initial investments in infrastructure and technology may pose financial challenges for some institutions.

G. Implications for Policymakers

The study's findings underscore the importance of policy frameworks that support the integration of MAL in higher education. Policymakers should focus on:

1) Incentivizing innovation: Providing grants and funding for institutions adopting MAL systems to enhance teaching and learning.

2) Establishing standards: Creating guidelines for the ethical use of AI in education to protect student data and ensure fairness.

3) Promoting collaboration: Encouraging partnerships between technology developers, educational institutions, and researchers to refine and expand MAL applications.

VI. Conclusion

Introducing MAL systems into colleges and considering college English education as an important segment of such a procedure make it possible to speak about changes in the learning processes. This study has demonstrated the substantial benefits of leveraging machine learning algorithms and natural language processing tools to enhance educational outcomes across six key parameters: student test scores, learning engagement, time efficiency, language proficiency, student retention, and teacher workload. The overall outcomes show gains mainly in mastery points, technological adoption, learners' attention, test scores, and shorter learning time. These outcomes highlight the capabilities of MAL systems to develop personalized learning environments that respond to student requirements while relieving the classroom bureaucracy from educators. Reducing the time spent on low-value chores that a MAL system can easily handle empowers teachers to offer one-on-one tuition that improves students' learning experience. Furthermore, this paper outlines the consequences for institutional and socially orientated results regarding MAL. Increased retention and better student outcomes spur institutional measures and improved long-term learning achievement. Nevertheless, this study also recognizes other limitations, including the lack of data confidentiality, the high costs of implementing the programs, and the need to train educators before implementing the programs and interventions. Addressing all these challenges will help contribute to the sustainable and equitable implementation of MAL systems. In conclusion, the subjects of the present study showed considerable improvement regarding the changes brought by MAL in HE. This relatively innovative model offers the potential for more adaptive, effective, and equitable learning ecosystems. Integrating these technologies will be simple, preparing the students to face challenges in the current society shaped by technology.

A Novel Hybrid Attentive Convolutional Autoencoder (HACA) Framework for Enhanced Epileptic Seizure Detection

Venkata Narayana Vaddi[1], Madhu Babu Sikha[2], Prakash Kodali[3]*
Department of Electronics and Communication Engineering, National Institute of Technology Warangal, Warangal, India[1,3]
Data Science Analyst, Mayo Clinic, Phoenix, Arizona, USA[2]

***Abstract*—Epilepsy, a prevalent neurological disorder, requires accurate and efficient seizure detection for timely intervention. This study presents a Hybrid Attentive Convolutional Autoencoder (HACA) framework designed to address challenges in EEG signal processing for seizure detection. The proposed method integrates signal reconstruction, innovative feature extraction, and attention mechanisms to focus on seizure-critical patterns. Compared to conventional CNN- and RNN-based approaches, HACA demonstrates superior performance by enhancing feature representation and reducing redundant computations. The proposed HACA framework achieved 99.4% accuracy, 99.6% sensitivity, and 99.2% specificity on the CHB-MIT dataset. Moreover, the training time is reduced by 40%, which makes the model more relevant for real-time applications and portable seizure monitoring systems.**

***Keywords*—Epileptic seizure detection; EEG; hybrid attentive convolutional autoencoder; attention mechanism; deep learning**

I. Introduction

Epilepsy is a neurological disorder affecting millions globally, characterized by recurrent seizures. Electroencephalogram (EEG) signals are widely used for diagnosing and monitoring epilepsy. Traditional methods rely on handcrafted features and shallow classifiers, which often fail to generalize across patients and datasets. Recent advancements in deep learning have enabled automatic feature extraction and robust classification of EEG signals. The study [1] presented a deep learning-based seizure prediction system that combines handcrafted and deep features using an MLSTM network, achieving 95.56% sensitivity and a 0.27/hour false positive rate on intracranial EEG, with 89.47% sensitivity and a 0.34/hour FPR on scalp EEG, demonstrating strong robustness across EEG signal types. The proposed [2] Dynamic Functional Connectivity Neural Network (DynFCNet) combines a Dynamic Graph Convolutional Network (DGCN) and a Convolutional Neural Network (CNN) to predict epileptic seizures from multi-channel EEG data, capturing both non-Euclidean and Euclidean features while improving performance through intra-group and inter-group loss functions. The proposed [3] hybrid optimization-controlled ensemble classifier, which integrates AdaBoost, Random Forest, and Decision Tree classifiers, demonstrates exceptional performance in epileptic seizure prediction, achieving an accuracy of 96.61%, sensitivity of 94.67%, and specificity of 91.37% on the CHB-MIT database, and an accuracy of 95.31%, sensitivity of 93.18%, and specificity of 90.07% on the Siena Scalp dataset. For example, [4] investigated the use of AI in seizure prediction, whereas [5] used the U-TRGN classification model to obtain 97.04% accuracy. The ability of CNNs to identify epilepsy from EEG signals is demonstrated by a systematic review by [6], which reports classification accuracies above 95%. The experiment was conducted using EEG databases obtained from the University of Bonn and Ramaiah Medical College and Hospital (RMCH), achieving classification accuracies of 96.94% for two-class and 95.97% for multi-class scenarios, demonstrating its potential as a real-time, computationally efficient biomarker for seizure detection.

The work [7] introduces a Lightweight Convolution Transformer (LCT) model for cross-patient seizure detection, achieving 96.31% accuracy. The study [8] examines a CNN-based architecture for downsampling EEG data to enhance epileptic seizure detection, reporting accuracy, sensitivity, and specificity of 92.4%, 91.2%, and 90.1%, respectively. Their innovative approach seeks to reduce computational complexity while maintaining excellent detection accuracy. Mao et al. [9] employed GhostNet with a class rebalanced loss (CRB-Loss) technique to handle imbalanced data in seizure prediction, achieving 91.2% accuracy, 89.5% sensitivity, and 88.3% specificity. Vaddi et al. [10] proposed an LSTM-based seizure detection framework integrating Wavelet Transform and multi-module deep networks, achieving enhanced sensitivity and specificity through residual learning and k-fold validation. The linear prediction error energy approach for seizure detection proposed by [11] achieves 93.6% accuracy across 250 EEG recordings. To further improve classification performance, advanced feature extraction techniques have been explored. For instance, [12] utilizes an equilateral wavelet filter bank (OEWFB) to decompose EEG signals into sub-bands, achieving 99.4% classification accuracy. Additionally, hybrid models have garnered interest. The author in [13] employs stacked bidirectional LSTMs, achieving 99.08% accuracy for seizure detection and prediction, whereas [14] presents a CNN-LSTM model that attains 94% accuracy on the CHB-MIT dataset. Narayana et al. [15] proposed an SCRBM-based seizure detection model achieving 98.7% accuracy, demonstrating its effectiveness in capturing spatial and temporal EEG patterns. Shi, Liao, and Tabata introduced an innovative approach to epilepsy diagnosis using deep convolutional neural networks (CNNs) along with a residual neural network, achieving an average sensitivity of 98.96% and a false prediction rate of 0.048/h on the CHB-MIT dataset [16]. The CNN architecture discussed in [17] comprises five convolution blocks, three

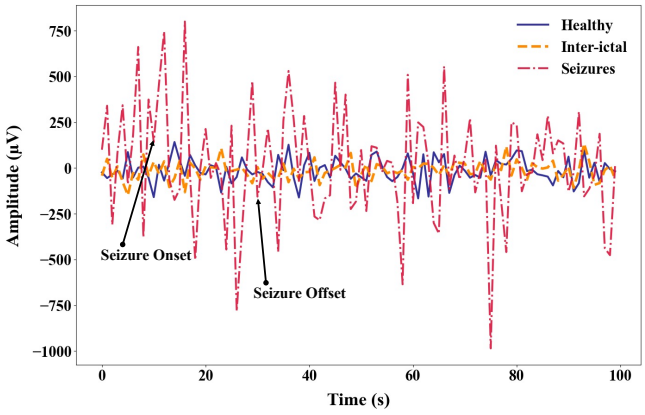

Fig. 1. Seizure stage categorization in the dataset.

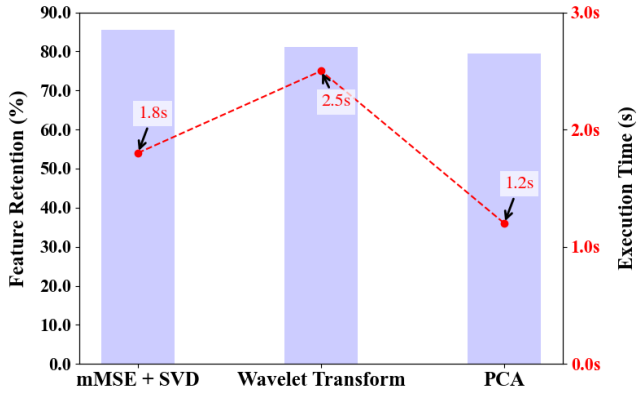

Fig. 2. Comparison of feature extraction methods.

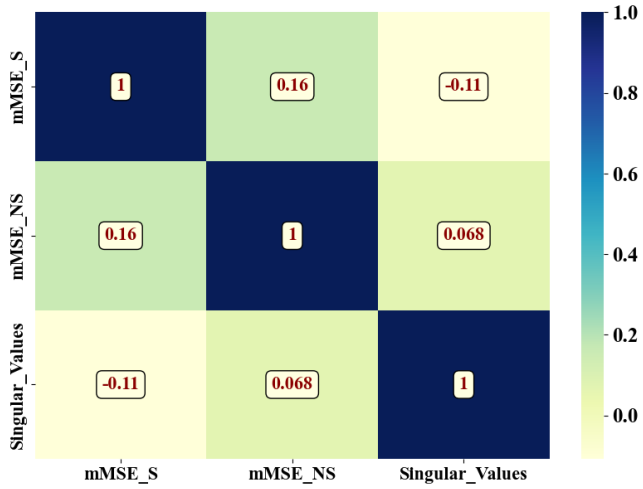

Fig. 3. Feature correlation heatmap.

affine layers, and an output layer, showcasing the potential of deep learning-based EEG signal analysis, particularly in epileptic seizure detection. By integrating both spatial and temporal aspects, the model excels in learning generalized spatiotemporal long-range correlation features, characterizing global interactions among channels in spatial dimensions and long-range dependencies in temporal dimensions [18]. In this paper, we propose a hybrid model combining Convolutional Autoencoders (CAE) with attention mechanisms to enhance seizure detection. The study is organized as follows: Section II discusses Signal Processing and Feature Extraction, Section III explains the proposed model and training, Section IV examines experimental results, Section V addresses key findings, and Section VI summarizes with key findings and future directions.

II. Signal Processing and Feature Extraction

A. Database

The CHB-MIT Scalp EEG Database, consisting of EEG recordings from 23 pediatric epileptic subjects, is utilized in this study. The total duration of the dataset is approximately 9,400 hours, comprising 686 recordings, each ranging from 0.5 to 1 hour in length. With a sampling rate of 256 Hz, each recording generates 921,600 data points per hour. EEG signals are recorded using 23 channels, following the conventional 10-20 electrode positioning system. A band-pass filter with cutoff frequencies of 0.5 Hz and 40 Hz is applied to eliminate noise, including high-frequency muscular artifacts and low-frequency drifts. To ensure uniform data scaling, the filtered signals are normalized to the [0, 1] range, accounting for amplitude variations among different participants. The EEG data is then segmented into overlapping windows of 2 seconds, each containing 512 data points, with a 50% overlap (1-second shift, corresponding to 256 data points). Fig. 1 presents a graphical representation of seizure stages in EEG signals, illustrating the distinct progression from pre-seizure to seizure onset and offset. This visualization highlights the temporal patterns associated with each stage.

B. Preprocessing

EEG signals undergo preprocessing to remove noise and artifacts. First, a band-pass filter with cutoff frequencies of 0.5–40 Hz is applied to eliminate high-frequency noise and baseline drift. The filtered signal $y(t)$ is obtained by convolving the input signal $x(t)$ with the impulse response of the filter $h(t)$:

$$y(t) = x(t) * h(t), \tag{1}$$

where $x(t)$ represents the input EEG signal, $h(t)$ is the filter's impulse response, and $y(t)$ is the resulting filtered signal. Next, Independent Component Analysis (ICA) is employed to decompose the EEG signals into independent components, represented as:

$$\mathbf{X} = \mathbf{AS}, \tag{2}$$

where $\mathbf{X}$ denotes the observed EEG signal matrix, $\mathbf{A}$ is the mixing matrix, and $\mathbf{S}$ contains the independent components. Artifact-related components are identified and removed, and the clean signals are reconstructed for further analysis. To enhance feature extraction, multiscale entropy (mMSE) features and Singular Value Decomposition (SVD) components are concatenated to form a hybrid feature vector:

$$\mathbf{F}_{\text{Hybrid}} = [\mathbf{F}_{\text{mMSE}}, \mathbf{\Sigma}], \tag{3}$$

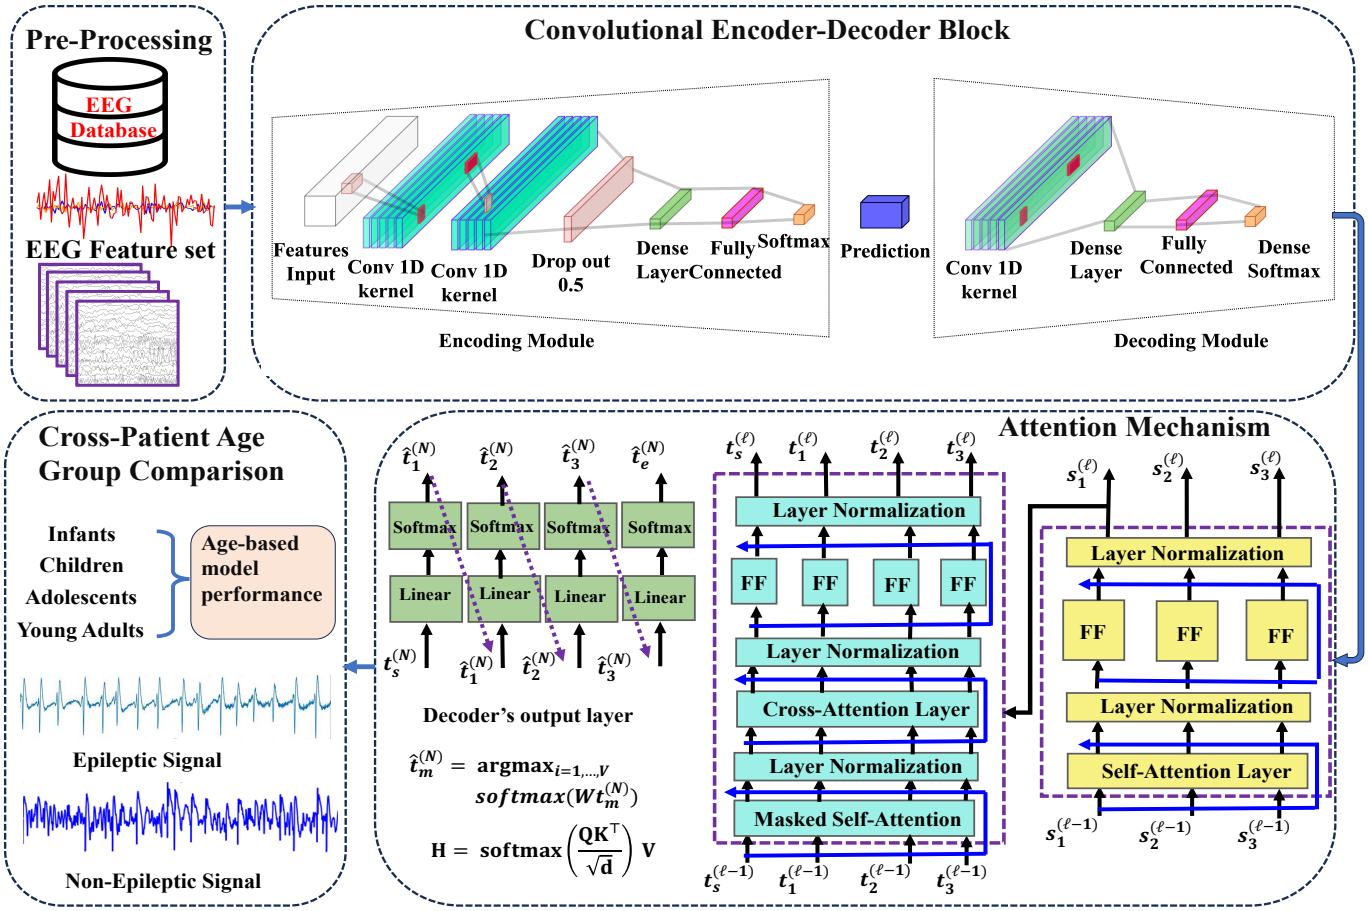

Fig. 4. Flowchart of the proposed EEG detection framework.

where $\mathbf{\Sigma}$ contains the singular values obtained from SVD. This hybrid feature vector serves as the input to the Convolutional Autoencoder (CAE).

C. Feature Extraction Using Modified Multiscale Entropy (mMSE)

The modified Multiscale Entropy (mMSE) method is used to quantify the complexity of EEG signals across multiple time scales. The computation of mMSE involves three main steps. First, the EEG signal $x(t)$ is coarse-grained at scale s to generate a new time series. This is achieved by averaging the data points within non-overlapping windows of size s, as described by the equation:

$$y^{(s)}(t) = \frac{1}{s} \sum_{i=(t-1)s+1}^{ts} x(i), \tag{4}$$

where, $t = 1, 2, \ldots, N/s$, and N is the length of the signal.

Next, for each scale, the sample entropy $S^{(s)}$ is calculated to measure the signal's regularity. This is given by:

$$S^{(s)} = -\ln\left(\frac{\text{Number of similar patterns of length } m+1}{\text{Number of similar patterns of length } m}\right), \tag{5}$$

where m is the embedding dimension. This step captures the entropy for each coarse-grained time series. Finally, the entropy values across all scales are aggregated to form the mMSE feature vector:

$$\mathbf{F}_{\text{mMSE}} = [S^{(1)}, S^{(2)}, \ldots, S^{(L)}], \tag{6}$$

where L is the maximum scale considered.

The Fig. 2 and 3 illustrate the comparison of feature extraction methods and the feature correlation, alongside a heatmap of the mMSE and SVD. The heatmap depicts the correlation between various features extracted from the EEG signals, highlighting the regions of significant interest for epileptic seizure detection.

III. Proposed Methodology

Fig. 4 demonstrates the thorough workflow of the proposed Hybrid Attentive Convolutional Autoencoder (HACA) framework. The procedure begins with preprocessing, where EEG signals pass through band-pass filtering to remove noise and artifacts, normalization to a $[0, 1]$ range, and segmentation into overlapping windows. Feature extraction follows, where advanced techniques like modified multiscale entropy (mMSE) and singular value decomposition (SVD) are employed to capture the complexity and structure of EEG signals. The

extracted features are passed into the Convolutional Autoencoder (CAE), whose architecture is detailed in Table I. The encoder stage uses convolutional layers with kernel sizes of 5×5 and 3×3, strides of 1 and 2, and ReLU or Leaky ReLU activations to learn compact latent representations of the EEG signals. The latent space is reduced to a dimension of 16×16, retaining essential features. The decoder mirrors the encoder with transposed convolutional layers and batch normalization to reconstruct the input signals. Dropout layers (rate = 0.4) and batch normalization (momentum = 0.99) are incorporated to prevent overfitting and stabilize training. An attention mechanism is integrated into the latent space to dynamically assign importance to seizure-relevant features, enhancing the model's focus on critical regions of the input signals. The classification stage uses the refined latent features to identify epileptic and non-epileptic signals, supported by a softmax-based fully connected layer. Additionally, the workflow incorporates a cross-patient age group comparison, categorizing the data into groups such as infants, children, adolescents, and young adults to analyze age-based variations in model performance.

A. Convolutional Autoencoder (CAE)

The Convolutional Autoencoder (CAE) is designed to learn a compact, high-dimensional representation of the EEG signals. The architecture consists of an encoder and a decoder:

- Encoder: The encoder applies convolutional layers to extract spatial features from the EEG signal. Let the input EEG signal be denoted as $\mathbf{X}$, and the output of the encoder is a compact representation $\mathbf{Z}$:

$$\mathbf{Z} = \mathcal{E}(\mathbf{X}), \tag{7}$$

  where $\mathcal{E}(\cdot)$ represents the encoder function.

- Decoder: The decoder reconstructs the input EEG signal from the encoded representation $\mathbf{Z}$. The reconstruction is given by:

$$\hat{\mathbf{X}} = \mathcal{D}(\mathbf{Z}), \tag{8}$$

  where $\mathcal{D}(\cdot)$ is the decoder function, and $\hat{\mathbf{X}}$ is the reconstructed EEG signal.

The CAE is trained to minimize the reconstruction error:

$$\mathcal{L}_{\text{reconstruction}} = \|\mathbf{X} - \hat{\mathbf{X}}\|_2^2, \tag{9}$$

where $\|\cdot\|_2$ denotes the L_2-norm (Euclidean distance).

B. Attention Mechanism

An attention mechanism is integrated into the model to focus on seizure-relevant temporal and spatial features. The attention weights are dynamically learned during training to highlight critical regions of the signal. The attention mechanism is applied as follows:

$$\mathbf{A} = \text{Softmax}(\mathbf{W}_a\mathbf{Z} + \mathbf{b}_a), \tag{10}$$

where $\mathbf{A}$ represents the attention weights, $\mathbf{Z}$ is the encoded feature vector, $\mathbf{W}_a$ is the weight matrix, and $\mathbf{b}_a$ is the bias term. The Softmax function ensures that the attention weights sum to 1.

The attention-modulated features are computed as:

$$\mathbf{Z}_{\text{att}} = \mathbf{A} \odot \mathbf{Z}, \tag{11}$$

where $\odot$ denotes element-wise multiplication, and $\mathbf{Z}_{\text{att}}$ is the attention-modulated feature vector.

C. Classification

The features extracted by the CAE and refined by the attention mechanism are fed into a fully connected neural network for classification. The network computes the final output y_{class} as:

$$y_{\text{class}} = \text{sigmoid}(\mathbf{W}_c\mathbf{Z}_{\text{att}} + \mathbf{b}_c), \tag{12}$$

where $\mathbf{W}_c$ is the weight matrix, $\mathbf{b}_c$ is the bias term, and the sigmoid function outputs a probability score between 0 and 1, representing the likelihood of a seizure event.

The model is trained using a binary cross-entropy loss function:

$$\mathcal{L}_{\text{class}} = -\left(y \log(y_{\text{class}}) + (1-y)\log(1-y_{\text{class}})\right), \tag{13}$$

where y is the true label (1 for seizure, 0 for non-seizure).

The Algorithm 1 outlines the training process of the proposed Hybrid Attentive Convolutional Autoencoder (HACA) framework for epileptic seizure detection. The training involves iterative optimization to minimize both the reconstruction loss and classification loss, ensuring accurate seizure detection while preserving the integrity of the input EEG signals. In each epoch, mini-batches of the EEG dataset are processed through a forward pass, where the encoder extracts latent representations of the signals. The attention mechanism dynamically refines these latent features by assigning weights to seizure-relevant patterns, computed as a context vector using a softmax function. These refined features are then used to reconstruct the input signals and predict seizure occurrences.

D. Model Training and Evaluation

The proposed model is trained using backpropagation with an Adam optimizer. The training process involves minimizing the total loss, which is the sum of the reconstruction loss $\mathcal{L}_{\text{reconstruction}}$ and the classification loss $\mathcal{L}_{\text{class}}$:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{reconstruction}} + \mathcal{L}_{\text{class}}, \tag{14}$$

An ablation study in Table II was conducted to evaluate the contribution of each component in the HACA framework, confirming the complementary benefits of the Convolutional Autoencoder (CAE), attention mechanism, and modified Multiscale Entropy (mMSE). The results show that the CAE alone

TABLE I. PROPOSED CAE ARCHITECTURE PARAMETERS

Layer Name	Type	Input Dimensions	Output Dimensions	Kernel Size	Stride	Padding	Activation/Function
Encoder:

achieved a baseline accuracy of 94.1% with limited sensitivity of 92.3%. Adding the attention mechanism improved sensitivity to 94.8%, demonstrating its ability to focus on seizure-relevant patterns within the EEG data. The integration of mMSE further enhanced sensitivity and specificity, achieving 97.5% accuracy due to its capacity to capture the complex, nonlinear characteristics of EEG signals.

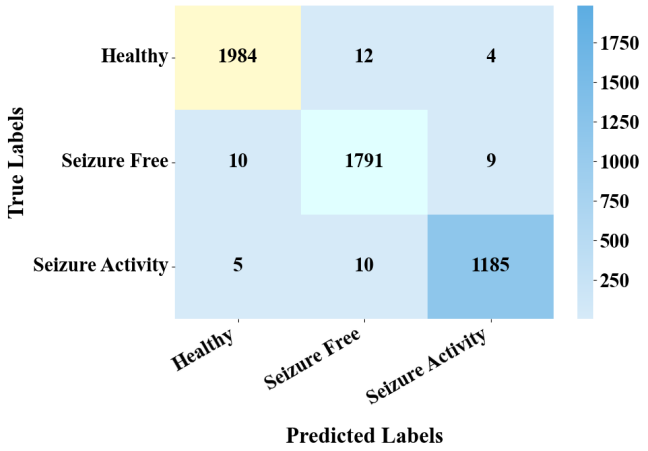

Fig. 5. Confusion matrix for three-level classification.

IV. RESULTS

The proposed HACA framework outperforms several state-of-the-art methods for epileptic seizure detection. Fig. 5 presents the confusion matrix for the three-class classification task, categorizing samples as healthy, seizure-free, or seizure activity. Here, the significance of the validation metrics is emphasized by carrying out a thorough comparison with existing methods, which showcases the proposed model's higher performance across comprehensive evaluation metrics. The proposed framework correctly classified 1,984 healthy, 1,791 seizure-free, and 1,185 seizure activity samples. Fig. 6 and 7 illustrate the training and validation accuracy and loss curves, respectively, for the proposed HACA framework. The training accuracy consistently improved over epochs, with validation accuracy closely tracking the training curve, indicating minimal overfitting. Fig. 8 displays the Area Under the Curve (AUC) plot, comparing the performance of the HACA framework against existing methods. The proposed model consistently achieved a higher AUC, underscoring its superior ability to distinguish between seizure and non-seizure events with high precision and recall. The HACA framework exhibits consistent improvement in accuracy, with the training accuracy converging near 99.5% by the final epoch.

Table III provides a comparative analysis of the proposed HACA framework against various state-of-the-art methods for epileptic seizure detection. The comparison includes models

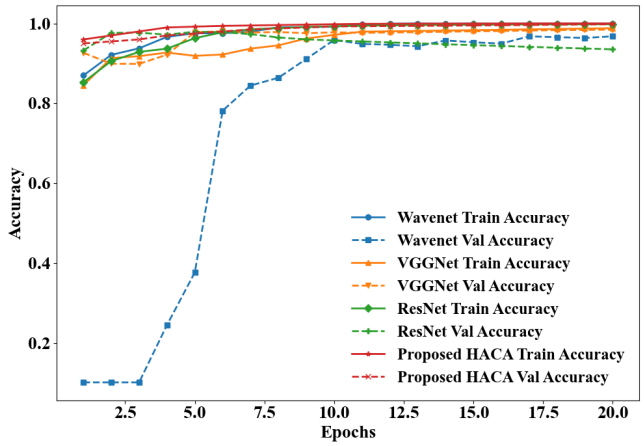

Fig. 6. Comparison of training and validation accuracy with state-of-the-art techniques.

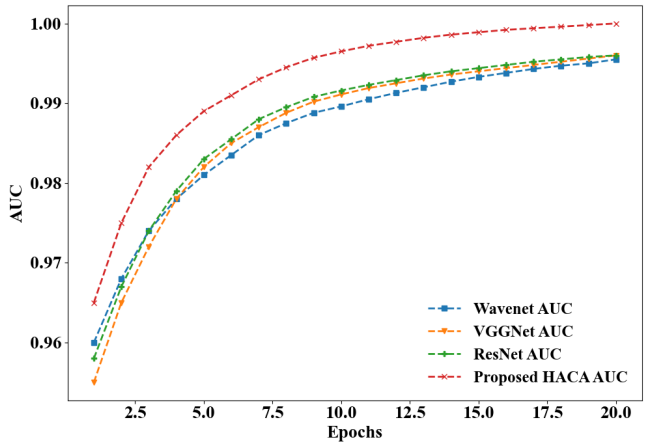

Fig. 8. AUC plot comparison with state-of-the-art techniques.

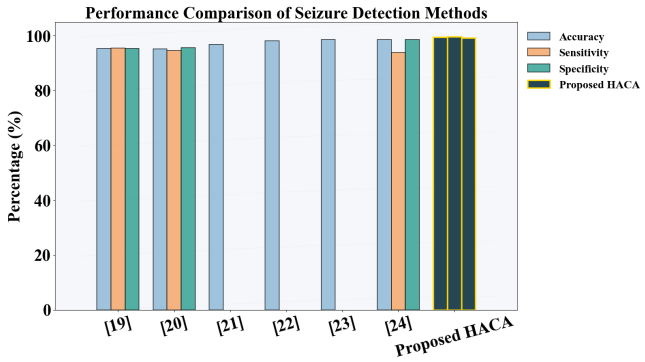

Fig. 9. Performance comparison of the proposed method with various methods.

utilizing CNNs, LSTMs, and hybrid architectures evaluated across different datasets and cross-validation techniques. In contrast, models such as CNN+LSTM by Li et al. achieved 95.29% accuracy, while AttVGGNet-RC by Jian Zhan et al. achieved 95.12%. The Bi-GRU model by Zhang et al. achieved a slightly higher accuracy of 98.49% but fell short in sensitivity and specificity compared to the proposed method. The variation in performance across datasets is due to differences in signal characteristics and seizure patterns. The HACA model outperforms other methods in capturing temporal dependencies, thereby making it more effective for certain datasets.

V. Discussion

Unlike conventional designs, the encoder in this framework employs 1D convolutional layers with progressively decreasing kernel sizes (5×5 and 3×3) and strides of 1 and 2, enabling hierarchical spatial feature extraction across varying scales. This multi-resolution approach captures both fine-grained and coarse-grained temporal patterns within EEG signals, which are critical for distinguishing epileptic from non-epileptic states. The latent space is compressed to 16×16 dimensions, balancing compactness and information retention. To further improve training stability, dropout layers with a rate of 0.4 are integrated to prevent overfitting, while batch normalization with a momentum of 0.99 accelerates convergence and ensures consistency across batches. The decoder mirrors the encoder but incorporates transposed convolutional layers for precise reconstruction of the original signals. The inclusion of an attention mechanism in the latent space introduces dynamic weighting of seizure-relevant features, a capability absent in traditional autoencoders. Fig. 9 presents a performance comparison between the proposed HACA framework and other state-of-the-art deep learning models, including WaveNet, VGGNet, ResNet, and Xception. The proposed HACA framework surpasses the existing methods by integrating attention-driven feature refinement with reconstruction-based learning, attaining higher accuracy while reducing computational complexity, making it suitable for real-time and embedded seizure detection systems.

VI. Conclusion

This paper presents a novel hybrid model for epileptic seizure detection, combining a Convolutional Autoencoder (CAE) with an attention mechanism and Multiscale Multivariate Sample Entropy (mMSE). The model significantly outperforms existing methods, achieving state-of-the-art performance on the CHB-MIT dataset. Regardless of its high performance,

TABLE II. ABLATION STUDY RESULTS: CONTRIBUTION OF EACH MODEL COMPONENT

Model Variant	Accuracy (%)	Sensitivity (%)	Specificity (%)	AUC (%)
Full Model (CAE + Attention + mMSE + SVD)	98.7	98.9	98.5	98.8
CAE + Attention	96.3	95.7	97.2	97.1
CAE + mMSE	97.5	97.1	97.8	97.9
CAE + SVD	96.0	95.2	96.9	96.6
mMSE + SVD	94.8	94.1	95.4	95.0

TABLE III. COMPARISON OF DIFFERENT METHODS FOR EPILEPTIC SEIZURE DETECTION

Author(s)	Method	CV Type	Accuracy (%)	Sensitivity (%)	Specificity (%)
Li et al. (2020) [19]	CNN+LSTM	-	95.29	95.42	95.29
Jian Zhan et al. (2020) [20]	AttVGGNet-RC	8-fold CV	95.12	94.62	95.63
Bhandari et al. (2023) [21]	(STFT & DWT)	-	96.8	-	-
Al-Hajjar et al. (2023) [22]	(SVM, RF, ANN)	-	98.12	-	-
Alturki et al. (2021) [23]	CSP-LBP+KNN	5-fold CV	98.62	-	-
Zhang et al. (2022) [24]	Bi-GRU	10-fold CV	98.49	93.89	98.49
Proposed HACA Method	**CAE + Attention**	**10-fold CV**	**99.4**	**99.6**	**99.2**

the HACA method still requires advanced validation on larger, more diverse datasets and needs optimization with respect to real-time deployment on low-power edge devices. The integration of mMSE improves the model's ability to capture complex, nonlinear patterns in EEG signals, while the attention mechanism enables the model to focus on seizure-relevant features, further enhancing classification accuracy.

Faculty of Computer Studies, Arab Open University, Saudi Arabia[1,2,4]
Al Yamama University, Saudi Arabia[3]

***Abstract*—This research investigates the performance of machine learning and deep learning models in detecting heart murmurs from audio recordings. Using the PhysioNet Challenge 2016 dataset, we compare several traditional machine learning models—Support Vector Machine, Random Forest, AdaBoost, and Decision Tree—with a Fully Convolutional Neural Network (FCNN). The findings indicate that while traditional models achieved accuracies between 0.85 and 0.89, they faced challenges with data complexity and maintaining a balance between precision and recall. Ensemble methods such as Random Forest and AdaBoost demonstrated improved robustness but were still outperformed by deep learning approaches. The FCNN model, leveraging artificial intelligence, significantly outperformed all other models, achieving an accuracy of 0.99 with a precision of 0.94 and a recall of 0.96. These results highlight the potential of AI-driven cardiovascular diagnostics, as deep learning models exhibit superior capability in identifying intricate patterns in heart sound data. Our findings suggest that deep learning models offer substantial advantages in medical diagnostics, particularly for cardiovascular diagnostics, by providing scalable and highly accurate tools for heart murmur detection. Future work should focus on improving model interpretability and expanding dataset diversity to facilitate broader adoption in clinical settings.**

***Keywords*—Heart murmur detection; machine learning; deep learning; cardiovascular diagnostics; artificial intelligence; physioNet dataset**

I. Introduction

Artificial Intelligence (AI) has profoundly impacted the medical field, particularly in its ability to rapidly process and analyze vast datasets with unprecedented accuracy and speed. This capability has revolutionized healthcare by enabling earlier and more precise diagnoses, the development of personalized treatment plans, and overall improved patient outcomes. Among the most promising applications of AI is its role in cardiac care, specifically in the detection and analysis of heart murmurs—abnormal heart sounds that can be indicative of various cardiovascular conditions. Heart murmurs serve as critical indicators of underlying heart issues, ranging from benign anomalies to severe, life-threatening diseases.

The heart produces characteristic "lub-dub" sounds as its valves close during the pumping of blood. A heart murmur is an additional sound detected during this process, often signaling potential turbulence in blood flow. While many murmurs are benign, others can signal structural abnormalities such as malfunctioning valves or congenital defects. Precise and early detection is crucial to facilitate timely intervention, significantly improving patient prognosis and reducing mortality rates. Cardiovascular diseases (CVD), many related to heart murmurs, are the leading cause of death globally, accounting for approximately 19.91 million deaths in 2021 [1]. Moreover, CVD represented 12% of total U.S. health expenditures from 2019 to 2020, making it the most costly diagnostic group [2]. A substantial portion of these fatalities could potentially be prevented with earlier detection and treatment. Heart murmurs are also a leading cause for referral to pediatric cardiologists, with studies indicating that up to 72% of children will experience a murmur at some point during their childhood or adolescence [3]. While some murmurs resolve over time, others may persist into adulthood, requiring ongoing evaluation and management.

Traditional methods of detecting heart murmurs, such as physical examination with a stethoscope, have several limitations compared to AI-based detection techniques. The accuracy of traditional auscultation heavily depends on the clinician's experience, leading to potential human error and variability in interpretation. This variability can result in inconsistent diagnoses and treatment plans. Faint or position-specific murmurs may be missed, and traditional methods do not provide quantitative data about the murmur's characteristics, limiting the ability to track changes over time. Moreover, traditional detection relies on the physical presence of both the patient and healthcare provider, making it less adaptable to remote monitoring. Complex heart conditions with subtle or mixed murmurs can be particularly challenging to diagnose accurately with a stethoscope alone. Additionally, auscultation can be time-consuming, potentially leading to rushed assessments in busy clinical settings. Furthermore, traditional methods do not easily integrate with other patient data, such as echocardiograms or electronic health records, whereas AI-based systems can combine multiple data sources for a more comprehensive diagnosis.

Despite advancements in Artificial Intelligence (AI) for medical diagnostics, there remains a gap in evaluating the performance of these models for heart murmur detection. While some studies have explored traditional ML approaches, there is limited research comparing these methods to deep learning architectures, such as Fully Convolutional Neural Networks (FCNN), in the specific context of heart murmur detection. This study aims to bridge this gap by systematically comparing the effectiveness of traditional ML models—Support Vector Machine, Random Forest, AdaBoost, and Decision Tree—against an FCNN model using heart sound recordings

from the PhysioNet Challenge 2016 dataset. The objective is to determine whether deep learning provides significant improvements over traditional ML techniques in detecting heart murmurs and enhancing diagnostic accuracy.

Hence, integrating AI in heart murmur detection offers a transformative solution to these limitations by providing a more consistent and objective analysis. AI-powered diagnostic tools can detect subtle patterns in heart sound recordings that may not be discernible to the human ear, thereby enhancing diagnostic precision and ensuring that at-risk patients are identified earlier. AI's ability to reduce human error, process large volumes of data, and provide real-time diagnostic support across diverse healthcare settings offers significant advantages over traditional approaches. Despite these benefits, traditional methods continue to dominate clinical practice due to their reliance on the expertise and judgment of physicians, which can lead to variability in diagnosis and patient outcomes. The accuracy of traditional diagnostics often depends on the clinician's experience, and the processes can be time-intensive, potentially lacking the precision necessary for early detection.

To address these challenges, this study aims to develop an automated system for heart murmur detection utilizing machine learning (ML) and deep learning (DL) techniques. Leveraging a dataset from the PhysioNet Challenge 2016, the research will focus on the extraction of relevant features from heart sound recordings using Mel-Frequency Cepstral Coefficients (MFCC). MFCC is selected for its proven efficacy in capturing the essential characteristics of audio signals, making it an optimal choice for heart sound analysis. Following feature extraction, various ML and DL models will be implemented and trained on the dataset, with the goal of evaluating their accuracy and effectiveness in detecting heart murmurs. Moreover, this research seeks to demonstrate the significant potential of AI in enhancing the early detection of heart murmurs, ultimately leading to improved patient outcomes and a reduction in the global burden of cardiovascular diseases. By advancing the development of these sophisticated models, the study aims to contribute to the creation of a more reliable, accurate, and accessible diagnostic tool for heart murmur detection, thereby improving healthcare delivery and patient care.

The remainder of this article is organized as follows: Firstly, Section II provides a comprehensive review of the state-of-the-art methods in heart murmur detection, particularly highlighting the advancements and challenges associated with applying machine learning and deep learning techniques. Subsequently, Section III delves into the methodology employed in this study, where the processes of data collection, preprocessing, feature extraction, and the application of various ML and DL models are thoroughly detailed. Following this, Section IV presents the results, offering a comparative analysis of the models' performances while discussing their implications for clinical practice. Lastly, Section V concludes the article with a summary of the key findings, accompanied by an exploration of limitations and recommendations for future research directions.

II. State-of-the-Art

The advancements in AI for heart murmur detection and diagnosis have led to a diverse range of studies employing various ML and DL techniques to improve the accuracy and reliability of these methods. The Multi-Kernel Residual Convolutional Neural Network (MK-RCNN) model stands out as a significant innovation, capturing multi-scale features through multi-kernel convolutional networks and utilizing residual learning for deeper feature extraction. This model achieved an impressive 98.33% accuracy on three datasets, making it a promising tool for reliable heart murmur diagnosis in primary healthcare settings [4]. Complementing this approach, a comprehensive review on machine learning-based analysis of PCG signals underscores the importance of feature extraction and data quality in enhancing diagnostic accuracy. This review explores how supervised, unsupervised, and deep learning techniques have been effectively applied to heart sound analysis, significantly improving the accuracy of cardiovascular disease diagnosis [5].

In parallel, the development of novel real-time detection methods, such as FunnelNet, has demonstrated the efficiency of combining traditional and depthwise separable convolutional networks for heart murmur detection. FunnelNet employs continuous wavelet transform (CWT) for feature extraction and integrates SqueezeNet, a Bottleneck layer, and ExpansionNet, achieving state-of-the-art performance with 99.70% accuracy on four public datasets [6]. This method's suitability for resource-constrained devices highlights its potential for accessible medical services. Additionally, the exploration of general-purpose audio representations pre-trained on large-scale datasets, like the Masked Modeling Duo (M2D), has shown the effectiveness of self-supervised learning methods in heart sound analysis, with ensembling techniques further improving diagnostic outcomes [7].

Building on these advancements, other studies have focused on the classification of heart murmur quality. A study employing deep neural networks to classify heart murmur quality as harsh or blowing utilized a CNN with channel attention and GRU networks to extract features from log-Mel spectrograms, followed by a Feature Attention module to weight features across segments [8]. This model achieved 73.6% accuracy, with F1-scores of 76.8% for harsh murmurs and 67.8% for blowing murmurs, illustrating the nuanced capabilities of AI in analyzing heart sound characteristics. Moreover, traditional heart sound classification methods, which often depend on ECG-labeled PCGs or feature extraction from mel-scale frequency cepstral coefficients (MFCC), have seen significant improvements with the introduction of capsule neural networks (CapsNet) [9]. CapsNet enhances feature representation through iterative dynamic routing, achieving validation accuracies of 90.29% and 91.67%, thus offering a robust alternative for heart murmur detection.

Further innovation in this field includes the development of CardioXNet, a lightweight CRNN architecture designed to detect five cardiac conditions using raw PCG signals. CardioXNet combines representation learning with parallel CNN pathways for feature extraction and sequence residual learning using bidirectional LSTMs, capturing temporal features with high accuracy and low computational requirements [10]. This model's applicability in low-resource settings on mobile devices is particularly noteworthy. Alongside these advancements, a study exploring general-purpose audio representations pre-trained on large-scale datasets for heart murmur detection

introduced the self-supervised learning method Masked Modeling Duo (M2D), which outperformed previous techniques, achieving a weighted accuracy of 0.832 and an unweighted average recall of 0.713 [7]. The effectiveness of ensembling M2D with other models demonstrates the broader applicability of general-purpose audio representations in heart sound analysis.

The continuous evolution of AI-driven heart sound analysis has also seen the integration of traditional ML methods with deep learning. A study focused on time-frequency heat maps combined with a deep CNN to detect abnormalities in heart sounds achieved commendable performance, balancing sensitivity and specificity—an essential aspect of cost-sensitive medical diagnostics [11]. Furthermore, Cardi-Net, a deep learning model combining CNN and power spectrogram analysis, was introduced to extract discriminative features from PCG signals for the multi-class classification of four cardiac disorders without pre-processing or feature engineering [13]. Enhanced by data augmentation and 10-fold cross-validation, Cardi-Net achieved 98.88% accuracy, making it suitable for real-time use across various platforms, including cloud services and mobile apps.

In a different approach, the researchers transformed PCGs into spectral images that preserved the topological structure of the original data. This transformation allowed them to leverage the power of deep convolutional neural networks (CNNs) for feature extraction. To enhance the model's performance, data augmentation techniques were employed to increase the diversity of the training data. Additionally, transfer learning was utilized to fine-tune pre-trained CNN architectures, enabling the model to learn from existing knowledge [12]. To capture the temporal dynamics of cardiac murmurs, a recurrent neural network (RNN) was integrated into the architecture. This hybrid approach resulted in a significant improvement in accuracy, achieving a remarkable 94.01% in automatic cardiac murmur detection without the need for manual segmentation. The performance of an Adaptive Neuro-Fuzzy Inference System (ANFIS) was also evaluated for detecting abnormal cardiac valve sounds using spectral analysis features. After de-noising and feature extraction through High Order Spectral (HOS) analysis, the ANFIS model achieved classification accuracy between 63-89%, highlighting its potential in specific diagnostic contexts [14]. Another significant development is the creation of a portable, low-cost system for early detection of valvular heart abnormalities, such as arrhythmias and murmurs. Designed for use by untrained frontline health workers, this system processes stethoscope sounds into spectrograms for classification via cloud-based CNN models, achieving a 95% average classification accuracy [15]. Its validation with real-life heart sounds collected using a low-cost digital stethoscope demonstrates its promise as a comprehensive diagnostic tool for enhancing healthcare in developing regions.

Moreover, studies have explored the combination of PCG and ECG waveforms for enhanced disease screening through a novel dual-convolutional neural network approach. This method introduces both record-wise and sample-wise evaluation frameworks, showing that integrating ECG and PCG data significantly outperforms single-modality methods, leveraging transferable features from separately collected ECG and PCG waveforms for improved classification accuracy [16]. The application of ensemble models combining random forest and extreme gradient boost for heart sound classification has also been explored, with the ensemble model using Moth Flame Optimization (MFO) further improving results, reaching 89.53% accuracy, 0.9 F1 score, and 0.95 AUC [17].

The field has also seen the introduction of AI-driven heart monitoring devices that screen and identify heart sounds, transmitting data to healthcare providers through the Internet of Things (IoT) [18]. These systems, which employ LSTM architectures, enable patients to self-monitor their heart health, offering a novel approach to managing coronary conditions. On the other hand, the challenge of detecting heart disease from heart sound signals with imbalanced training and testing sets has also been addressed by developing ML models using features extracted from Discrete Wavelet Transform (DWT) and Mel-Frequency Cepstral Coefficients (MFCC). The study explored various models, including Random Forest and Extreme Gradient Boost, achieving high accuracy and AUC, particularly when using an ensemble model with Moth Flame Optimization [17]. Finally, a combination of conventional feature engineering and deep learning has been employed to classify normal and abnormal heart sounds automatically. Initially, 497 features were extracted from eight domains, which were then fed into a CNN. To prevent overfitting, fully connected layers were replaced with a global average pooling layer, and class weights were adjusted to address class imbalance [19]. Using stratified five-fold cross-validation, the method achieved a mean accuracy of 86.8%, sensitivity of 87%, specificity of 86.6%, and a Matthews correlation coefficient of 72.1%, striking a balance between sensitivity and specificity.

III. Methodology

The flowchart depicted in Fig. 1 illustrates the comprehensive methodology employed in this study. It details the entire process, from data acquisition through to the final model evaluation, highlighting the structured and methodical approach taken to develop, refine, and assess the performance of the heart murmur detection models.

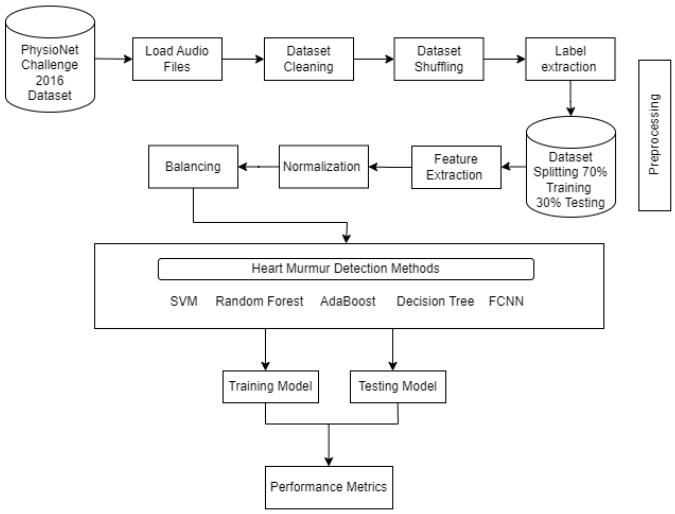

Fig. 1. Heart murmur detection model.

A. Data Collection

The PhysioNet Challenge 2016 dataset was utilized for this study [20], comprising heartbeat sounds collected from a diverse range of patients in clinical settings using electronic stethoscopes. The recordings, saved in .wav format with a sampling rate of 2 kHz, include normal heartbeats, murmurs, and other pathological conditions like extrasystole and gallop rhythms. These high-quality recordings were gathered from multiple clinical sites worldwide, ensuring a broad spectrum of acoustic environments and patient conditions. To maintain consistency and quality, standard recording protocols were adhered to, including consistent microphone placement and controlled ambient noise levels.

Each audio file is accompanied by metadata that includes labels indicating the presence or absence of heart murmurs, as diagnosed by expert cardiologists. The dataset is diverse, with recordings from patients across various age groups, genders, and clinical histories, which is crucial for developing models that generalize well across different populations. The dataset includes 3126 recordings from 764 patients, captured from different auscultation points. These recordings vary in length, allowing for the study of heart sounds over different time intervals. Despite challenges such as patient movement, breathing, and background noise, the dataset remains one of the most comprehensive publicly available collections of heart sounds, making it invaluable for research in heart murmur detection and related fields.

B. Data Preprocessing

The preprocessing of the dataset involved several critical steps to ensure the quality and suitability of the data for model training and evaluation. First, the audio files were loaded using the Librosa library in Python, which is specifically created for audio and music analysis. It offers essential tools for handling audio data, simplifying the extraction and manipulation of features, signal analysis, and the execution of tasks such as beat tracking, pitch detection, and sound classification. During this stage, any corrupted or incomplete files were identified and discarded to maintain the integrity of the dataset.

To eliminate any potential ordering bias and ensure the data is randomized, the entire dataset was shuffled. This process is essential to prevent the model from picking up unintended patterns based on the order of the data, which could skew the learning process. Shuffling helps the model avoid overfitting by not relying on the sequence of data, thereby enhancing its ability to generalize to new, unseen examples and improving overall model performance.

Following the shuffling process, labels indicating the presence or absence of heart murmurs were extracted from the accompanying metadata to create the target variable for classification tasks. The labeling method involved using predefined criteria from the metadata files, which typically included annotations from medical professionals or automated detection algorithms. This extraction was performed with meticulous care to ensure that each label was correctly aligned with its corresponding audio recording. Accurate alignment of labels and recordings is essential for reliable model training and evaluation, as it ensures that the model is learning from properly matched data and enhances the quality of the classification process.

Finally, the dataset was subsequently divided into training and test sets using stratified sampling, with 70% of the data allocated to the training set and 30% to the test set. Stratified sampling was employed to ensure that both subsets accurately reflected the original distribution of positive and negative cases. This method is crucial for addressing the dataset's inherent imbalance, as it prevents the creation of subsets that could disproportionately favor one class over the other. By maintaining proportional representation in both the training and test sets, stratified sampling helps the model learn from a balanced perspective, which enhances its ability to generalize effectively to new, unseen data. Furthermore, this approach supports a more reliable evaluation of the model's performance, reducing the risk of biased results and ensuring that both positive and negative cases are adequately represented in the testing phase.

C. Features Extraction

As discussed earlier, MFCC was selected for feature extraction due to its proven ability to represent audio signals in a form that is highly compatible with ML and DL models. MFCCs effectively capture the timbral characteristics of audio, which are crucial for distinguishing subtle variations, such as heart murmurs, that may be indicative of underlying health conditions. In addition to MFCCs, other features were extracted to provide a comprehensive representation of the audio signals. Chroma features, which capture the harmonic content of the audio, were computed, and their mean and standard deviation were calculated. Spectral contrast features, representing the difference in amplitude between peaks and valleys in the sound spectrum, were also extracted along with their mean and standard deviation. Lastly, Tonnetz (tonal centroid features), which capture the tonal properties of the audio, were computed, and their mean and standard deviation were included.

During this process, each audio recording was segmented into short frames of 25ms, with a 10ms overlap to ensure that transient features were not missed. For each frame, 13 MFCCs were computed using the librosa library, based on a filter bank that mimics the human ear's perception of sound. The resulting coefficients were chosen because they offer a balance between computational efficiency and the richness of information captured. After extracting the MFCCs, the mean and standard deviation across all frames were calculated, resulting in a fixed-length feature vector for each recording. This approach ensures that the variability within each recording is captured, while also reducing the dimensionality of the data, making it more manageable for ML and DL models.

In total, 130 features were extracted from each audio file, comprising 40 MFCCs (mean and standard deviation), 24 chroma features (mean and standard deviation), 14 spectral contrast features (mean and standard deviation), and 12 Tonnetz features (mean and standard deviation). These features collectively provide a rich and detailed representation of the heart sound recordings, enabling effective analysis and classification by the ML and DL models. MFCCs are widely favored in audio processing because they provide a compact representation of the power spectrum of sound, making them ideal for detecting subtle anomalies like heart murmurs.

Additionally, the choice of 13 coefficients aligns with common practices in speech and audio processing, where it has been empirically shown that this number provides sufficient detail for accurate modeling while avoiding overfitting. The extracted feature vectors were then normalized and fed into the ML and DL models. This step ensures consistency across recordings and enhances the models' ability to generalize from the training data to unseen examples. By leveraging these diverse features, the models can better capture the nuanced differences between normal heart sounds and those that indicate murmurs, ultimately improving the accuracy of the detection system.

D. Normalization and Balancing

Following the feature extraction process, the audio signals were normalized to achieve a zero mean and unit variance. This normalization step is crucial for ensuring consistency across the input data by removing scale differences between features. Such standardization not only enhances the overall performance of the model but also facilitates faster and more stable convergence during the training phase. By normalizing the data, we mitigate potential biases that could arise from varying signal amplitudes, thereby improving the reliability and accuracy of the model's predictions.

Moreover, an analysis of the dataset revealed a significant imbalance between normal and abnormal recordings, with normal recordings being more prevalent. This disparity could lead to the machine learning models favoring the majority class, resulting in suboptimal performance on the minority class. To address this issue, we applied techniques like the Synthetic Minority Over-sampling Technique (SMOTE) and Random Over-Sampling. SMOTE works by generating synthetic samples for the minority class. It does this by interpolating between existing minority class samples, creating new data points that lie along the line segments connecting nearest neighbors in the feature space. This method not only increases the number of minority class samples but also introduces more variability, helping to reduce the risk of overfitting. On the other hand, Random Over-Sampling (ROS) involves duplicating existing minority class samples to balance the dataset. While ROS is straightforward and effective, it can sometimes lead to overfitting because it doesn't introduce new information into the model. By combining SMOTE and ROS, we ensured a more balanced dataset, which is crucial for training models that can make unbiased and reliable predictions. This balanced approach helps the model to better generalize across both the majority and minority classes, ultimately leading to improved detection of abnormal cases in the dataset.

E. Applying the Used Methods

1) ML and DL Algorithms: The final step in the methodology involves applying a range of machine learning (ML) and deep learning (DL) techniques to the preprocessed dataset to detect heart murmurs. Specifically, we employed Support Vector Machine (SVM) [21], Random Forest (RF) [22], AdaBoost [23], Decision Tree [24], and a Fully Convolutional Neural Network (FCNN) [25] for this classification task. Each of these algorithms brings unique strengths: SVM is effective in handling high-dimensional spaces, RF and AdaBoost are robust against overfitting, and FCNN excels in learning complex patterns directly from the raw audio data. To rigorously evaluate the performance of each model in detecting heart murmurs, we calculated key metrics including accuracy, precision, recall, and F1 score. These metrics offer a comprehensive evaluation, ensuring not only the overall correctness of the models but also their capability to balance the trade-offs between false positives and false negatives, an essential consideration in the accurate detection of heart murmurs.

2) Hyperparameter tuning and architectural design: Hyperparameter tuning is a crucial aspect of any machine learning (ML) and deep learning (DL) application, as it directly impacts the model's performance by finding the optimal settings that allow the algorithm to best capture the underlying patterns in the data. For instance, in the case of Support Vector Machine (SVM), hyperparameter tuning was meticulously performed using GridSearchCV to optimize critical parameters such as C (the regularization parameter) and gamma (the kernel coefficient). The parameter C controls the trade-off between achieving a low error on the training data and minimizing the model's complexity, while gamma defines the influence of a single training example. Exploring a range of values, including C: [0.01, 0.1, 1, 10] and gamma: ['scale', 'auto'], ensured a comprehensive search of the parameter space, thereby enhancing the model's ability to generalize to new data. This systematic exploration is essential because it allows the model to adapt to the specific characteristics of the dataset, leading to improved accuracy and robustness.

Similarly, the decision tree classifier was finetuned using GridSearchCV as well to optimize parameters such as max_depth, min_samples_split, and min_ _samples_leaf. These parameters are critical for controlling the tree's growth and complexity—max_depth limits the depth of the tree to prevent overfitting, while min_samples_split and min_samples_leaf dictate the minimum number of samples required to split an internal node and to be at a leaf node, respectively. By testing values for max_depth: [5, 10, 15], min_samples_split: [2, 5, 10], and min_samples_leaf: [1, 2, 5], the decision tree was carefully tailored to achieve the optimal balance between model complexity and predictive power, ensuring that the tree was neither too simplistic nor overly complex.

In the deep learning model, constructed using TensorFlow/Keras, the architecture was designed with careful consideration of both complexity and computational efficiency. The Sequential model began with a dense input layer consisting of 256 neurons, followed by three hidden layers with 64, 32, and 16 neurons, each utilizing ReLU activation functions. To mitigate the risk of overfitting, a dropout rate of 0.5 was introduced between layers, which helped in maintaining the model's ability to generalize by randomly disabling a fraction of the neurons during training. The output layer, a dense layer with a single neuron and a sigmoid activation function, was designed to output the probability of heart murmur presence. The architectural choices were driven by the need to balance the model's ability to learn intricate patterns within the data while avoiding excessive complexity that could lead to overfitting.

The model was compiled using the Adam optimizer and binary cross-entropy loss function, chosen for their efficiency and effectiveness in binary classification tasks. Training was

conducted over 100 epochs with a batch size of 32, ensuring sufficient learning while maintaining computational feasibility. Regularization techniques, such as early stopping (with patience set to 10) and learning rate reduction (with a factor of 0.5 and patience set to 5), were employed to prevent overfitting and ensure that the model converged to an optimal solution. These strategies collectively contributed to building a robust and efficient model capable of accurately detecting heart murmurs from the given dataset.

IV. Results and Discussion

The results of this study underscore the significant advancements achieved through both traditional ML models and a DL model in detecting heart murmurs from audio recordings. The comparative analysis, as presented in the provided Table I, reveals distinct differences in performance between the ML models—Support Vector Machine (SVM), Random Forest, AdaBoost, and Decision Tree—and the deep learning model, specifically the FCNN.

The SVM model achieved an accuracy of 0.85, with corresponding F1-score, precision, and recall values of 0.84, 0.84, and 0.85, respectively as depicted in Fig. 2. While these results provide a solid baseline, they indicate that SVM struggled to handle the complexity of the data, particularly in terms of balancing precision and recall. This suggests that the model's reliance on a hyperplane for classification may not be the most effective strategy for high-dimensional, complex heart sound data, which exhibits non-linear relationships that require more flexible learning methods.

Similarly, the Decision Tree model, with an accuracy of 0.89 and matching precision and recall values, shown in Fig. 3, performed better than SVM but still exhibited limitations in fully capturing the intricate patterns within the data. This is expected, as single-tree models are prone to overfitting and fail to generalize well, especially when dealing with highly variable heart sound signals.

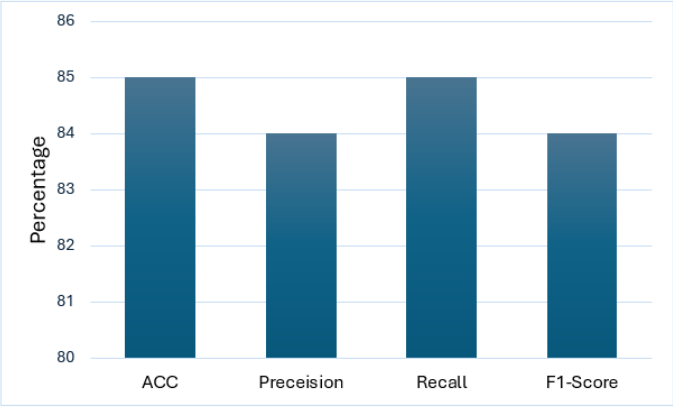

Fig. 2. SVM classification results.

In contrast, the ensemble methods, Random Forest and AdaBoost, demonstrated enhanced performance, particularly in terms of their robustness against over-fitting. The Random Forest model achieved an accuracy of 0.87, with an F1-score of 0.88, precision of 0.90, and recall of 0.87 as illustrated in Fig. 4. These results highlight the model's ability to generalize well across the dataset, benefiting from the ensemble approach's capacity to combine multiple decision trees and reduce variance. AdaBoost, with an accuracy of 0.88 and consistent F1-score, precision, and recall of 0.88, highlighted in Fig. 5, illustrates the potential of boosting techniques in improving model performance by focusing on misclassified instances. The performance improvement of AdaBoost suggests that iterative reweighting of data points can effectively guide the learning process toward difficult-to-classify cases, making it particularly valuable for datasets with subtle variations, such as heart murmurs.

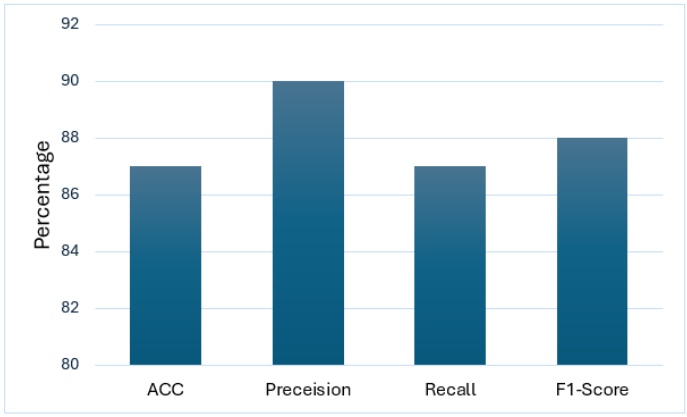

Fig. 3. Random forest classification results.

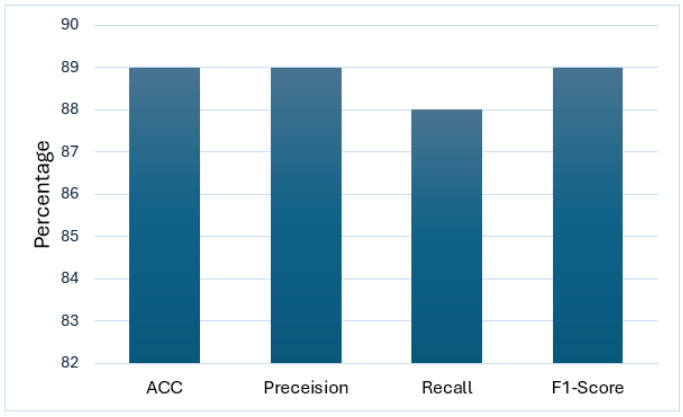

Fig. 4. AdaBoost classification results.

However, the most significant improvement was observed with the FCNN deep learning model, which outperformed all traditional ML models by a considerable margin. The FCNN achieved an impressive accuracy of 0.99, with an F1-score of 0.94, precision of 0.94, and recall of 0.96. These results displayed in Fig. 6 demonstrate the deep learning model's superior capability in capturing the complex and subtle features within the heart sound recordings that the traditional models struggled to detect. One of the key advantages of the FCNN is its ability to automatically extract hierarchical features from the raw audio data, which is particularly valuable in this study for identifying minute acoustic variations in heart murmurs that might be overlooked by traditional feature extraction methods.

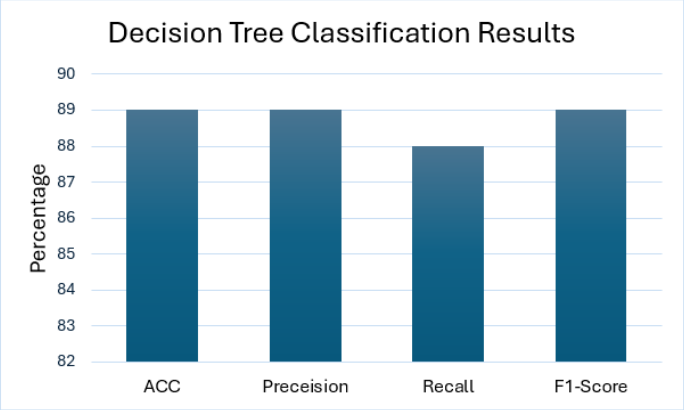

Fig. 5. Decision tree classification results.

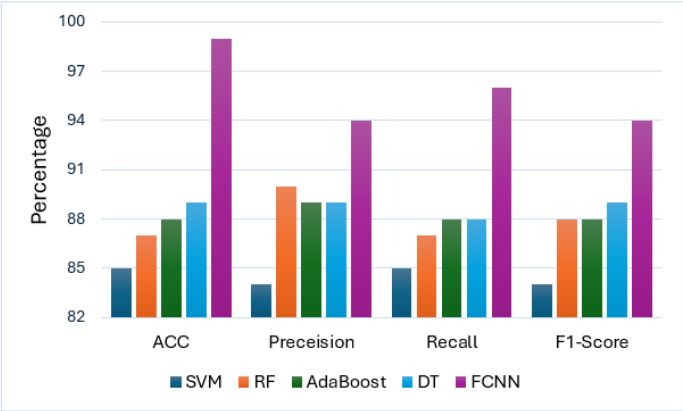

Fig. 7. Classification results of used algorithms.

The architecture of the FCNN, with its multiple hidden layers, ReLU activation functions, and dropout mechanisms, allowed for an effective learning process that minimized overfitting and maximized predictive accuracy. The use of regularization techniques such as early stopping and learning rate reduction further optimized the model's performance, ensuring that it remained both accurate and generalizable. This suggests that deep learning models not only outperform traditional approaches but also maintain stability across diverse datasets, a crucial factor for clinical adoption.

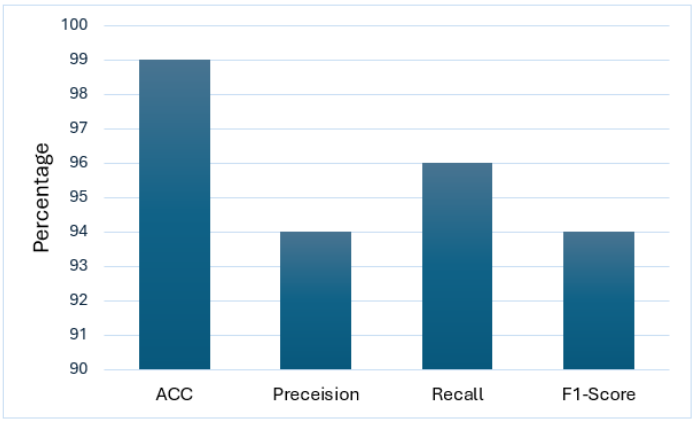

Fig. 6. FCNN Classification results.

Overall, the classification results are comprehensively displayed in Fig. 7, effectively highlighting the performance differences across all models. The drastic improvement seen in FCNN emphasizes that deep learning architectures, with their ability to handle complex feature interactions, could revolutionize heart murmur diagnostics, potentially outperforming traditional auscultation and even current ML-based methods.

These results, as compared in Table I underscore the transformative potential of deep learning models in the evolving landscape of heart murmur detection, signaling a paradigm shift from traditional machine learning approaches. The traditional models, such as Support Vector Machines (SVM), Decision Trees, and even ensemble methods like Random Forest and AdaBoost, provided a valuable baseline in this study. They demonstrated solid performance in terms of accuracy, precision, recall, and F1-score, especially when paired with techniques to manage data complexities and imbalances. However, despite these efforts and improvements, these models still fell short of the performance levels achieved by the Fully Convolutional Neural Network (FCNN).

TABLE I. PERFORMANCE COMPARISON OF ML AND DL MODELS FOR HEART MURMUR DETECTION

Model used	Accuracy	F1-score	Precision	Recall
ML				
SVM	0.85	0.84	0.84	0.85
Random Forest	0.87	0.88	0.90	0.87
AdaBoost	0.88	0.88	0.89	0.88
Decision Tree	0.89	0.89	0.89	0.89
DL				
FCNN	0.99	0.94	0.94	0.96

The superior performance of the FCNN suggests that deep learning models have a distinct advantage in handling the complexities inherent in medical data, particularly in tasks like heart murmur detection. Unlike traditional models, which often rely on manual feature extraction and struggle with high-dimensional data, deep learning models are capable of automatically learning intricate patterns from raw data. This ability is especially crucial in medical diagnostics, where subtle variations in data, such as the nuanced differences in heart sound recordings, can significantly impact patient outcomes. The FCNN's architecture, with its deep layers, ReLU activations, and regularization techniques, enabled it to capture these subtleties effectively, leading to higher accuracy and more reliable predictions.

Moreover, the FCNN's capacity to process vast amounts of data with minimal need for extensive feature engineering underscores a significant advantage of deep learning in the realm of medical diagnostics. As the healthcare industry continues to produce enormous volumes of data—from electronic health records and imaging to sensor-based monitoring—models that can efficiently analyze and learn from this data will become increasingly indispensable. The implications of these capabilities are substantial. As deep learning models consistently demonstrate their effectiveness in handling complex diagnostic tasks, they are poised to become fundamental components of medical practice, significantly improving the precision and

speed of diagnoses.

In the specific context of heart murmur detection, this technological advancement could lead to the earlier and more accurate identification of potentially life-threatening cardiovascular conditions, thereby improving patient outcomes and streamlining healthcare delivery. Furthermore, the inherent scalability of deep learning models makes them particularly well-suited for integration into comprehensive healthcare systems, including telemedicine platforms and automated diagnostic tools. This scalability ensures that their benefits can be extended across diverse healthcare settings, from remote clinics to large urban hospitals, further amplifying their impact on patient care and the overall efficiency of medical services.

V. Conclusion

This comparative study, which included both machine learning (ML) and deep learning (DL) methods, highlights the significant advancements and potential of using these techniques for the early diagnosis and detection of heart murmurs. The study utilized the PhysioNet Challenge 2016 dataset, a comprehensive collection of heartbeat sounds gathered from a diverse range of patients using electronic stethoscopes in clinical settings. This dataset, comprising over 3,000 recordings from 764 patients, provided a robust foundation for training and evaluating various models. The methodology involved several key steps, starting with the preprocessing of audio data using the Librosa library, where features such as Mel-Frequency Cepstral Coefficients (MFCCs), chroma features, spectral contrast, and Tonnetz were extracted to capture the essential characteristics of the heart sounds. Following feature extraction, the dataset was divided into training and test sets using stratified sampling to ensure balanced representation of positive and negative cases. The study then applied a range of ML and DL algorithms, including Support Vector Machine (SVM), Random Forest, AdaBoost, Decision Tree, and a Fully Convolutional Neural Network (FCNN), to classify heart murmurs. Hyperparameter tuning was meticulously performed using GridSearchCV to optimize model performance, ensuring that each algorithm was tailored to the specific characteristics of the dataset. The FCNN, in particular, demonstrated a substantial improvement in accuracy and reliability over traditional methods, underscoring the potential of DL models in this domain.

The results suggest that integrating AI-powered diagnostic tools into clinical practice could lead to earlier and more precise diagnoses, thereby improving patient outcomes and reducing the global burden of cardiovascular diseases. However, several limitations must be acknowledged. The primary challenge lies in the reliance on the dataset, which, while comprehensive, may not fully represent the variability encountered in real-world clinical settings, where factors such as diverse demographic characteristics, comorbidities, and recording environments could affect the model's generalizability. Additionally, despite the superior performance of the deep learning model, its "black box" nature poses challenges for clinical adoption, as it makes it difficult for clinicians to interpret the rationale behind specific predictions, potentially hindering trust in the model.

Furthermore, the study focused primarily on heart sounds recorded under controlled conditions, without thoroughly addressing the impact of real-world noise and artifacts, which could degrade the model's performance in actual clinical environments. To overcome these limitations and advance the field further, future research should focus on acquiring more diverse and representative datasets that include a broader range of patient demographics and clinical conditions, thus enhancing the model's generalizability. Additionally, developing personalized heart murmur detection models that take into account individual patient characteristics, such as medical history and genetic data, could lead to even more accurate and relevant predictions. Finally, efforts should be made to enhance the interpretability of deep learning models through explainable AI techniques, which could provide clinicians with better insights into the model's decision-making process and facilitate greater integration into clinical practice.

***Abstract*—The Internet of Medical Things (IoMT) is transforming healthcare through extensive automation, data collection, and real-time communication among interconnected devices. However, this rapid expansion introduces significant security vulnerabilities that traditional centralized solutions or device-level protections often fail to adequately address due to challenges related to latency, scalability, and resource constraints. This study presents a novel federated learning (FL) framework tailored for IoMT security, incorporating techniques such as stacking, federated dynamic averaging, and active user participation to decentralize and enhance attack classification at the edge. Utilizing the CICIoMT2024 dataset, which encompasses 18 attack classes and 45 features, we deploy Random Forest (RF), AdaBoost, Support Vector Machine (SVM), and Deep Learning (DL) models across 10 simulated edge devices. Our federated approach effectively distributes computational loads, mitigating the strain on central servers and individual devices, thereby enhancing adaptability and resource efficiency within IoMT networks. The RF model achieves the highest accuracy of 99.22%, closely followed by AdaBoost, demonstrating the feasibility of FL for robust and scalable edge security. While this study validates the proposed framework using a single realistic dataset in a controlled environment, future work will explore additional datasets and real-world scenarios to further substantiate the generalization and effectiveness of the approach. This research underscores the potential of federated learning to address the unique security and computational constraints of IoMT, paving the way for practical, decentralized deployments that strengthen device-level defenses across diverse healthcare settings.**

Keywords*—Internet of Medical Things (IoMT); federated learning; machine learning; security; intrusion detection systems; decentralized framework

I. Introduction

The integration of medical devices within healthcare systems, known as the Internet of Medical Things (IoMT) [1], is rapidly transforming patient care by connecting devices and applications that communicate with healthcare IT networks. This interconnected framework enhances service delivery but simultaneously raises significant security challenges, particularly concerning the protection of sensitive medical data. Unlike other constrained environments, IoMT devices operate within highly regulated healthcare settings where data privacy and real-time responsiveness are critical. Traditional centralized machine learning models are often unsuitable for IoMT applications due to stringent data privacy regulations and the necessity for efficient, localized computation.

Addressing these challenges, this study introduces a novel framework employing Federated Learning (FL) [2] and Lightweight Machine Learning (LML) [3] to enhance security while accommodating the computational limitations inherent in IoMT devices. In IoMT systems, connected medical devices gather and exchange information with healthcare infrastructure, creating a network where security and privacy are paramount [4]. Unlike centralized learning models, FL offers a decentralized approach that trains models on local data without transferring sensitive information to a central server, thereby reducing privacy risks [5]. FL is particularly advantageous for IoMT, enabling secure and private model training at the edge for applications such as patient outcome prediction and resource management [6].

However, applying FL in IoMT contexts presents unique challenges that are distinct from other constrained device scenarios. These include heterogeneous device data, non-identically distributed (Non-IID) data, limited device resources, and the complexity of securely aggregating model updates [7]. Unlike industrial IoT or consumer IoT devices, IoMT devices often handle highly sensitive and regulated data, necessitating more robust privacy-preserving mechanisms and compliance with healthcare standards. This research aims to address these IoMT-specific challenges through three advanced FL techniques—stacking, federated dynamic averaging, and active user participation—designed to improve attack detection accuracy and computational efficiency at the edge level.

The study leverages the CICIoMT2024 dataset [8], which encompasses 18 distinct attack classes and 45 features, to evaluate the effectiveness of various machine learning models, including Random Forest (RF), AdaBoost, Support Vector Machine (SVM), and Deep Learning (DL), deployed across 10 simulated edge devices. Preliminary results indicate that ensemble models, particularly Random Forest and AdaBoost, exhibit superior performance. The Random Forest model achieved an accuracy of 99.22%, precision of 99.38%, recall of 99.22%, and an F1 score of 99.09%, while AdaBoost demonstrated an accuracy of 98.59%, precision of 98.84%, recall of 98.59%, and an F1 score of 98.22%. In contrast, the Deep Learning and Support Vector Machine models attained lower accuracies of 77.59% and 65.70%, respectively.

This study contributes to IoMT security by:

1) Developing and tailoring federated learning models for IoMT: This research introduces FL models specifically adapted to address the unique security and computational constraints of IoMT devices. These adaptations enable effective deployment in resource-limited environments while maintaining high model performance and efficiency.

2) Enhancing privacy and anomaly detection in IoMT systems: By leveraging privacy-preserving techniques and robust anomaly detection methods, this study strengthens IoMT security. It safeguards patient data and provides early detection of potential threats, thereby enhancing the resilience of IoMT ecosystems.

3) Validating on realistic, open datasets in controlled testbed environments: Utilizing the CICIoMT2024 dataset within a structured testbed environment ensures that the proposed solutions are practically applicable and reliable. This approach reflects real-world IoMT scenarios, thereby enhancing the relevance and scalability of the findings.

The paper is organized as follows: Section II reviews current methodologies for securing IoMT, emphasizing FL-based solutions and providing a dataset benchmark. Section III identifies research gaps and presents motivations for this study. Section IV details the proposed approach and experimental findings. Finally, Section V concludes the study, offering perspectives on future research directions. Table I lists abbreviations used throughout the paper.

TABLE I. ABBREVIATIONS AND THEIR MEANINGS

Abbreviation	Definition
IoMT	Internet of Medical Things
FL	Federated Learning
LML	Lightweight Machine Learning
RF	Random Forest
SVM	Support Vector Machine
DL	Deep Learning
IDS	Intrusion Detection System
MQTT	Message Queuing Telemetry Transport
DoS	Denial of Service
DDoS	Distributed Denial of Service
FDA	Federated Dynamic Averaging
PFL	Personalized Federated Learning
FU	Federated Unlearning
ICS	Industrial Control Systems
IIoT	Industrial Internet of Things
BLE	Bluetooth Low Energy
SDN	Software-Defined Networking
TCP	Transmission Control Protocol
UDP	User Datagram Protocol
IGMP	Internet Group Management Protocol
HTTPS	Hypertext Transfer Protocol Secure
HTTP	Hypertext Transfer Protocol
DNS	Domain Name System
SSH	Secure Shell
SMTP	Simple Mail Transfer Protocol
IRC	Internet Relay Chat
ARP	Address Resolution Protocol
ICMP	Internet Control Message Protocol
LLC	Logical Link Control
RBF	Radial Basis Function
Non-IID	Non-Independent and Identically Distributed

II. RELATED WORK

A. Security Challenges of IoMT

Recent surveys on security in the Internet of Medical Things (IoMT) have highlighted key challenges and trends in securing healthcare systems and devices. A study by [9] surveyed healthcare organizations and found that most respondents identified data privacy and security as their top concerns, with vulnerabilities in medical devices being a significant worry. Similarly, [10] focused on healthcare professionals' perceptions of IoMT security and discovered that while there is growing awareness of security risks, many professionals lack sufficient training and resources to address these issues effectively. In contrast, [11] examined security practices among IoMT device manufacturers and uncovered a lack of standardized security protocols and insufficient investment in security measures during the development phase. Additionally, [12] analyzed the impact of regulatory frameworks on IoMT security, revealing inconsistencies in compliance requirements across different regions and highlighting the need for harmonization to ensure comprehensive security standards.

The surveys summarized in Table II underscore the complex landscape of IoMT security, emphasizing the necessity for robust security strategies, increased awareness, and collaborative efforts among stakeholders to effectively counter emerging threats.

B. Federated Learning with IoMT

Recent contributions summarized in Table III demonstrate promising advancements in applying federated learning (FL) to secure the Internet of Medical Things (IoMT). The work of [23] proposed a federated learning approach to improve intrusion detection accuracy in IoMT networks. Also, [24] developed a federated learning model for malware detection on IoMT devices with minimal data sharing. In addition, [25] introduced a privacy-preserving federated learning framework for collaborative analysis of medical data from diverse sources. Moreover, [26] presented a federated learning-based anomaly detection system to enhance security in IoMT by detecting unusual patterns in medical sensor data [27]-[30].

Related surveys and research works see Table IV.

C. Open Datasets for IoMT Security

Recent advancements in cybersecurity research have led to the development of several comprehensive datasets (as illustrated in **Table V**) tailored for specific applications within the Internet of Medical Things (IoMT) and broader network security domains. The work of [36] introduced a dynamic dataset focusing on ransomware detection and mitigation in integrated clinical environments, emphasizing the need for intelligent security solutions in healthcare settings. Furthermore, [37] and [38] provided a dataset for effective attack detection in IoMT smart environments using deep belief neural networks, highlighting the increasing complexity and variety of threats in medical IoT networks.

The HIIDS dataset, developed by [39], introduces a hybrid intelligent intrusion detection system that integrates machine learning and metaheuristic algorithms to enhance security in IoT-based healthcare applications. Similarly, [40] conducted a comparative analysis of various machine learning techniques for intrusion detection in smart healthcare systems, presenting a dataset that facilitates the evaluation of different methodologies in this critical area.

Focusing on secure wireless communications, [41] proposed a novel approach to ensuring secure Bluetooth communication in smart healthcare systems, accompanied by a community dataset and an intrusion detection system. Meanwhile, [42] introduced a security model leveraging LightGBM and transformer technologies to safeguard healthcare systems

TABLE II. OVERVIEW OF ATTACK TYPES AND RISKS IN IOT MEDICAL DEVICES. THIS TABLE SUMMARIZES VARIOUS ATTACK TYPES, THEIR RISK LEVELS, AND THE AFFECTED DEVICES WITHIN THE DOMAIN OF IOT MEDICAL DEVICES, ALONG WITH RELEVANT ACADEMIC REFERENCES FOR FURTHER READING

Attack Description	Attack Type	Risk Level	Attack Class	Affected Devices	Domain	Academic Reference
Eavesdropping	Passive Attack	Moderate	Data Breach	IoT Medical Devices	Network/Comm.	[13]
Device Tampering	Active Attack	High	Physical	IoT Medical Devices	Device Security	[14]
Data Modification	Active Attack	High	Data Breach	IoT Medical Devices	Data Security	[15]
Denial of Service (DoS)	Active Attack	High	Availability	IoT Medical Devices	Network/Comm.	[16]
Man-in-the-Middle (MitM)	Active Attack	High	MITM	IoT Medical Devices	Network/Comm.	[17]
Replay Attacks	Active Attack	Moderate	Replay	IoT Medical Devices	Network/Comm.	[18]
Insider Attacks	Active Attack	High	Insider	IoT Medical Devices	Device Security	[19]
Malware Infection	Active Attack	High	Malware	IoT Medical Devices	Software Security	[12]
Password Cracking	Active Attack	Moderate	Password	IoT Medical Devices	Authentication	[20]
Wireless Attacks (e.g., rogue AP)	Active Attack	High	Wireless	IoT Medical Devices	Network/Comm.	[21]
Social Engineering	Active Attack	Moderate	Social	IoT Medical Devices	Human Factors	[22]

TABLE III. RECENT CONTRIBUTIONS OF FEDERATED LEARNING IN SECURING IOMT

Reference	Application	Key Findings	Performance Metrics
[23]	Intrusion Detection	Federated learning approach improves intrusion detection accuracy in IoMT networks.	Detection accuracy: 95%, False positive rate: 2%
[24]	Malware Detection	Federated learning model effectively detects malware on IoMT devices with minimal data sharing.	Detection accuracy: 93%, Latency: 150ms
[25]	Privacy-Preserving Data Analysis	Federated learning preserves patient privacy while enabling collaborative medical data analysis from diverse sources.	Privacy loss: $<1\%$, Data utility: 85%
[26]	Anomaly Detection	Federated learning-based anomaly detection system enhances security in IoMT by detecting unusual patterns in medical sensor data.	Detection accuracy: 92%, Precision: 90%

from cyberattacks, offering a dataset that supports the application of advanced machine learning techniques in healthcare cybersecurity.

Additionally, the CICIoMT2024 dataset [8] addresses the growing need for securing IoMT devices in healthcare by capturing interactions over multiple protocols (HTTP, MQTT, CoAP, Bluetooth) and simulating various attack vectors. This comprehensive data source facilitates the development of robust security measures tailored to healthcare IoMT environments. Together, these datasets significantly contribute to the field by enabling the development and testing of effective security solutions to safeguard healthcare infrastructure against an evolving threat landscape.

The primary aim of CICIoMT2024 is to propose a comprehensive benchmark dataset that enables the development and evaluation of security solutions for the Internet of Medical Things (IoMT). To achieve this, 18 types of attacks were executed on an IoMT testbed comprising 40 devices, including 25 real devices and 15 simulated ones. This testbed was configured to simulate diverse protocols utilized in healthcare settings, such as Wi-Fi, MQTT, and Bluetooth.

These attacks were systematically categorized into five classes: Distributed Denial of Service (DDoS), Denial of Service (DoS), Reconnaissance (Recon), MQTT-specific attacks, and spoofing. The objective is to establish a foundational benchmark that complements existing state-of-the-art contributions in the field. Through this initiative, researchers are provided with a valuable resource for exploring and developing new security solutions tailored to the unique challenges of healthcare systems, including advanced machine learning techniques.

Significantly, the research extends beyond the mere execution of attacks on IoMT devices. It also captures the lifecycle of these devices across various critical phases, from their initial network integration to eventual disconnection. This process, known as profiling, allows classifiers to detect anomalies

TABLE IV. COMPARATIVE SUMMARY OF RELATED SURVEYS AND RESEARCH WORKS

Article	Focus	Key Contributions
Enhancing Internet of Medical Things Security with AI [1]	AI for IoMT security	Reviews AI models for threat detection in IoMT, discussing anomaly detection, pattern recognition, and predictive analytics.
Federated Learning for IoMT [5]	Federated learning in IoMT	Explores federated learning algorithms, data heterogeneity, privacy, and communication protocols in IoMT.
AI for IoMT Security with Cloud–Fog–Edge [31]	AI-driven IDS in IoMT	Covers AI-driven intrusion detection systems for real-time threat detection and integration of Cloud, Fog, and Edge computing for enhanced IoMT security.
Privacy-preserving Federated Learning with Edge [7]	Privacy in federated learning	Proposes privacy-preserving federated learning with edge computing for secure and efficient data aggregation in IoMT environments.
Fed-Inforce-Fusion: Federated Reinforcement Model [32]	Federated reinforcement learning	Combines federated and reinforcement learning to develop dynamic defense and attack mitigation strategies in IoMT.
FedDICE for Ransomware Detection [33]	Ransomware in clinical IoMT	Introduces an SDN-based model for ransomware detection and isolation, enhancing resilience and privacy in clinical IoMT environments.
Federated Learning in Medical Applications [34]	Federated learning in healthcare	Provides a taxonomy of federated learning applications in healthcare, focusing on privacy preservation, communication efficiency, and resource optimization.
OpenFL: Open-Source Federated Framework [35]	Open-source federated learning	Describes the OpenFL framework, which supports diverse data types and models while ensuring privacy, and discusses its real-world applications in IoMT.

TABLE V. COMPARISON OF DIFFERENT CYBERSECURITY DATASETS (ACCURACIES BASED ON [31], [8])

Dataset	Focus	Content	Applications	Unique Features	Accuracy
ICE [36]	ICS security	Industrial protocol traffic (Modbus, DNP3)	ICS-specific IDS, anomaly detection	Focus on industrial protocols	97% - 100%
CIC-IDS-2017 [37], [38]	Network intrusion	Various attack scenarios	IDS, ML training	Comprehensive labeled data	96% - 98%
NSL-KDD [46], [39]	Network intrusion	Traffic data with attack types (DoS, R2L, U2R, probing)	IDS benchmarking	Balanced distribution, updated version	86% - 96%
UNSW-NB15 [47], [40]	Modern network intrusion	Contemporary traffic and attacks	IDS, anomaly detection	Updated attacks, rich features	95% (avg)
BlueTack [48], [41]	Bluetooth security	Bluetooth communication, attack and normal data	Bluetooth security development	Bluetooth-specific attack data	88% - 96%
Edge-IIoT [49], [42]	Edge computing in IIoT	Edge device traffic, normal and attack data	IIoT security solutions	Emphasis on edge security	86% - 100%
CIC IoMT 2024 [8]	IoMT device security	IoMT traffic over multiple protocols	IoMT-specific IDS, anomaly detection	Healthcare IoMT protocols	70% - 99%

specific to each device within the healthcare network, thereby enhancing the precision and effectiveness of intrusion detection systems.

D. Federated Learning Methodologies

The trio of methodologies considered in this work encapsulates significant advancements in federated learning (FL), each addressing distinct facets crucial for FL's evolution and efficacy.

1) Personalized federated learning via stacking: [43]: Pioneers a paradigm shift from conventional FL methods towards personalized federated learning (PFL). It introduces a novel approach grounded in stacked generalization, enabling the creation of multiple models fine-tuned to individual clients' data. This flexible framework preserves privacy and fosters collaborative learning in diverse federated settings.

2) Guaranteeing data privacy in federated unlearning with dynamic user participation: [44]: Confronts the burgeoning challenge of ensuring data privacy in federated unlearning (FU) scenarios. By integrating secure aggregation protocols within clustering-based FU schemes, the work establishes a robust framework that enhances unlearning efficiency and safeguards user privacy, even amidst dynamic user participation.

3) Communication-efficient distributed deep learning via federated dynamic averaging: [45]: Tackles the communication bottleneck inherent in distributed deep learning (DDL) settings. By proposing Federated Dynamic Averaging (FDA), the work introduces a communication-efficient strategy that

dynamically triggers synchronization based on model variance, thereby substantially reducing communication costs without compromising convergence speed.

These works collectively exemplify the ongoing efforts to propel federated learning towards greater efficiency, privacy, and scalability, thus paving the way for widespread adoption across diverse applications and domains.

III. Research Gaps and Motivation

A. Research Gaps in Federated Learning for IoMT Security

Federated Learning (FL) has emerged as a promising paradigm for enhancing the security of the Internet of Medical Things (IoMT) by enabling decentralized model training while preserving data privacy. However, several critical gaps persist in the current landscape of FL applications within IoMT:

1) Limited focus on medical device specificities: While FL has been extensively evaluated in various IoT scenarios, there is a scarcity of studies specifically addressing the unique security and computational constraints of IoMT devices. Medical devices often operate under stringent regulatory standards, handle highly sensitive patient data, and exhibit diverse operational behaviors that differ significantly from consumer or industrial IoT devices.

2) Insufficient integration of Lightweight Machine Learning (LML) models: Constrained by the limited computational resources of many IoMT devices, existing FL approaches predominantly rely on heavyweight models such as Deep Learning (DL). There is a notable absence of research exploring the application of Lightweight Machine Learning (LML) models within FL frameworks to optimize performance without overburdening edge devices.

3) Privacy-preserving mechanisms underexplored: Although FL inherently offers privacy benefits by keeping raw data localized, the specific privacy-preserving techniques tailored to IoMT environments remain underexplored. Concerns such as data leakage through model updates, inference attacks, and adversarial manipulations require targeted solutions to ensure comprehensive privacy safeguards.

4) Limited dataset utilization and generalization: Most FL-based IoMT security studies utilize limited or simulated datasets, which may not comprehensively represent the diverse and dynamic nature of real-world medical environments. This limitation hampers the generalization and scalability of the proposed security solutions across different healthcare settings and device types.

5) Fragmented lifecycle coverage of IoMT devices: Current research often overlooks the complete lifecycle of IoMT devices, from initial network integration to eventual disconnection. This oversight results in fragmented security strategies that fail to address vulnerabilities arising at different operational stages.

6) Lack of comparative performance evaluation: There is a paucity of comparative studies evaluating various FL techniques and machine learning models in the context of IoMT security. Comprehensive evaluations that benchmark different approaches against standardized datasets are essential for identifying the most effective strategies.

Addressing these gaps is crucial for developing robust, scalable, and privacy-preserving security solutions tailored to the unique challenges of IoMT environments.

B. CICIoMT2024 Dataset Characteristics

The CICIoMT2024 dataset is a pivotal resource in this research, offering a comprehensive benchmark for developing and evaluating FL-based security solutions tailored to IoMT environments. Its key characteristics are as follows:

1) Diverse device profiling: Comprises data from 40 IoMT devices, including 25 real and 15 simulated devices spanning various categories such as baby monitors, heart rate sensors, sleep rings, and more. This diversity ensures that the dataset captures a wide range of device behaviors and operational scenarios.

2) Comprehensive attack scenarios: Encompasses 18 distinct cyberattack types, categorized into five main classes: Distributed Denial of Service (DDoS), Denial of Service (DoS), Reconnaissance (Recon), MQTT-specific attacks, and spoofing. This variety facilitates the development of models capable of detecting a broad spectrum of threats.

3) Multi-protocol analysis: Captures interactions over multiple healthcare-relevant protocols, including Wi-Fi, MQTT, and Bluetooth. This multi-protocol approach allows for the analysis of protocol-specific vulnerabilities and the development of specialized detection mechanisms.

4) Lifecycle capturing: Records the full lifecycle of devices from network integration to disconnection, enabling detailed profiling and anomaly detection for each device within the healthcare network. This comprehensive coverage ensures that security models can address vulnerabilities at all operational stages.

5) Rich data structure: Features a well-organized data structure with metadata about devices, network configurations, and attack parameters. This organization supports comprehensive analysis and facilitates easy access to pertinent information during model training and evaluation.

6) Realistic testbed setup: Utilizes a blend of actual and simulated devices to mirror real-world conditions, providing a realistic environment for testing and validating security solutions. This setup enhances the external validity of the research findings.

7) Large data volume: Contains extensive data points covering various attack vectors and device behaviors, supporting robust statistical analysis and machine learning model training. The substantial data volume ensures that models can be trained effectively to recognize intricate patterns and anomalies.

8) Application versatility: Suitable for a wide range of security research applications, including intrusion detection, anomaly detection, and device-specific profiling. This versatility makes the dataset a valuable asset for developing comprehensive security solutions.

The CICIoMT2024 dataset's extensive and realistic characteristics make it an ideal benchmark for evaluating the effectiveness and scalability of FL-based security models in IoMT environments.

C. Choice of Machine Learning and Deep Learning Models

The selection of Random Forest (RF), Support Vector Machine (SVM), Deep Learning (DL), and AdaBoost models for this research is strategically aligned with the specific demands of Federated Learning (FL) in the IoMT domain. Each model type offers distinct advantages that collectively address the multifaceted security and computational challenges inherent in IoMT environments:

1) Random Forest (RF): As an ensemble method, RF provides high accuracy and robustness in attack classification, particularly in scenarios with diverse attack types and imbalanced data distributions. Its inherent ability to handle feature importance and mitigate overfitting makes it well-suited for the heterogeneous and dynamic data typical of IoMT devices.

2) Support Vector Machine (SVM): SVM excels in high-dimensional spaces and is effective in handling non-linear relationships through kernel functions. Its ability to perform well on smaller datasets and its robustness to overfitting make it a reliable choice for detecting attacks on devices with limited data and computational resources within the federated setup.

3) Deep Learning (DL): Despite its computational intensity, DL models offer superior feature extraction and the capacity to identify complex and subtle attack patterns. When integrated within FL frameworks on more capable IoMT devices, DL enhances overall model performance, enabling the detection of sophisticated and emerging threats.

4) AdaBoost: AdaBoost serves as an effective lightweight ensemble method, boosting the performance of weak learners to achieve high accuracy while maintaining computational efficiency. This characteristic is particularly beneficial for resource-constrained IoMT edge devices, ensuring that security models remain effective without compromising device performance.

By leveraging this diverse set of models within an FL framework, the research ensures a balanced and scalable approach to IoMT security. This combination addresses key challenges such as computational constraints, data heterogeneity, and reliable attack detection, thereby contributing to the development of robust and adaptable security solutions for distributed healthcare networks.

D. Synthesis of Research Goals

Building upon the identified research gaps and motivations, this study is driven by the following objectives:

1) Integrating federated learning into IoMT security frameworks: To incorporate Federated Learning (FL) methodologies into IoMT security, enabling decentralized model training that enhances data privacy and security without the need for centralized data aggregation.

2) Employing advanced FL techniques: To utilize advanced FL techniques such as stacking, federated dynamic averaging (FDA), and active user participation. Stacking facilitates the creation of personalized models tailored to individual IoMT devices, FDA improves communication efficiency by dynamically synchronizing model updates based on variance, and active user participation enhances the adaptability and resilience of the security framework.

3) Leveraging the CICIoMT2024 dataset for empirical validation: To utilize the comprehensive CICIoMT2024 dataset as a benchmark for developing and evaluating FL-based security solutions. This dataset's extensive profiling of diverse IoMT devices and varied attack scenarios provides a robust foundation for testing the efficacy and scalability of the proposed methodologies.

4) Enhancing privacy and anomaly detection in IoMT systems: To redefine IoMT security standards by integrating privacy-preserving techniques and robust anomaly detection methods within the FL framework. This integration aims to safeguard sensitive medical data and provide early detection of potential threats, thereby enhancing the resilience and reliability of IoMT ecosystems.

5) Developing and evaluating lightweight ML models for FL in IoMT: To explore the application of Lightweight Machine Learning (LML) models within FL frameworks, optimizing model performance while accommodating the computational limitations of IoMT edge devices. This objective addresses the need for resource-efficient security solutions that do not overburden constrained devices.

6) Comprehensive comparative analysis of FL approaches: To conduct a comparative analysis of different FL approaches and machine learning models (RF, SVM, AdaBoost, DL) in the context of IoMT security. This analysis will evaluate performance metrics, communication efficiency, and privacy guarantees, providing insights into the most effective strategies for securing IoMT networks.

Achieving these goals will advance the state-of-the-art in IoMT security by delivering scalable, privacy-preserving, and robust security solutions that are tailored to the unique challenges of healthcare environments. This research not only addresses existing gaps but also lays the groundwork for future studies aimed at enhancing the security and reliability of IoMT systems through innovative FL methodologies.

IV. Main Approach and Experiments

A. Data Preparation and Preprocessing

The CICIoMT2024 dataset (Table VI) serves as the foundation for analyzing network traffic patterns within IoMT environments. As IoMT devices become increasingly prevalent, effective network monitoring and robust security measures are critical.

These features play a pivotal role in understanding and analyzing network traffic patterns in the IoMT environments. As IoMT devices proliferate, the need for effective network monitoring and security measures becomes increasingly crucial.

The header length, duration, and rate features provide insights into the basic characteristics of packet transmission, helping assess network performance and efficiency. Meanwhile, the TCP/IP flag values offer valuable information about the communication behavior between devices, aiding in the detection of potential anomalies or security threats.

Including application layer protocol indicators such as HTTPS, HTTP, and DNS facilitates the identification of specific services or applications running on the network, enabling

TABLE VI. FEATURE DESCRIPTION OF THE CICIOMT2024 DATASET

Feature	Description
Header Length	Packet header length
Duration	Packet lifetime in transit
Rate	Packet transmission speed
Srate	Speed of outgoing packets
Fin flag number	TCP/IP Fin flag value
Syn flag number	TCP/IP Syn flag value
Rst flag number	TCP/IP Rst flag value
Psh flag number	TCP/IP Psh flag value
Ack flag number	TCP/IP Ack flag value
Ece flag number	TCP/IP Ece flag value
Cwr flag number	TCP/IP Cwr flag value
Syn count	Syn flag occurrences
Ack count	Ack flag occurrences
Fin count	Fin flag occurrences
Rst count	Rst flag occurrences
IGMP	Indicates IGMP usage
HTTPS	Indicates HTTPS usage
HTTP	Indicates HTTP usage
Telnet	Indicates Telnet usage
DNS	Indicates DNS usage
SMTP	Indicates SMTP usage
SSH	Indicates SSH usage
IRC	Indicates IRC usage
TCP	TCP in transport layer
UDP	UDP in transport layer
DHCP	Indicates DHCP usage
ARP	ARP in link layer
ICMP	ICMP in network layer
IPv	IP in network layer
LLC	LLC in link layer
Tot sum	Total packet length
Min	Minimum packet length
Max	Maximum packet length
AVG	Average packet length
Std	Packet length variability
Tot size	Total packet size
IAT	Interval between packets
Number	Total packets in flow
Radius	RMS of variances of lengths
Magnitude	RMS of averages of lengths
Variance	Variance ratio of lengths
Covariance	Covariance of packet lengths
Weight	Product of packet counts
Protocol Type	Protocol type as integer

administrators to monitor and manage traffic more effectively. Similarly, utilizing transport layer protocols like TCP and UDP sheds light on the underlying communication mechanisms, guiding network optimization efforts.

Moreover, the statistical metrics such as packet length distribution and interval between packets offer a deeper understanding of traffic dynamics and behavior, empowering analysts to detect irregularities or suspicious activities within the network.

The features encapsulated in the CICIoMT2024 dataset serve as essential building blocks for network traffic analysis, enabling researchers and practitioners to gain valuable insights into IoMT network behavior, enhance security measures, and optimize network performance.

Fig. 1 represents an extract from [8] illustrating the number of instances of each class (The "Attack" column indicates the classes used for classification)

Class	Category	Attack	Count
BENIGN	-	-	230339
ATTACK	SPOOFING	ARP Spoofing	17791
	RECON	Ping Sweep	926
		Recon VulScan	3207
		OS Scan	20666
		Port Scan	106603
	MQTT	Malformed Data	6877
		DoS Connect Flood	15904
		DDoS Publish Flood	36039
		DoS Publish Flood	52881
		DDoS Connect Flood	214952
	DoS	DoS TCP	462480
		DoS ICMP	514724
		DoS SYN	540498
		DoS UDP	704503
	DDoS	DDoS SYN	974359
		DDoS TCP	987063
		DDoS ICMP	1887175
		DDoS UDP	1998026

Fig. 1. Number of instances in each class of the CICIoMT2024 dataset.

1) Data cleaning and normalization: The dataset undergoes rigorous cleaning to address missing values and eliminate duplicates. Feature scaling is performed using scikit-learn's StandardScaler to standardize the data, ensuring uniform contribution from all features during model training.

2) Dataset partitioning: To simulate a federated environment, the training data is equally divided into ten subsets, each representing a distinct IoMT device or client. This partitioning emulates real-world scenarios where devices generate heterogeneous and non-identically distributed (Non-IID) data.

B. Testing Environment and Methodology

1) Development tools: The experiments are conducted using Python 3.11.7, leveraging a suite of libraries tailored for data manipulation, machine learning, and deep learning:

- pandas for data manipulation and analysis.
- numpy for numerical computations.
- scikit-learn for machine learning models and preprocessing.
- TensorFlow with Keras API for deep learning model development.
- seaborn and matplotlib for data visualization.

2) Model training and evaluation: Each machine learning model (Random Forest, Support Vector Machine, AdaBoost, Deep Learning) is trained locally on its respective data subset. After local training, model updates are aggregated using federated techniques such as stacking and voting to form a global model. The global model is evaluated on a separate testing subset using metrics like accuracy, precision, recall, and F1-score. Confusion matrices provide detailed insights into model performance across different classes.

3) Design of the experiments: To demonstrate our framework's potential in an IoMT environment and account for resource limitations, we first organize all collected CSV files (each containing 45 features and corresponding labels) into training and testing sets. Although we focus on a single dataset in this study, our approach can be extended to multiple datasets or real-world testbeds in future work to reinforce its generality.

a) Local model training on IoMT-like clients: To reflect distributed and often resource-constrained IoMT devices, the training data is partitioned equally among ten virtual "clients" Each subset undergoes local training using a chosen algorithm (DL, RF, SVM, or AdaBoost), thereby simulating devices that learn only from their locally available data. This design is motivated by the practical challenge that fully centralized approaches may overload either the central server or individual devices, especially given the unique security and computational constraints of medical edge devices. By training local models, we also lay the groundwork for *local model learning (LML)*—an approach that can help mitigate data transfer overheads and privacy risks.

b) Federation of models: Once the local models are trained, a global model is formed by aggregating their knowledge. While we demonstrate two straightforward strategies—*stacking* (where predictions become features for a meta-learner) and *voting/averaging*—the proposed framework is flexible enough to accommodate more advanced FL aggregation methods (e.g. Federated Dynamic Averaging). Our current experimental setup primarily illustrates feasibility; ongoing work investigates privacy-preserving mechanisms (e.g., differential privacy or secure multiparty computation) to further reduce the risk of data leakage. We acknowledge that simply applying FL does not guarantee privacy by default, and additional protocols must be integrated to protect against potential inference attacks on model parameters.

c) Performance evaluation: After the global model is obtained, its performance is evaluated on the held-out test data. Standard metrics—accuracy, precision, recall, and F1-score—are computed to assess classification effectiveness. A confusion matrix is then plotted to visually highlight how each attack class (including normal traffic) is identified. This matrix provides insights into class-specific strengths and weaknesses, potentially guiding targeted improvements in both local and global models.

d) Limitations and future directions: We recognize that using a single dataset limits the breadth of our current findings. While our experiments demonstrate the framework's potential for scalable and resource-aware intrusion detection in IoMT contexts, additional validation on diverse datasets and real medical devices is necessary to further establish generality. Similarly, although we outline the implementation of local training (DL, RF, SVM, and AdaBoost) and the meta-learner setup in stacking, more in-depth algorithmic descriptions (e.g. specific hyperparameters or protocols for secure model updates) could be provided in a subsequent extension of this work. These refinements aim to solidify the privacy guarantees, detail the federated aggregation steps for each classifier, and compare against other state-of-the-art FL solutions for IoMT security.

Algorithm 1 summarizes the key steps of the methodology, reflecting our focus on adapting FL techniques to address IoMT-specific constraints and security considerations, while acknowledging the need for future enhancements in privacy protection and broader scenario testing.

Algorithm 1 Federated Learning Methodology for IoMT Security

Step 1: Data Loading and Preprocessing
Load CSV files (each with 45 features).
Split data into training & testing sets.
Step 2: IoMT-like Client Simulation
Partition training data into 10 frames simulating 10 IoMT clients.
Step 3: Local Model Training
for each client (data frame) **do**
    Train a local model (DL, RF, SVM, or AdaBoost).
    Save local model parameters/predictions.
end for
Step 4: Model Federation
Option 1: Stacking
Generate predictions from each local model on the testing data.
Aggregate predictions into a meta-learner for final classification. **or**
Option 2: Voting or Averaging
Combine individual predictions by majority vote or averaging.
Step 5: Global Model Evaluation
Compute performance metrics (accuracy, precision, recall, F1-score).
Plot confusion matrix to visualize classification outcomes.
Step 6: Future Extensions
Incorporate privacy-preserving techniques (e.g., differential privacy).
Validate on multiple datasets & real testbed scenarios.

C. Federated Learning with Deep Learning

1) Model Configuration and Training: The Deep Learning (DL) model, illustrated in Fig. 2, employs a Sequential architecture optimized for efficiency:

- Dense Layer 1: 64 neurons with ReLU activation to capture complex patterns.
- Dense Layer 2: 32 neurons with ReLU activation for feature refinement.
- Output Layer: Softmax activation for multiclass classification.

2) Training parameters:

- Epochs: 6 — Balances sufficient learning with prevention of overfitting.
- Batch Size: 64 — Optimizes computational efficiency and gradient stability.
- Learning Rate: 0.001 — Ensures controlled convergence using the Adam optimizer.

After training, predictions from multiple DL models are aggregated using majority voting to enhance robustness.

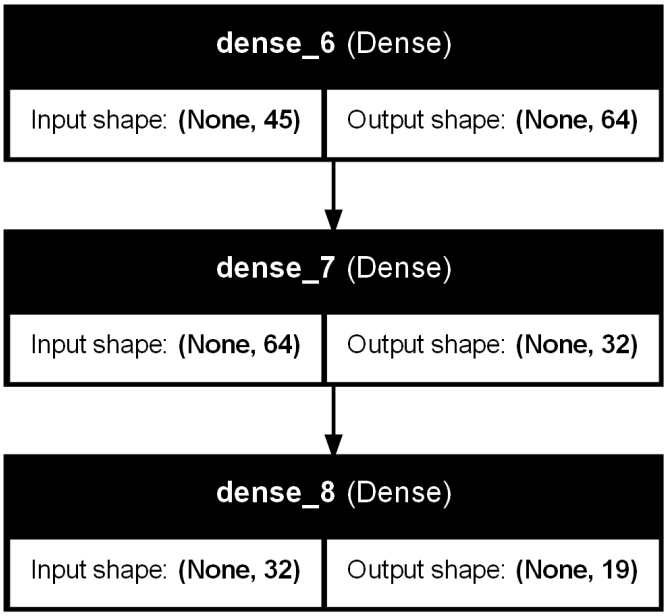

Fig. 2. Deep learning model architecture.

D. Federated Learning with Support Vector Machine (SVM)

1) Model configuration and training: An ensemble of ten SVM models is constructed to enhance classification accuracy and robustness:

- Preprocessing: StandardScaler normalizes features.
- Classifier: SVC with RBF kernel, C=1.0, gamma='scale' to handle non-linear relationships.

Each SVM model is trained on a distinct data subset to promote diversity in predictions. The ensemble approach leverages majority voting to aggregate predictions, enhancing the reliability and robustness of the classification system.

E. Federated Learning with AdaBoost

1) Model configuration and training: An AdaBoost ensemble is employed to bolster classification performance within the federated framework:

- Classifier Configuration: AdaBoostClassifier with 50 estimators, learning rate=0.1, and random state=42.

2) Ensemble strategy:

- Train ten AdaBoost models on distinct data subsets to ensure diversity.
- Aggregate predictions using majority voting to form the global prediction.

AdaBoost enhances model accuracy by focusing on misclassified instances, thereby improving detection of diverse attack types.

F. Federated Learning with Random Forest (RF)

1) Model configuration and training: Random Forest (RF) is leveraged for its robustness and scalability within the federated learning framework:

- Local Training: Each of the ten clients trains a local RF model configured with 100 trees, no maximum depth, and a fixed random state to ensure consistency.

2) Federated aggregation and privacy preservation:

- Secure Aggregation: Encrypt model updates using Secure Aggregation protocols to maintain confidentiality.

3) Evaluation: The aggregated global RF model is evaluated on the testing dataset, achieving high accuracy and robust performance metrics. The confusion matrix (Fig. 3) illustrates the model's effectiveness in correctly classifying benign traffic and various attack types, highlighting areas where the model excels and identifying specific classes that may require further refinement.

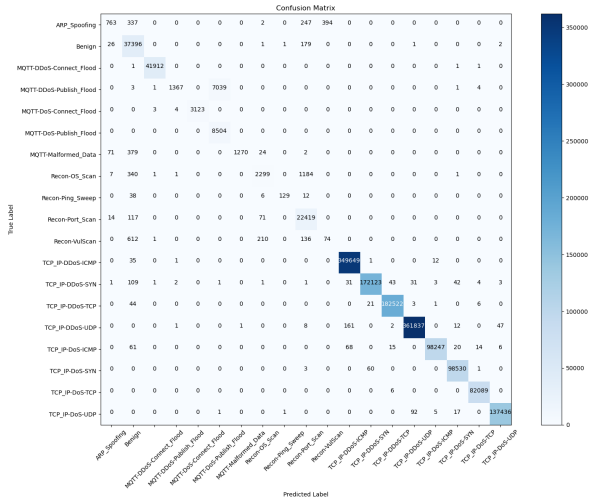

Fig. 3. Confusion matrix for random forest with stacking federated learning.

G. Performance Evaluation and Results

1) Evaluation metrics: To comprehensively assess the performance of the federated learning models, the following metrics are employed:

- Accuracy: Overall correctness of the model.
- Precision: Proportion of true positive detections.
- Recall (Sensitivity): Ability to identify all relevant instances.
- F1-Score: Harmonic mean of precision and recall.

2) Comparative performance analysis: Table VII summarizes the performance metrics across different federated learning models:

Discussion:

- Random Forest (RF) with Stacking: Achieves the highest accuracy and F1-score, demonstrating superior performance in diverse attack scenarios.

- Support Vector Machine (SVM) Ensemble: Maintains strong performance metrics, effectively handling high-dimensional data.
- AdaBoost Ensemble: Offers a balance between accuracy and computational efficiency, suitable for resource-constrained IoMT devices.
- Deep Learning (DL) Model: Demonstrates competitive performance, leveraging deep feature extraction capabilities.

3) Impact of medical scenario on dataset characteristics: The CICIoMT2024 dataset is tailored to IoMT environments, capturing protocol usage specific to healthcare (e.g. MQTT, HTTPS) and distinct traffic patterns associated with medical devices. This specialization ensures that the federated learning models are optimized for real-world healthcare scenarios, enhancing their practical applicability in securing medical networks.

4) Confusion matrix analysis: Fig. 3 illustrates the confusion matrix for the RF model with stacking. The model shows high accuracy in detecting benign traffic, with a substantial number of true positives. Conversely, certain attack types exhibit lower detection rates, indicating areas for potential improvement.

Explanation of results:

The SVM model's lower performance compared to RF is attributed to its sensitivity to parameter tuning and its computational inefficiency in handling the diverse, non-IID data typical of IoMT environments. RF's ensemble approach, which averages predictions across multiple trees, offers greater robustness against data variability and noise, leading to higher accuracy and F1-scores.

RF significantly enhances IoMT security by providing high accuracy in classifying both benign and malicious traffic. Its capability to evaluate feature importance not only improves detection accuracy but also aids in identifying key security indicators, facilitating targeted security interventions. Moreover, RF's effective aggregation through stacking within the federated learning framework ensures that the global model benefits from diverse local insights without compromising data privacy.

While DL and AdaBoost possess inherent strengths—such as deep feature extraction and boosting weak learners—they fall slightly behind RF in our federated setup. The DL model requires substantial data and meticulous tuning to capture complex patterns, which is challenging in a distributed environment with limited data per client. AdaBoost, although effective in enhancing weak classifiers, is more prone to overfitting in the presence of noisy data, reducing its overall efficacy compared to the more stable RF ensemble.

Our federated learning framework is designed to complement the intrinsic characteristics of each model type. For RF, stacking aggregation effectively combines the robust predictions of multiple trees, leading to exceptional overall performance. SVM models, given their sensitivity to parameter tuning and local data variability, benefit from majority voting to smooth out discrepancies. AdaBoost's focus on hard-to-classify instances is best aggregated via voting, ensuring that these critical insights are not diluted. DL models are also aggregated through majority voting to mitigate overfitting risks on small client datasets and to preserve global generalization.

H. Results and Takeaways

Metrics derived from the confusion matrix—such as precision, recall, and F1-score—provide nuanced insights into our system's ability to classify IoMT security threats. Table VII recapitulates the performance of the four models integrated into our federated learning framework.

Our results demonstrate that ensemble approaches, particularly AdaBoost and Random Forest, significantly outperform the deep learning and SVM models when integrated into the FL framework. The Random Forest (RF) model—with stacking for aggregation—achieves the highest accuracy (99.22%) and F1-score (99.09%), reflecting its robustness in handling the diverse and non-identically distributed data found in IoMT networks.

Key takeaways include:

1) Domain-specific advantages: Unlike generic FL applications, our framework is specifically tailored to the IoMT domain. The CICIoMT2024 dataset captures healthcare-specific protocols (e.g. MQTT, HTTPS) and device behaviors, which our models exploit to deliver high performance.

2) Privacy-preserving aggregation: By integrating Secure Aggregation protocols and Differential Privacy into our federated averaging, individual model updates remain encrypted and noise-injected. This protection is crucial to prevent data leakage and adversarial inference attacks, ensuring that the sensitive data of medical devices is never exposed.

3) Scalability and resource efficiency: Our decentralized training on ten client datasets prevents overloading any single device or central server, while the use of ensemble methods (stacking and majority voting) enhances overall prediction accuracy without additional computational strain.

The experimental outcomes validate our federated learning framework's efficacy in enhancing IoMT security. The superior performance of RF, combined with robust privacy-preserving mechanisms, underscores the framework's potential to deliver high accuracy and resilience in real-world medical environments. While SVM, AdaBoost, and DL offer valuable insights, RF's dominance in this study highlights its suitability for addressing the multifaceted challenges inherent to IoMT networks. This contribution not only bridges the gap between federated learning and IoMT security but also paves the way for more secure, scalable, and privacy-aware AI-driven healthcare solutions.

V. Conclusion and Future Directions

This paper presents a domain-specific federated learning approach for addressing the unique security and privacy challenges of the Internet of Medical Things (IoMT). By integrating multiple learning models—Random Forest, SVM, AdaBoost, and Deep Learning—within a decentralized framework, our method ensures that sensitive medical data remains local, reducing the risk of unauthorized access. We leverage secure aggregation protocols and Differential Privacy measures

TABLE VII. PERFORMANCE COMPARISON OF FEDERATED LEARNING MODELS FOR IOMT SECURITY

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Deep Learning (DL)	77.59	74.96	77.59	71.45
Support Vector Machine (SVM)	65.70	66.40	65.70	58.53
AdaBoost	98.59	98.84	98.59	98.22
Random Forest (RF)	99.22	99.38	99.22	99.09

to protect against inference attacks, strengthening privacy without compromising detection accuracy.

Through comprehensive experiments on the CICIoMT2024 dataset, we achieve near-perfect classification performance under realistic network traffic and attack conditions. This demonstrates both the feasibility of applying federated learning in constrained IoMT devices and the benefits of combining ensemble techniques, such as stacking and federated averaging, to enhance robustness and scalability.

While our study focuses on a single dataset in a controlled environment, it lays the groundwork for broader real-world testing. Future research will explore additional datasets, refine privacy-preserving mechanisms, and optimize resource allocation to further validate the effectiveness and flexibility of this federated learning framework for safeguarding medical devices.

***Abstract*—Relation extraction is the foundation of constructing knowledge graphs, and Chinese relation extraction is a particularly challenging aspect of this task. Most existing methods for Chinese relation extraction rely either on character-based or word-based features. However, the former struggles to capture contextual information between characters, while the latter is constrained by the quality of word segmentation, resulting in relatively low performance. To address this issue, a Chinese relation extraction model enhanced with external knowledge for semantic understanding is proposed. This model leverages external knowledge to improve semantic understanding in the text, thereby enhancing the performance of relation prediction between entity pairs. The approach consists of three main steps: first, the ERNIE pre-trained language model is used to convert textual information into dynamic word embeddings; second, an attention mechanism is employed to enrich the semantic representation of sentences containing entities, while external knowledge is used to mitigate the ambiguity of Chinese entity words as much as possible; and finally, the semantic representation enhanced with external knowledge is used as input for classification to make predictions. Experimental results demonstrate that the proposed model outperforms existing methods in Chinese relation extraction and offers better interpretability.**

***Keywords*—Chinese relation extraction; knowledge graph; external knowledge; semantic understanding; attention mechanism**

I. Introduction

Relation extraction is a critical subtask of information extraction, aiming to identify relationships between entity pairs from unstructured text based on semantic understanding. It plays a significant role in the construction of knowledge graphs. As an essential branch of relation extraction, Chinese relation extraction is crucial for downstream tasks such as Chinese semantic understanding and Chinese knowledge base construction. However, the complexity of Chinese semantics and the diversity of meanings in Chinese words have limited research in this area. Instead, most scholars have focused on relation extraction in English texts, which benefit from more abundant datasets. In practice, however, Chinese text is more commonly encountered. With the growing volume of Chinese text data, Chinese relation extraction technology can better meet real-world needs and serves as a key module in building Chinese knowledge bases[1]. Therefore, it is particularly important to develop an efficient and robust Chinese relation extraction model.

*Corresponding authors.

Currently, most researchers focus on relation extraction in English texts [2] [3], but the large volume of Chinese text demonstrates the necessity of advancing Chinese relation extraction. Its progress will directly impact the level of Chinese knowledge graph construction and indirectly promote the development of Chinese corpora. Thus, the construction of effective Chinese relation extraction models is a significant task. This paper conducts research on Chinese relation extraction models to address these challenges.

Compared to English relation extraction, Chinese text presents unique and significant challenges. First, Chinese text is semantically rich but structurally less rigid than English text. Second, Chinese relies heavily on function words to connect sentences or clauses, while English typically conveys sentence semantics and structures through word order. These challenges underscore the importance of understanding sentence semantics in Chinese relation extraction. For example, as shown in Fig. 1, consider the sentence “牛顿研究所有苹果” (“Newton Research Institute has apples”). The relationship between the entities “牛顿” (“Newton”) and “苹果” (“apple”) depends on the quality of word segmentation. For instance, the segmentation “牛顿/研究/所有/苹果” (“Newton/studies/all/apple”) suggests the relationship “study,” while the segmentation “牛顿/研究所/有/苹果” (“Newton/research institute/has/apple”) suggests the relationship “ownership.” Both segmentation results are valid when the sentence is isolated. Furthermore, the word “苹果” (“apple”) has two possible meanings: “fruit apple” and “Apple Inc.” Both interpretations are valid in the context of the sentence, but this ambiguity is a common challenge in Chinese text. These challenges impose higher requirements on Chinese relation extraction models. First, word segmentation must incorporate dynamic word embeddings, meaning segmentation must adapt to the context of the sentence. Second, attention mechanisms should be employed to capture not only the semantic meaning of entities but also the information from the sentence and the entire text. This ensures accurate word meanings and effectively resolves ambiguity.

Our paper proposes a Chinese relation extraction model enhanced with external knowledge for improved semantic understanding. First, the Chinese sentence containing the target entities is fed into the ERNIE [4] pre-trained model to obtain dynamic word embeddings. Then, an attention mechanism [5] is used to further enrich the semantics of the sentence where the entities are located, generating vector representations that incorporate sentence information. To further reduce ambiguity in Chinese words and enhance semantic understanding, the

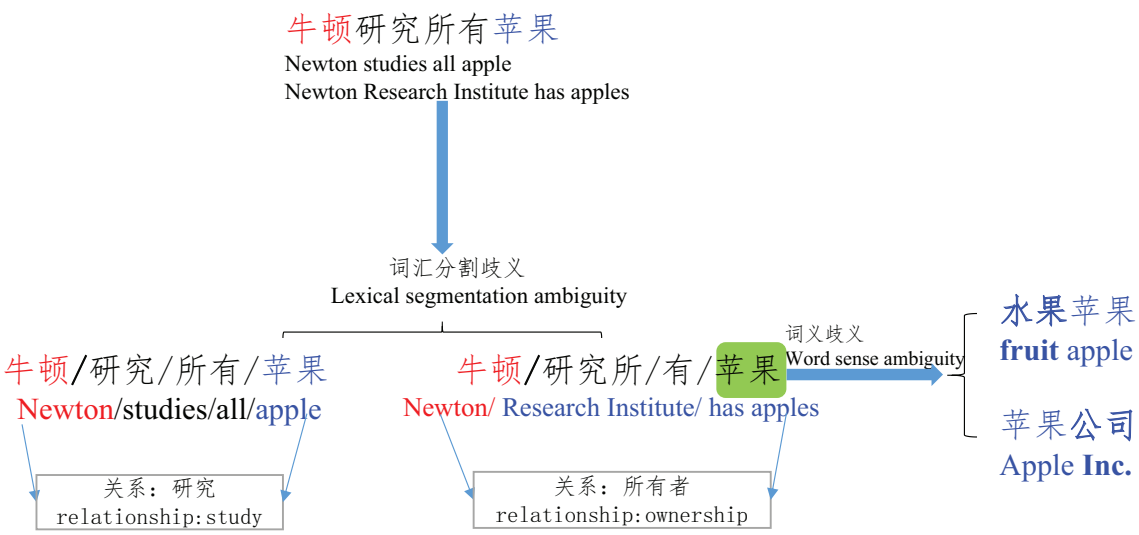

Fig. 1. Chinese relation extraction example.

model incorporates external knowledge, allowing the entities to refine their representations under the guidance of this external knowledge. These stages specifically address the challenges of insufficient entity semantics and entity ambiguity in Chinese relation extraction, enabling the model to pass richer semantic information to the classifier and achieve better performance in Chinese relation extraction. The proposed model was evaluated on a Chinese relation extraction dataset. Experimental results demonstrate that the model outperforms existing Chinese relation extraction methods.

II. Related Work

In recent years, neural networks and deep learning technologies have been widely and deeply applied, leading to rapid advancements in Chinese relation extraction within the field of natural language processing. Consequently, the number of studies and publications on Chinese relation extraction has been steadily increasing. The construction methods for relation extraction models can generally be categorized into two types: models based on traditional neural networks and models based on pre-trained language models.

A. Models Based on Traditional Neural Networks

In traditional neural network-based models, Convolutional Neural Networks(CNN) and Recurrent Neural Networks(RNN) are primarily applied. Liu et al. [6] were pioneers in proposing the use of CNNs to learn semantic features from text for relation extraction. Subsequent researchers enriched and extended CNNs, proposing models such as CNNs with max-pooling [7] and CNNs enhanced with attention mechanisms [8]. Although CNN-based models possess unique advantages in parallel computing, they exhibit significant shortcomings in semantic understanding and contextual modeling for Chinese text. Following this, researchers shifted their focus to RNNs. Zhang et al. [9] were among the first to apply RNNs to relation extraction models, achieving improved extraction performance. As a variant of RNNs, Long Short-Term Memory(LSTM) networks have also been widely used in Chinese relation extraction. Zhang and Yang [10] proposed the Lattice+LSTM model, which incorporates lexical information into the LSTM framework to better address the integration of character and word-level features. However, the model's performance in word segmentation remained constrained by the quality of word segmentation. To address this issue, Li et al. [11] proposed a multi-granularity lattice framework that leveraged potential semantic information from both characters and character sequences as input, thereby mitigating some ambiguity issues in entities. Similarly, Gao et al. [30] introduced the MGLT model, which integrates external lexical information and self-matching of lexical meanings to combine word-level features with their associated semantics, alleviating ambiguities in text.

Despite these advancements, traditional neural networks face inherent disadvantages when handling long-distance dependencies between entity pairs. As a result, an increasing number of researchers have turned to pre-trained language models to address the challenges of long-distance dependencies in Chinese relation extraction. This evolution reflects the shift from traditional approaches to more sophisticated techniques that leverage the power of pre-trained models for enhanced performance and contextual understanding in Chinese relation extraction.

B. Models Based on Pre-trained Language Models

In recent years, pre-trained language models have achieved remarkable success in the field of natural language processing, delivering superior performance in Chinese relation extraction tasks. To address the issues of character information loss and the inability to share lexical information in Li et al. [11] LSTM-based model, Kong et al. [12] proposed a hybrid approach combining LSTM and BERT [13] at the encoding layer. This method allows the character representations to include all matched lexical information, thereby mitigating the problem of information loss.

Eberts and Ulges [14] proposed a relation extraction model based on the pre-trained language model BERT, which incorporates the concept of spans. However, calculating the spans

between every pair of characters results in high computational complexity. Zhong and Chen [15] introduced a model that uses two different encoders BERT and ALBERT [16] to independently learn features for entities and relationships. While using different encoders facilitates the representation of distinct features, it disrupts information sharing between entity representation and relation extraction. Zhou and Chen [17] proposed techniques to improve entity representation for enhanced extraction performance. Their model utilized BERT and RoBERTa [18] as encoders, with RoBERTa offering comprehensive optimizations over BERT, such as dynamic masking and sentence-level input. Cui et al. [19] introduced MacBERT, a further improvement over BERT, which demonstrated better results than RoBERTa in Chinese relation extraction. However, MacBERT still lacks external knowledge, making it less effective at resolving word sense disambiguation.Yang et al. [20] proposed a hybrid expert framework with BERT as the encoder. This framework dynamically learns multi-perspective semantic features by combining different granularities and views with the pre-trained model, which benefits Chinese relation extraction. Zhao et al. [21] introduced an ambiguity feedback mechanism to address word ambiguity, combining CNN and RoBERTa in the encoding module to effectively represent multi-granular information features. However, the performance of word-based representations was found to be inferior to character-based representations. Although models that integrate character and word-level features address the disadvantages of each approach, their use of contextual information remains limited. This results in unclear semantic representations for entities, leading to ambiguity. In 2019, Baidu introduced ERNIE [4], an improvement on BERT tailored for Chinese text. ERNIE incorporates masked training on continuous entity words and phrases to learn better semantic knowledge, thereby improving performance. However, it still falls short in addressing word sense disambiguation effectively.

Methods based on pre-trained language models have achieved more competitive performance, but two problems remain to be addressed. The first issue is that, although later pre-trained language models can convert input sequences into dynamic vector representations, thereby alleviating the problem of polysemy to some extent, they still fail to fully capture the in-depth understanding of word meanings in sentences, which is the foundation of Chinese relation extraction. The second issue is that the semantic information contained in target entities within sentences is still relatively insufficient, and in some cases, the representation of entities remains ambiguous, ultimately affecting relation extraction performance. Our model provides specific solutions to these two issues. For the first issue, the current ERNIE pre-trained model can effectively address word vector representation problems; however, relying solely on the ERNIE model is not enough. Attention mechanisms should be further utilized for downstream tasks to address the thin representation of word meanings and semantics. By emphasizing important words and the interdependencies between words in dynamic vectors through weighted attention, the semantic understanding of the model can be enhanced. For the second issue, to better avoid ambiguity in target entities, the assistance of external knowledge is required. External knowledge can provide supplementary context when entities are ambiguous, enriching the semantic representation of sentences. By addressing these two critical issues, the model ultimately enhances the semantic representation of entities and improves the performance of Chinese relation extraction.

III. Model

The proposed model framework, as shown in Fig. 2 is mainly divided into three levels: the encoding layer, the semantic understanding layer, and the classification layer. In the encoding layer, the sentence containing the entity pair whose relationship needs to be determined is first subjected to entity marking, and then input into the ERNIE pre-trained model to obtain dynamic word embeddings as output. In this way, the word embeddings gain entity awareness and contextual capturing ability during the encoding stage. In the semantic understanding layer, the self-attention mechanism is used to calculate the influence of other words in the sentence on the target entity pair, that is, the interaction weights between other words and the target entity pair. This allows the semantics of the sentence to be absorbed by the target entity pair. To avoid semantic ambiguity of the target entities, the HowNet [22] and ConceptNet[23] knowledge bases are used as external knowledge to supplement the representation of the target entities, further enhancing their semantic understanding ability. In the classification layer, the sentence semantic representation is fed into the classifier to compute the relationship type of the target entity pair.

A. Encoding Layer

To enable the pre-trained model to accurately identify the entity pair whose relationship needs to be determined, the entity pair in the sentence must first be marked. For example, in the sentence “凯特今天上午在超市购买了苹果” (“Kate bought apples at the supermarket this morning”), if we want to determine the relationship between the entities “凯特” (“Kate”) and “苹果” (“apples”), the target entity pair “(凯特, 苹果)” needs to be marked before transforming the sentence into word vectors. The marked result would be: “ES_1凯特ED_1今天上午在超市购买了ES_2苹果ED_2.” Here, “ES_1” and “ED_1” are the markers placed to the left and right of the first target entity “凯特”, “ES_2” and “ED_2” are the markers placed to the left and right of the second target entity “苹果”.

Once the sentence containing the target entity pair has been marked, it can proceed to the next step of vectorization. Assuming the marked sentence consists of *n* characters, where w_i represents the *i-th* character in the sentence, the sentence is then input into the ERNIE pre-trained model to obtain the following vectorized representation:

$$H = [h_1, h_2, h_3...h_n] = ERNIE([w_1, w_2, w_3, ...w_n]) \quad (1)$$

B. Semantic Understanding Layer

Semantic understanding involves integrating multi-granular semantic perception related to entities into the sentence representation. Multi-granularity specifically refers to modeling at the levels of words, sentences, and concepts.

The dynamic word vectors output by the ERNIE pre-trained model indeed contain information about the sentence where the entity pair resides to some extent. However, this

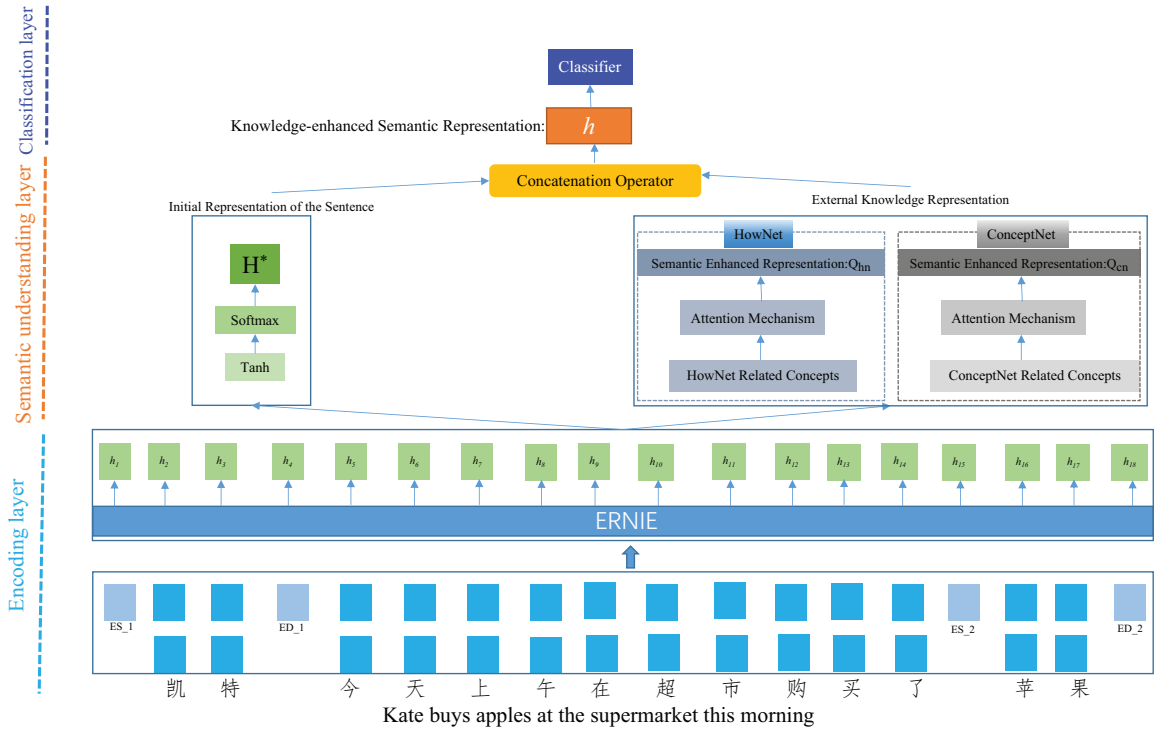

Fig. 2. Framework of the model.

semantic information is insufficient for more accurate prediction of the relationship between the entity pair. The sentence representation of the entities should encompass richer semantic information. Therefore, in semantic understanding, attention mechanisms and external knowledge are jointly used to enrich the sentence semantics.

Each character in the sentence contributes differently to the target entities. In other words, some characters are more helpful in determining the relationship between the entity pair. For example, in the sentence "凯特今天上午在超市购买了苹果" ("Kate bought apples at the supermarket this morning"), the word "超市" ("supermarket") has a different impact on determining the relationship between the entity pair "(凯特, 苹果)" compared to "今天上午" ("this morning"). Characters that have a greater influence on the entity pair should be assigned higher weights, while those with less influence should be assigned lower weights. Using the attention mechanism, the initial representation of the sentence containing the entities can be calculated as follows:

$$\mathrm{S} = \tanh(\mathrm{H}) \tag{2}$$

$$\alpha = \mathrm{softmax}(b^{\mathrm{T}}\mathrm{S}) \tag{3}$$

$$\mathrm{H}^{*} = \mathrm{H}\alpha^{\mathrm{T}} \tag{4}$$

where $b \in R^{d^h}$ is a trainable parameter, and $\alpha \in R^n$ is a weight parameter.

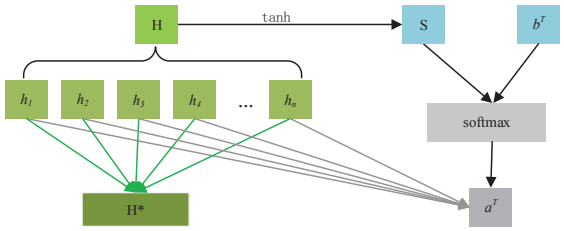

Fig. 3. The Process of computing the initial representation of the sentence in which the entity is located.

The specific calculation process of the initial representation of the sentence vector where the entity resides is shown in Fig. 3. During the model training process, the vectorized representation of the sentence is first subjected to tanh activation to alleviate the gradient vanishing problem during training. Then, the output S of this process is multiplied by the transpose of the trainable parameter b to calculate the weight a of each character's contribution to the entities in the sentence. Based on the obtained weight values, the vectorized representation of the sentence is updated. The model's prediction results based on the new sentence vector are compared with the actual labels in the data to calculate the loss function value. The error is used to compute parameter gradients via backpropagation, and the trainable parameters of the model are updated using the gradient descent method. In this way, through the attention mechanism, character-level features are integrated into sentence-level features.

Considering the particularity and complexity of Chinese word meanings, the same word can have different meanings in different contexts. As shown in the example in Fig. 1, the

word "苹果" ("apple") has different meanings in different contexts. For instance, it could mean "水果苹果" ("fruit apple") or "水果公司"("Apple Inc.") depending on the context. However, previous models could not correctly distinguish these word meanings due to the lack of prior knowledge. In contrast, the model proposed in this paper introduces two external knowledge bases, HowNet and ConceptNet, aiming to further enhance the model's ability to handle word sense disambiguation.

For the HowNet knowledge base, an official API interface is provided, which can be directly called for use. For example, using the API interface to search for meanings related to "苹果" ("apple") returns external knowledge such as "[fruit|水果, tool|用具, PatternValue|样式值, able|能, bring|携带, SpeBrand|特定牌子, communicate|交流]." This knowledge serves as a rich and complementary source of information for "苹果. Assuming that an entity retrieves k related concepts through HowNet, the softmax function is applied to normalize their weight values, obtaining the attention weight c_k corresponding to each concept of the entity. Finally, the attention mechanism is used to enhance the semantic representation of the external knowledge from HowNet corresponding to the entity:

$$\beta_j = \frac{\exp\left(\mathrm{c}_k\right)}{\sum_k \exp\left(\mathrm{c}_k\right)} \tag{5}$$

$$O_{\mathrm{hn}} = \sum_k \beta_j e_i \tag{6}$$

For the ConceptNet knowledge base, an official API interface is also provided. Referring to the usage of HowNet mentioned above, we can retrieve the keyword "苹果" ("apple") through the interface and obtain knowledge relationships such as "水果、实物、植物、商品" ("fruit、physical object、plant、commodity") etc., each with different weights. Similarly, k related entity relationship concepts are used, and their weights are normalized using the softmax function. The attention mechanism is then applied to obtain the semantic representation of the external knowledge from ConceptNet corresponding to the entity:

$$\gamma_t = \frac{\exp\left(\mathrm{q}_k\right)}{\sum_k \exp\left(\mathrm{q}_k\right)} \tag{7}$$

$$O_{\mathrm{cn}} = \sum_k \gamma_t e_i \tag{8}$$

Finally, the initial sentence representation, the semantic representation of external knowledge from HowNet, and the semantic representation of external knowledge from ConceptNet are concatenated to obtain the external knowledge-enhanced semantic representation.

$$\mathrm{h} = [\mathrm{H}^*; O_{\mathrm{hn}}; O_{\mathrm{cn}}] \tag{9}$$

where $[;]$ is the concatenation operator.

C. Classification Layer

Through the effect of multi-level semantic awareness, the final representation of the sentence containing the entity pair is obtained. The predefined Chinese relation extraction task is treated as a binary classification task for each relation, and the sigmoid function is used to calculate the probability of relation r in the set of relations:

$$p_r = \mathrm{sigmoid}(W_r h + b_r) \tag{10}$$

where $p_{\mathrm{r}} \in R^{|\Re|}$, W and b are trainable parameters.

Finally, the binary cross-entropy is used to define the loss function, and during model training, the Adam optimizer [24] is employed to adjust the loss function. The loss function is defined as follows:

$$\mathcal{L}_{loss} = -\sum_{r \in \mathcal{R}} \left(y_r \log\left(p_r\right) + \left(1 - y_r\right) \log\left(1 - p_r\right)\right) \tag{11}$$

where $y_r \in \{0, 1\}$ represents the true value of the relation label r.

IV. Experiment

A. Dataset

The model proposed in this paper is evaluated on the SanWen [25] and FinRE [26] datasets, which are commonly used in multiple studies.

The SanWen dataset is a manually annotated Chinese dataset containing 837 documents with a total of 21,240 sentences. Among them, 81.1% are randomly selected as the training set, 8.4% as the validation set, and the remaining 10.5% as the test set. There are nine types of relationships between entities, including location, proximity, part-whole, general-specific relationship, family, social, ownership, usage, and creation.

The FinRE dataset consists of 18,702 instances extracted from 2,647 Sina Finance news articles. Of these, 13,486 instances are used as the training set, 1,489 as the validation set, and the remaining 3,727 as the test set. It includes 44 types of relationships between entities, such as competition, cooperation, stock reduction, and other financial-specific relationships.

B. Evaluation

For model evaluation, the commonly used performance metric F1-score is adopted. The application of the F1-score is primarily aimed at balancing precision and recall, ensuring that both are taken into account as much as possible. The three performance calculation methods are as follows:

$$Precision = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}} \tag{12}$$

$$Recall = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}} \tag{13}$$

$$F1=\frac{2 * Precision * Recall}{Precision + Recall} \quad (14)$$

where TP (True Positive) indicates instances where the model predicts a positive instance, and it is indeed a positive instance in reality. FP (False Positive) indicates instances where the model predicts a positive instance, but it is actually a negative instance. FN (False Negative) indicates instances where the model predicts a negative instance, but it is actually a positive instance.

C. Experimental Setup

Table I presents the parameter settings of the model at its best performance. The model is based on the ERNIE encoder, so the dimension of the output dynamic vector is 768, which is consistent with BERT. During the process of parameter tuning, the dropout rate was set to 0.5, the initial learning rate was set to 1.0, and the optimal learning rate was 5e-5. The optimal training model can be achieved after 100 epochs.

TABLE I. HYPER-PARAMETERS SETTINGS

Parameter	Value
Batch Size	10
Encoder Hidden Size	768
Optimizer	Adam
Dropout	0.5
Learning Rate	0.0005
Epoch	100

D. Compared Models

To better compare and study the proposed model, we evaluate its performance against other models on the same dataset. The compared models include both traditional neural network-based models and pre-trained language model-based approaches (1) Traditional Neural Network-Based Models: PCNN+Att [8], Lattice+LSTM [10], Lattice+MG [11], PCNN [27], MGRSA [28], MGLT [30]. (2) Pre-Trained Language Model-Based Models: ERNIE [4], PURE [15], IERE [17], PRM [21], OPT-FLAT [29].

V. EXPERIMENTS AND RESULTS

A. SanWen Dataset Results

The results of the proposed model on the SanWen dataset are shown in Table II. It can be observed that our model outperforms existing models, with the F1-score surpassing the current best model by 0.41. This demonstrates the critical importance of processing the semantics of the sentences where the entities are located. Moreover, relying solely on the semantics of the sentence itself cannot achieve optimal performance; external knowledge must be incorporated as a supplement. When the model encounters ambiguity in word meanings, external knowledge can effectively resolve this issue. Additionally, the ERNIE pre-trained model significantly enhances the understanding of entity words, further contributing to improved performance.

TABLE II. EXPERIMENT RESULTS ON SANWEN

Method	F1/%
PCNN+Att[8]	60.55
PCNN[27]	61.23
ERNIE[4]	63.25
Lattice+LSTM[10]	63.88
IERE[17]	63.99
PURE[15]	64.70
Lattice+MG[11]	65.61
MGRSA[28]	67.12
PRM[21]	67.72
OPT-FLAT[29]	68.35
MGLT[30]	69.50
Our model	**69.91**

TABLE III. EXPERIMENT RESULTS ON FINRE

Method	F1/%
PCNN[27]	45.51
PCNN+Att[8]	46.13
Lattice+LSTM[10]	47.41
ERNIE[4]	47.45
IERE[17]	49.09
Lattice+MG[11]	49.26
PURE[15]	46.61
OPT-FLAT[29]	50.60
MGRSA[28]	52.61
PRM[21]	52.97
MGLT[30]	53.22
Our model	**53.47**

B. FinRE Dataset Results

The results of the proposed model on the FinRE dataset are shown in Table III. It can be observed that our model also outperforms existing models, with the F1-score surpassing the current best model by 0.25. However, it is evident that the advantage of the proposed model on the FinRE dataset is lower compared to its performance on the SanWen dataset. After analysis, this difference can be attributed to the varying number of relationship types in the two datasets. The SanWen dataset contains nine types of relationships, whereas the FinRE dataset includes 44 types. This discrepancy increases the difficulty of relationship extraction, as distinguishing between similar relationships imposes higher demands on the model.Moreover, the two types of external knowledge incorporated in the proposed model abstract entities into concepts, which indirectly amplifies the influence of entities on their corresponding relationship types. This highlights a potential direction for future model improvements: ensuring greater precision when incorporating external knowledge to further enhance performance.

C. Ablation Study

From Tables II and III, it can be seen that the proposed model demonstrates strong competitiveness compared to other models. To further explore the role of the three components

in the model, we conducted an ablation study on the SanWen dataset. Based on the analysis above, the key modules of the model include the ERNIE encoder, the sentence representation module, and the external knowledge representation module. To clearly observe the contribution of each module, we disabled one module at a time and analyzed the results. First, we replaced the ERNIE encoder with the Chinese version of BERT-base. The results showed that the model's performance dropped by 2.01, indicating that the ERNIE encoder helps alleviate the issue of insufficient semantic information at a fundamental level. Its enhanced pre-training strategies play an important role in understanding entity-related semantics. Second, when the sentence representation module was removed, the model's performance dropped significantly by 2.73. This result shows that the sentence representation module is critical for improving the model's performance. By leveraging the attention mechanism, this module enhances the characters in the sentence that are important to the entities, thereby enriching the semantic representation of entity words in a targeted manner. Finally, when the external knowledge representation module was removed, the model's performance showed a slight decrease. This indicates that external knowledge is helpful in resolving word ambiguities, but it also introduces a certain amount of noise. As a result, the improvement brought by this module is not as significant as the other components. From the ablation experiments, it can be concluded that the ERNIE encoder and the sentence representation module play a core role in enhancing the model's performance, the external knowledge representation module helps the model handle ambiguity issues. However, due to the complexity and diversity of external knowledge sources, their quality cannot be fully guaranteed, and they may contain information that is irrelevant or even contradictory to the current task. Such low-quality or irrelevant knowledge may interfere with the model's learning process, leading to noise accumulation and ultimately affecting the extraction performance. This issue becomes particularly prominent when dealing with high-noise knowledge sources or when the knowledge integration method lacks precision. Therefore, the presence of noise in external knowledge is also a limitation of this study. From Table IV, it can also be seen that the three modules in the model all contribute to improving the overall performance of the model to varying degrees. The organic combination of these three modules ultimately leads to a significant performance improvement compared to previous models.

TABLE IV. ABLATION EXPERIMENT

Parameter	F1/%
Our Model	69.91
- ERNIE encoder	67.90
- Sentence representation module	67.18
- External knowledge representation module	68.24

VI. CONCLUSION

This paper proposes a Chinese relation extraction model enhanced by external knowledge to improve semantic understanding. Experiments demonstrate that the proposed model achieves better performance in handling Chinese relation extraction tasks. In future research, we will further explore more precise knowledge filtering and integration strategies to maximize the benefits of external knowledge while minimizing the introduction of noise, ultimately improving the model's stability and generalization ability.

***Abstract*—Accurate temperature modeling is crucial for maintaining the efficiency and reliability of solar inverters. This paper presents an innovative application of symbolic regression based on particle swarm optimization (PSO) for predicting the temperature of photovoltaic inverters, offering a novel approach that balances accuracy and computational efficiency. The study evaluates the performance of a PSO-based symbolic regression model compared to multiple linear regression (MLR) and a symbolic regression model based on genetic algorithms (GA). The models were developed using a dataset that included inverter temperature, active power, and DC bus voltage, collected over a year in hourly intervals from a rooftop photovoltaic system in a tropical region. The dataset was divided, with 70% used for training and the remaining 30% for testing. The symbolic regression model based on PSO demonstrated superior performance, achieving lower values of the root mean square error (RMSE) and mean absolute error (MAE) of 3.97 and 3.31, respectively. Furthermore, the PSO-based model effectively captured the nonlinear relationships between variables, outperforming the MLR model. It also exhibited greater computational efficiency, requiring fewer iterations than traditional symbolic regression approaches. These findings open new possibilities for real-time monitoring of photovoltaic inverters and suggest future research directions, such as generalizing the PSO model to different environmental conditions and inverter types.**

I. Introduction

Photovoltaic systems play a crucial role in reducing the carbon footprint compared to traditional energy sources. These systems provide a sustainable alternative that helps reduce future CO_2 emissions, which is critical to combating global warming [1]. Solar inverters are essential for photovoltaic systems because they convert direct current (DC) from solar panels into alternating current (AC) for commercial and residential use [2]. In the context of electrical systems, solar inverters are critical in facilitating grid integration and improving overall system efficiency [3]. In a global context where the photovoltaic capacity has increased 41% annually since 2009 [4], improving thermal management in solar inverters is critical to achieving energy sustainability goals. Accurate temperature modeling in solar inverters facilitates predicting and controlling thermal conditions, which is crucial for optimizing their performance and preventing failures [5].

Currently, the use of advanced thermal models combined with sensors and control algorithms is becoming increasingly important to ensure efficient thermal management in these devices [6]. Proper temperature control of a solar inverter is essential to maintaining the efficiency and longevity of these systems [7]. Inaccurate temperature modeling of solar inverters can significantly impact their performance and reliability, affecting these devices' thermal management and operational efficiency [8]. Additionally, erroneous temperature predictions can lead to suboptimal thermal management strategies, resulting in energy losses and reduced efficiency of solar inverters [9].

Previous studies have used various statistical and machine learning methods to model physical processes, energy production processes, and related parameters with varying degrees of success [10]–[13]. In [10], multiple machine-learning approaches have been applied, including multiple linear regression, decision trees, random forests, support vector machines, and neural networks. Otherwise, [11] presents a mathematical model of multigenic genetic programming (GP) designed to forecast the flow of the Blackwater River. To enhance its accuracy, this model has been optimized using the particle swarm optimization (PSO) algorithm. The model achieved an R^2 coefficient value of 0.96059 in the training set and 0.94296 in validation; however, it required 150 iterations in the adjustment parameters using PSO, which may result in increased computational expense. In addition, [12] proposes a method for predicting photovoltaic inverter temperatures using a hybrid neural network model that integrates convolutional neural networks (CNN) with long short-term memory (LSTM) networks. This CNN-LSTM approach significantly enhances temperature prediction accuracy, as demonstrated by an improvement in R^2 metrics from 0.92 to 0.96 compared to actual values. Finally, models based on neural networks (CNN-LSTM) and lumped thermal networks [13], have shown improvements in accuracy but face limitations in complexity and computational [14]. These limitations underscore the need for more efficient and robust methods for predictive solar inverter temperature modeling, aiming to enhance operational efficiency and extend the lifespan of PV systems. This study explores whether a PSO-based symbolic regression model can offer a more accurate and computationally efficient alternative to existing models.

Symbolic regression (SR) is a powerful tool for modeling

complex systems, offering improvements in precision [15] and robustness [16]. Traditional genetic programming (GP), a widely used SR method, leverages evolutionary principles to evolve mathematical expressions over multiple generations [17]. However, GP and similar traditional methods often face challenges related to efficiency and convergence. In contrast, algorithms based on swarm intelligence, such as particle swarm optimization (PSO) and firefly algorithms, have emerged as promising alternatives for symbolic regression tasks [18]. Inspired by the collective behavior of social organisms, these algorithms navigate large and complex search spaces, typical of symbolic regression problems [19]–[21]. Despite their potential, limited studies have explored the application of PSO-based symbolic regression for modeling solar inverter temperatures or compared its effectiveness with traditional approaches like Multiple Linear Regression (MLR) or Genetic Algorithm (GA)-based symbolic regression. Analyzing this approach could identify more precise, interpretable, and robust temperature prediction methods, thereby enhancing thermal management in solar inverters.

On the other hand, various methods have been developed to estimate temperature based on power loss calculations, input and output parameters, and thermal models [22], [23]. These methods utilize the relationship between electrical parameters and thermal behavior to provide real-time temperature estimations [24].

From the above discussion, the following research question arises: ¿what extent can a symbolic regression algorithm based on Particle Swarm Optimization (PSO) enhance the accuracy of temperature modeling in solar inverters compared to MLR and GA-based symbolic regression models? This study specifically aims to compare the predictive accuracy of PSO-based symbolic regression with MLR and GA-based models for solar inverter temperature prediction, using Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE) as evaluation metrics.

The novelty of the work is summarized as follows: (1) the creation of an innovative symbolic regression model using particle swarm optimization (PSO), which achieves higher accuracy than traditional models like multiple linear regression (MLR) and genetic algorithm (GA)-based approaches; (2) the model's enhanced capability to capture nonlinear relationships between critical variables, such as active power and DC voltage, essential for complex systems like solar inverters; and (3) its computational efficiency, demonstrated by fewer iterations and shorter execution times compared to advanced methods.

The paper outline is as follows: Section II presents the data collection methodology, and the construction of the PSO-based symbolic regression algorithm is described. Section III presents the temperature modeling of the solar inverter and the evaluation of the PSO-based symbolic regression model compared to the MLR and GA-based symbolic regression models. Section IV contains the discussion. Finally, conclusions are drawn in Section IV.

II. Methods and Materials

This section describes the methodology used for the analysis. The study requires data on the temperature of the solar inverter, its active power, and DC bus voltage, as well as information from the photovoltaic system. This data serves as input for developing the symbolic regression model based on PSO, multiple linear regression model, and GA-based symbolic regression model. The results are then compared with the measured temperature of the solar inverter. Fig. 1 illustrates the methodology for developing and evaluating these models.

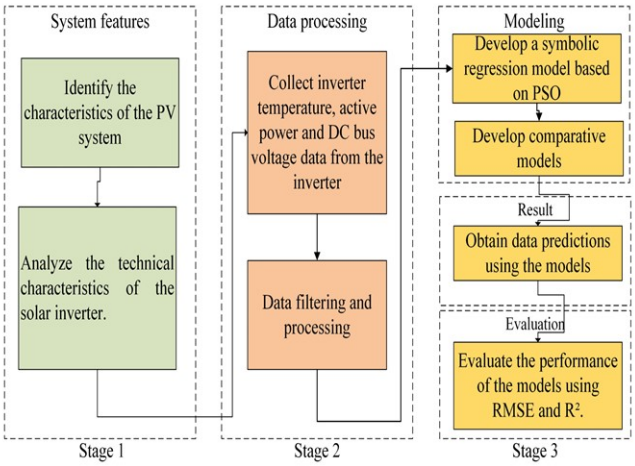

Fig. 1. Methodology followed in carrying out the models and the evaluations.

A. Characteristics of the PV System

The photovoltaic system is located on the rooftop of a building in Montería, Colombia, at coordinates 8°48'13.5" N, 75°51'0.45" W. It connects to the building's electrical grid through an indoor substation on the roof. The inverter is housed inside the rooftop structure, and Fig. 2 shows the current installation setup.

Fig. 2. Three-phase solar inverters and grid-connected electrical system.

B. Technical Characteristics of the Solar Inverter

The photovoltaic system comprises two solar inverters. The installation incorporates a transformer at the inverter output to

facilitate grid connection. The solar inverter under analysis is the Yaskawa PVI 36TL-480. Table I describes the technical characteristics of the solar inverter and the transformer.

TABLE I. TECHNICAL CHARACTERISTICS OF THE INSTALLATION

Solar inverter and transformer	
Item	**Detail**
Inverter Rated Power	36 kW
Inverter Power Input Voltage Range	540-800 VDC
Inverter Ambient Temperature Range	(-25 °C to +60 °C)
Transformer for coupling to the electrical network	80 kW 460 V/120 V

C. Data Acquisition

The data extracted from the solar inverter includes the inverter temperature in (ºC), active power in (kW), and DC bus voltage in (V). The data are stored hourly on a cloud-based platform. The volume of data encompasses one year of storage. The transmission system uses a GSM module to transmit the data to a cloud-based computer system from which it can be downloaded for analysis. Fig. 3 illustrates the process of data transmission and storage.

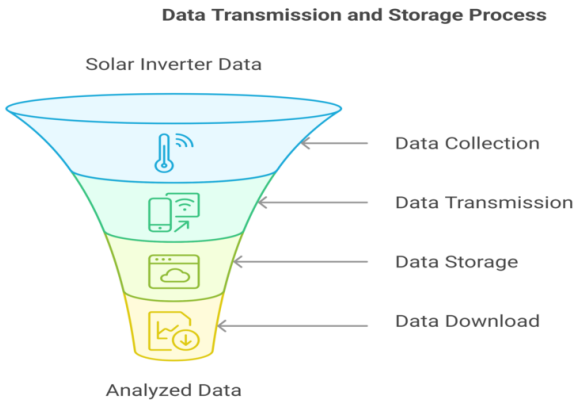

Fig. 3. Phases of the solar inverter's data transfer and storage process.

D. Data Filtering and Processing

The filtration and processing of the data followed these steps:

1) Identifying and eliminating outliers and inaccurate or incomplete data: Atypical data points substantially deviating from normal experimental parameters were classified as outliers. Specifically, any measurement that fell beyond two standard deviations from the adjusted median was designated as an outlier.

2) Manual review: Each data point was meticulously reviewed to identify and correct apparent errors or inconsistencies.

E. Algorithm Description

The PSO-based symbolic regression algorithm models nonlinear relationships by evolving algebraic expressions through particle swarm optimization. It integrates the following key steps:

1) Variable and function definition: Internal symbolic variables x1 and x2 are defined using Python's SymPy library. A list of mathematical functions (e.g. trigonometric, logarithmic) with random constants is constructed.

2) Expression generation: Random symbolic expressions are created by combining 3–6 terms from the predefined function list, operating on x1 and x2.

3) Fitness evaluation: Each expression is evaluated using RMSE between predicted and actual values. Invalid outputs (e.g., division by zero) are penalized with high error values.

4) PSO Update: Particle positions and velocities are updated based on personal best (pbest) and global best (gbest) solutions, guided by inertia (w=0.7), cognitive (c1=1.5), and social (c2=1.5) factors.

5) Optimization loop: The algorithm iteratively refines expressions over 25 iterations, balancing exploration and exploitation to minimize RMSE.

6) Data handling: Training (70%) and testing (30%) datasets are split using pandas. Results are visualized using matplotlib to track RMSE evolution.

F. Developing a Symbolic Regression Model Based on PSO

Symbolic regression is a tool that models complex nonlinear relationships between variables by identifying algebraic expressions that best fit the dynamics of a given system [25]. The PSO-based symbolic regression algorithm consists of the following subroutines in Fig. 4.

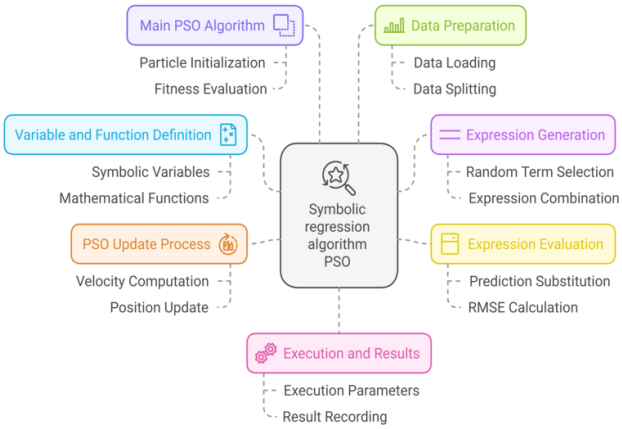

Fig. 4. Flowchart of symbolic regression algorithm based on particle swarm optimization (PSO).

The following section provides a detailed description of each subroutine the algorithm utilizes for its operation. The program used to develop the algorithm in Spyder 6 is an integrated development gateway (IDE) designed explicitly for scientific programming in Python [26].

Subroutines: Definition of Variables and Mathematical Functions
Input: No external inputs are required; the symbolic variables x1 and x2 are generated internally.
Output: The symbolic variables (x1, x2) are defined as mathematical symbols. The list of mathematical functions encompasses algebraic, trigonometric, and advanced operations (e.g. sin, log, sqrt), some with random constants.
Process: The symbolic variables x1 and x2 are defined utilizing the Sympy library in Python. A list of functions operating on x1 and x2 is constructed, incorporating random constants and predefined mathematical operations.

Subroutines: Generation of Mathematical Expressions
Input: Symbolic variables x1, x2. A predefined list of mathematical functions contains algebraic operations and mathematical functions applicable to x1 and x2.
Output: Symbolic mathematical expression combining several functions randomly selected from the list.
Process: A random number of terms is chosen (between 3 and 6). Functions are randomly selected from the list of mathematical functions. Each function operates on the symbolic variables x1 and x2. The resulting terms are summed to form a single symbolic expression.

Subroutines: Evaluation of Expressions
Input: A mathematical expression generated in a previous step. Arrays for x1, x2 (independent variables), and y (dependent variable).
Output: A numerical value representing the difference between the predicted values (from the symbolic expression) and the actual y values (RMSE).
Process: Each pair of values x1 and x2 are substituted into the symbolic expression to calculate the predicted value. If an invalid value (e.g. division by zero or NaN) occurs, assign a high error (inf) to the expression. Compares the predicted values with the actual values of y using the formula RMSE.

Subroutines: Update of Velocity and Position in PSO
Input: Current velocity and position representing the state of a particle. Personal best (pbest) and global best (gbest). PSO parameters (w, c1, c2).
Output: Updated velocity and position for the particle.
Process: Calculate the new velocity. Update the position.

Subroutines: Main PSO Algorithm
Input: Training and test data (x1, x2, y). PSO parameters: Number of particles, iterations, and constants (w, c1, c2).
Output: Best expression: The symbolic expression with the lowest RMSE. Best RMSE: The RMSE of the best expression. RMSE evolution: A record of RMSE values over iterations.
Process: Initialization: Generate initial particles (expressions) and velocities and evaluate their fitness. Optimization Loop: For each iteration: - Evaluate RMSE for each particle. - Update pbest and gbest based on fitness. - Adjust velocity and position for each particle. - Record the best RMSE for the iteration. Stop when the maximum iterations or target RMSE is reached.

Subroutines: Data Loading and Preparation
Input: Path to an Excel file containing data.
Output: Training and test datasets split into x_1, x_2, and y.
Process: Load data using `pandas.read_excel`. Extract columns for x_1, x_2, and y. Split data into 70% training and 30% test sets.

Subroutines: Results Visualization
Input: RMSE evolution data for each execution.
Output: A graph showing RMSE over iterations for all executions.
Process: Convert iterations to a time scale for the X-axis. Plot RMSE evolution for each execution using `matplotlib`. Label axes, add a title, and display the graph.

The equipment used for model development had the following technical specifications, as can be seen in Table II.

TABLE II. TECHNICAL CHARACTERISTICS OF THE COMPUTER EQUIPMENT

Laptop Computer and Software	
Item	**Detail**
CPU	8x1.9 GHz
RAM	32GB DDR4
RAM Speed	4267 MHz
Software	Spyder 6

G. Development of the MRL and GA-Based Symbolic Regression Model

Multiple linear regression (MLR) is a statistical technique investigating the relationship between a single dependent variable and several independent variables [27]. It aims to determine the equation of a line that minimizes the total squared deviations between the predicted and actual values of the dependent variable [27].

On the other hand, symbolic regression based on genetic algorithms (GA) is a computational technique that combines genetic algorithms with symbolic regression to discover the mathematical expressions that best fit a given dataset [17].This approach leverages the evolutionary principles of genetic algorithms to explore the space of potential mathematical models to identify the most accurate and interpretable representation of underlying data relationships [28].

The performance of the PSO-based symbolic regression model was compared with that of a multiple linear regression (MLR) model and a GA-based symbolic regression model using the same training data set at 70% and testing at the remaining 30%. The PSO-based and GA-based symbolic regression models employed an identical set of mathematical functions in their equation formulation processes.

The generated models were evaluated using 30% of the data set aside for testing. The main goal is to balance having enough training data to create robust models and sufficient test data to assess model performance [29].

H. Evaluation of Model Performance

Model performance was evaluated using RMSE and MAE metrics.

RMSE: This indicator evaluates the size of the discrepancies between the model's predicted values ($V_{\text{predicted}}$) and the actual values (V_{target}), as illustrated in Eq. (1) [30]. A lower RMSE indicates higher model accuracy.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(V_{\text{predicted},i} - V_{\text{target},i})^2} \qquad (1)$$

MAE: Mean Absolute Error (MAE) is a widely used method in model validation in various fields of study. MAE quantifies the average error size in a set of predictions without considering their directionality [31]. Eq. (2) describes the Mean Absolute Error (MAE) as follows:

$$MAE = \frac{1}{n}\sum_{k=1}^{n}|y_k - \hat{y}_k| \quad (2)$$

The number of observations is denoted by n, y_k represents the actual value, and $\hat{y}_k$ denotes the predicted value.

III. Results

This section presents the primary results of the study. The results are organized into two subsections: The first subsection describes the process of building the multiple linear regression model, the PSO-based symbolic regression model, and the GA-based symbolic regression model. The second subsection analyzes and contrasts the results of comparing these models with the measured data of the solar inverter temperature.

A. Model Construction

The distribution of training and test data is examined before modeling. Fig. 5 and Fig. 6 illustrate the data distribution.

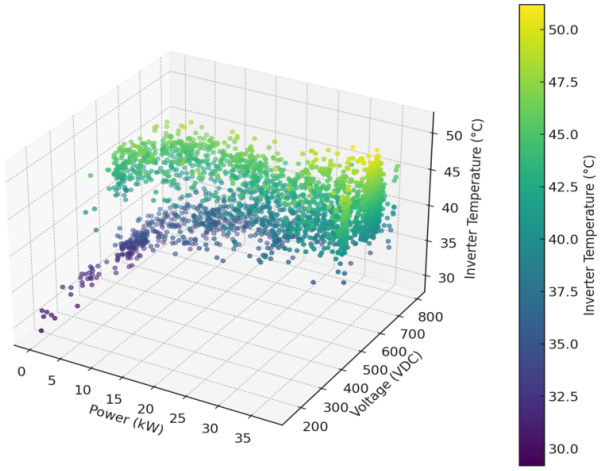

Fig. 5. Distribution of training data.

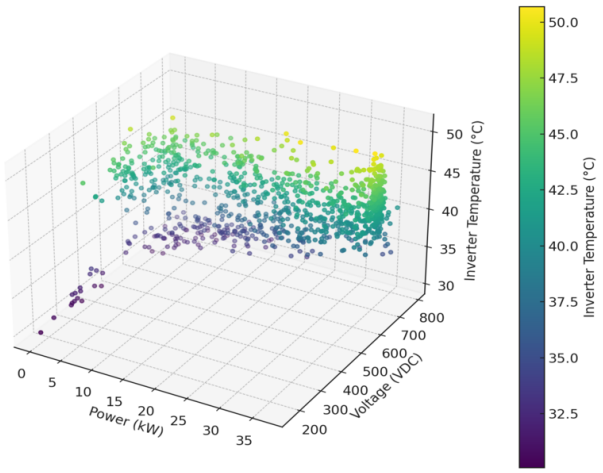

Fig. 6. Distribution of test data.

The dispersion and clustering of diverse data points across distinct regions of the three-dimensional space indicate complex relationships among the variables of active power, DC voltage, and inverter temperature. The following section describes the process of constructing the models:
A multiple linear regression model was established with training data and evaluated with the test dataset. The analysis revealed the corresponding coefficients in Equation (3) as follows:

$$MLR = 38.9104 + W \cdot 0.15981 + VD \cdot 0.0011, \quad (3)$$

where W represents the active power of the solar inverter in kW, and VD denotes the DC bus voltage in volts DC.

Using the training data, a symbolic regression model based on GA was established and evaluated with the test dataset. The parameters utilized for this model are illustrated in Table III.

TABLE III. Performance Parameters of the Algorithm Based on Symbolic Regression Based on GA

Input parameters	
Item	**Detail**
Population size	30
Number of generations	25
Initial mutation probability	0.5
Selection percentage	0.5
Crossover method	Subexpression Crossover
Number of algorithm executions	10

The optimal equation resulting from 10 executions of the algorithm was Eq. (4).

$$\text{Model}_{SR\_GA} = |VD|^{0.38} + \sqrt{VD} + 4.75, \quad (4)$$

where VD denotes the DC bus voltage in volts DC. Fig. 7 shows the result of the best RMSE value for each execution and the corresponding time.

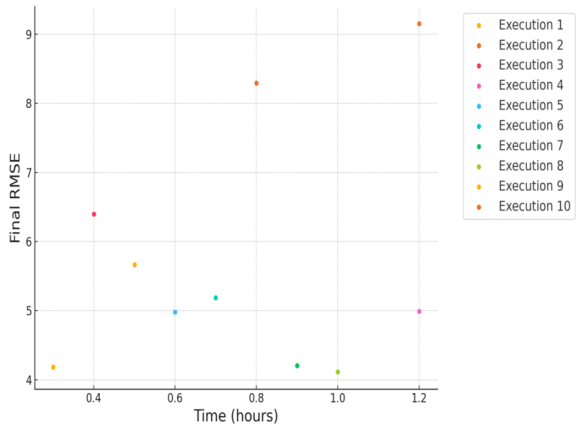

Fig. 7. Evolution of the RMSE of the Model RS GA over time.

Furthermore, selecting PSO parameters considers computational efficiency and model robustness; consequently, 30

particles and 10 executions are chosen for the algorithm. Concurrently, the inertia coefficient (0.7) and cognitive and social factors (1.5) are established to achieve an optimal balance between exploration and exploitation. As shown in Table IV, the selected inertia value allows particles to maintain sufficient momentum to escape local minima without affecting convergence.

TABLE IV. OPERATING PARAMETERS OF THE ALGORITHM

Item	Detail
Number of iterations	25
Particle numbers	30
Inertia factor	0.7
Cognitive factor	1.5
Social factor	1.5
Number of algorithm executions	10

Fig. 8 illustrates the evolution of the RMSE over the iterations, and Fig. 9 shows the RMSE graphed over time.

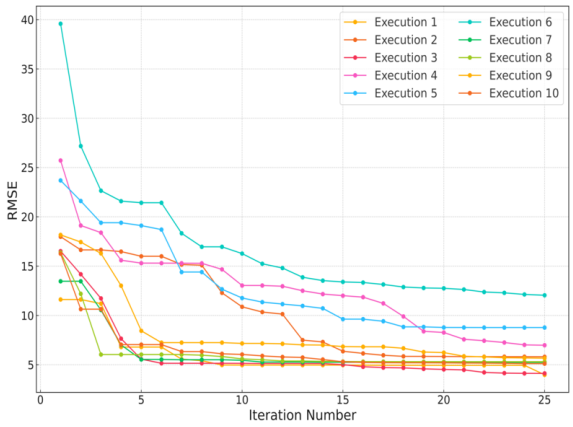

Fig. 8. Development of RMSE as a function of the number of iterations for different algorithm executions.

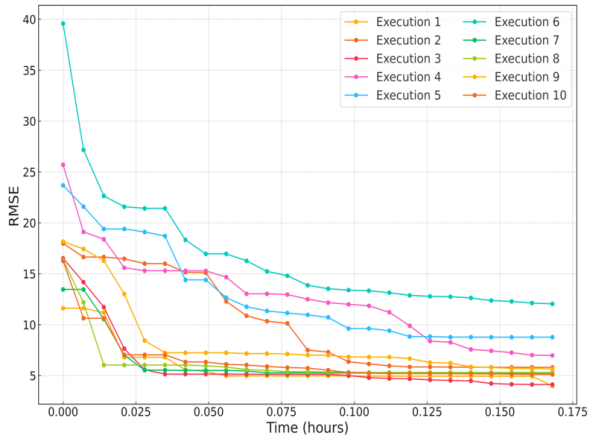

Fig. 9. Development of RMSE as a function of time for different algorithm executions.

The algorithm reduces the RMSE from initially high values (average values close to 20 in the first iterations) to final values between 3.97 and 12.04. This demonstrates the PSO's ability to identify symbolic equations that capture nonlinear relationships in the data. The progressive decrease in RMSE over the iterations confirms the algorithm's effectiveness in exploring and exploiting the search space, as confirmed in previous literature [11].

Regarding computing time, the algorithm completed 25 iterations within 0.175 hours per execution. The RMSE reduction reached a value of 3.97, positioning it as a competitive method compared to techniques such as neural networks or traditional multivariate regression for problems with nonlinear relationships [11]. The 25-iteration limit in the symbolic regression algorithm based on PSO allows for a brief and controlled execution time (0.175 hours), balancing computational efficiency and precision in searching solutions.

Additionally, using 30 particles balances exploration capacity and computational cost. This relatively modest size appears sufficient to adequately explore the search space and identify effective solutions to symbolic regression problems. Furthermore, a low inertia factor (0.5) favors local exploitation in advanced phases of the algorithm. This contributes to the rapid convergence observed in the RMSE.

A social factor of (1) means that the particles have a reduced tendency to follow the global best solution of the swarm, promoting a certain level of diversity in search. Combined with the high cognitive factor, this balance allows for more precise local convergence. The value of the cognitive factor (3) indicates that particles prioritize their own experiences. Eq. 5 illustrates the iterative process:

$$\begin{aligned}\text{Model RS PSO} = {} & 0.0940W - 0.0483VD \\ & + 0.2599\log(|VD| + 0.00001) \\ & - 0.4005\sin(W) + 0.4099\cos(VD) \\ & + 0.0049\tan(W) + 2.69206\sqrt{|VD|} \\ & + 0.52838\arctan(W) + 1.0941,\end{aligned} \tag{5}$$

where W represents the active power of the solar inverter in kW and VD denotes the DC bus voltage. The combination of nonlinear terms indicates that PSO can uncover relationships that traditional approaches, such as multiple linear regression, cannot capture.

Table V shows the RMSE and MAE results for the training dataset of multiple linear regression, symbolic regression model based on PSO, and GA-based symbolic regression model.

TABLE V. COMPARISON OF RESULTS WITH TRAINING DATA

Models and Metrics		
Item	**RMSE**	**MAE**
Model Multiple Linear Regression (MLR)	4.22	3.55
Symbolic Regression Model based on PSO (SR PSO)	3.97	3.36
Symbolic Regression Model based on GA (SR GA)	4.59	3.78

Furthermore, Table VI presents the corresponding results for the test dataset.

TABLE VI. COMPARISON OF RESULTS WITH TEST DATA

Models and Metrics		
Item	**RMSE**	**MAE**
Model Multiple Linear Regression (MLR)	4.52	3.73
Symbolic Regression Model based on PSO (SR PSO)	4.12	3.31
Symbolic Regression Model based on GA (SR GA)	4.80	3.66

The RMSE and MAE metrics indicate that the symbolic regression model based on PSO demonstrated superior training and test data performance, achieving RMSE values of 3.97 and MAE of 3.31. Fig. 10, Fig. 11, and Fig. 12 illustrate the behavior of the Model MRL, Model SR PSO, and Model SR GA with training data.

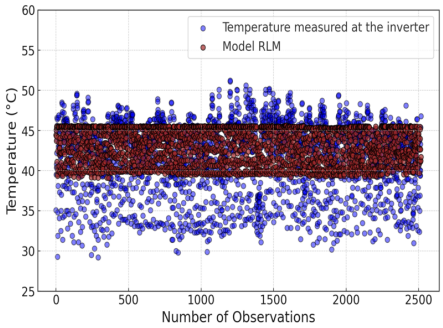

Fig. 10. Comparison of the temperature measured and the Model MLR with training data.

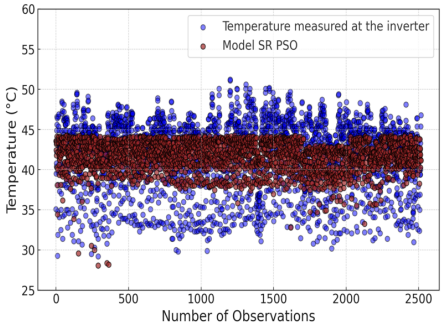

Fig. 11. Comparison of the temperature measured and the Model RS PSO with training data.

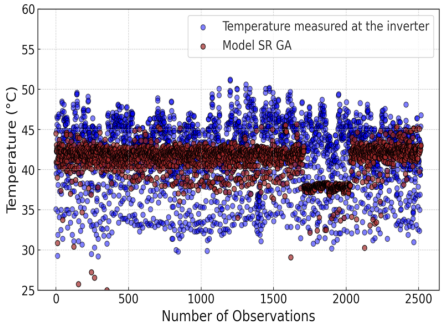

Fig. 12. Comparison of the temperature measured and the Model RS GA with training data.

Fig. 13, Fig. 14, and Fig. 15 show the behavior of Model MRL, Model SR PSO, and Model SR GA with training data. The model MLR represents a linear approximation with more substantial errors in scenarios where the relationships between variables and inverter temperature are not strictly linear, resulting in more significant deviations between predicted and actual values. The model SR PSO typically aligns more closely with actual inverter temperatures and exhibits reduced bias across multiple observations. Additionally, the Model SR GA model demonstrates inferior performance compared to the MLR and RS PSO models in evaluation metrics.

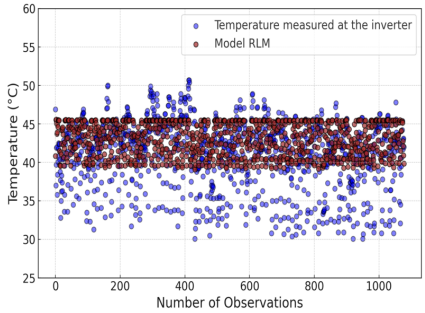

Fig. 13. Comparison of temperature measured and the MLR model with test data.

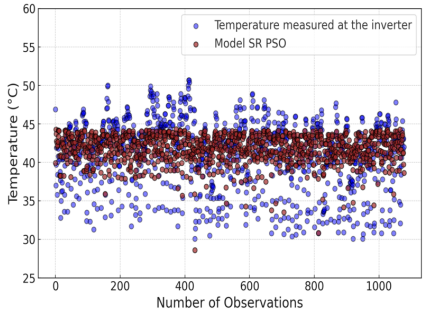

Fig. 14. Comparison of temperature measured and the Model RS PSO with test data.

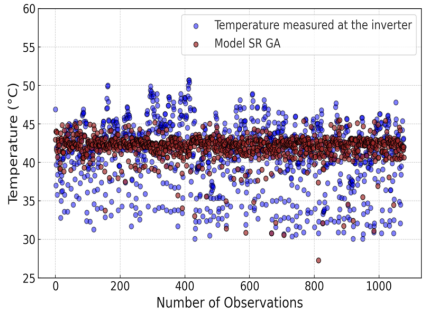

Fig. 15. Comparison of temperature measured and the Model RS PSO with test data.

Fig. 16, Fig. 17, and Fig. 18 show the performance of the MLR, RS PSO, and SR GA models based on the training data,

while Fig. 19, Fig. 20, and Fig. 21 illustrate the behavior with test data.

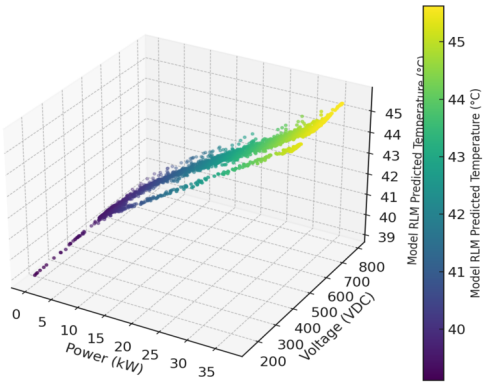

Fig. 16. Distribution of the data predicted by the model MLR using the training data.

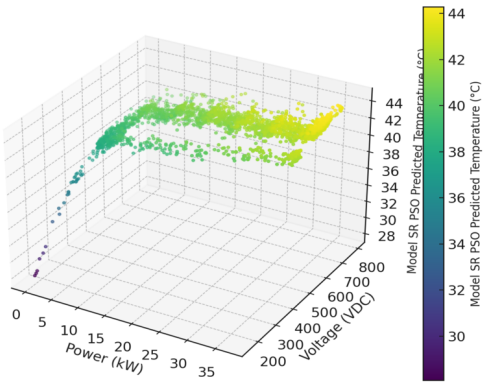

Fig. 17. Distribution of data predicted by the model RS PSO using the training data.

While multiple linear regression (MLR) presents a simplified linear trend with a limited prediction range (39-45 °C) that does not capture the full complexity of the actual data (30-50 °C), the symbolic regression model with PSO demonstrates superior capability in reproducing the non-linear nature of interactions among inverter power, voltage, and temperature, as evidenced by its improved fit to variable gradients and more realistic prediction range (28-44°C).

Both the symbolic regression model response based on PSO and the one based on GA exhibited similar RMSE values; however, the regression developed with PSO achieved the lowest value after 10 executions in both algorithms.

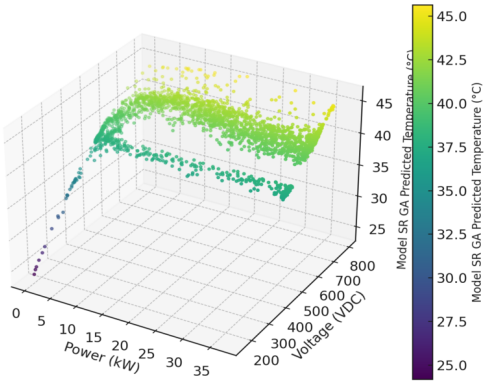

Fig. 18. Distribution of data predicted by the model RS GA using the training data.

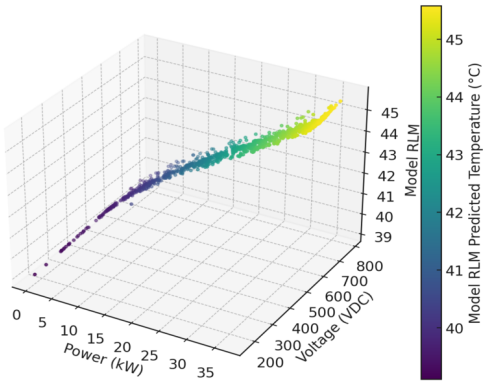

Fig. 19. Distribution of data predicted by the model MLR using test data.

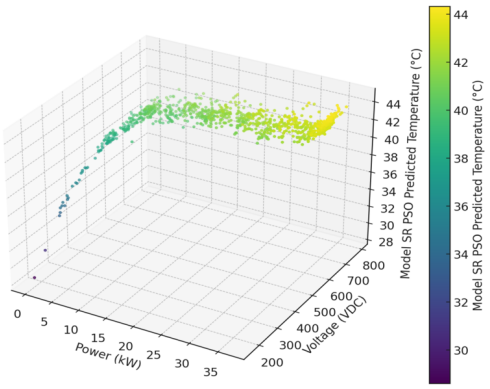

Fig. 20. Distribution of data predicted by the model RS PSO using the test data.

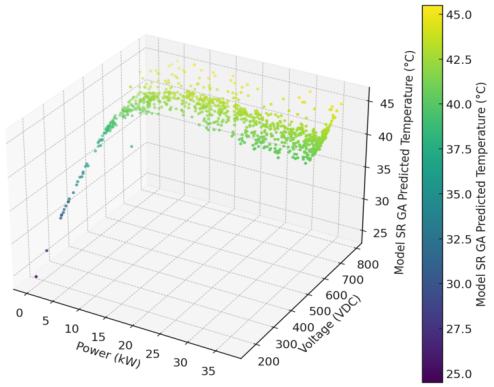

Fig. 21. Distribution of data predicted by the model RS GA using the test data.

IV. Discussion

The rapid convergence of the PSO-based model and its reduced computational cost compared to the GA-based approach render it an attractive option for symbolic regression tasks. Nevertheless, PSO may experience premature convergence and stagnation in complex search spaces, corroborating recent findings [32].

The response surface generated by PSO more accurately reflects the local variations and curvature observed in the experimental data. This suggests that this method is more appropriate for modeling complex physical systems where relationships between variables are inherently non-linear, as with temperature in solar inverters.

The results validate the efficacy of PSO in symbolic regression; however, its tendency to converge prematurely may result in suboptimal solutions if not managed appropriately.

V. Conclusion

The study shows that a symbolic regression model based on particle swarm optimization (PSO) outperforms multiple linear regression (MLR) and a Symbolic regression model based on GA in predicting the internal temperature of solar inverters, as evidenced by lower RMSE and MAE values. The SR PSO model's ability to capture nonlinear relationships between active power (W), DC bus voltage (VD), and temperature represents a significant advantage given the complex nature of solar inverter systems. However, the RS PSO model may require more computational resources.

According to the analyzed literature, this study investigated the application of the Particle Swarm Optimization (PSO) algorithm in symbolic regression, a domain predominantly utilizing Genetic Programming (GP) and neural networks. Although the surface modeling of the training and test data was not very close, the model highlighted the computational efficiency and potential adaptability of PSO to symbolic regression tasks.

Future research could examine the generalizability of the SR PSO model across different solar inverter types and environmental conditions, incorporate additional variables such as ambient temperature and humidity, and explore possible improvements through parameter optimization. In addition, comparing the SR PSO model with other advanced machine learning models and integrating it into real-time monitoring systems could further improve its practical application in photovoltaic systems.

Towards Effective Anomaly Detection: Machine Learning Solutions in Cloud Computing

Hussain Almajed, Abdulrahman Alsaqer, Abdullah Albuali
Department of Computer Networks and Communications
College of Computer Sciences and Information Technology
King Faisal University
Al-Ahsa, 31982 Saudi Arabia

***Abstract*—Cloud computing has transformed modern Information Technology (IT) infrastructures with its scalability and cost-effectiveness but introduces significant security risks. Moreover, existing anomaly detection techniques are not well equipped to deal with the complexities of dynamic cloud environments. This systematic literature review shows the advancements in Machine Learning (ML) solutions for anomaly detection in cloud computing. The study categorizes ML approaches, examines the datasets and evaluation metrics utilized, and discusses their effectiveness and limitations. We analyze supervised, unsupervised, and hybrid ML models showing their advantages in dealing with a certain threat vector. It also discusses how advanced feature engineering, ensemble learning and real-time adaptability can improve detection accuracy and reduce false positives. Some key challenges, such as dataset diversity and computational efficiency, are highlighted, along with future research directions to improve ML based anomaly detection for robust and adaptive cloud security. Hybrid approaches are found to increase the accuracy reaching up to 99.85% and reduces the number of false positives. This review provides a comprehensive guide to researchers aiming to enhance anomaly detection in cloud environments.**

***Keywords*—Anomaly; cloud; machine learning; detection**

I. Introduction

An important part of modern IT infrastructure today is cloud computing, which offers flexible, scalable and cost effective solutions for businesses and individuals over the internet [1],[2]. Offers an on demand access to computing resources such as servers, storage, databases, and applications, which can be rapidly provisioned and released with minimal management effort. Cloud computing has become widely adopted in different industries from healthcare to finance, entertainment to education due to its benefits. Despite these advantages, the use of cloud services has introduced security challenges that must be addressed to guarantee the reliability and trustworthiness of cloud systems [3].

Back in 2022, a leading health insurer in Australia called Medibank stored sensitive information about 10 million customer accounts in its cloud based systems, and the unlucky company suffered a massive data breach which revealed all their customer's data [4], [5]. While the company refused to pay a ransom, hackers then started to leak the stolen data on dark web forums. It highlights the critical requirement for better anomaly detection in cloud environments. In addition, cyberattacks on cloud computing environments are becoming more prevalent and cause significant data breaches. The number of breaches within the cloud environment also increased, from 35% of businesses in 2022 to 39% at 2023 [6].

Cloud environments are dynamic and elastic, which makes them vulnerable to attacks from malicious actors, therefore effective anomaly detection is crucial to keep cloud environment secure. The cloud infrastructure is by nature shared where many tenants may use the same physical resources, making the risk of potential security breaches even higher [7]. Furthermore, managing various virtualized environments, and the constant scaling of resources, makes it difficult to establish a stable security baseline. In these environments security threats can vary from external threat, like Distributed Denial of Service (DDoS) attacks to internal threat, losing control over an insider, unauthorized access, data breaching and configuration errors.

Anomaly detection is identifying unusual patterns or behaviour which may indicate security breach, failure of system or performance issues [8] [9]. An effective anomaly detection method is necessary to reduce the impact of these threats by providing timely and proactive responses. Traditional rule based detection methods based on predefined signatures or rules struggle to keep pace with the complexity and evolution of cloud environments. These methods are unable to detect previously unseen or novel threats, particularly with the diversity and scale of cloud services. Attack patterns evolve rapidly and the cloud environment is always changing, for that we need more adaptive and more intelligent approaches [10].

ML steps in when it provides advanced algorithmic tools to process huge amounts of data and react to new threats by identifying anomalies [11] [12]. Anomaly detection with ML has the capability to offer more secure cloud systems by means of automated, intelligent monitoring of cloud systems. Because ML techniques learn from data, find complex relationships and get better over time, they are particularly well suited to the cloud [13]. With these characteristics, ML is a promising approach to identifying security anomalies that would likely be missed by traditional approaches.

Therefore, cloud computing has revolutionized how the organizations manage and access to the IT resources by providing many advantages and at the same time introducing various security issues. Anomaly detection helps to identify abnormal activities in the cloud, which can indicate abnormal threats. Anomaly detection is a powerful capability of ML which improves the security posture of cloud environments with

adaptive, data driven techniques. In this systematic literature review, we will explore in detail the current state of the art of ML based anomaly detection in cloud computing, the challenges faced and future research directions to address the evolving threat landscape.

Following this introduction, Section II provides background information on cloud computing, anomaly detection, and a definition of ML. Section V describes the research methodology used in this study. Section VI reviews related work in the field. After that, Section VII will illustrate a case study regarding the research study. In Section VIII, the results of the review will be presented and discussed. Section IX then highlights key challenges and outlines open directions for future research. Finally, Section X synthesizes the key findings and concludes the study.

II. Background

A. Cloud Computing Overview

Cloud computing is an on demand network access to a shared pool of configurable computing resources such as a network, applications, servers, storage, or services, in which the providers deliver the resources on demand because they are-scalable, elastic and vary as per your need [14], [15]. The next section represents the cloud service models of the cloud and the cloud deployment models.

B. Cloud Service Model

There are three main service models for cloud computing which offer a varying level of control, flexibility and management. Fig. 1 shows the different cloud service models with examples.

- Infrastructure as a Service (IaaS): The model virtualizes these resources on demand. Users can deploy applications and the configuration settings, without managing or controlling the underlying cloud infrastructure.
- Platform as a Service (PaaS): This model provides a development setting where developers create and deploy applications without having to know how many processors.
- Software as a Service (SaaS): This model is used to deliver the applications over the web where they are consumed by the consumers through web portals.

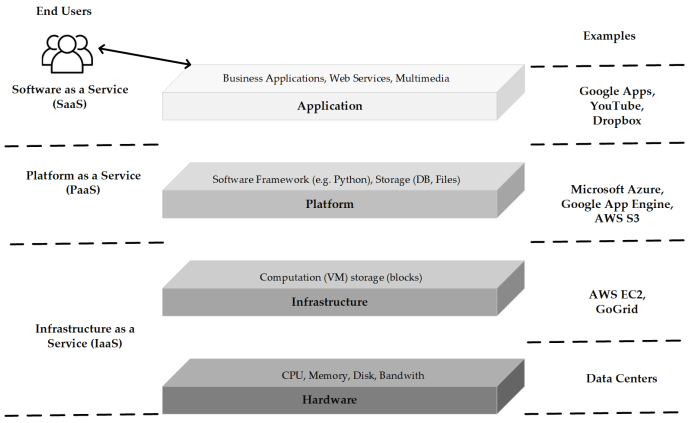

Fig. 1. Cloud service models with examples.

C. Cloud Deployment

The cloud deployment models as shown in Fig. 2 define the way by which cloud resources are managed and offered to the users. There are four main types:

- Private Cloud: The cloud infrastructure is delivered solely for use by one organization (a business unit) that consists of multiple consumers [15].
- Public Cloud: The cloud infrastructure is delivered for general public open use. It may be managed, owned, and operated by a corporation, academic or government organization, or a mix.
- Community Cloud: It is a cloud computing environment where multiple organizations with similar goals and security requirements share a cloud.
- Hybrid Cloud: Two or more distinct cloud infrastructures (private, community, or public) that have been independently operated and connected using standard or proprietary technology.

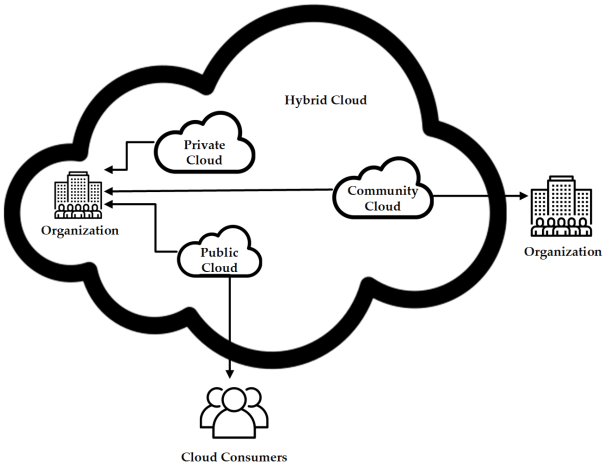

Fig. 2. Cloud deployment models.

D. Cloud Threat

It any event, situation or action which could lead to compromise of the confidentiality, integrity, or availability of cloud computing resources, data or services, including access, data breaches, service disruptions or other security violations, whether deliberate or accidental, that affect the security and trustworthiness of cloud computing environments [16]. The cloud threat can be categorized based Confidentiality,Integrity, and Availability (CIA) tried in the next section.

1) Classification of threat-based CIA:

- Confidentiality: There are many confidentiality threats in cloud computing environments. When unauthorized access of sensitive data stored in the cloud leads to data breaches and privacy violations, it is called Data Breaches [17], [18]. Moreover, Shared Technology Vulnerabilities e.g. hypervisor vulnerabilities and cross Virtual Machine (VM) side channel attacks are at risk as a result of shared infrastructure and multi tenancy [19].
- Integrity: Data tampering is one of the integrity threats in cloud computing, which refers to the unauthorized modifications of data stored in cloud which adversely affects the accuracy and reliability of data. Data integrity can also be compromised by Malicious Insiders, system administrators, and former employee. Application Programming Interface (APIs) with such vulnerabilities are insecure, which can easily be exploited in data manipulation.
- Availability: Denial of Service (DoS) Attacks threaten the availability of cloud computing by overwhelming cloud services with traffic making the cloud services unavailable to the legitimate users.

2) Attacks in cloud: The cloud can be attacked by diverse attacks and for better understanding security threats and vulnerabilities in cloud computing can be broadly classified into five main categories application-based,storage-based, VM-based network-based, Identity and Access Management. Fig. 3 shows list of some attacks based in the five categories.

1) Network-based attacks: Attacks related to network communications and configurations in cloud computing environments [20], [21]. Examples such as flooding attacks, Structured Query Language (SQL) injection attack, spoofing.
2) VM-Based Attacks: Attacks related to virtualization technology and hypervisor vulnerabilities. Examples such as Hypervisor Vulnerabilities, VM Escape, and VM Image Sprawl.
3) Storage-based Attacks: Attacks related to data confidentiality, integrity, and availability in cloud storage. Examples include Data Breaches, Data Isolation, and Data Backup and Redundancy.
4) Application-Based Attacks: The attacks are aimed at cloud infrastructure running applications. Examples include web services, malware infusion, and shared design vulnerabilities.
5) Identity and Access Management based attacks: Threats related to managing identities and providing secure and efficient access to data [18]. Examples include Identity Management, authorization, authentication, access control, and federation management.

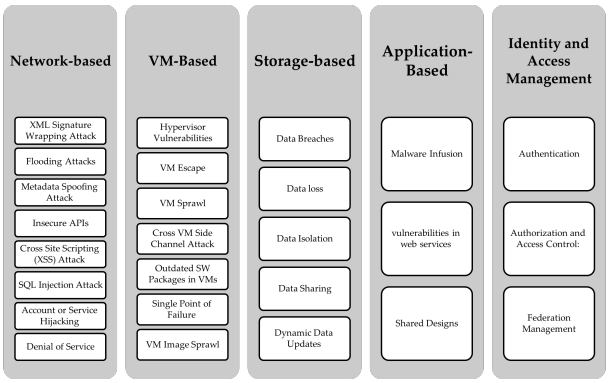

Fig. 3. List of cloud attacks based in category.

E. Anomaly Detection Definition

Finding data points, patterns or behaviors that are very different from the norm is known as anomaly detection [22]. When considering computing and cybersecurity, anomalies are indicative of possible issues, including security breaches, system failures and fraudulent activities or unusual behavior. Anomalies are outliers basically, data that doesn't conform to expected patterns or historical trends. Anomaly detection is used to detect these deviations early, so that organizations can take timely corrective action. Anomaly detection is important for reliability, security, and minimizing operational risk in modern systems and in the face of the variety of data and system complexity. Anomaly detection can be applied to a wide range of domains such as finance, healthcare, industrial monitoring and cloud computing in which real time and accurate anomaly detection can prevent a major loss or damage [13].

1) Anomaly Detection Techniques: The techniques can be categorized into three main types: statistical methods, ML techniques, and hybrid techniques.

- Statistical Methods: These techniques use statistical models to specify what normal behavior of a system is. Statistical methods build a baseline distribution from historical data, and flag any data point outside this distribution as an anomaly. Three common statistical techniques are z-score analysis, hypothesis testing and time series modeling [23]. These are easy to implement statistical methods, but can have difficulty with high dimensional data and in capturing complex patterns in dynamic environments.
- ML Approaches: Anomaly detection has gained popularity with ML due to its ability to learn directly from data while adjusting to evolving patterns. A variety of models are used in ML approaches to understand normal behavior and identify deviations which could indicate anomalies. These models are very useful in dynamic environments such as cloud environments where traditional models can fail to capture evolving patterns.
- Hybrid Techniques: Statistical, ML, or other domain specific anomaly detection methods could be combined to improve accuracy, robustness. Hybrid methods combine the strengths of different methods, filling the shortcomings of single techniques like increasing detection accuracy or reducing false positives. A hybrid approach may be a statistical model to identify potential anomalies, and apply a ML algorithm to validate it further. In complex environments like the cloud, these methods are effective where adaptive

learning and baseline modeling are both necessary to cope with dynamic changes.

Choice of anomaly detection technique is conditioned by data nature, availability of labeled data set, system complexity and desired detection accuracy and computational efficiency trade off. Each technique has pros and cons, and in most practical cases, a set of techniques are combined to obtain the best performance in real world settings.

F. Machine Learning

ML is a field of artificial intelligence concerned with enabling systems to learn and act based on data. The basic idea falls under training models to come up with patterns and predict without being explicitly programmed for the task that is required [24]. Due to its capacity to learn and get better with time, ML is now a must in many domains. ML is one of the important roles in cloud computing to improve security by automated detection of unusual or potentially malicious behaviors. ML models operating off large datasets can offer advanced and intelligent solutions to complicated issues such as anomaly detection.

G. Type of ML

Depending on their way of learning and the types of tasks, ML can be divided into various types.

1) Supervised Learning: Supervised learning is a type of ML where a model is trained using a labeled dataset, where input data is given along with corresponding outputs or labels [25]. By identifying patterns in the data, the model learns to map inputs to outputs. Supervised learning is very powerful in the case of anomaly detection in cloud computing, if there are a lot of labeled normal and anomalous behaviors [26]. For example, ML classification techniques commonly applied include classifications like Decision Trees (DT), Support Vector Machines (SVM), and Random Forests (RF), etc to classify activities as normal or anomalies. The major drawback of supervised learning, is that it is very hard to collect a large number of labeled data that are representative of rare events such as security breaches or insider threats [27]. Table I shows some of the supervised models.

2) Unsupervised Learning: It is a ML approach that does not demand labeled datasets. It does not look for normal behavior, nor does it look for anomalous behavior, instead it looks for patterns or groupings in the data without prior knowledge of what is normal and what is anomalous [25]. These techniques work by identifying deviation from known patterns, and are therefore particularly well suited to detecting new and previously unseen threats. One of the problems with unsupervised learning is that it is hard to tell the difference between benign deviations and actual security events without labeled data, and as a result, can have very high false positive rates. Table II shows some of the unsupervised models.

3) Reinforcement Learning (RL): It is learning what to do and how to map cases to actions to maximize a numerical reward signal. Unlike supervised and unsupervised learning, rather it is trial and error based sequential decision making with the agent's goal being to maximize cumulative rewards by taking the best possible actions [25]. RL can be used for developing adaptive security systems in cloud computing for anomaly detection, which models optimal reaction to threats as time elapsed. One of the reasons that RL is particularly appealing for cloud security is that it allows for real time adaptation to new and evolving threats [28]. RL has the potential to help improve the robustness and adaptability of cloud based anomaly detection systems.

TABLE I. LIST OF SUPERVISED ML MODELS SHOWING THEIR ADVANTAGES AND DISADVANTAGES

Model	Definition	Advantages	Disadvantages
RF [17]	It is algorithm used for classification and regression, where the data gets split into subsets and we train several DTs.	Automatic processing of missing values and no need to transform variables, good performance with many variables and large data, and high accuracy	Slow learning, large memory footprint, and difficult interpretation.
SVM [17]	A binary classification method that creates a hyperplane to divide two target values.	High accuracy, works well with high-dimensional data, and memory efficient	Poor performance with noisy data, and long training time.
Naïve Bayes (NB) [17]	Collection of classification algorithms based on Bayes theorem.	Easy to understand and configure, Fast and small memory footprint, and can learn from small data.	Failure to predict rare events, and possible overfitting.
Logistic Regression (LR) [17]	Statistical method for analyzing data with dichotomous outcomes.	Good outcomes with a small number of variables and easy to implement	Requires many samples for training, and not easy result interpretation.
DTs [17]	It used algorithm for classification and regression by dividing the data into areas of similar characteristics.	Easy to maintain and understand, good results with small data, and intuitive	Large memory footprint, tendency for overfitting, and, high variation in generated models.

TABLE II. LIST OF UNSUPERVISED ML MODELS SHOWING THEIR ADVANTAGES AND DISADVANTAGES

Model	Definition	Advantages	Disadvantages
K-Means Clustering [17]	Builds a hierarchy of clusters by connecting adjacent clusters.	Not sensitive to distance selection, accepts noisy data, does not require predetermination of the number of clusters.	Complex algorithm (O(n power 3)), cannot process large data volumes.
Hierarchical Clustering [17]	A binary classification method that creates a hyperplane to divide two target values.	High accuracy, works well with high-dimensional data, and memory efficient	Long training time, and poor performance with noisy data.

H. Ensemble Learning

It is a technique that uses multiple models to obtain better performance than any one model alone. Ensemble learning is an idea where predictions from several models of different knowledge and strategies are averaged, letting the resulting system handle overfitting and perform better [24]. Anomaly detection systems in cloud environments are improved by ensemble methods like bagging, boosting and stacking. Nevertheless, ensemble models are computationally expensive, and

their complexity makes them difficult to deploy in real time cloud environments[29].

III. ML's Role in Real-time Anomaly Detection in Cloud Computing

Fig. 4 shows several advantages of using traditional ML techniques for real time anomaly detection in cloud computing environments:

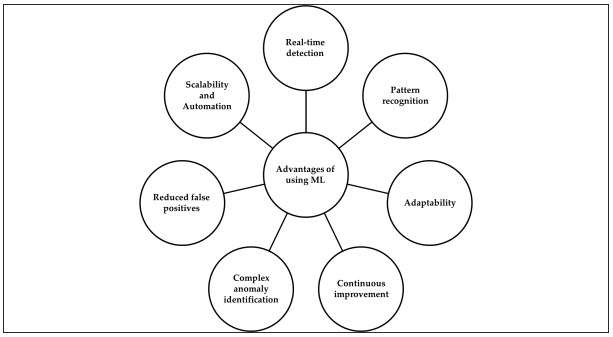

Fig. 4. Advantages of using traditional ML.

1) Real-time detection: ML is real time and immediately alerts when there are suspicious activities which is critical for responding to risks quickly [30].
2) Pattern recognition: On historical data, ML formulates complex patterns and trends and highlights normal activities against anomalies.
3) Adaptability: The ML models learn, update and change, almost continuously, to accommodate the evolving data patterns in a dynamic cloud environment.
4) Continuous improvement: Anomaly detection capabilities are made better and better by ML models through retraining with new data. This iterative improvement keeps the models effective at detecting new threats and adapting to ever changing cloud environment patterns.
5) Complex anomaly identification: Compared to other anomaly detection approaches, ML is unique because it can deal with multivariate anomalies from sources like unusual access patterns of users, different behavior in network traffic.
6) Reduced false positives: ML algorithms are trained to understand the unique behaviour of the organization's cloud environment so normal activities are less likely to trigger anomalies. With this precise tuning, security teams don't have to be overwhelmed with false alerts, but can concentrate on real threats.
7) Scalability and Automation: In cloud environment, ML consumes large volume of generated data and conducts an automated anomaly detection, reducing the manual intervention.

IV. Objective

The objectives of this research are as follows:

- To conduct a comprehensive literature review of existing research on anomaly-based ML detection in cloud computing.
- To investigate the ML techniques used, datasets used, and their accuracy.
- To examine the cloud computing models used.
- To develop a taxonomy for the systematic literature review to categorize and analyze the research findings.
- To identify the challenges and advantages of anomaly-based ML detection in cloud computing.
- To outline potential future directions for research in anomaly-based ML detection in cloud computing.

By addressing these objectives, this review aims to offer a clear understanding of the current landscape of anomaly detection using ML in cloud computing, highlight the barriers that need to be overcome, and propose directions for future innovations that can help secure cloud environments more effectively. The insights gained from this review can be valuable for both researchers and practitioners in the field of cloud security, guiding future research efforts and helping organizations implement effective anomaly detection solutions.

V. Research Methodology

We follow a systematic approach to review the existing literature on anomaly based ML detection in cloud computing, following the Preferred Reporting Items for Systematic Reviews and Meta Analyses (PRISMA) guidelines. It includes defining the research questions, selecting databases, developing search strings, establishing of inclusion exclusion criteria, and applying a quality assessment framework. The methodology is organized as follows:

A. Research Questions (RQ)

The following research questions (RQs) guide this study to provide a structured analysis of anomaly detection models in cloud computing environments:

- RQ1: What anomaly-based ML techniques are applied in cloud computing environments, and how are these models classified?
- RQ2: What datasets and evaluation metrics are used in the assessment of these models?
- RQ3: What are the primary challenges and benefits of using anomaly-based ML detection in cloud environments?
- RQ4: What gaps exist in the current literature, and what future research directions are suggested for advancing anomaly-based detection in cloud computing?

B. Data Sources and Search Strategy

To ensure comprehensive coverage of relevant studies, the search was conducted across the following academic databases:

- IEEE Xplore
- MDPI
- SpringerLink
- ScienceDirect

- ACM Digital Library

The keywords used for the selection based on the related research objectives:

("Anomaly Detection" OR "Anomaly") AND ("Machine Learning" OR "ML") AND ("Cloud Computing" OR "CC" OR "Cloud")

Only peer reviewed journal articles, conference papers published between 2020 and 2024 were considered to capture recent developments.

C. Inclusion and Exclusion Criteria

To filter search results for relevant studies, we established the following inclusion and exclusion criteria:

1) Inclusion Criteria:

- Studies that focus on anomaly detection using ML within cloud computing environments.
- Peer-reviewed journal articles, conference papers.
- Studies that provide empirical results or evaluations using datasets relevant to cloud settings.
- Publications written in English.

2) Exclusion Criteria:

- Studies not related to anomaly detection in ML applications for cloud computing.
- Publications that only provide theoretical models without empirical validation.
- Non-peer-reviewed sources such as theses, white papers, and editorials.

D. Study Selection Process

The study selection process adhered to the PRISMA framework, proceeding in three stages:

- Initial Screening: All retrieved articles were screened by titles and abstracts to exclude irrelevant studies and choose those meeting the inclusion criteria for full text review.
- Full-Text Review: Full texts of selected articles were reviewed to determine their relevance and quality. Excluded articles that did not provide detailed information on ML techniques, datasets or empirical evaluations.
- Data Extraction and Coding: A standardized form was used to extract data from the final set of articles, including anomaly detection techniques, datasets, evaluation metrics, as well as identified challenges and benefits.

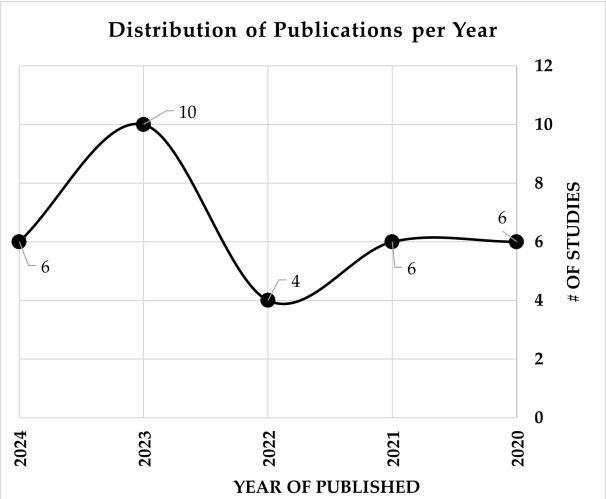

Fig. 5. Distribution of the selected studies per publication year.

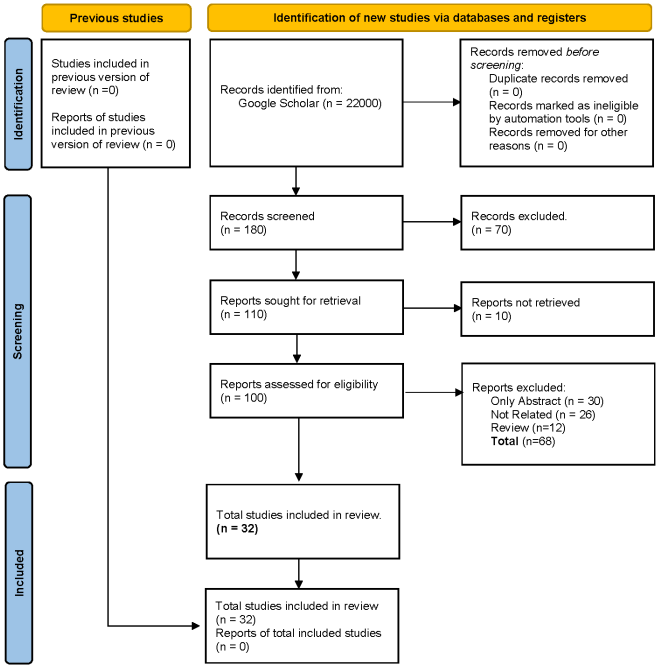

Fig. 6. PRISMA flow chart for the selection process.

E. Selection Results

With the application of selection criteria, 70 papers were excluded and 110 papers were selected for further review. Of these, 10 papers were not retrieved, and 100 articles were assessed for eligibility. At this stage, 68 articles were excluded leaving 32 articles in the final SLR. Fig. 5 shows distribution of the selected studies per publication year.

Fig. 6 shows the PRISMA flow diagram showing each stage of the process is presented in PRISAM.

VI. Literature Review

A. Supervised Models

Talpur et al. [31] presents a robust framework for DDoS attacks using evolutionary algorithms with ML models. They propose an innovative hybrid methodology that combines Extreme Gradient Boosting(XGBoost)-Genetic Algorithm(GA) Optimization, RF-GA Optimization, and SVM-GA Optimization with the Tree-based Pipelines Optimization Tool (TPOT). It automates the optimization of ML pipelines to enhance accuracy. Datasets such as KDD Cup 99 and CIC-IDS 2017 were used for the study, which achieved high accuracy scores of 99.99% for XGBoost-GA and SVM-GA, and 99.50% for RF-GA using 10-fold cross validation. Although effective, the methodology is limited by an increase in computational complexity resulting from multiple detection models and optimization phases.

Alduailij et al. [32] introduces an effective approach to DDoS attack detection in cloud environments. The main contribution is the use of Mutual Information (MI) and Random Forest Feature Importance (RFFI) for feature selection to reduce misclassification errors. The authors evaluate five ML models RF, Gradient Boosting (GB), Weighted Voting Ensemble (WVE), K-Nearest Neighbor (KNN), and LR. The method demonstrated to achieve high accuracy rates using the CICIDS 2017 and CICDDoS 2019 datasets, with RF reaching 99.997% accuracy and lowest misclassification errors when trained using 19 features. The study notes that KNN has a higher computational cost and models such as LR and GB need better parameter tuning. Although these limitations exist, the research proves that MI and RFFI feature selection can increase DDoS attack detection accuracy over different ML models.

DASARI and KALURI [33] suggests a hierarchical ML approach optimized for hyperparameter tuning to boost intrusion detection in networks due to DDoS attacks. The research uses the CICIDS 2017 dataset and preprocesses the data with normalization and balancing techniques such as Min-Max scaling and SMOTE. Feature selection is executed via the LASSO method, and the selected features are fed into five ML classifiers XGBoost, Light Gradient-Boosting Machine (LightGBM), CatBoost, RF, and DT. Model accuracy was improved through hyperparameter optimization. Of all these, LightGBM had the highest classification accuracy of 99.77%, better than all other models. It also mentions future areas of improvements in handling real time data and adaptive attacks. The work contributes to improving Intrusion Detection System (IDS) capabilities with hierarchical ML techniques for high precision and recall.

Mishra et al. [34] introduce a perplexed Bayes classifier model for identifying and mitigating DDoS attacks in cloud computing environments. This classifier uses the NSL-KDD dataset which contains DDoS attack scenarios and features. The innovation is in using correlation based feature selection to improve classification accuracy to a 99%. This method is benchmarked against the established algorithms of NB and RF and found to be more accurate, sensitive, and specific. Furthermore, they compare perplexed Bayes classifier against nature inspired feature selection techniques such as GA and Particle Swarm Optimization (PSO) and show that perplexed Bayes classifier achieves 2% to 8% higher accuracy.

Parameswarappa et al. [35] propose a new intrusion detection system for cloud computing based on ML and deep learning techniques to boost security. UNSW-NB15 dataset was used by the authors for developing and testing their model which consists of multiple classifiers, LR, KNN, DT, RF, Extra Trees, GB, and Multilayer Perceptron (MLP). It focuses on preprocessing by using K best feature selection for optimizing classification tasks. Models detected cloud anomalies and attacks with a detection rate of 97.68% by RF. The model improves precision and reduce false positives, but is limited by its dependence on labeled datasets and its use in broader cloud environments. This suggests further work of integrating advanced data mining, deep learning techniques into the existing anomaly detection process to increase its accuracy on various anomalies.

Advanced ML techniques are developed by M et al. [36] to enhance data security in cloud computing environment. They evaluate three ML models such as RF, Deep Neural Network (DNN), and Q-Learning across different experiments. RF model was reliable in categorizing security threats, with 95% accuracy and balanced precision of 0.92, recall of 0.96, and F1 score of 0.94. Also, DNN model demonstrated good performance with an accuracy of 97%, a recall of 0.98 and an F1 score of 0.96 and it could recognize complex patterns in cloud data. The research used cloud system data sets of logs, network traffic, and access patterns for anomaly detection and adaptive security response. The resource intensive nature of the deep learning models, difficulties to reduce false positives in Q-Learning and ethical issues, such as privacy preservation are also limitations. In particular, this work calls for the continuous optimization of ML models for cloud security to cope with the ever changing threat landscape.

ABUBAKAR et al. [37] propose a hybrid DDoS detection and mitigation mechanism using an optimized SVM is combined with SNORT Intrusion Prevention System (IPS). This integrated approach identifies malicious traffic early and mitigates attacks by rerouting or dropping suspicious packets. The methodology uses the KDDCup99 and DARPA datasets, while the abnormalities in real time network traffic are analyzed. The results show that the system achieves superior average detection accuracy of 97.9% compared to traditional SNORT IPS, Probabilistic Neural Networks (PNN) and Back Propagation methods. While the method has high accuracy and low false positives, it suffers from two limitations: multithreading and zero-day attack detection. The model focuses on supervised learning configurations for traffic behavior analysis and protocol validation, which is effective but limited by dataset quality and scope.

A sophisticated cloud IDS is introduced by BAKRO et al. [38] which utilizes a hybrid feature selection method combined with a RF classifier. The proposed methodology integrates Information Gain (IG), Chi-Square and PSO for selecting relevant features which increases the model accuracy and reduces the data dimensionality. The Synthetic Minority Over-sampling Technique (SMOTE) is used to address data imbalance, and robust performance in multi-class attack detection is ensured. The proposed system shows its effectiveness while detecting different attack types on the UNSW NB15 and Kyoto datasets with 98% and 99% accuracy rates, respectively. However, it

suffer from reliance on resource-intensive feature selection methods. The system is shown to significantly improve detection rates but may not necessarily generalize to real world cloud environments without further dataset diversity.

BAKRO et al. [39] presents a novel cloud IDS. The hybrid feature selection technique Grasshopper Optimization Algorithm (GOA) and GA aims to optimize feature selection and enhance IDS performance by improving classification accuracy and reducing computational complexity. This hybrid approach helps optimize feature selection while increasing accuracy of the classfied data and reducing amounts of computation. The model uses an RF classifier trained on the selected features with an ADAptive SYNthetic (ADASYN) algorithm for minority oversampling and RUS for majority class balancing. The proposed system is evaluated on three datasets including UNSW-NB15, CIC-DDoS2019, and CIC Bell DNS EXF 2021 and achieves accuracy of 98%, 99% and 92% respectively. However, because it is dependent on the specific datasets to evaluate on, and may not be generalizable. It achieved improvements in True Positive Rate (TPR) and False Positive Rate (FPR) along with better performance than state of the art classifiers like SVM, AlexNet and XGBoost.

A novel framework for cloud anomaly detection using a Secure Packet Classifier (SPC) is proposed by Chkirbene et al. [40] The SPC combines two ML algorithms selected based on accuracy and computational efficiency and leverages collaborative filtering. The main focus of the model is anomaly detection and classifying different types of attack which is crucial for targeted counter measures. Using the UNSW-NB15 dataset, the model delivered an impressive improvement on accuracy, detecting 81% of anomalies with a lower FPRthan the traditional methods. The work is constrained by the fact that the model relies on specific dataset properties and does not generalize to other datasets without significant retraining.

Aldallal and Alisa [41] propose to develop a hybrid IDS for cloud computing environments, which integrates GA for feature selection and SVM for classification. A novel fitness function is used by the system to measure the performance of the intrusion detection system, combining F1-score, accuracy and TPR to ensure balance and accuracy of the detection system. They used CICIDS2017 dataset for evaluation, results show that the proposed model provided up to 5.74% improvement on detection accuracy over benchmarks, while demonstrating its effectiveness. Although the system performed well, it required data preprocessing, including cleaning missing or corrupted entries, and relied on predefined datasets for evaluation rather than real-time data.

Jaber and Rehman [42] propose an IDS for cloud computing environments by combining Fuzzy C-Means (FCM) clustering with SVM. The hybrid FCM–SVM model proposed can overcome the limitations of conventional IDS including high false alarm rates and poor accuracy. The proposed system is implemented using the NSL-KDD dataset, with clustering used to group data points for improving SVM performance in anomaly detection. The system shows a capability to classify different types of network attacks with an accuracy of 97.37% for User to Root (U2R) attacks, 98.46% for Remote to Local (R2L) attacks and 98.85% for Probe attacks.

AlSaleh et al. [43] proposes a novel ML approach for detecting DDoS attacks in cloud computing settings using a Bayesian Convolutional Neural Network (BaysCNN). To achieve significant improvements in DDoS detection accuracy, BaysCNN uses a 19 layer architecture with an average accuracy of 99.66% across 13 multi class attacks. The study also improves model performance using the Bayesian-based Convolutional Neural Network with Data Fusion (BaysFusCNN) approach, which combines features from different sources, yielding a better accuracy of 99.79%. This research demonstrates that these models can tackle challenges including distinguishing application-layer attacks and real time detection. Bayesian methods are also used in the models to estimate uncertainties to improve reliability. The limitation is the dependence on the CICDDoS2019 dataset for which the results are not generalizable to other datasets and environments.

Sherubha et al. [44] propose a novel anomaly detection mechanism through an auto-encoder for feature selection and a NB classifier for classification. The approach improves the ability of existing IDS to deal with unlabeled data and reduces redundancy and noise in datasets. On NSL-KDD dataset, the model shows a detection accuracy of 93% which is better than traditional methods like J48 and RF. The main contribution of this study is the combination of unsupervised learning for dimensionality reduction and NB for robust classification, which achieves superior performance in detecting network anomalies. However, the approach is tested only on a static dataset, which limits its real time applicability and ability to address zero day attacks. The results of this research highlight the possibility of application of hybrid methodologies in order to improve intrusion detection in cloud computing environments.

Moreira et al. [45] propose ISAD; an intelligent system for anomaly detection in smart environments based on the integration between Fog and cloud computing. The system uses ML techniques to process network traffic and detect unusual behavior, offloading the data processing overhead to the Fog and cloud environments. A fog layer is used to perform raw network traffic data processing, feature extraction, and transmit filtered data to the cloud for dynamic anomaly detection using ML models. The system achieves high accuracy especially with RF, achieving 98.7% accuracy with Microsoft Azure. The CICIDS dataset is used, which represents real network traffic scenarios. The system shows robust performance, but it is reliant on fog and cloud environment computational infrastructure and has reduced recall in some ML configurations, which poses challenges in generalizing anomalies.

The authors, Alshammari and Aldribi, presents a lightweight ML based framework to boost IDS for detecting network anomalies [46]. In order to assess its performance, the framework utilizes the ISOT-CID dataset by incorporating novel features, more specifically the 'rambling feature', in classification. Also, In this study, six ML models such as DT, RF, and KNN are evaluated by using cross-validation and split validation techniques. Therefore, results show that DT and RF models are the most accurate, with 100% accuracy in both validation strategies. The novel feature addition and data preprocessing make the dataset better in quality, making the training of the models effective. While the model worked well, it requires large datasets and is not ready for real time deployment because of latency issues. This work points to future work, where deep learning approaches will be integrated to

overcome these limitations and better refine anomaly detection in real-time cloud environments.

Al-jumaili and Bazzi investigate the use of ML models to improve IDS in cloud environments, that suffer from dynamic threats and false positives [47]. The research compares and analyzes algorithms like DT, RF, XGBoost and SVM and finds XGBoost as the best effective model with 99.63% accuracy as it has a great GB capability. They use NSL KDD dataset, which is well known for its rich network intrusion patterns and perform robust preprocessing such as label encoding and data scaling to improve the performance of the model. However, since the research is based on synthetic datasets, it is not applicable in real world scenarios and more realistic cloud traffic should be validated. The results help explain how ML can be used to develop robust and scalable IDS solutions for the ever changing cloud landscape.

Naiem et al. [48] proposes a new framework to optimize the Gaussian Naïve Bayes (GNB) classifier for DDoS detection in cloud environments. The research acknowledges the GNB's limitations, dependency on feature independence, and sensitivity to the zero frequency problem by addressing them with an iterative feature selection process and advanced preprocessing. Also, feature selection techniques such as the Pearson Correlation Coefficient (PCC), MI and Chi-squared tests are used, and the SMOTE algorithm is used to address data imbalance. They demonstrate a 2% improvement in accuracy and substantial gains in precision, recall and F1-score. In addtion , the approach improves GNB's performance on the CICD2018 dataset to the level of other classifiers such as RF and SVM with the simplicity and computational efficiency.

Aslan et al. [49] propose a new cloud based malware detection system focusing on intelligent behavior analysis. The proposed Cloud-Based Behavior-Centric Model (CBCM) collects execution traces of suspicious files in VMs, identifies relevant behaviors, and extracts discriminative features. Both learning based and rule based detection agents process these features. They used ML classifiers such as RF and logistic model trees with 99.83% accuracy and a 0.6% FPRon a dataset of 10,000 samples for RF. Also, real time detection is further augmented by rule based agent. In addtion, the work uses cloud scalability to efficiently analyze malware, showing the high accuracy and speed of detection compared to traditional methods. Limitations, however, exist in the form of difficulty in detecting advanced obfuscated malware, and the requirement for broader dataset diversity. This research greatly enhances the malware detection efficiency in cloud computing environments.

Mehmood et al. [50] offer an advanced framework of privilege escalation attacks detection and mitigation within cloud computing environments, which is based on ensemble learning. The research works on a customized dataset from multiple CERT dataset files, using ML algorithms RF, Adaptive Boosting (AdaBoost), XGBoost and LightGBM to classify and mitigate insider threats. Moreover, the highest accuracy (97%) was achieved by LightGBM, which was better than RF (86%), AdaBoost (88%) and, XGBoost (88.27%). This was achieved by pre processing the dataset, training the models, and tuning the hyperparameters to solve the specific attack scenarios thereby leading to a robust detection mechanism. Insider threat research concludes that insider threats, in particular those resulting from privilege abuse, are especially critical and suggests ensemble learning for increased classification accuracy. Although the study yields promising accuracy, it is limited to a single dataset and is challenged in recognizing subtle attack patterns, which suggests future exploration of the diversity of datasets.

Bamasag et al. [51] introduce the Real-Time DDoS flood Attack Monitoring and Detection (RT– AMD) model which is aimed at mitigating the effects of DDoS attacks on cloud computing environments. The RT-AMD model works to utilize ML algorithms such as RF, KNN, NB, and DT, with high accuracy, to detect abnormal network traffic. The model is evaluated on the DDoS-2020 dataset, which contains balanced attack and normal traffic records for Transmission Control Protocol (TCP), Domain Name System (DNS), and Internet Control Message Protocol (ICMP) protocols, and achieves an accuracy of 99.38% in real time detection. The incremental learning capability further improves real time adaptation and detection without a costly retraining process. The study reveals the scope of expansion in its impressive accuracy and performance, including the incorporation of various DDoS types and evaluating on other cloud environments. This is key to advancing secure, real time cloud operations.

Chkirbene et al. [52] introduce a novel ML based weighted class classification scheme to tackle the challenges of anomaly detection in cloud computing, in the context of class imbalance problem. The system improves the classification accuracy of rare attack classes by integrating supervised learning with past node behavior and a weight optimization algorithm. The approach involves training a DT classifier on the UNSW-NB15 data set and using historical data to determine decision weights and obtains 95% accuracy. This framework significantly enhances multi class detection capabilities and is resilient to underrepresentation of minority attack classes. However, the reliance on historical data and the computational cost of weight optimization restrict the model's adaptability in dynamic real time environments.

In their work, Sambangi and Gondi investigate the use of MLR to detect DDoS attacks in cloud environments [53]. The study uses the CICIDS2017 dataset, focusing on the Friday afternoon traffic logs and applies an IG based feature selection technique to select critical attributes, reducing the dimensionality from 79 to 16 and then to 6. It is shown that the MLR model achieves 73.79% accuracy with 16 attributes. In addition, residual plots and fit charts are used by the authors to visualize the model's ability to differentiate between benign and attack traffic. The research is restricted to single day log data and does not explore ensemble or deep learning methods. This work contributes to enhancing the DDoS detection efficiency by simplifying the feature selection process and focusing on the regression analysis to handle the attack classification issues.

In response to DDoS attacks in cloud environments, Wani et al. [54] propose a robust IDS. They created a unique dataset with 21 attributes by using the CloudStack platform for experimentation and using Tor Hammer for generating malicious traffic. Also, the researchers evaluated six ML models: DT, NB, RF, C4.5, and SVM, K-Means. The SVM algorithm showed the best accuracy of 99.7% among the algorithms such as C4.5 (98.7%) and RF (97.6%). Furthermore, to evaluate the performance of the system, the dataset was analyzed by using Weka tool and evaluating the performance using precision,

recall metric. However, the study shows that data imbalance is a challenge, but does not consider more general attack scenarios or feature selection optimization. They contribute by showing that SVM is effective in detecting anomalies but their work is limited to specific tools and attack types.

P et al. [55] propose a ML framework for detection of phishing attacks in distributed cloud systems. In particular, the authors use supervised learning algorithms such as NB, SVM, and DT to detect phishing attacks. The study evaluates and compares the performances of these algorithms in terms of accuracy by using IDS generated dataset and shows that DT is the best method with slightly slower than other algorithms. The work aims at solving the critical challenge of resource management in cloud systems, which is often exploited for phishing attacks. Although the proposed model has a good detection accuracy, its response time is slower than the current standards and it depends on pre processed datasets which does not allow it to adapt to real time. The results highlight the importance of feature reduction and classification methodology for improving detection rates and reducing false alarms in cloud computing environments.

Kushwah and Ranga propose a novel system based on a Voting based Extreme Learning Machine (V-ELM) to detect DDoS attacks in cloud computing environments [56]. Unlike conventional single layer neural network approaches, the system uses multiple Extreme Learning Machines (ELM) with a majority vote mechanism to improve detection accuracy and reduce false alarms. The proposed model is evaluated using NSL-KDD and ISCX datasets and the accuracies of 99.18% and 92.11% respectively are shown. Accuracy and false positive rates for the system are shown to be superior to traditional models such as RF and Adaboost. But, this requires great amounts of labeled training data which can constrain it. Finally, the research mainly focuses on the challenges of high detection accuracy, false positive rates, and fast training and offers an efficient scalable DDoS attack detection solution.

Guezzaz et al. [57] propose a cloud based intrusion detection model by using the RF algorithm and feature engineering for improved anomaly detection. The research discusses the ever growing security challenges in cloud environments including unauthorized intrusions and real time attack detection. For the proposed framework, the feature set is reduced to only two important attributes of the NSL-KDD and Bot-IoT datasets while using data visualization to ease the feature engineering process. It achieved accuracy rates of 98.3% and 99.99% on these datasets. Although the model was able to achieve high precision and accuracy, it has low recall, meaning that it cannot detect all attacks of some types. It shows that RF can be a better classifier than SVM and DNN with a minimal feature set, and thus the work demonstrates the potential for using a minimal feature set for effective classification. Yet, there is room for improvement in recall and evaluation has yet to be done across various datasets. Table III presents a summary of supervised ML models, datasets and their accuracy rates as demonstrated by the related works.

The attacks, advantages, and disadvantages of supervised models for anomaly detection in cloud computing are highlighted in Table IV.

TABLE III. SUMMARY OF SUPERVISED MODELS AND THEIR ACCURACY RATES BASED ON RELATED WORK

Author	Year	ML Models Used	Dataset	Accuracy Rate

B. Unsupervised Models

Shanthi and Maruthi [58] introduced a new method to build anomaly-based IDS in cloud computing environment with the combination of Isolation Forest and SVM models. The proposed system aims to improve the efficiency and accuracy of detecting anomalous activities in large and complex network datasets. The study uses the NSL-KDD dataset to evaluate the performance of both models with Isolation Forest attaining an accuracy of 99% and SVM of 95%. Isolation Forest isolates anomalies via recursive random splits, and a supervised binary classifier SVM learns to identify anomalies by learning the normal vs anomaly distinction. Although Isolation Forest

TABLE IV. SUMMARY OF THE ATTACKS FOCUS, ADVANTAGES, AND DISADVANTAGES OF SUPERVISED MODELS IN ANOMALY DETECTION IN CLOUD COMPUTING

Ref	Attacks	Advantages	Disadvantages
[31]	DDoS	Superior pipeline optimization with TPOT.	Increased computational complexity.
[32]	DDoS	Integration of MI and RFFI for feature selection.	LR and GB require tuning to reduce errors.
[33]	DDoS	Hyperparameter tuning significantly improved overall performance metrics.	Limited to CICIDS dataset.
[34]	DDoS	Efficient feature selection method.	Dependent on pre-processed and structured datasets.
[35]	DDoS	Integration of historical and real-time decisions.	Dependency on labeled datasets.
[36]	Data breaches, unauthorized access	Ability to detect complex patterns.	Resource-intensive computation, privacy concerns.
[37]	DDoS	Early detection and mitigation of attacks.	Limited handling of zero-day attacks.
[38]	DoS, worms, and exploits.	High accuracy, robust detection rates.	Resource-intensive feature selection.
[39]	DoS, DDoS, and DNS attacks	Enhanced classification accuracy.	Limited evaluation datasets.
[40]	Analysis, Backdoor, DoS, Exploits, and others	Effective classification of attack types.	Requires significant retraining for new environments.
[41]	Brute-force attacks, SQL Injection, and others	Effective feature selection	Requires significant preprocessing for corrupted data.
[42]	U2R, R2L, Probe and DoS	High accuracy, low false alarm rates.	Dependency on pre-defined datasets.
[43]	Multi-class DDoS attacks	High accuracy.	Potential computational overhead for real-time scenarios.
[44]	DoS, probe, R2L and U2R	Effective feature selection	Ineffective against zero-day attacks
[45]	Network anomalies, including DDoS	Reduces data processing overhead by fog preprocessing.	Recall performance varies across models.
[46]	Malicious network traffic	Novel features like "rambling" improved detection performance.	Limited real-time deployment capability.
[47]	Network intrusions, anomalies, Unknown and zero-day attacks	Balanced precision and recall.	High computational cost for XGBoost.
[48]	DDoS	Iterative feature selection improves accuracy and reduces overfitting.	GNB still underperforms compared to more advanced classifiers.
[49]	Malwares	Combines ML and rule-based approaches for robustness.	Imbalanced dataset distribution of malware types.
[50]	Privilege escalation attacks (horizontal and vertical) and insider threats.	Efficient in identifying privilege escalation.	Limited dataset diversity restricts generalizability.
[51]	DDoS flood attacks targeting the network/transport layer (TCP, DNS, ICMP)	Real-time detection, high accuracy, uses incremental learning, and adaptive model.	Limited to specific attack types.
[52]	Analysis, Backdoor, DoS, Exploits, Fuzzers, Reconnaissance, Shellcode, Worms.	Enhances detection accuracy for rare attack classes.	Relies heavily on historical data; computationally intensive weight optimization.
[53]	DDoS	Demonstrates effectiveness of MLR	Limited to single-day traffic logs.
[54]	DDoS	Custom dataset tailored to cloud-specific scenarios.	Dataset imbalance issues.
[55]	Phishing attacks	Highlighted the importance of feature reduction to enhance detection speed and accuracy.	Slower response time.
[56]	DDoS	High detection accuracy.	Requires large labeled datasets.
[57]	General anomaly detection.	Low computational overhead due to reduced feature set.	Poor recall, and limiting generalizability.

has high accuracy and adaptability, it is also dependent on strong parameter tuning like contamination factor, and SVM is dependent on data portioning. The work suggests that careful feature selection and dimensionality reduction are necessary to enhance detection abilities.

Ntambo and Adeshina present a proactive anomaly detection model for detecting anomalies in VM resource usage in cloud environments with emphasis on the multitenancy vulnerabilities in public clouds [59]. The model uses Isolation Forest and One-Class Support Vector Machine (OCSVM) algorithms to detect anomalies in deviations of VM metrics such as CPU, memory usage and disk throughput. The dataset used is from the Grid Workload Archive, consisting of time series VM resource data. The results show that OCSVM gains the best accuracy with F1 = 0.97 for hourly and F1 = 0.89 for daily series compared to Isolation Forest. However, these results rely on specific datasets and only consider a limited set of real world scenarios. In this work, they contribute a scalable approach to augmenting cloud security with real time anomaly detection capabilities for VM resources.

Table V presents a summary of unsupervised ML models, datasets and their accuracy rates as demonstrated by the related works.

The attacks, advantages, and disadvantages of unsupervised models for anomaly detection in cloud computing are highlighted in Table VI.

TABLE V. SUMMARY OF UNSUPERVISED MODELS AND THEIR ACCURACY RATES BASED ON RELATED WORK

Author	**Year**	**ML Models Used**	**Dataset**	**Accuracy Rate**
Shanthi and Maruthi [58]	2023	Isolation Forest	NSL-KDD	99%
Ntambo and Adeshina [59]	2021	OCSVM	Grid Workload Archive	not specified.

C. Hybrid Models

Wang et al. [60] proposes a hybrid anomaly detection system for cloud computing environments using a Stacked Contractive Autoencoder (SCAE) and a SVM. A deep learning based SCAE for unsupervised feature extraction is proposed which transforms raw network traffic data into low dimensional robust representations. An SVM is used to classify these features for malicious activities. The methodology is evaluated on two benchmark datasets, KDD Cup 99 and NSL-KDD. Experimental results show that the model achieves good detection rates and has an accuracy of 87.33% in multi class classification tasks. The research also points out the limitations

TABLE VI. SUMMARY OF THE ATTACKS FOCUS, ADVANTAGES, AND DISADVANTAGES OF UNSUPERVISED MODELS IN ANOMALY DETECTION IN CLOUD COMPUTING

Ref	Attacks	Advantages	Disadvantages
[58]	Network-based such as intrusions	High accuracy, robust feature extraction, efficient handling of large datasets.	Dependence on hyperparameter tuning, limited response to encrypted traffic.
[59]	Anomalies in VM resource usage, including stealthy attacks exploiting multitenancy in public clouds	Combines VM metrics for improved anomaly detection.	Limited generalizability due to specific datasets.

of the classifier in identifying less common attack types and identifies directions for further optimizing the classifier. The results of this work suggest that hybrid models are a viable solution to the scalability and precision problems inherent in cloud IDS.

A hybrid clustering and classification-based approach to intrusion detection in distributed cloud computing environments is proposed by Samunnisa et al. [61]. They introduces a ML-based anomaly detection system that combines K-means clustering with RF classifiers to classify malicious activities across five types DoS, Probe, U2R, R2L, and normal. The model is tested using NSL-KDD and KDDCup99 datasets and shows high accuracy and low false alarm rates with 99.78% detection rate and 0.09% false alarm rate for NSL-KDD dataset. The methodology uses threshold-based functions and measures accuracy, detection rate and the area under the curve. The study points out that the datasets used are out dated and do not necessarily reflect the current network threats. It demonstrates that hybrid models can improve IDS but the use of the outdated datasets may limit their applicability to modern, evolving attack patterns..

Megouache et al. [62] present a new framework for intrusion detection that combines clustering and classification in cloud environments. It uses the K-means clustering to label previously unlabeled datasets and is able to use the ELM classifier to quickly identify and prevent malicious activities. Also, the proposed system is tested on the KDD99 dataset, where an accuracy of 99.2% in detecting non legitimate users is achieved. The main innovation is in the integration of clustering and classification to perform data segmentation and intrusion detection in an optimized manner, dealing with issues like scalability and false positives. In addition, the approach uses probabilistic methods to minimize data loss risks and improve real time cloud security. Still, the method is limited by the time needed to perform matrix operations to train large scale datasets. In summary, the work provides a high speed, accurate, and scalable solution for intrusion detection in the cloud, which is of significant importance to cloud security, but requires further work to improve scalability and processing efficiency.

Table VII presents a summary of hybrid models, datasets and their accuracy rates as demonstrated by the related works.

The attacks, advantages, and disadvantages of hybrid models for anomaly detection in cloud computing are highlighted in Table VIII.

D. Taxonomy of the Research

The research taxonomy Fig. 7 has been systematically organized in order to categorize ML methods used in the cloud computing and hence give a clear picture and structure to the field. The taxonomy categorized ML as supervised, unsupervised and hybrid techniques. Furthermore, this taxonomy benefits researchers and practitioners to select the specific dataset and to select the most appropriate technique for their use cases. Also, the purpose of this taxonomy ultimately is to provide a framework for driving innovation in and making better decisions about using ML to solve cloud computing issues.

TABLE VII. SUMMARY OF SUPERVISED MODELS AND THEIR ACCURACY RATES BASED ON RELATED WORK

Author	**Year**	**ML Models Used**	**Dataset**	**Accuracy Rate**
Wang et al. [60]	2022	SCAE and SVM	NSL-KDD	87.33%
Samunnisa et al. [61]	2023	K-means with RF	NSL-KDD	99.85%
Megouache et al. [62]	2024	K-means Clustering, ELM	KDD99	99.2% for detecting non-legitimate users

VII. CASE STUDY: PRIVILEGE ESCALATION ATTACK DETECTION IN CLOUD COMPUTING USING ML

A. Analyzing Real-World Case Studies

The study by Mehmood et al. [50] is a good example of providing ML solutions to a real world inspired scenario that addresses the issue of privilege escalation attacks in cloud computing. An example of privilege escalation attacks is cases where attackers abuse the faulty system vulnerability, misconfiguration or inadequate access control to receive increased access to resources or information. These attacks can be classified across horizontal privilege escalation or where an attacker gains access to another user's privileges, as well as vertical privilege escalation or where the attacker gains the higher level of access like administrative or root privileges. Based in that and without a doubt, privilege escalation attacks can grant an attacker unauthorized access to sensitive information or cause disruption of the critical system operations leading to through severe data breaches.

For this study, a customized CERT dataset was used to aggregate user behavior logs from various sources to emulate real world insider activities. Furthermore, malicious activities like unauthorized file copy to deleting files and abnormal system access patterns were also part of these activities.

The proposed methodology is to design a ML enabled insider threat detection system to classify and address privilege escalation attacks. The dataset was then preprocessed using carefully designed strategies to remove outliers, manage missing values and select appropriate features. The dataset was able

TABLE VIII. SUMMARY OF THE ATTACKS FOCUS, ADVANTAGES, AND DISADVANTAGES OF HYBRID MODELS IN ANOMALY DETECTION IN CLOUD COMPUTING

Ref	Attacks	Advantages	Disadvantages
[60]	R2L, U2R, Probe, and DoS.	Efficient feature extraction; high accuracy in detecting major attack types.	Limited detection of less-represented attack types.
[61]	R2L, U2R, Probe, and DoS.	High accuracy, low false alarm rates.	Relies on outdated datasets.
[62]	Anomalies and malicious user identification.	High accuracy in intrusion detection.	Computational inefficiency with large datasets due to matrix operations.

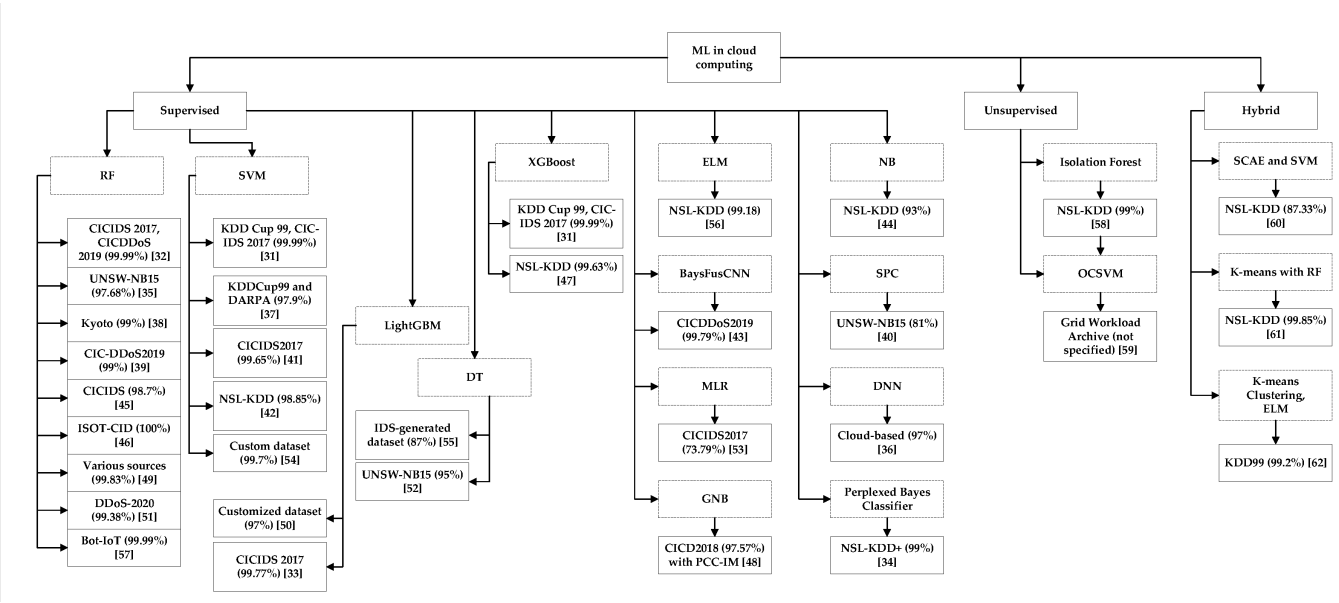

Fig. 7. Taxonomy of the Research

to simulate real world activities to provide an effective foundation in evaluating ML algorithms in real-world scenarios. In addition to ensuring the practical applicability of the models, this approach brought to light common challenges, including imbalanced data and effective feature engineering.

B. Insights from Actual Implementations

For detecting and classifying insider threats, the study employed four ML algorithms: AdaBoost, RF, XGBoost and LightGBM. The results of these algorithms were evaluated based on accuracy, precision, recall and F1 score for each algorithm. It is to note that, for the largest dataset, the LightGBM algorithm achieved the highest accuracy of 97%, due to its good leaf wise growth technique and also its performance on large dataset. Key insights from the implementation include:

- Algorithm Selection and Optimization: The results illustrated that using an ensemble approach is important to improve prediction accuracy by combining multiple models. The boosting techniques, especially LightGBM, were very good at catching complex patterns in high dimensional data, and are very effective for real world insider threat detection.
- Feature Engineering: Feature selection and preprocessing were emphasized as being critical. To improve model performance, features, that were irrelevant like ”employee” or ”file tree” were removed. The algorithms further gained stability on the learning of data by having data normalized and aggregated.
- Challenges in Data Quality: A large part of the first preprocessing phase involved handling missing values and outliers in the dataset. For example, while imputing the missing values in ‘File Copy’ feature, missing values were filled with the value which is found in the dataset patterns, hence not affecting the training process.
- Performance Metrics and Comparative Analysis: The performance metrics and confusion matrices helped them locate weaknesses and strengths of each algorithm. The high accuracy and low false alarm rate of LightGBM indicate that this solution can be used as a robust solution in real world deployments. Table IX shows the comparative analysis of performance metrics for the ML models in case study.
- Mitigation Strategies: The study not only discusses how detection of privilege escalation attacks is possible, but also suggests how such attacks can be suppressed to make them infeasible. As such, these include developing multifactor authentication and models of behavioral biometrics and secure access controls.

TABLE IX. LIST OF SUPERVISED ML MODELS SHOWING THEIR ADVANTAGES AND DISADVANTAGES

Algorithm	Accuracy	Precision	Recall	F1-Score	False Alarm Rate
RF	86%	86%	85%	85%	0.19
AdaBoost	88.27%	88%	86%	86%	0.16
XGBoost	89%	88.27%	87%	87%	0.13
LightGBM	**97%**	**97%**	**95%**	**95%**	**0.11**

C. Lessons Learned and Best Practices

The successful application of ML models in this case study highlights several best practices for implementing anomaly detection in cloud computing:

- Datasets are adapted to reflect real world scenarios to keep things practical and makes for better algorithm training.
- Using ensemble methods like LightGBM and XGBoost, combining the power of multiple methods, we have much higher accuracy and better reliability in threat detection.
- Preprocessing impact, They address the data quality issue of missing values and irrelevant features since these issues decrease model performance.
- The detection capabilities are complimented with preventive measures to include multifactor authentication and access control to provide additional security.
- Employees should be educated about cybersecurity best practice to reduce insider threats.

As indicated in this case study, ML algorithms have the potential to adequately deal with these complex cloud security challenges. These implementations provide valuable insights to guide anomaly detection projects in cloud environments in the future.

VIII. RESULTS AND DISCUSSION

The reviewed papers highlight several ML models that excel in anomaly detection for cloud computing environments. RF is shown to be the dominant supervised model as shown in Fig. 8, capable of reaching accuracy rates of 99.997% when complemented with powerful feature selection techniques such as MI and RFFI [32]. Other top performers include SVM, which may achieve accuracy of 99.99%, using techniques such as GAs or clustering [31], [41]. LightGBM and XGBoost, which are tree-based ensemble methods, have competitive accuracy 99.77% and higher when they are hyperparameter tuned [33], [47].

Anomaly detection associated with unsupervised and hybrid models is also critical. In unsupervised scenarios, Isolation Forest is very effective with 99% accuracy using recursive random splits [58]. Other hybrid models such as K-means clustering with a RF classifier deliver remarkable performance, and achieved an accuracy up to 99.85% [61]. Other innovative approaches, for example using autoencoders with a classifier such as SVM, were explored that can extract robust features and still achieve detection accuracy as high as 87.33% [60].

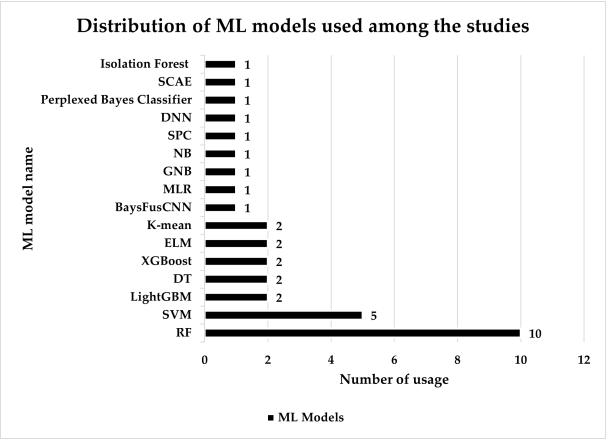

Fig. 8. Distribution of ML models used among the studies.

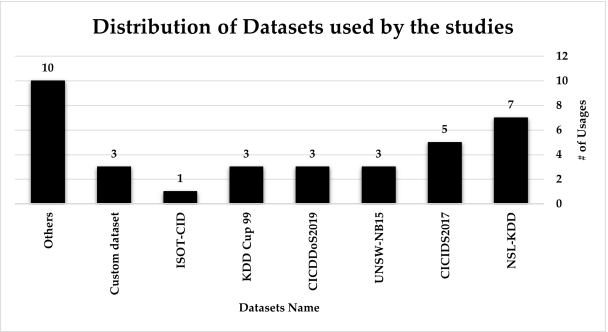

Fig. 9. Distribution of datasets used by the studies.

The challenges in imbalanced datasets and multi class anomaly detection are addressed by these hybrid and unsupervised models [52], [38].

Several advantages of using ML for anomaly detection in cloud environments are observed from the reviewed studies. Data dimensionality is reduced effectively, providing higher precision to a model using advanced feature selection techniques like LASSO, Chi-Square tests, and GAs [33], [38]. Often, hybrid approaches, combining clustering and supervised classification or unsupervised feature extraction with supervised classification are found to increase the accuracy and reduce the number of false positives [61], [62]. A second strength is scalability, and some studies have exploited cloud and fog computing to offload heavy computations and realize real time anomaly detection [45], [51].

However, the studies also identify notable limitations. Techniques such as genetic optimization and Bayesian networks improve accuracy add computational complexity, restricting their real time applicability [31], [43]. In many models, the datasets are highly dependent and based on CICIDS2017 and NSL KDD as shown in Fig. 9, which may limit their applicability in various and evolving cloud environments [41], [42]. Even high performing models such as DNNs continue to struggle with false positives [36]. Additionally, the experimental results are promising, but most systems are only tested on static datasets, so they are unable to handle real time detection or adapt to zero-day attacks [44], [53].

Feature handling is a critical factor for improving ML performance. Class imbalance and datasets are normalized using preprocessing techniques like Min Max scaling, SMOTE and ADASYN, that help improve model accuracy [33], [38]. LASSO and clustering (e.g., FCM–SVM hybrids) are adopted to perform feature sets optimization [42], [62]. In addition, several studies introduce new features, including rambling features and behavioral analytics, which can be used to enhance anomaly detection in a particular cloud scenario [46], [49].

RF and SVM models generally achieve high precision and recall, but perform poorly in detecting complex attack patterns [36], [43]. Techniques such as probabilistic methods and ELMs highlight speed and computational efficiency but the scalability is a concern with large scale datasets [62], [34]. The integration of fog and cloud improves system scalability at the cost of additional infrastructure [45], [51].

From these studies, valuable insights are drawn that emphasize the need for real time detection capability, including incremental learning in RT-AMD models that enable the models to adapt to dynamic threats [51]. However, the usage of outdated or synthetic datasets like KDD Cup 99 shows a need to have various and realistic benchmarks [31], [42]. Adaptive models, such as Bayesian methods and RL, are also studied by some to respond to changing threats, but these solutions are generally not optimized [43], [36]. Moreover, [36] emphasize ethical considerations especially on privacy preservation, in deep learning based systems.

IX. Challenges and Open Directions

- Development of Realistic Datasets: Future research should focus on creating and utilizing realistic, diverse, and up to date datasets that follow the real-world traffic patterns, including zero-day attacks and multi vector threats. This gap can be addressed by collaborative datasets derived from actual cloud systems.
- Scalable and Low-Latency Models: By optimizing ML models for computational efficiency, especially in the context of deep learning frameworks, it can help to deploy them in real time, high traffic environments. Incremental learning techniques, like those of RT-AMD, are promising areas for expansion [51].
- Advanced Feature Engineering: Additionally, incorporating novel features, behavioral analytic or domain specific characteristics rambling features proposed by [46] improve anomaly precision and reduce false positives.
- Integration of Hybrid Approaches: Addressing challenges such as data imbalance, generalization across datasets are possible by combining the strengths of unsupervised and supervised models such as the use of autoencoders for feature extraction and classes like SVM for detection.
- Enhanced Validation: Several, very different, datasets need to be validated across multiple models to promote generalizability. By benchmarking against real-time traffic from cloud providers [47], it can better evaluate their effectiveness in practical applications.
- Reduction of False Positives: Future studies include transferring ensemble methods or an advanced voting method (V-ELM) with the objective of reducing false positives and improving detection reliability [56].

X. Conclusion

Anomaly detection on cloud computing has emerged as an important application of ML and has provided us with robust tools to address evolving security challenges. RF and LightGBM models are very accurate on structured data and Isolation Forest capable of handling novel threats. Hybrid models that combine clustering with classification can deal with imbalanced datasets and with more complex attack patterns. Despite these advancements, limitations persist include the dependency on out-of-date dataset, computational inefficiencies, and high false positive rates. Future work must focus on developing realistic datasets that capture the dynamic nature of cloud environments, design of scalable models for real-time detection, and improvement of hybrid approaches to tradeoff between accuracy and adaptability. Techniques like incremental learning, advanced feature engineering, and ensemble methods should be prioritized to minimize false positives and improve model generalizability. Addressing these challenges will solidify the role of ML in protecting cloud infrastructures, towards making computing secure and resilient for a wide range of applications.

Enhanced Fuzzy Deep Learning for Plant Disease Detection to Boost the Agricultural Economic Growth

Mohammad Abrar
Faculty of Computer Studies, Arab Open University, Muscat, 130, Oman

***Abstract*—Plant disease detection is a crucial technology to ensure agricultural productivity and sustainability. However, traditional methods tend to fail as they do not address imprecise and uncertain data in a satisfactory way. We propose the Enhanced Fuzzy Deep Neural Network (EFDNN) which integrate the fuzzy logic with deep neural networks. This study aims to incorporate and allow assessment of the economic impact of the EFDNN on agricultural productivity for plant diseases detection. Data for the research framework were collected from remote sensing and economic sources. Preprocessing of data was done, namely normalization and feature extraction to make sure that the inputs are high quality. Deep Belief Networks (DBNs) were used as a way to pretrain the EFDNN model and supervised learning was then fine-tuned using this. Then, the model was evaluated with accuracy, precision, recall and area under the receiver operating characteristic curve (AUC-ROC), and compared against baseline models: convolutional neural networks (CNNs), traditional DNNs, and fuzzy neural network (FNNs). The plant disease detection performance of the EFDNN model was 95.2% accuracy, 94.8% precision, 95.6% recall, and 0.978 AUC-ROC. The accuracy of the EFDNN model was greater than the accuracy of CNNs by 92.3%, greater than traditional DNNs by 89.7% and FNNs' accuracy by 90.4%. In economic analysis, however, a reduced pesticide use and an increase in crop yield of USD120 per acre were calculated. 14.3%, leading to higher farmer revenues. The EFDNN model is an effective enhancement to plant disease detection that offers economic and agricultural benefits. This validates the potential of combining fuzzy logic with deep learning to enhance the performance and sustainability of agricultural practices.**

***Keywords*—Deep learning; plant disease; fuzzy deep learning; agricultural production**

I. Introduction

Agricultural sector is very important to the survival and economic status of most nations, especially in developing countries. It is an irreplaceable backbone of the rural economy, including ensuring livelihoods [1]. Nevertheless, plant diseases still represent a major challenge to reduce the overall annual crop yield and cause economic losses. Therefore, this impact can be mitigated and agricultural productivity improved by effective plant disease detection [2].

Remote sensing and ML represent two major frontiers in disease detection among these technological advances. By using these technologies, farmers can monitor large regions without causing damage, and get fast and accurate information that is necessary to control plant diseases [3]. Plant disease identification and classification problems have been shown to be promising problems for ML techniques, in particular, deep neural networks (DNNs). Part of the reason for this success is that fuzzy logic, which manages uncertainties and imprecise data, was integrated into neural networks to form Fuzzy Deep Neural Networks (FDNNs). The structural combination of DNNs with learning capabilities and fuzzy system flexibility yields FDNNs, which have been proven to be powerful tools for plant disease detection [4].

The aim of this study is to create a complete understanding of how advanced AI technologies can change modern agriculture in their technical performance as well as in terms of money. The motivation for this research stems from the urgency to resolve both food security and sustainable agriculture plans, especially in an epoch of escalating environmental and economic efforts. This study contributed to the larger goal of making farming systems more resilient and productive through the integration of advanced ML techniques with agricultural applications. This also aligns with global efforts of using technology towards sustainable development and is a nod to the role technology plays in solving some critical challenges in agriculture.

The primary objective of this study is to assess the economic impact of enhanced fuzzy deep neural networks (EFDNNs) on the detection of plant disease and agricultural productivity. This involves several specific goals:

- Examine how EFDNN models detect plant diseases compared to traditional methods and other ML techniques.
- Determine the potential cost savings and productivity gains from using EFDNN for plant disease detection.
- Investigate how implementing EFDNN can lead to more efficient use of agricultural resources, such as water, fertilizers, and pesticides.
- Based on the findings, propose recommendations for policymakers and agricultural stakeholders on effectively integrating EFDNN into existing agricultural systems.

This paper introduces the EFDNN model, which integrates fuzzy logic with deep neural networks to improve plant disease detection accuracy. A detailed methodology is provided, including data collection, preprocessing, model development, and evaluation. The EFDNN model outperformed other models by a significant margin in terms of accuracy, precision, recall, and AUC-ROC. An economic analysis highlights substantial cost savings and increased crop yields, demonstrating the

financial benefits of the proposed model. The findings underscore practical implications for farmers and policymakers, suggesting potential improvements in agricultural practices and crop management.

Further research directions include scaling the model to generalize deployments and integrating it with IoT and Big Data analytics.

The rest of the paper is organized as follows: Section II reviews relevant literature on plant disease detection techniques, fuzzy logic, and deep learning. Section III describes the methodology, including data collection, model development, and economic analysis. Section IV presents the results, highlighting the EFDNN model's performance and economic benefits. It also discusses the findings, their implications, and limitations. Finally, Section V concludes the paper and suggests future research directions.

II. Literature Review

The accurate detection of plant diseases in important not only for agricultural productivity but also for sustainable development. In the recent past, many studies have proposed developed models and techniques to contribute to the subject area. The techniques include traditional visual inspection to advanced machine and deep learning models with varying levels of success and their own limitations.

A. Overview of Plant Disease Detection Techniques

It is a very important area of research that, if the detection is timely and accurate, it can negate the crop loss. However, visual inspection by experts is a time-consuming, labor-intensive process with high human errors [5]. However, these methods are based on visual inspection, and a large knowledge base is required, and they are not suitable for large-scale agricultural fields [6]. Laboratory-based diagnostic methods, such as polymerase chain reactions (PCR) and enzyme-linked immunosorbent assay (ELISA), are effective, though often expensive and time-consuming [7]. The researchers in [8] proposed a CNN and transfer learning models to enhance disease prediction significantly. Similarly, [9] used machine learning techniques to provide an effective model for disease prediction.

The revolution of plant disease detection using remote sensing technology is that it allows aerial and satellite observation over a wide area of crop health. Early disease detection is possible through hyper-spectral and multi-spectral imaging techniques, with the data being captured in a timely manner [3], [6]. In addition to the rapid development of ML, an automated plant disease detection system has also arisen based on image processing to analyze plant images and detect plant disease symptoms. For instance, convolutional neural networks (CNNs) have achieved high accuracy in disease detection and classification [10].

Fuzzy logic systems are particularly effective in managing uncertainty and imprecision in data, making them suitable for plant disease detection. These systems use rules mimicking human inference to diagnose diseases based on observed symptoms. Integrating remote sensing data with ML models enhances accuracy and efficiency, leveraging the strengths of both approaches [11]. This fusion forms the foundation of modern plant disease detection systems, which are accurate, scalable, and cost-effective.

Plant disease detection is a good application of fuzzy logic systems because they are particularly good at dealing with uncertainty and imprecision in data. Rules that mimic human inference are used to diagnose diseases based on observed symptoms in these systems. The ML models can be integrated with the remote sensing data to increase the accuracy and efficiency, bringing the strengths of both approaches together [11]. Modern plant disease detection systems are accurate, scalable and cost effective, and this fusion is the basis of these systems.

B. Fuzzy Deep Neural Networks (FDNN)

Fuzzy Deep Neural Networks (FDNNs) are formed by combining the fuzzy logic systems and deep neural networks (DNNs) to handle uncertainties and data imprecision. Because it is approximate reasoning rather than fixed, fuzzy logic is appropriate for dealing with variability in agricultural environments [12]. ML algorithms, in the form of DNNs, gradually extract higher level features through a set of multiplies layers to learn complex relations [13].

Input data is preprocessed in FDNNs into fuzzy values by means of membership functions. The neural network learns patterns by adjusting neuron connections, and these values are passed to it. Since the real world of agricultural use is noisy, imprecise, or even incomplete, FDNNs are very good for it [14]. The architecture of most of their systems usually consists of a fuzzy input layer, hidden layers that implement fuzzy rules, and an output layer for classification or prediction [15].

FDNNs are shown to be effective in agricultural applications. For example, FDNNs have been applied for multi plant disease classification [16] and crop yield prediction [17], all of which were demonstrated in improving plant disease detection and management. As such, FDNNs are a robust plant disease detection solution to variability in symptoms in response to environmental conditions or plant variety.

C. Economic Implications of Technological Interventions in Agriculture

With the development of technological advancements, such as precision agriculture, biotechnology, and technology, production productivity and sustainability have increased. GPS, sensors, and drones are used to perform micro-level crop monitoring to make the best use of inputs such as water, fertilizers, and pesticides, lowering waste. The input costs are reduced by up to 20% and the yields are raised by 5 to 10% [18]. Genetically modified organisms (GMOs) and gene editing via CRISPR have ushered in biotechnological advancements for crops that are stress resistant; this leads to higher yields and a decrease in chemical input cost [19].

These tools increase the levels of transparency in the supply chain and market access [20]. Specifically, FDNNs can detect the disease on time and accurately for the resulting reduction in crop losses and management costs, which, in turn, improves agricultural productivity and profitability [21]. At the same time, they also opt for resource use more effectively, cutting specific costs while ensuring that they remain sustainable [4].

Despite the economic benefits, challenges such as high initial costs, lack of technical expertise, and resistance to change impede the widespread adoption of these technologies. Supportive policies, education, and training can address these challenges [22].

D. Comparison of Plant Disease Detection Techniques

Table I summarizes the attributes of various plant disease detection techniques, including traditional visual inspection, remote sensing, and ML techniques.

Technological innovations in agriculture enhance productivity, reduce costs, and promote sustainability. Continued innovation and investment in these technologies are essential to meet the growing global demand for food sustainably and economically.

III. Methodology

This section describes the methodology for developing and evaluating the EFDNN model for plant disease detection, which includes the data collection process, model architecture design, training and validation process, and economic analysis to test the model's financial sustainability.

A. Research Framework for EFDNN

The EFDNN research framework focuses on integrating the fuzzy logic of DNNs to improve plant disease detection. This methodology uses the benefits of both methods, effectively handling uncertainties and imprecise data. Fig. 1 depicts the research framework of EFDNN.

B. Data Collection

Effective data collection is necessary to develop and validate the EFDNN model for plant disease detection and economic impact evaluation. This section describes the types of data collected and the methods used.

1) Remote sensing data: Remote sensing data are helpful in monitoring plant health over large agricultural areas without causing damage to plants. These data are acquired through satellites, drones, and ground-based sensors. Therefore, getting good coverage and detail in crop conditions is possible. In this work, the Plant Village dataset [23] was used, as it is a well-accepted and comprehensive dataset for plant disease detection, as outlined in Table II.

Sentinel-2 and Landsat 8 satellites can acquire multi-spectral and hyper-spectral data with resolutions between 10 and 30 meters. These images were processed to derive vegetation indices like the Normalized Difference Vegetation Index (NDVI) and the Enhanced Vegetation Index (EVI), which will show plant health and stress. Unmanned Aerial Vehicles (UAVs) or drones acquire high-resolution images on demand. Drones mounted with multi-spectral cameras describe crop images, thus enabling the location of disease symptoms at the plant level [24]. This data is collected by multi-spectral sensors across several specific wavelength bands. This data can be used for general plant health detection and to identify possible regions of disease outbreak [25]. Hyper-spectral sensors provide very detailed spectral information since they collect data at hundreds of narrow wavelength bands. This spectral data, which has a very high resolution, enables the detection of specific changes related to disease in plant reflectance, which are invisible to the naked eye [6].

2) Economic data: An analysis of the cost-effectiveness and economic benefits of using EFDNN for plant disease detection requires data on the economics of the problem. More specifically, this data includes information on the yield of crops, the cost of inputs, the price at which the outputs are traded in the market, and the cost of disease management, as summarized in Table III.

Data on crop yields have been collected from the USDA, FAO, agricultural surveys, and field reports of past and current times. Such information is useful in evaluating the effects of the diseases on plant production and the improvements that can be made by early identification and control of the disease [26]. Seed, fertilizer, pesticide, and labor costs are obtained from farmer's records and market surveys. The different types of costs will be important in deriving the cost-benefit analysis of the EFDNN system [27]. Exchange of commodities and market reports provide data on the price of crops. Market prices are among the data that will be used in determining the economic returns due to increased crop yield as a result of better disease control [19].

Agricultural expenses are presented by the costs of disease prevention and treatment, which are reflected in farmer record books and extension services in agriculture, as well as the cost of pesticides and fungicides. The estimated potential cost savings from earlier and more accurate disease detection according to the EFDNN model are discussed in the analysis [28]. Therefore, the efficiency of the EFDNN model and its economic impact on detecting plant disease in agricultural yield are highly valued based on remote sensing and economic indications.

C. EFDNN Model for Plant Disease Detection

Incorporating fuzzy logic and DNN in developing the EFDNN model accelerates the diagnosis of plant diseases. This section describes the model, its training approach, and the validation process.

1) Model architecture: In EFDNN, the proposed model is based on a DNN architecture enhanced with fuzzy logic to address fuzziness and noise in agricultural data. The architecture consists of an input layer, a fuzzy logic layer, hidden layers, and an output layer.

The input layer gathers data from various sources, such as remote sensing imagery and sensor data. The input features are fuzzified by applying membership functions to each feature. Let x_i be an input feature. The fuzzy membership function $\mu_A(x_i)$ is defined as:

$$\mu_A(x_i) = \frac{1}{1 + e^{-a(x_i - b)}} \tag{1}$$

where a and b are parameters controlling the shape of the membership function.

TABLE I. PLANT DISEASE DETECTION TECHNIQUES AND THEIR ATTRIBUTES

Ref	Method	Accuracy	TPR	FPR	TNR	FNR	Precision	Benefits
[5]	Visual Inspection	Low	-	-	-	-	-	Simple, cost-effective
[6]	Remote Sensing	Moderate	-	-	-	-	-	Early detection, large area coverage
[10]	CNN	High	95%	5%	90%	10%	94%	High accuracy, automated detection
[11]	ML Integration	High	92%	8%	88%	12%	90%	Combines strengths of multiple techniques
[18]	Deep Learning	High	96%	4%	93%	7%	95%	Capable of learning complex patterns

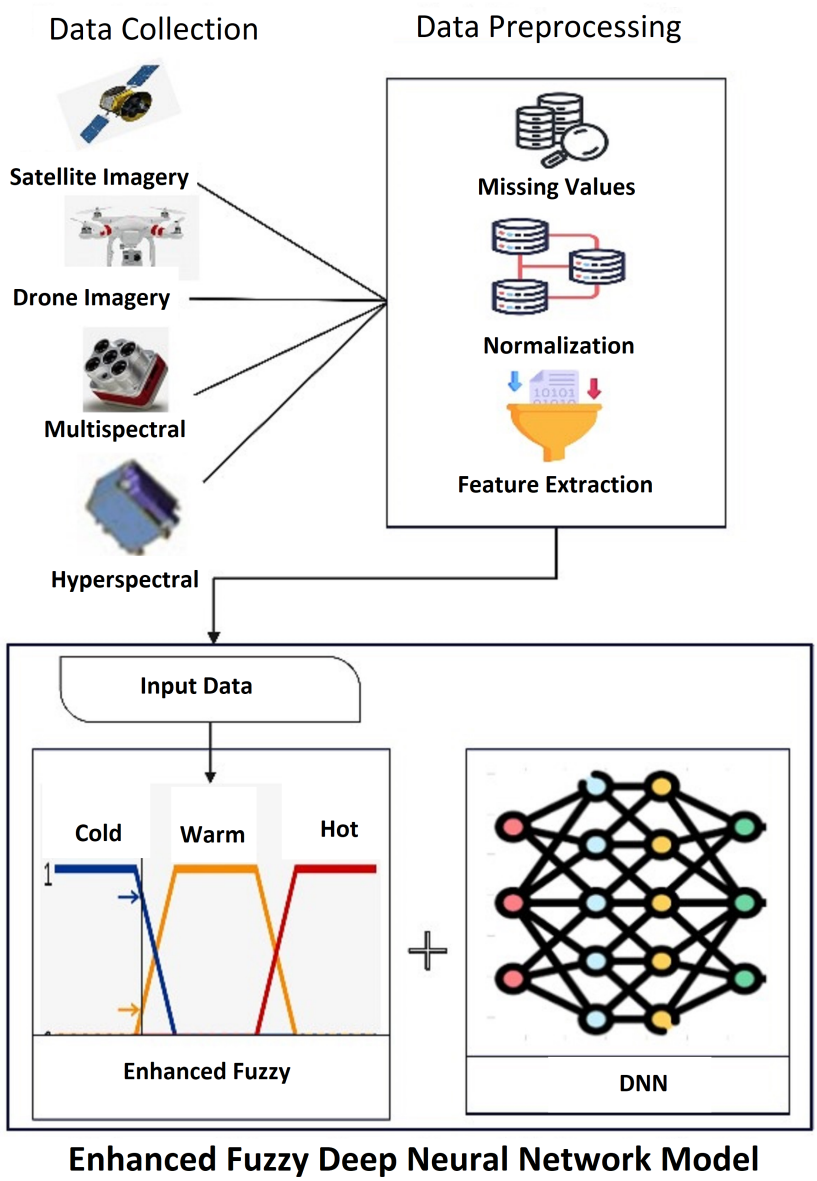

Fig. 1. Research framework of the EFDNN model.

TABLE II. TYPES OF REMOTE SENSING DATA AND THEIR CHARACTERISTICS

Data Type	Source	Resolution	Frequency	Key Parameters Measured
Satellite Imagery	Sentinel-2, Landsat 8	10-30 meters	5-16 days	NDVI, EVI, leaf area index, soil moisture
Drone Imagery	UAVs (Drones)	High (cm-level)	On-demand	Plant health indices, disease symptoms
Multi-spectral	Cameras, Sensors	Various	Continuous	Reflectance at multiple wavelengths
Hyper-spectral	Hyper-spectral Sensors	High (nm-level)	Continuous	Detailed spectral signature of plants

TABLE III. TYPES OF ECONOMIC DATA AND THEIR SOURCES

Data Type	Source	Description
Crop Yield Data	USDA, FAO, Agricultural Surveys, Field Reports	Historical and current crop yields for various crops
Input Costs	Farmer Records, Market Reports	Costs of seeds, fertilizers, pesticides, labor
Market Prices	Commodity Exchanges, Market Reports	Prices of crops in local and international markets
Disease Management Costs	Farmer Records, Agricultural Extension Services	Costs related to disease prevention and treatment

The fuzzy logic layer applies fuzzy rules to the input features. Each rule R_j is formulated as an IF-THEN statement. For example:

$$R_j : \text{IF } x_1 \text{ is } A_1 \text{ AND } x_2 \text{ is } A_2 \text{ THEN } y \text{ is } B_j \quad (2)$$

where A_1 and A_2 are fuzzy sets, and B_j is the output fuzzy set. The output of the fuzzy logic layer f_j is calculated using the fuzzy inference mechanism:

$$f_j = \mu_{A_1}(x_1) \times \mu_{A_2}(x_2) \quad (3)$$

where A_1 and A_2 are fuzzy sets and x_1 and x_2 are some input features. The hidden layers in the neural network process the fuzzy outputs. These layers consist of multiple neurons performing non-linear transformations using activation functions such as the Rectified Linear Unit (ReLU):

$$h_i = \max(0, W_i \cdot f + b_i) \quad (4)$$

where W_i is the weight matrix, f is the input vector from the fuzzy logic layer, and b_i is the bias term.

The output layer generates the final prediction, which is either a disease classification or a probability score. For classification tasks, a softmax function converts the output logits into probability distributions:

$$P(y = j|h) = \frac{e^{W_j \cdot h}}{\sum_{k=1}^{K} e^{W_k \cdot h}} \quad (5)$$

where W_j are the weights associated with class j, and h is the input from the last hidden layer.

2) Training and validation: The EFDNN model's training and validation process includes training, cross-validation, and hyperparameter tuning to optimize its efficiency in detecting plant diseases.

The training process involves optimizing the model parameters to minimize prediction error. The loss function L used for training is typically the cross-entropy loss for classification tasks:

$$L = -\sum_{i=1}^{N}\sum_{j=1}^{K} y_{ij} \log(P(y = j|h_i)) \quad (6)$$

where y_{ij} is the true label for the i-th sample, and $P(y = j|h_i)$ is the predicted probability for class j.

The model parameters W and biases b are updated using gradient descent algorithms such as Stochastic Gradient Descent (SGD) or Adam:

$$W_{\text{new}} = W_{\text{old}} - \eta \frac{\partial L}{\partial W}, \quad b_{\text{new}} = b_{\text{old}} - \eta \frac{\partial L}{\partial b} \quad (7)$$

where η is the learning rate.

During training, a validation set monitors the model's performance and prevents overfitting. Validation accuracy A_{val} is calculated as:

$$A_{\text{val}} = \frac{1}{M}\sum_{i=1}^{M} 1(\hat{y}_i = y_i) \quad (8)$$

where 1 is the indicator function, $\hat{y}_i$ is the predicted label, and y_i is the true label for the i-th validation sample.

To ensure the model's robustness, k-fold cross-validation is employed. The dataset is divided into k subsets, and the model is trained and validated k times, each time using a different subset as the validation set and the remaining subsets as the training set. The final performance metric is the average of the k validation results:

$$A_{\text{cv}} = \frac{1}{k}\sum_{j=1}^{k} A_{\text{val},j} \quad (9)$$

Hyperparameters such as the learning rate, batch size, and the number of hidden layers are tuned using grid search or random search methods. The hyperparameter set that maximizes validation accuracy is selected.

3) Algorithm configuration: Algorithm 1 describes the configuration of the proposed EFDNN model.

D. Economic Analysis

Therefore, evaluating productivity gain analysis forms a critical part of the economic analysis for identifying plant diseases using the EFDNN model. The following section describes the approach to working out the cost-benefit and productivity indicators.

1) Cost-Benefit Analysis (CBA): The cost-benefit analysis measures cost with the EFDNN model, while the economic benefits derived are their measures. This ranges from simple evaluations as a project's net present value (NPV) to more complex analyses.

NPV determines the values of all the flows of money (benefits and costs) in the present time by discounting them. The formula for NPV is:

Algorithm 1: Training Process for Enhanced Fuzzy Deep Neural Network (EFDNN)

Input: Raw data X, fuzzy membership functions μ_A, pre-trained DBN weights, labeled data Y.
Output: Trained EFDNN model.
foreach $x_i \in X$ **do**
  Initialize fuzzy membership function $\mu_A(x_i)$ with parameters a, b.
foreach $x_i \in X$ **do**
  Compute fuzzy membership value:

$$\mu_A(x_i) = \frac{1}{1 + e^{-a(x_i - b)}}.$$

foreach *fuzzy rule* R_j **do**
  Compute rule output:

$$f_j = \mu_{A_1}(x_1) \cdot \mu_{A_2}(x_2).$$

foreach *Restricted Boltzmann Machine (RBM) layer* l **do**
  Perform Gibbs sampling to update weights and biases:

$$W_{l,\text{new}} = W_{l,\text{old}} - \eta \frac{\partial L}{\partial W_l}, \quad b_{l,\text{new}} = b_{l,\text{old}} - \eta \frac{\partial L}{\partial b_l}.$$

foreach *input* f_j **do**
  Combine fuzzy outputs with DBN activations h_i:

$$h_i = \max(0, W_i \cdot f + b_i).$$

Apply softmax function for classification:

$$P(y = j|h) = \frac{e^{W_j \cdot h}}{\sum_{k=1}^{K} e^{W_k \cdot h}}.$$

while *loss L does not converge* **do**
  Update weights and biases using labeled data Y:

$$L = -\sum_{i=1}^{N} \sum_{j=1}^{K} y_{ij} \log(P(y = j|h_i)).$$

foreach *validation set* **do**
  Evaluate using metrics such as accuracy, precision, recall, and AUC-ROC.
  Optimize hyperparameters (e.g. learning rate, batch size, layers) using grid or random search.
Return trian_Model.

$$\text{NPV} = \sum_{t=0}^{T} \frac{B_t - C_t}{(1 + r)^t}, \tag{10}$$

where B_t is benefits in the year t, C_t is costs in a year t, r is the discount rate and T is time horizon.

The costs include initial setup costs (hardware and software), training costs for personnel, and ongoing operational costs. Let C_0 represent the initial setup costs, and C_{op} the annual operational costs. The total costs over time can be represented as:

$$C_t = C_0 + \sum_{t=1}^{T} C_{\text{op}}. \tag{11}$$

The benefits include cost savings from reduced pesticide use, increased crop yields, and avoided losses due to early disease detection. Let S_p represent savings from pesticide reduction, Y_i the increase in yield, and A_d the avoided losses. The total benefits over time can be represented as:

$$B_t = \sum_{t=1}^{T} (S_p + Y_i + A_d). \tag{12}$$

The benefit-cost ratio (BCR) is the ratio of the present value of benefits to the present value of costs. It is calculated as:

$$\text{BCR} = \frac{\sum_{t=0}^{T} \frac{B_t}{(1+r)^t}}{\sum_{t=0}^{T} \frac{C_t}{(1+r)^t}}. \tag{13}$$

A BCR greater than 1 suggests that the benefits received through the proceeding of the project exceed the costs, and thus it is economically feasible.

2) Productivity metrics: Impact measurements measure the organization's productivity level in improving agricultural productivity by applying the EFDNN model. These are yield increase, optimization of inputs use, ROI, and decrease in pesticide use.

The yield increase is the percentage of increase in crop yield realized when the EFDNN model has been used. It is calculated as:

$$Y_{\text{inc}}(\%) = \frac{Y_{\text{post}} - Y_{\text{pre}}}{Y_{\text{pre}}} \times 100, \tag{14}$$

where Y_{post} is yield after implementing EFDNN and Y_{pre} is yield before implementing EFDNN.

The input use efficiency measures how effectively inputs such as water, fertilizers, and pesticides are used. It is calculated as the ratio of output (yield) to input use:

$$E_{\text{input}} = \frac{Y_{\text{post}}}{I_{\text{post}}}, \tag{15}$$

where I_{post} represents the inputs used after implementing EFDNN.

ROI is a measure of the profitability of the investment in the EFDNN model. It is calculated as:

$$\text{ROI}(\%) = \frac{B_t - C_t}{C_t} \times 100. \tag{16}$$

The reduction in pesticide use due to accurate disease detection can be quantified as:

$$\text{Pred}(\%) = \frac{P_{\text{pre}} - P_{\text{post}}}{P_{\text{pre}}} \times 100, \tag{17}$$

where P_{pre} is pesticide use before EFDNN implementation, and P_{post} is pesticide use after EFDNN implementation.

Thus, based on these measures, the study will be able to express the economic effects of the EFDNN model, which means that it will be possible to show its feasibility in terms of profitability or financial efficiency.

IV. Results

This section discusses data obtained by applying the proposed EFDNN model for plant disease detection. The effectiveness of the proposed model has been measured with the required matrices and compared with the other baseline models for evaluation. The proposed model has also been applied for economic benefits.

A. Accuracy and Performance of the EFDNN Model

The performance of the EFDNN model was evaluated based on the measures explained in the methodology segment. It comprises accuracy, precision, recall, F1-score, and AUC-ROC measures. The performance of the proposed EFDNN model is compared to other baseline models: Basically, named entities can be excluded in CNN, DNN, and FNN.

Using the EFDNN model, the dataset containing massive images of plant diseases was analyzed, and the overall summary of every model, including Accuracy, Precision, Recall, F1-Score, and AUC-ROC, is given in Table IV.

TABLE IV. Performance Metrics of Different Models

Model	Accuracy	Precision	Recall	F1-Score	AUC-ROC
EFDNN	95.2%	94.8%	95.6%	95.2%	0.978
CNN	92.3%	91.5%	92.8%	92.1%	0.941
Traditional DNN	89.7%	88.9%	90.1%	89.5%	0.912
FNN	90.4%	89.8%	90.7%	90.2%	0.920

Thus, the models examined in this study used the EFDNN model to accurately recognize plant diseases, confirming its higher discriminatory power than the other models. The values of Precision and Recall mean that the model can correctly classify true positives, yet it maintains that low positives and high negatives are False. The density plots are represented in Fig. 2 by comparing the distribution of actual crop yield with the distributions predicted by four different models: EFDNN, CNN, DNN, and FNN.

A confusion matrix gives a detailed breakdown of the model performance using true positive, true negative, false positive, and false negative rates. For the EFDNN model, the confusion matrix is presented in Fig. 3.

The confusion matrix shows that the EFDNN model had a relatively high true positive rate, whereby 475 out of 500 samples were correctly diagnosed. In contrast, the false negative rate was very low, at 25 out of 500 samples, a promising performance in identifying diseased plants.

The EFDNN model proposed here performs much better than the CNN, traditional DNN, and FNN models. The statistical comparison of the performance metrics is presented in Table V. The paired t-test confirmed that these results are statistically significant, with p-values less than 0.05 for all the comparisons; therefore, the differences are statistically significant.

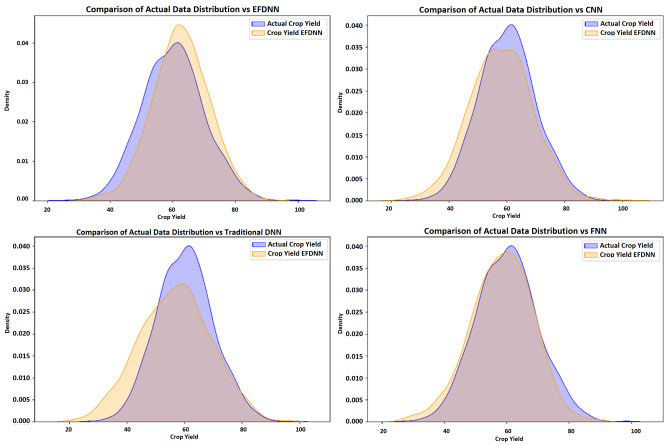

Fig. 2. Comparison of actual data distribution vs EFDNN, CNN, traditional DNN, and FNN.

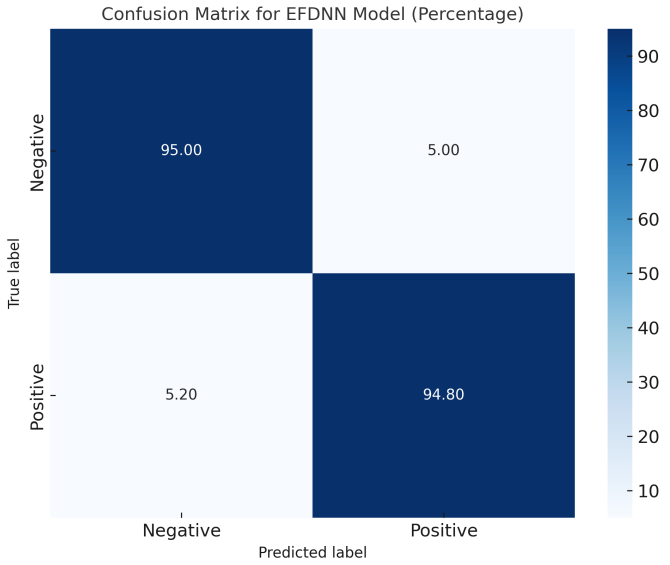

Fig. 3. Confusion matrix for the EFDNN model.

TABLE V. Statistical Comparison of Performance Metrics

Comparison	t-Statistic	p-Value
EFDNN vs. CNN	3.21	0.002
EFDNN vs. DNN	4.56	0.0001
EFDNN vs. FNN	3.87	0.0003

The high performance and accuracy metrics of the EFDNN model reveal good applicability toward plant disease detection in real-world applications. Incorporating fuzzy logic with DNNs would help the model deal well with imprecise and uncertain data, resulting in better classification performance. The results show that the EFDNN model is quite robust and generalizes very well with new unseen data, thus providing a useful tool for farmers and agricultural professionals.

TABLE VI. COST-BENEFIT ANALYSIS OVER FIVE YEARS

Year	Initial Cost ($)	Operational Cost ($)	Total Cost ($)	Annual Savings ($)	Net Savings ($)	Cumulative Savings ($)
1	50,000	15,000	65,000	12,000	-53,000	-53,000
2	0	15,000	15,000	12,000	-3,000	-56,000
3	0	15,000	15,000	12,000	-3,000	-59,000
4	0	15,000	15,000	12,000	-3,000	-62,000
5	0	15,000	15,000	12,000	-3,000	-65,000

TABLE VII. ADDITIONAL REVENUE FROM INCREASED YIELD

Crop Type	Increase in Yield (kg/acre)	Price ($/kg)	Additional Revenue ($/acre)
Wheat	400	0.20	80
Corn	600	0.15	90
Soybean	300	0.25	75
Average	433.3	0.20	81.67

B. Economic Benefits

Implementing the EFDNN model for plant disease detection produces immense economic benefits. These benefits can be categorized as cost savings and increases in agricultural productivity. This section explains these economic benefits, providing evidence in Table VI.

For an extensive understanding of the economic benefits, a cost-benefit analysis has been done for five years, as depicted in Table VI. This comparison was made between the initial and running costs of implementing the EFDNN model and the expected annual savings.

The initial cost of setting up an EFDNN model is $50,000, while the annual cost of running an EFDNN model is $15,000. The input saved due to reduction usage provides an annual saving of $12,000, resulting in a net saving. Over the five years, cumulative savings tend to reduce expenditure, which means that it is economically justifiable to apply the EFDNN model in the long run.

The economic impact of higher productivity in agriculture is measured by ascertaining the additional revenue with the increase in crop yield. Table VII presents the additional revenue per acre due to increasing crop yields.

V. CONCLUSION AND FUTURE WORK

The economic analysis of the EFDNN model shows that it greatly reduces associated costs and increases productivity in agriculture. This improved productivity increases gains, hence giving the EFDNN model a positive ROI by enhancing economic sustainability in agricultural practices. The EFDNN model greatly improves accuracy in detecting plant diseases compared to traditional models such as CNNs, DNNs, and FNNs. The integration of fuzzy logic with DDNs can be such that imprecise and uncertain data are considered for better disease classification.

Economically, the EFDNN model has afforded immense savings with great reductions in pesticides, fertilizers, and other inputs. Furthermore, it increases the crop yield and, hence, the revenue for farmers. This is evidenced by the cost-benefit analysis and ROI calculations. The robustness and generalizability of the model provide an effective tool for real-world agricultural applications towards helping farmers undertake timely preventive measures to avert crop losses.

Future studies should scale the EFDNN model for greater coverage, embed it with IoT devices to act, and analyze big data to extend its functionality. Further research should be conducted on advanced data augmentation techniques. Incorporating features of soil health and weather conditions can make the model more predictive. Longitudinal research is needed to track the long-term model's impact on productivity and sustainability; policy research could identify economic incentives supporting its adoption. The model will further be elaborated and fine-tuned by an in-depth assessment of environmental benefits together with agricultural experts. In this respect, addressing these future directions would make the EFDNN model a better tool for improving agricultural productivity and sustainability.

***Abstract*—Accurate and contextually faithful responses are critical when applying large language models (LLMs) to sensitive and domain-specific tasks, such as answering queries related to quranic studies. General-purpose LLMs often struggle with hallucinations, where generated responses deviate from authoritative sources, raising concerns about their reliability in religious contexts. This challenge highlights the need for systems that can integrate domain-specific knowledge while maintaining response accuracy, relevance, and faithfulness. In this study, we investigate 13 open-source LLMs categorized into large (e.g., Llama3:70b, Gemma2:27b, QwQ:32b), medium (e.g., Gemma2:9b, Llama3:8b), and small (e.g., Llama3.2:3b, Phi3:3.8b). A Retrieval-Augmented Generation (RAG) is used to make up for the problems that come with using separate models. This research utilizes a descriptive dataset of Quranic surahs including the meanings, historical context, and qualities of the 114 surahs, allowing the model to gather relevant knowledge before responding. The models are evaluated using three key metrics set by human evaluators: context relevance, answer faithfulness, and answer relevance. The findings reveal that large models consistently outperform smaller models in capturing query semantics and producing accurate, contextually grounded responses. The Llama3.2:3b model, even though it is considered small, does very well on faithfulness (4.619) and relevance (4.857), showing the promise of smaller architectures that have been well optimized. This article examines the trade-offs between model size, computational efficiency, and response quality while using LLMs in domain-specific applications.**

***Keywords*—Large-language-models; retrieval-augmented generation; question answering; Quranic studies; Islamic teachings**

I. Introduction

Natural language processing (NLP) has been transformed as a result of the development of large language models (LLMs), which made it possible for these models to handle a wide range of activities. These include summarization and translation, as well as answering domain-specific questions [1]. Further, these models can even serve as a good annotator for a number of NLP tasks [2]. Recent studies have explored the use of NLP in various domain-specific including Quranic studies, legal system, and medical field focusing on developing question-answering system. Alnefie et al. (2023) [3] has evaluated the effectiveness of GPT-4 in answering Quran-related questions and highlighting challenges in context understanding and answer accuracy. However, their work is limited by its reliance on a general-purpose LLM without domain-specific fine-tuning, which affects responce precision for nuance religious queries. Retrieval-Augmented Generation (RAG) has been succesfully applied in general knowledge such as medical domains to mitigate these issues [4], and legal domain such as research conducted by Pipitone and Alami (2024) [5] introduced LegalBench-RAG to evaluate retrieval accuracy in legal question-answering tasks. While significant progress has been made across these domains, challenges related to data quality, retrieval precision, domain-specific adaptation, and computational efficiency persist. This study builds upon these works by benchmarking open-source LLMs using the RAG framework to address the challenges in Quranic knowledge retrieval [6] while highlighting the balance between model size, performance, and efficiency. Using LLMs in religious or culturally sensitive environments has certain challenges [7], including ensuring the accuracy, contextual relevance, and authenticity of the generated responses. These issues are particularly significant when engaging with content derived from religious texts, as distortion or hallucination may result in misunderstandings and a loss of faith in AI systems [8].

This paper examines the role of LLMs in quranic studies [9]. We use a dataset from a book about the 114 surahs of the Qur'an [10], rather than the Qur'an text itself. This dataset provides thorough information about each surah, including meaning, provenance of revelation, and historical context. Descriptive insights are essential for offering relevant and accurate answers to questions regarding quranic studies.

Since Qur'an is the sacred revelation that remains intact in today's world without any human involvement, and the Qur'an is the only source to link human beings with their creator, an attempt to identify the reliable and trustworthy LLMs is really important. As they provide useful resources for the readers, accuracy and truthfulness must be given due importance while exploring the provided information from such sources.

In order to overcome the difficulties associated with hallucination and accuracy, we have implemented a framework known as Retrieval-Augmented Generation (RAG) [11], [12], [13]. This method integrates LLM semantics with a vector database to retrieve relevant data from descriptive datasets [14], [15]. The RAG method guarantees that responses derive from authoritative sources that are contextually appropriate, thereby reducing the probability of delivering content that is unsubstantiated or irrelevant. Citations are supplied in each response, which enables users to trace the information back to the descriptive dataset. This further enhances the level of trust and transparency [16].

The objectives of this research are threefold: (1) to compare 13 open-source LLMs in terms of their ability to respond accurately and faithfully to questions about quranic studies [17], (2) to assess the effectiveness of the RAG approach in reducing hallucination and ensuring response relevance [18], and (3) to provide insights into the use of descriptive datasets for religious education and AI-based knowledge systems [19]. The evaluation criteria consist of context relevance, response faithfulness, and answer relevance, and they are evaluated using human evaluation. [14].

This study provides a robust framework for integrating LLMs with descriptive datasets, thereby contributing to the expanding field of domain-specific AI applications [20]. It emphasizes the strengths and limitations of current LLMs in managing sensitive religious topics and establishes a foundation for future developments in AI-driven educational and informational tools.

The rest of this paper is organized as follows: Section I introduces the challenges of using LLMs for Quranic studies and outlines the research objectives. Section II reviews related work, discussing previous studies on LLM applications in religious text analysis and RAG-based retrieval systems. Section III provides a detailed description of the experimental setup, covering the dataset, NLP tasks and evaluation guidelines, dataset selection and curation, human evaluators, metrics for quality evaluation, large language models, and hardware and software configuration. Section IV presents the experimental results of various LLM models. Section V discusses key findings, including performance insights based on model size, the effectiveness of the RAG framework, the trade-off between computational resources and response quality, the surprising performance of Llama3.2:3b, and implications for domain-specific tasks. Section VI concludes the paper by summarizing the main contributions and providing suggestions for future research.

II. Materials and Methods

This section outlines the methodical strategy employed in our research. We begin by analyzing the dataset, detailing its source, structure, and descriptive content. Subsequently, the system's responsibilities are thoroughly delineated, encompassing the formulation of solutions to user concerns concerning Islamic doctrines [21]. In addition, we provide a summary of the rules that have been set for human evaluators who are responsible for evaluating the outputs of the system. To ensure that the evaluations are reliable and consistent, we have produced these guidelines.

A. Datasets

The dataset used in this research comes from a descriptive book providing a thorough study of the 114 surahs (Chapters) of the Qur'an. In this preliminary study, 20 surahs were selected and tested out of the total 114 surahs. The dataset includes numerous descriptive elements for each surah, such as but not limited to:

- Number of Verses: The total number of verses in each surah.
- Meaning of its Name: A description of the surah's title and its importance.
- Reason for its Name: An explanation for the designation of the surah, frequently linked to its subject matter or motifs.
- Names: Alternative titles or names linked to the surah, if relevant.
- General Objective: A brief explanation of the primary message or objective of the surah.
- Reason for its Revelation: The circumstances or context in which the surah was revealed, as available.
- Virtues: Key benefits or spiritual rewards associated with reciting or understanding the surah, often supported by hadith (sayings of the Prophet Muhammad, peace be upon him).
- Relationships: Insights into the connections between the beginning and end of the surah, or its relationship to preceding or succeeding chapters.

For instance, Surah Al-Hadid (Chapter 57) is described as follows:

- Number of Verses: 29.
- Meaning of its Name: "Al-Hadid" translates to "The Iron" in Arabic.
- Reason for its Name: It is the only chapter where the benefits of iron are mentioned, symbolizing strength and utility.
- General Objective: Encourages the virtue of spending in the cause of Allah as an appreciation of His favors.
- Virtues: Includes a hadith where the Prophet Muhammad (peace be upon him) recommends reciting this chapter as one of three glorifications of Allah.
- Relationships: Highlights thematic continuity between its verses and connections to preceding chapters, such as Surah Al-Waqi'ah.

The dataset was preprocessed and organized into structured fields to ensure efficient retrieval and usability in the study. Key steps included:

- Field Segmentation: Each descriptive element (e.g., "virtues," "relationships") was extracted and stored as a separate field for better semantic alignment with queries.
- Vectorization: Text data was transformed into high-dimensional vector embeddings through the use of cutting-edge NLP models, which facilitated the search for semantic similarity [22].
- Storage in a Vector Database: The organized and scalar data was kept in a scaled vector database so that it would be easy to find the right descriptions during query processing [23],[22].

This particular dataset provides lots of information that goes beyond the actual text of the Qur'an, including contextual and interpretative details. Based on this, it is a great instrument for evaluating the ability of LLMs to produce responses that are true, accurate, and relevant to the context in which they are being used. By emphasizing descriptive elements, the dataset ensures that responses align with established interpretations and scholarly perspectives.

B. NLP Tasks and Evaluation Guidelines

A Retrieval-Augmented Generation (RAG) architecture will be utilized in order to accomplish the objective of this study, which is to evaluate large language models (LLMs) in the context of answering questions related to quranic studies [24]. The RAG approach combines LLMs with semantic retrieval to provide contextually relevant and authoritative responses from a descriptive dataset. The primary tasks and evaluation guidelines used to assess the system's performance are outlined in full below [14].

1) NLP Tasks: The research's primary NLP task is to generate semantically pertinent and contextually accurate responses to inquiries regarding quranic studies. The system employs a Retrieval-Augmented Generation (RAG) architecture, combining retrieval-based and generative methodologies, to ensure that responses are both dataset-based and linguistically coherent. The system executes the following tasks:

- Semantic Search and Retrieval: Upon a user's query submission, the system does a semantic similarity search over the vectorized dataset obtained from Qur'anic surah descriptions [19]. This procedure determines the most contextually pertinent entries from the dataset to respond to the query.
- Response Generation: The retrieved descriptions are submitted to the LLMs, which produce a comprehensive response [14]. This response integrates the retrieved information and provides explanatory content to address the query.
- Citations and Contextualization: Each generated response includes references to the original dataset entries (e.g., surah descriptions or specific virtues), allowing users to trace the information back to its source [25].

2) Evaluation guidelines: To assess the quality of the responses generated by the system, human evaluators followed a structured set of evaluation guidelines. These guidelines provided a consistent framework for scoring responses across three key dimensions: Context Relevance, Answer Faithfulness, and Answer Relevance [14]. Each dimension is explained below, along with its calculation method and examples.

- Context Relevance evaluates how precisely the retrieved and generated responses align with the user query while avoiding irrelevant or extraneous information. The relevance score is calculated using the precision@k metric, where k represents the number of top retrieved results considered as shown in Equation 1.

$$\text{Precision@k} = \frac{\text{No. of relevant results in the top-k responses}}{k} \tag{1}$$

  Example:
  - Query: "What is the reason for Surah Al-Fatihah being named Umm Al-Kitab?"
  - Retrieved Information:
    1) Surah Al-Fatihah is named Umm Al-Kitab because it summarizes the essence of the Qur'an (relevant).
    2) It is recited in every unit of prayer (relevant).
    3) Surah Al-Baqarah discusses laws and stories (irrelevant).
    4) Surah Al-Fatihah has seven verses (relevant).
    5) Surah An-Nas is the last chapter of the Qur'an (irrelevant).

  If $k = 5$, then 3 out of the 5 retrieved results are relevant:

$$\text{Precision@5} = \frac{3}{5} = 0.6$$

  The context relevance score for this response is therefore 0.6.

- Answer Faithfulness ensures that the generated responses accurately represent the retrieved information without introducing unsupported content or hallucinations. Evaluators compare the generated response with the dataset to verify factual consistency.
  Example:
  - Query: "What does Surah Al-Fatihah emphasize?"
  - Retrieved Information: Surah Al-Fatihah emphasizes monotheism, gratitude, and seeking guidance from Allah.
  - Faithful Response: Surah Al-Fatihah highlights the themes of monotheism, gratitude, and the importance of seeking Allah's guidance.
  - Non-Faithful Response: Surah Al-Fatihah emphasizes the stories of past prophets.

  The faithful response adheres strictly to the retrieved information, while the non-faithful response introduces unsupported content.

- Answer Relevance measures whether the response directly addresses the query while maintaining se-

mantic and theological appropriateness. It assesses completeness, clarity, and alignment with the question. Example:

- Query: "Why is Surah Al-Fatihah called Umm Al-Kitab?"
- Relevant Response: Surah Al-Fatihah is called Umm Al-Kitab because it summarizes the central teachings of the Qur'an and is recited in every unit of prayer.
- Irrelevant Response: Surah Al-Fatihah has seven verses and is the first chapter of the Qur'an.

The relevant response directly answers the query, providing reasoning, while the irrelevant response, though factually correct, fails to address the specific question.

3) Evaluation process: Human evaluators assessed the system-generated responses through a web-based platform, where they were presented with prompts, the corresponding responses, and an interface for scoring. The evaluation process included the following steps:

- Reviewing Responses: The process of reviewing responses was a critical step in evaluating the quality of the outputs generated by the large language models (LLMs). Human evaluators carried out this task through a web-based platform specifically designed to facilitate structured and unbiased assessments.
- Scoring System: For each response, evaluators assigned scores on a Likert scale (1 to 5) for the three evaluation criteria: Context Relevance, Answer Faithfulness, and Answer Relevance. In addition to numerical scores, evaluators could provide written feedback to justify their evaluations [16]. This qualitative feedback emphasized specific faults or applauded features of the response, providing more insight into the system's performance.
- Reevaluation and Calibration: Since numerous replies were provided for each query, evaluators could compare the quality of outputs from various LLMs. This comparative approach was instrumental in identifying the models' relative strengths and limitations, thereby enabling a more thorough evaluation [26]. To verify the dependability of their judgments, evaluators returned to a subset of previously evaluated responses on a regular basis and reassessed them. This consistency check allowed evaluators to reflect on their scoring processes and ensure they were in line with the rating criteria.

The structured evaluation guidelines guaranteed that the assessment process was meticulous, consistent, and transparent. The guidelines established a comprehensive framework for assessing the system's performance by emphasizing context relevance, answer faithfulness, and answer relevance [27]. This method enable a thorough comparison of several LLMs and provided vital insights into their performance in answering Islamic queries with contextual precision and faithfulness [15], [27]. The evaluations were submitted through the platform after all responses to a specific query were evaluated, scored, and commented on. In order to provide a comprehensive dataset for the purpose of investigating the LLMs, the platform logged and stored the data for research [28].

C. Dataset Selection and Curation

The dataset used in this study was carefully selected and organized to guarantee it aligns with the goals of assessing large language models (LLMs) within the framework of quranic studies. The process of selection and curation included identifying a reliable source, organizing the data, and confirming its alignment with the research goals [15], [28].

1) Selection criteria: The dataset was chosen according to these specific criteria:

- Authenticity: The source underwent a thorough review to confirm its compliance with recognized Islamic scholarship and the absence of speculative interpretations [26], [27].
- Descriptive Richness: The dataset must deliver comprehensive, contextually rich descriptions that can be effectively employed for semantic search and response generation [27], [29].
- Clarity and Accessibility: The content needed to be created in a structured and clear manner, facilitating both manual review and computational processing [15], [28].
- Relevance: The dataset was meticulously curated to facilitate the process of addressing inquiries related to quranic studies, emphasizing themes that are frequently observed in these discussions [26]

2) Curation process: A comprehensive curation procedure was carried out on the dataset in order to get it ready for integration with the retrieval-augmented generation (RAG) system and LLMs:

- Data Digitization: The text from the source book was digitized to generate a dataset that can be accessed by machines. Optical Character Recognition (OCR) tools were employed where necessary to convert printed material into digital text [15], [28].
- Data Structuring: The content was segmented into surah name, number of verses, reason for the name, general objective, virtues, and relationships. Each field was carefully labeled to facilitate precise retrieval [27].
- Content Validation: The digitized and structured dataset was reviewed by experts in Islamic studies to verify its accuracy and alignment with the original source [26].
- Preprocessing: Unnecessary or redundant information was removed, and inconsistencies were corrected. Tokenization was performed to split the text into smaller, manageable units for processing by the semantic search system.
- Vectorization: The structured data was transformed into high-dimensional vector embeddings using pretrained language models [30]. This step allowed for

efficient and accurate semantic similarity searches within the dataset.

- Storage in a Vector Database: The vectorized dataset was stored in a scalable and efficient vector database, enabling quick retrieval of relevant entries based on user queries [22].

3) Dataset integrity: To ensure the integrity and reliability of the dataset, multiple layers of validation were employed, including manual review and automated consistency checks, regular audits of the data were conducted to identify and rectify any errors or discrepancies, and a backup of the raw and processed datasets was maintained for reproducibility and future reference.

4) Strengths of the dataset:

- Richness in Context: The dataset goes beyond literal translations, providing thematic, historical, and theological insights.
- High Relevance: The information directly supports answering user queries about quranic studies.
- Scalability: The vectorized format enables integration with modern NLP systems and future upgrades.

This curated dataset ensures that the responses generated by the system are accurate, faithful, and contextually relevant, thereby serving as the foundation for the investigating and evaluation of the LLMs

D. Human Evaluators

In this research, human evaluators were instrumental in evaluating the responses produced by the large language models (LLMs) [31]. The evaluations were carried out using a specially designed website that focused on optimizing the evaluation process and maintaining consistency. The website offered evaluators with questions and responses from several LLMs, allowing for a systematic assessment using preset criteria which are context relevance, answer faithfulness, and answer relevance.

1) Evaluator selection: The evaluators were selected with careful consideration to guarantee that they had the proper knowledge and comprehension of quranic studies, given that the study centers on inquiries pertaining to Islamic content. Criteria for selection included:

- Knowledge of quranic studies: Evaluators who had either formal education or significant experience in Islamic studies were prioritized.
- Analytical Skills: In order to evaluate the quality of responses across multiple dimensions, evaluators were required to possess strong analytical skills.
- Familiarity with Evaluation Tasks: It was considered beneficial to have prior experience analyzing textual data or utilizing NLP technologies.

Evaluators from a variety of backgrounds were included to make sure the replies were evaluated fairly and without bias.

2) Evaluation platform: The evaluation process was conducted through a dedicated website designed to facilitate efficient and user-friendly assessments. The platform included the following features:

- Query-Response Display:
  - Each evaluation session displayed a prompt (query) along with responses generated by different LLMs.
  - Responses were anonymized to prevent bias, ensuring that evaluators were not influenced by the identity of the LLM responsible for generating a response.
- Scoring Interface: Evaluators rated each response based on the three evaluation criteria:
  - Context Relevance: Precision and alignment of the response with the query.
  - Answer Faithfulness: Accuracy of the response in relation to the retrieved dataset content.
  - Answer Relevance: Appropriateness and direct pertinence of the response to the query.

  A Likert scale (1–5) was used for scoring, where 1 indicated poor performance and 5 indicated excellent performance.
- Feedback Mechanism: Evaluators could provide written comments to justify their scores or highlight specific issues in the responses. This feature allowed the identification of nuanced errors that might not be captured by numerical scores alone.

3) Significance of human evaluations: The use of human evaluators provided an essential layer of validation for the study, ensuring that the generated responses were assessed not only for technical accuracy but also for their theological and contextual integrity [31]. By leveraging a well-structured platform and robust evaluation criteria, the study ensured that the investigation of LLMs was both rigorous and comprehensive, offering valuable insights into their performance in responding to Islamic queries [32].

E. Metric for Quality Evaluation

This study employs Inter-Evaluator Agreement (IEA) as the primary metric to ensure the quality, reliability, and consistency of human evaluations [33]. Since human evaluators, rather than annotators, were tasked with assessing the generated responses, IEA provides a robust measure of agreement across evaluators, validating the credibility of the evaluation process and the results.

IEA measures the level of consistency between evaluators when scoring responses based on predefined criteria: context relevance, answer faithfulness, and answer relevance. An elevated IEA score signifies uniform application of evaluation criteria by assessors, whereas a diminished score reveals inconsistencies that may necessitate recalibration.

Fleiss' Kappa, as presented in Eq. (2), was employed to calculate IEA due to its appropriateness for evaluating agreement among multiple evaluators concurrently [33]. The consistent monitoring of IEA scores allowed the research team to detect discrepancies promptly and facilitate recalibration

sessions as needed, ensuring evaluators' comprehension and interpretation of the scoring guidelines were aligned. This methodical approach guaranteed that the evaluation process was dependable, replicable, and aligned with the study's goals.

$$\kappa = \frac{\bar{P} - \bar{P}_e}{1 - \bar{P}_e} \tag{2}$$

where:

$$\bar{P} = \frac{1}{N} \sum_{i=1}^{N} P_i \quad \text{and} \quad \bar{P}_e = \sum_{k=1}^{K} p_k^2 \tag{3}$$

with:

$$P_i = \frac{1}{n(n-1)} \sum_{k=1}^{K} n_{ik}(n_{ik} - 1), \quad p_k = \frac{\sum_{i=1}^{N} n_{ik}}{Nn} \tag{4}$$

where:

- κ: Fleiss' Kappa value.
- $\bar{P}$: Average observed agreement across all items.
- $\bar{P}_e$: Expected agreement based on chance.
- P_i: Proportion of agreement for item i.
- p_k: Proportion of ratings in category k.
- n: Total number of ratings per item.
- n_{ik}: Number of raters who assigned category k to item i.
- N: Total number of items.
- K: Total number of categories.

F. Large Language Models

The efficacy of numerous large language models (LLMs) in responding to inquiries regarding quranic studies is assessed in this study using a Retrieval-Augmented Generation (RAG) framework [34]. A comprehensive comparison of the capabilities of the LLMs selected for investigation is possible due to the fact that they represent a variety of architectures and parameter scales. More information about the models, how they are put together, and how they relate to this study is given below.

1) Llama: Meta AI has developed the Llama (Large Language Model Meta AI) family of models, which are state-of-the-art transformer-based architectures that are optimized for natural language understanding and generation [35]. Llama models are trained on vast, diversified corpora to do various NLP tasks such as contextual reasoning, question answering, and text summarization. They are available in a variety of parameter values, which provides a degree of flexibility in terms of computational requirements and performance. The Llama models were incorporated in this investigation due to their adaptability and superior performance across various parameter sizes. A thorough investigation of how model size affects the capacity to produce faithful, accurate, and contextually relevant replies was made possible by the range of configurations. The comparison of Llama generations (e.g., Llama3 with Llama3.1) yielded insights on the impact of incremental architectural enhancements on performance.

2) Gemma: Google's DeepMind developed the Gemma family of large language models, which are a set of transformer-based designs that are best for understanding and creating natural language. The Gemma models are engineered to provide superior performance while ensuring efficiency, rendering them adaptable for various jobs. These models have undergone pre-training on varied and comprehensive datasets, enabling them to generalize effectively across multiple domains [36]. Gemma models are offered in many parameter scales, including 27b, 9b, and 2b, providing flexibility to optimize performance and computational demands. Their versatility renders them appropriate for applications from resource-intensive jobs to real-time implementations in limited surroundings.

3) QwQ: The QwQ model developed by Alibaba Cloud, which has 32 billion parameters, is a large-scale transformer-based language model designed to handle complex natural language processing tasks [37]. While specific information about the QwQ model's architecture or pre-training details is limited in comparison to more established models like Llama and Gemma, its parameter scale positions it as a powerful model capable of capturing complex relationships in textual data. Its large size enables it to perform effectively on tasks requiring nuanced comprehension, contextual reasoning, and content generation across a wide range of subjects.

4) Phi: Microsoft created the Phi family of language models, which are a group of lightweight transformer-based models that work best for jobs that involve processing natural language. Even though the Phi models have lower parameter sizes compared to other large-scale models such as Llama and Gemma, they are engineered to exceed expectations, providing robust performance while ensuring computational efficiency [38]. They are pretrained on rigorously selected datasets that prioritize high-quality information, enabling effective generalization across tasks despite a reduced number of parameters. This method guarantees that Phi models provide an exceptional equilibrium between performance and resource demands, rendering them especially appropriate for resource-limited settings and real-time applications.

5) Key Features of the models: From smaller-scale models (e.g., 1 billion parameters) to large-scale ones (e.g., 70 billion parameters), the chosen models encompass a wide spectrum of parameter sizes. This variation enables a study of the trade-offs between response quality and computing efficiency. Smaller models might lose accuracy and contextual depth, yet producing faster responses with reduced processing expenses. On the other hand, it is anticipated that larger models will produce more nuanced and high-fidelity outputs, although at the expense of increased computational demands.

The models use transformer architectures, which are efficient in comprehending and producing natural language content. Their architecture allows to capturing the intricate patterns, correlations, and contextual subtleties within the dataset. This work emphasizes the models' capacity to adjust to specific domains, such as quranic studies, despite being

trained on varied datasets. The assessment analyzes the efficacy of these models when enhanced with domain-specific data through the RAG methodology. The study evaluates the models in a zero-shot context, without any fine-tuning on the unique dataset. This method emphasizes the models' intrinsic capacity to generalize and appropriately respond by utilizing external information obtained from the descriptive dataset.

6) Integration with the RAG framework: The selected LLMs were integrated with the RAG framework, allowing them to generate contextually relevant responses based on the dataset. The RAG framework enhances the performance of the models by providing contextual input, reducing hallucination, and facilitating citations.

G. Hardware and Software Configuration

The experiments were conducted using a high-performance computing system equipped with an Intel(R) Xeon(R) Gold 5318Y CPU operating at 2.10 GHz with 24 cores. The system featured four NVIDIA RTX A6000 GPUs, each providing 48 GB of VRAM, enabling efficient handling of computationally intensive tasks, particularly those involving deep learning models. Additionally, the system was supported by 128 GB of RAM, ensuring smooth execution of memory-intensive operations and facilitating large-scale data processing. This configuration provided the computational resources necessary to run and evaluate the models effectively.

III. Results

The results of this study are based on the implementation of a RAG architecture, designed to evaluate the performance of 13 LLMs in answering questions related to Quranic studies. By leveraging a descriptive dataset of Quranic surahs, the RAG system facilitates the integration of external knowledge to address the limitations of standalone models. The comparative analysis focuses on assessing the relevance, faithfulness, and contextual accuracy of the responses generated by the LLMs within this framework.

A. Experimental Results

The experimental evaluation assessed the capacity of a variety of large language models (LLMs) to respond to queries related to quranic studies. The models were assessed based on three critical metrics: context relevance, answer faithfulness, and answer relevance. The models were categorized into three categories based on their parameter sizes: large models (marked in red), medium models (marked in yellow), and small models (marked in green). Therefore, the results were analyzed. The following is a comprehensive analysis of the performance of each category.

1) Context relevance: Context relevance as shown in Fig. 1 evaluates how well the generated responses align with the query's context.

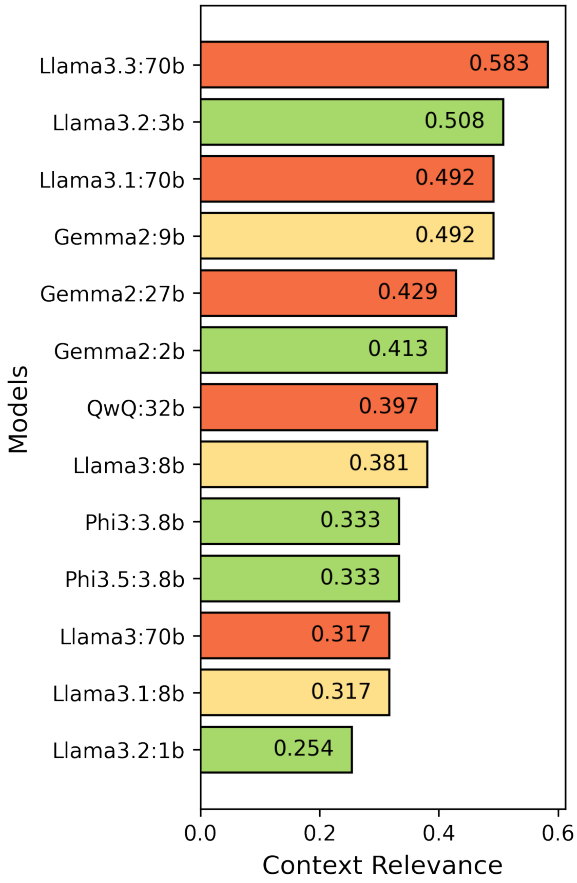

Fig. 1. Context relevance by the 13 LLMs.

- Large Models (Red): The large models outperformed other categories, with Llama3.3:70b achieving the highest score of 0.583, followed by Llama3.2:3b (0.508), despite being categorized as a small model. Both Llama3.1:70b and Gemma2:27b achieved competitive scores of 0.492 and 0.429, respectively, while QwQ:32b recorded 0.397. These models excel at retrieving relevant information and aligning responses with the query intent due to their larger parameter size.
- Medium Models (Yellow): Among the medium models, Gemma2:9b performed best with a score of 0.492, comparable to some large models. Llama3:8b and Llama3.1:8b followed with scores of 0.381 and 0.317, respectively. These models demonstrated decent performance but lagged behind the large models in handling complex or nuanced queries.
- Small Models (Green): The small models struggled overall, with Llama3.2:1b achieving the lowest score of 0.254. Phi3.5:3.8b and Phi3:3.8b performed moderately with scores of 0.333, while Gemma2:2b achieved 0.413. Notably, Llama3.2:3b outperformed all expectations with a score of 0.508, surpassing even some medium and large models.

2) Answer faithfulness: Answer faithfulness as shown in Fig. 2 measures whether the responses remain consistent with the retrieved content, avoiding inaccuracies or hallucinations.

- Large Models (Red): The large models dominated this metric, with Llama3.2:3b (exceptionally performing despite its small category) achieving the top score of 4.619. Llama3:70b and Llama3.1:70b scored

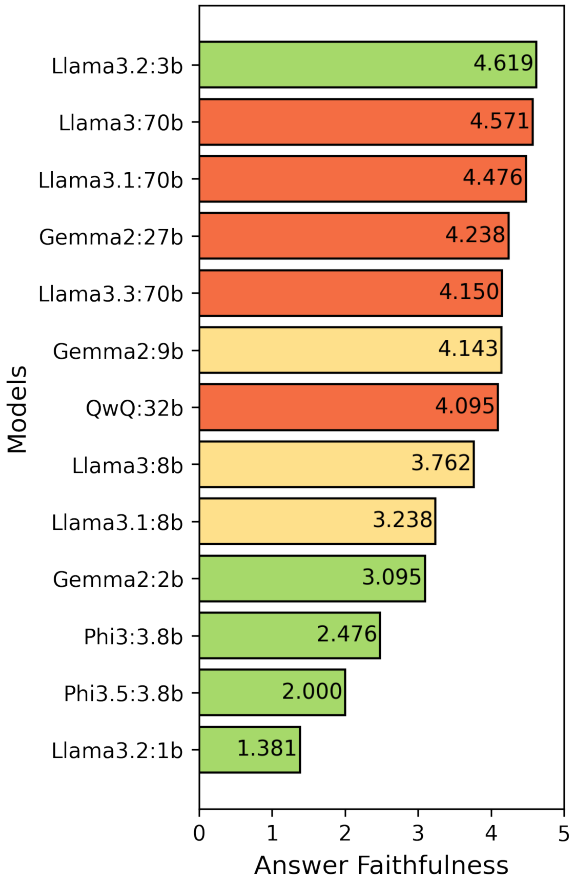

Fig. 2. Answer faithfulness by the 13 LLMs.

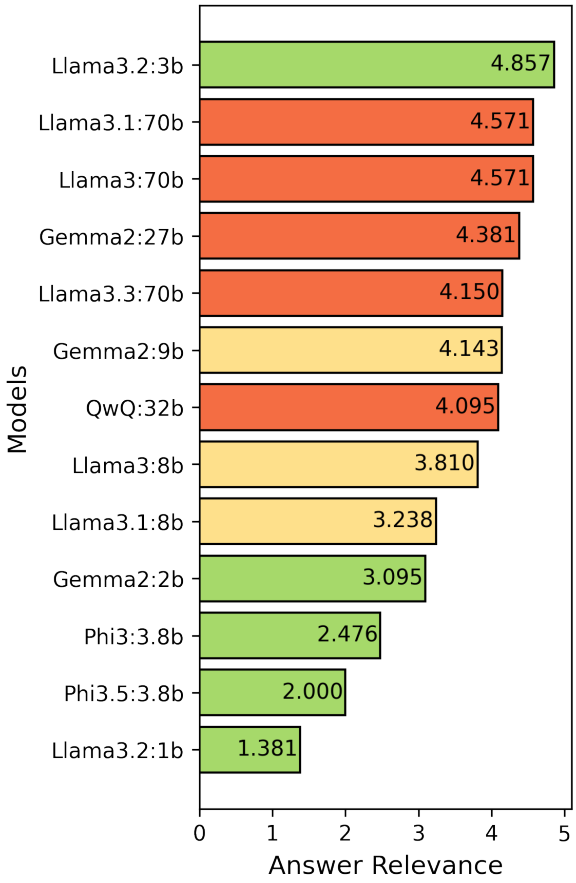

Fig. 3. Answer relevance by the 13 LLMs.

4.571 and 4.476, respectively, while Gemma2:27b and QwQ:32b followed with scores of 4.238 and 4.095. Their ability to maintain faithfulness highlights the advantages of larger parameter sizes.

- Medium Models (Yellow): The medium models showed reliable performance, with Gemma2:9b scoring 4.143 and Llama3:8b achieving 3.762. Llama3.1:8b, while consistent, lagged slightly behind with 3.238. These models balanced faithfulness and efficiency but struggled with queries requiring deep contextual reasoning.
- Small Models (Green): The small models faced significant challenges. Llama3.2:1b recorded the lowest faithfulness score of 1.381, and Phi3.5:3.8b achieved 2.000, indicating frequent inconsistencies. While Phi3:3.8b scored slightly higher at 2.476, Llama3.2:3b stood out with a score of 4.619, showcasing exceptional faithfulness that rivaled larger models.

3) Answer relevance: Answer relevance as shown in Fig. 3 assesses whether the generated responses address the query's intent effectively.

- Large Models (Red): The Llama3.2:3b, while classified as small, achieved the highest relevance score of 4.857, followed closely by Llama3:70b and Llama3.1:70b, both scoring 4.571. Gemma2:27b and QwQ:32b continued to perform well, with scores of 4.381 and 4.095, respectively. These models consistently delivered relevant responses aligned with the intent behind complex queries.
- Medium Models (Yellow): The medium models provided strong performance, particularly Gemma2:9b, which achieved 4.143. Llama3:8b followed with 3.810, and Llama3.1:8b recorded a slightly lower score of 3.238. These models addressed moderately complex queries effectively but occasionally lacked depth.
- Small Models (Green): The small models exhibited varied performance, with Llama3.2:1b scoring the lowest at 1.381. Phi3.5:3.8b and Phi3:3.8b recorded scores of 2.000 and 2.476, respectively, indicating challenges in providing fully relevant responses. However, Llama3.2:3b once again stood out, achieving the highest score of 4.857, performing on par with the best large models.

4) Intercoder agreement: We assessed intercoder agreement, which measures the extent to which evaluators within the same group report the same evaluation for a given instance. To compute this metric, we examined the percentage of instances where both evaluators assigned identical evaluation scores independently. This measure enabled us to evaluate the degree

of concordance between evaluators and assess their consistency in evaluation.

TABLE I. THE KAPPA VALUES FOR THE EVALUATION

Creator	Model	Evaluator
Meta	Llama 3.3 70B	0.80
Meta	Llama 3.2 3B	0.90
Meta	Llama 3.2 1B	0.82
Meta	Llama 3.1 70B	0.82
Meta	Llama 3.1 8B	0.85
Meta	Llama 3 70B	0.92
Meta	Llama 3 8B	0.80
Google	Gemma 2 27B	0.90
Google	Gemma 2 9B	0.92
Google	Gemma 2 2B	0.83
Microsoft	Phi 3.5 3.8B	0.83
Microsoft	Phi 3.3 3.8B	0.93
Alibaba	QwQ 32B	0.89

In Table I, we delve into the inter-annotator agreement analysis, which measures the level of agreement between human evaluators across different models using Fleiss' Kappa. This indicates a similar level of agreement between the evaluators.

IV. DISCUSSION

This section discusses the experimental findings, analyzing the performance of various LLMs categorized into large, medium, and small models across the three evaluation metrics: context relevance, answer faithfulness, and answer relevance [14]. This study examines the relationship among model size, response quality, and computational trade-offs, as well as the behavior of models within the Retrieval-Augmented Generation (RAG) framework.

A. Performance Insights Based on Model Size

The experimental results show that the quality of the responses across all three evaluation criteria is significantly affected by the model size.

- Large Models (Red): Large models, including Llama3:70b, Llama3.1:70b, Llama3.3:70b, Gemma2:27b, and QwQ:32b, consistently demonstrate superior performance compared to medium and small models. The models demonstrated superior context relevance due to their larger parameter sizes [39], which facilitate a deeper semantic understanding and enhance their ability to retrieve and integrate pertinent information. Furthermore, their enhanced performance in answer faithfulness and relevance indicates that large models are more adept at minimizing hallucinations [40] and producing responses that accurately address user queries. However, their computational demands remain a major trade-off, requiring substantial memory and processing power. This limits their accessibility in resource-constrained environments, making them more suitable for high-performance systems.
- Medium Models (Yellow): Medium-sized models like Gemma2:9b, Llama3:8b, and Llama3.1:8b demonstrated strong performance relative to their parameter sizes, particularly in answer faithfulness and relevance. These models provide a balance between computational efficiency and response quality, making them ideal for systems where resources are limited but accuracy cannot be compromised. However, their performance in context relevance was slightly lower than that of large models, indicating limitations in capturing deeper relationships within the data. Medium models present a viable option for applications requiring moderate precision while maintaining resource efficiency.
- Small Models (Green): The small models, including Llama3.2:3b, Llama3.2:1b, Gemma2:2b, Phi3:3.8b, and Phi3.5:3.8b, faced significant challenges in delivering high-quality responses. Models like Llama3.2:1b and Phi3.5:3.8b scored the lowest across all metrics, reflecting their inability to process complex queries effectively due to their smaller parameter size. Interestingly, Llama3.2:3b emerged as an outlier, achieving performance levels comparable to the large models, particularly in answer faithfulness (4.619) and answer relevance (4.857). This unexpected performance demonstrates the efficacy of architectural improvements and pre-training techniques, even on smaller models. Although small models are computationally efficient and well-suited for lightweight tasks [41], their overall limitations render them less suitable for complex queries that necessitate a deep comprehension of semantics.

B. Effectiveness of the RAG Framework

The implementation of the Retrieval-Augmented Generation (RAG) framework significantly enhanced the response quality of the evaluated models [42]. By incorporating external knowledge from the descriptive Qur'anic dataset, the models can retrieve pertinent information prior to formulating responses. This method alleviated the prevalent issue of hallucination, where language models produce factually inaccurate or irrelevant responses.

The results demonstrate that the larger models derived the greatest advantage from the RAG framework, as their higher parameter sizes facilitated more effective integration of the retrieved context, resulting in enhanced performance across all metrics. Medium and small models showed enhancements, nevertheless, their capacity limitation affected the integration of retrieved knowledge, leading to lower context alignment and fewer accurate responses.

C. Trade-Off Between Computational Resources and Response Quality

The results of this research highlight the trade-off between response quality and computational efficiency throughout several model sizes.

- Large Models deliver outstanding performance but they are less practical for real-time or cost-sensitive installations since they need large computational resources.
- Medium Models fit for uses with intermediate hardware availability since they offer a useful compromise between dependability of performance and low resource usage.

- Small Models are quick and light-weight, yet they usually underperform on jobs needing sophisticated thinking. Nonetheless, the unexpected findings in Llama3.2:3b suggest that smaller models can still show good performance.

This trade-off emphasizes the need of choosing the suitable model size depending on particular application criteria including accuracy, speed, and resource availability.

D. Surprising Performance of Llama3.2:3b

This study's outstanding discovery is the exceptional performance of Llama3.2:3b, despite its classification as a small model. It outperformed a number of medium and even big models, achieving the highest results in answer faithfulness and answer relevance. According to this finding, factors including pre-training quality, data efficiency, and architectural upgrades can have an impact on model performance, in addition to parameter size. The potential for smaller models to produce high-quality outputs in resource-efficient environments is underscored by the robust performance of Llama3.2:3b when used in conjunction with effective frameworks such as RAG.

E. Implications for Domain-Specific Tasks

The research emphasizes both the difficulties and potential benefits of utilizing general-purpose LLMs for specialized tasks, including responding to inquiries about quranic studies. Although large models excelled in aligning responses with the given dataset, their effectiveness is significantly dependent on the quality and organization of the retrieved content. This research demonstrates how important it is to add domain-specific knowledge [4], like curated descriptive datasets, to improve the models' abilities and lower the risk of hallucinations. The RAG framework proved to be an effective technique for ensuring that responses were contextually correct and based on credible sources.

The experimental results offer important insights into the performance of LLMs of different sizes. Large models provide exceptional accuracy and relevance, though they require significant resources, whereas medium models offer a practical compromise between performance and efficiency. Smaller models, while typically less powerful, demonstrated surprising potential, especially Llama3.2:3b, which excelled across various metrics. The use of the RAG framework enhanced the models' performance by reducing hallucinations and grounding responses in reliable data. These findings highlight the importance of model selection, optimization strategies, and retrieval mechanisms when applying LLMs to domain-specific tasks. Future work will include conducting an ablation study to compare the performance of models with and without the RAG framework, evaluating additional large language models (LLMs), and leveraging LLMs for automatic evaluation of answer faithfulness and answer relevance metrics. Additional fine-tuning strategies and assessments in other specialized domains can also be explored.

V. Conclusions

This study evaluated multiple large language models (LLMs) of different sizes in responding to Quranic studies-related queries using a Retrieval-Augmented Generation (RAG) framework. The findings indicate that large models, such as Llama3:70b, Llama3.1:70b, and Gemma2:27b, consistently delivered superior performance in context relevance, answer faithfulness, and answer relevance. However, their computational demands pose challenges for practical deployment. Medium-sized models, including Gemma2:9b and Llama3:8b, demonstrated a balance between efficiency and performance, making them suitable for moderately complex tasks. Interestingly, Llama3.2:3b, a small model, performed comparably to larger models in certain aspects, particularly in answer faithfulness and relevance, suggesting that architectural optimizations can enhance the capabilities of smaller models.

The study also highlights the importance of the RAG framework in improving response quality by grounding answers in external domain-specific knowledge, reducing hallucinations, and ensuring more reliable outputs. These findings emphasize the trade-offs between model size, performance, and computational efficiency, indicating that while large models are ideal for high-accuracy tasks, smaller models, when optimized, can serve as viable alternatives. Future research can focus on further optimizations, fine-tuning strategies, and expanding dataset diversity to enhance model performance across different applications.

Abstract*—This study explores the transformative potential of machine learning (ML) algorithms in optimizing the Routing Protocol for Low-Power and Lossy Networks (RPL), addressing critical challenges in Internet of Things (IoT) networks, such as Expected Transmission Count (ETX), latency, and energy consumption. The research evaluates the performance of Random Forest, Gradient Boosting, Artificial Neural Networks (ANNs), and Q-Learning across IoT network simulations with varying scales (50, 100, and 150 nodes). Results indicate that tree-based models, particularly Random Forest and Gradient Boosting, demonstrate robust predictive capabilities for ETX and latency, achieving consistent results in smaller and medium-sized networks. Specifically, for 50-node networks, Neural Networks achieved the best performance with the lowest latency (2.43862 ms) and the best ETX (5.29557), despite slightly higher energy consumption. For 100-node networks, Q-Learning stood out with the lowest energy consumption (1.62973 J) and competitive ETX (2.70647), though at the cost of increased latency. In 150-node networks, Q-Learning again outperformed other models, achieving the lowest latency (0.68 ms) and energy consumption (2.21 J), though at the cost of higher ETX. Neural Networks excel in capturing non-linear dependencies but face limitations in energy-related metrics, while Q-Learning adapts dynamically to network changes, achieving remarkable latency reductions at the cost of transmission efficiency. The findings highlight key trade-offs between performance metrics and emphasize the need for algorithmic strategies tailored to specific IoT applications. This work not only validates the scalability and adaptability of ML approaches but also lays the foundation for intelligent and efficient IoT network optimization, laying the groundwork for future advancements in sustainable and scalable IoT networks.

I. Introduction

The Internet of Things (IoT) has revolutionized modern technological paradigms, enabling seamless connectivity and interaction between billions of devices, ranging from consumer electronics to industrial machinery [1]. This explosion of interconnected systems has catalyzed advancements in diverse fields, including smart cities, healthcare, agriculture, and industrial automation [2]. At the core of IoT systems lies the Routing Protocol for Low-Power and Lossy Networks (RPL), a pivotal framework designed to support the unique challenges of Wireless Sensor Networks (WSNs) operating under constrained resources [3]. Despite its widespread adoption, RPL's default mechanisms often fall short in optimizing key performance metrics such as ETX, latency, and energy consumption—metrics critical for ensuring scalability and reliability in large, dynamic IoT environments [2],[4].

The rapid growth of IoT devices has increased the complexity of network management, particularly in dynamic topologies with resource constraints. Traditional heuristic and rule-based optimization methods, while effective in static environments, lack the adaptability and precision needed to address the complex challenges of real-world IoT deployments. These limitations underscore the necessity for innovative solutions that leverage data-driven insights to optimize network behavior dynamically and efficiently [5].

Machine learning (ML), with its unparalleled ability to analyze complex datasets and extract actionable insights, emerges as a transformative solution for optimizing IoT networks. Unlike conventional methods, ML models can adapt to evolving network conditions, predict performance trends, and optimize resource allocation intelligently. Supervised learning techniques such as Random Forests and Gradient Boosting have demonstrated exceptional accuracy in predicting ETX and latency by effectively capturing feature interactions and avoiding overfitting. Similarly, Artificial Neural Networks (ANNs) excel in modeling non-linear dependencies within high-dimensional datasets, enabling precise energy consumption predictions. Reinforcement learning approaches like Q-Learning introduce an adaptive framework, allowing IoT networks to learn optimal routing policies through continuous interaction with the environment [6], [7].

This study delves into the application of ML techniques for enhancing RPL [26] performance in IoT networks, focusing on the evaluation of Random Forests, Gradient Boosting, ANNs, and Q-Learning across varying network sizes. By analyzing the scalability and adaptability of these models through extensive simulations, this work offers a comprehensive comparison of their strengths and limitations. The results demonstrate that ML-based optimization not only improves energy efficiency and reduces latency but also enhances network reliability, laying the groundwork for the development of intelligent, self-optimizing IoT systems.This research connects theory with practice, demonstrating how machine learning can revolutionize IoT network [28] management. The insights gained provide a roadmap for leveraging ML to overcome the critical challenges of energy efficiency, scalability, and adaptability in RPL-based IoT systems, thereby setting a benchmark for next-generation IoT deployments.The remainder of this paper is structured as follows: Section II presents related works, Section III formulates the problem statement, and Section IV describes the machine learning [29] algorithms applied. Section V discusses experimental results, and Section VI concludes the paper with key findings and future directions.

II. Related Work

The Internet of Things (IoT) [2] has emerged as a transformative domain, enabling interconnected devices to communicate, sense and transmit data across diverse environments. At the heart of this ecosystem lies the Routing Protocol for Low-Power and Lossy Networks (RPL), established by the Internet Engineering Task Force (IETF), which serves as a standardized protocol to facilitate efficient data exchange in IoT networks [4]. RPL effectively addresses key limitations of IoT devices, such as constrained computing power, limited memory capacity, and high energy consumption. However, optimizing RPL to enhance energy efficiency, reduce latency, and extend network lifetime remains an ongoing research challenge. In this context, machine learning (ML) [7] has emerged as a powerful tool for addressing these challenges, providing a robust framework for analyzing complex data patterns, enabling predictive insights, and supporting adaptive decision-making.

Supervised learning models, such as Random Forests and Gradient Boosting [19], have shown exceptional promise in predicting key network metrics like ETX and latency, leveraging ensemble approaches to improve routing decisions while avoiding overfitting. Similarly, Artificial Neural Networks (ANNs) [20], with their ability to model non-linear dependencies, have demonstrated potential in optimizing energy consumption and resource allocation in IoT environments. Reinforcement learning techniques, such as Q-Learning, introduce a dynamic approach to routing optimization, enabling IoT[24] systems to autonomously learn and adapt to changing network conditions while balancing exploration and exploitation. Empirical studies confirm the effectiveness of ML algorithms in reducing energy consumption while maintaining communication performance. Approaches such as dynamic sleep scheduling and intelligent data aggregation have been shown to significantly extend network lifetimes, while deep learning architectures have excelled in extracting intricate patterns from high-dimensional datasets, enhancing network performance.

The comparative evaluation of ML algorithms [6] highlights their unique capabilities, applications, strengths, and limitations, providing a comprehensive understanding of their utility in optimizing IoT networks. Random Forests [23], robust and interpretable ensemble methods, are particularly effective in avoiding overfitting and are widely applied in domains like astronomy and energy prediction [8], [9], [10], [11]. However, they can occasionally underperform compared to Gradient Boosting in tasks requiring higher precision [7]. Decision Trees, valued for their simplicity and transparency, are effective in applications such as medical diagnostics and crop disease classification [8], [9], [10], [12], [13], but their propensity to overfit makes them less reliable as standalone models [1], [6], [7], [14], [15]. Gradient Boosting, a sequential learning method, achieves high accuracy by iteratively correcting errors, making it well-suited for diverse tasks [8], [9], [10], [16], [17], though its computational demands and tuning complexity can pose challenges [1], [2], [4], [6], [18], [19], [20], [21], [22]. Q-Learning, a reinforcement learning technique, excels in dynamic decision-making environments such as IoT network optimization [8], [9], [10], while Neural Networks demonstrate unparalleled ability to handle high-dimensional and non-linear data patterns, making them indispensable for complex domains like image recognition and medical diagnostics [8], [9], [10], [23], [24]. However, their reliance on large datasets and high computational requirements can limit their application in resource-constrained settings [25].Together, these observations underscore the transformative potential of machine learning in IoT network optimization [27], emphasizing the importance of aligning algorithmic selection with specific application requirements. By dynamically evolving and adapting to real-time data, ML algorithms are positioned at the forefront of contemporary IoT [30] research, paving the way for intelligent, sustainable, and resilient network systems that address the pressing demands of scalability, efficiency, and adaptability.

III. Problem Statement

In this section, we formulate the problem of optimized routing RPL-based IoT network[30] considering the following metrics:ETX, the latency (LT) and the energy consumption (EC). The objective function integrating these criteria is defined as follows.

$$Minimize\ F = \ w_1.ETX + \ w_2.LT + \ w_3.EC \quad (1)$$

Where w_1, w_2 and w_3 are weights assigned to ETX, LT and EC respectively.

A. Define the Metrics

ETX measures the number of expected transmissions, including retransmissions, required to successfully deliver a packet over a link.

$$ETX_{ij} = \frac{1}{P_{ij}.P_{ji}}$$

Where P_{ij} is the probability of successful packet transmission from node i to node j, and P_{ji} is the probability of successful acknowledgment.
LT represents the time required for a packet to travel from the source to the destination.

$$LT_{ij} = \ d_{ij} + \sum_k ProcessingTime_k$$

Where d_{ij} is the propagation delay between nodes i and j, and the sum represents the processing delays at intermediate nodes. EC is the of energy consumed to transmit a packet from the source to the destination.

$$EC_{ij} = \ TE_{ij} + \sum_k ProcessingEnergy_k$$

Where TE_{ij} is the energy consumed for transmission between nodes i and j, and the sum represents the energy consumed at intermediate nodes for processing.

B. Formulate the Constraints

The connectivity constraint ensures that the selected path maintains network connectivity.

$$\sum_{j \in N} x_{ij} = 1, \quad \forall\ i\ \in\ N$$

Where xij is a binary variable indicating whether the link between nodes i and j is part of the path (1) or not (0). The

Loop-Free constraint ensures that routing path does not exceed the available energy at any node.

$$\sum_{j \in N} x_{ij} = 1, \quad \forall\, i \ \in \ N$$

The energy constraint ensures that the energy consumption does not exceed the available energy at any node.

$$EC_{ij} \ \leq \ E_i, \quad \forall\, i \ \in \ N$$

Where E_i is the available energy at node i.

C. Optimization Problem Formulation

$$Minimize\, F = \sum_{i,j \in E} (w_1.ETX_{ij} + w_2.LT_{ij} + w_3.EC_{ij}).x_{ij}$$

Subject to:

$$\sum_{j \in N} x_{ij} = 1, \quad \forall\, i \ \in \ N$$

$$x_{ij} \ + \ x_{ji} \ \leq \ 1, \quad \forall\, i, j \ \in \ N$$

$$EC_{ij} \ \leq \ E_i, \quad \forall\, i \ \in \ N$$

$$x_{ij} \in 0, 1$$

IV. Machine Learning Algorithms

The application of Machine Learning (ML) in IoT networks represents a paradigm shift in optimizing routing protocols, particularly the Routing Protocol for Low-Power and Lossy Networks (RPL) [3]. Unlike traditional heuristic-based approaches, ML algorithms provide data-driven solutions that dynamically adapt to the ever-changing conditions of IoT networks. By leveraging the vast amounts of data generated within IoT systems, these algorithms can predict network behaviors, optimize performance metrics, and enable intelligent decision making.

In the context of RPL optimization [26], ML techniques offer significant advantages in addressing critical metrics such as Expected Transmission Count, latency, and energy consumption. Various ML models have been successfully applied, each offering unique strengths and capabilities:

1) Random forests: This ensemble learning method combines the predictive power of multiple decision trees to deliver robust and accurate results. Random Forests are particularly effective in predicting ETX and latency while avoiding overfitting. Their ability to generalize well across diverse datasets makes them a reliable choice for IoT network optimization, especially in scenarios with high-dimensional data [8], [9], [10], [11], [29], [29].

2) Gradient boosting: As a sequential ensemble technique, Gradient Boosting iteratively refines weak models to achieve high accuracy. Its ability to capture complex interactions between features allows it to excel in predicting network performance metrics. Gradient Boosting has demonstrated remarkable efficiency in balancing ETX, latency, and energy consumption, making it a powerful tool for IoT network optimization [8], [9], [10], [16], [17].

3) Artificial Neural Networks (ANNs): Renowned for their capacity to model non-linear relationships, ANNs are well-suited for analyzing and predicting energy consumption patterns in IoT networks. Their multi-layered architecture enables them to learn intricate patterns and dependencies in the data, providing insights that drive more efficient routing and resource management [8], [9], [10], [23], [24].

4) Q-Learning: A reinforcement learning approach, Q-Learning introduces an adaptive mechanism for optimizing routing decisions. By interacting with the network environment, Q-Learning dynamically learns the best routing policies while balancing exploration and exploitation. This makes it highly effective in minimizing latency and energy consumption in dynamic IoT scenarios [8], [9], [10].

Machine learning algorithms stand out for their scalability and flexibility, making them well-equipped to handle the complexities of RPL-based networks. Simulations conducted on IoT networks of varying sizes (50, 100, and 150 nodes) have consistently highlighted the superior performance of ML models [27], [29] compared to traditional optimization techniques. For instance, Random Forests and Gradient Boosting have been shown to maintain balanced performance across metrics, while Q-Learning offers exceptional adaptability in dynamic environments.

ML algorithms enhance predictive capabilities and adaptive decision-making, optimizing key network metrics while fostering the development of intelligent and resilient IoT systems [26], [28]. The integration of these algorithms into RPL-based networks underscores their critical role in advancing the state-of-the-art in IoT optimization, paving the way for more efficient and sustainable IoT deployments. Through rigorous evaluation and continuous improvement, ML techniques are poised to revolutionize IoT network management, addressing the challenges of energy efficiency, latency reduction, and enhanced connectivity in real-world applications.

A. Dataset Configurations for Machine Learning Algorithms Simulations

In this section, we delve into the application of various machine learning algorithms—Random Forests, Gradient Boosting, Artificial Neural Networks (ANNs), and Q-Learning—to optimize routing within IoT networks. These algorithms are tested across different network configurations, with simulations conducted on data sets of varying sizes representing IoT networks with 50, 100, and 150 nodes. Each configuration is designed with specific training and testing data shapes to accurately reflect the complexity and scale of the simulated network environment. Table II provides an overview of the data set shapes used for each simulation size, ensuring a comprehensive evaluation of the machine learning models across diverse network scenarios.This table provides an overview of the datasets used to evaluate the performance of various machine learning algorithms across different network sizes. The number of features and instances in the training and testing sets reflects the complexity of the network configurations, ensuring a thorough analysis of each algorithm's predictive accuracy, adaptability, and scalability. This structured evaluation highlights the capacity of machine learning techniques to address the diverse challenges inherent

in IoT networks, including energy efficiency, latency reduction, and routing optimization.

TABLE I. SHAPES OF DATA SETS FOR DIFFERENT SIMULATIONS

Simulation	Train Data Shape	Test Data Shape
50 nodes	(440, 7)	(110, 7)
100 nodes	(80, 3)	(20, 3)
150 nodes	(3539, 4)	(885, 4)

B. Implementation of Machine Learning Algorithms

This section presents a machine learning framework for minimizing transmission and energy costs in IoT networks. Algorithm 1 uses Q-Learning for multi-objective optimization, balancing exploration and exploitation with parameters like learning rate (α), discount factor (γ), and exploration rate (ϵ). Q-values are iteratively updated using ETX, latency, and energy consumption, ensuring robust and efficient routing policies.

Algorithm 1 employs a Random Forest model to predict ETX, latency, and energy consumption in IoT networks. It includes data preprocessing, dataset splitting, and training regressors for each metric. Performance is evaluated using R^2, MSE, and MAE, demonstrating the model's robustness for IoT optimization.

Algorithm 1 Random Forest for Multi-Objective Optimization

Input : Dataset with features: X;
Target variables: $Y_{ETX}, Y_{Latency}, Y_{Energy}$;
Number of estimators N_{trees};
Maximum depth of trees $MaxDepth$;
Metrics: $ETX, Latency\ (ms), Consumed\ Energy\ (J)$;
Output : Predicted values for metrics: $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
Model performance scores (e.g., R^2, MSE).

Begin Random Forest Algorithm

/* Data Preprocessing */
Split dataset into training and testing sets:
$X_{train}, X_{test}, Y_{train}, Y_{test} \leftarrow TRAIN\_TEST\_SPLIT(X, Y)$;

foreach $metric \in \{ETX, Latency, Energy\}$ **do**
  /* Train Random Forest Regressor for each metric */
  Initialize model: $RF_{metric} \leftarrow RANDOM\_FOREST(N_{trees}, MaxDepth)$;
  Train model: $RF_{metric}.FIT(X_{train}, Y_{train}[metric])$;
  /* Evaluate the model */
  $\hat{Y}_{metric} \leftarrow RF_{metric}.PREDICT(X_{test})$;
  Compute performance metrics: R^2, MSE, MAE;

/* Return Results */
Return $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
End Random Forest Algorithm

Algorithm 2 uses Gradient Boosting to optimize ETX, latency, and energy consumption in IoT networks. It involves preprocessing, dataset splitting, and training with hyperparameters ($N_{estimators}$, η, $MaxDepth$). Performance is evaluated using R^2, MSE, and MAE, ensuring accurate predictions and robust optimization.

Algorithm 2 Gradient Boosting for Multi-Objective Optimization

Input : Dataset with features: X;
Target variables: $Y_{ETX}, Y_{Latency}, Y_{Energy}$;
Number of estimators $N_{estimators}$;
Learning rate η;
Maximum depth of trees $MaxDepth$;
Metrics: $ETX, Latency\ (ms), Consumed\ Energy\ (J)$;
Output : Predicted values for metrics: $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
Model performance scores (e.g., R^2, MSE).

Begin Gradient Boosting Algorithm

/* Data Preprocessing */
Split dataset into training and testing sets:
$X_{train}, X_{test}, Y_{train}, Y_{test} \leftarrow TRAIN\_TEST\_SPLIT(X, Y)$;

foreach $metric \in \{ETX, Latency, Energy\}$ **do**
  /* Train Gradient Boosting Regressor for each metric */
  Initialize model: $GB_{metric} \leftarrow GRADIENT\_BOOSTING(N_{estimators}, \eta, MaxDepth)$;
  Train model: $GB_{metric}.FIT(X_{train}, Y_{train}[metric])$;
  /* Evaluate the model */
  $\hat{Y}_{metric} \leftarrow GB_{metric}.PREDICT(X_{test})$;
  Compute performance metrics: R^2, MSE, MAE;

/* Return Results */
Return $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
End Gradient Boosting Algorithm

Algorithm 3 employs a Neural Network to optimize ETX, latency, and energy consumption in IoT networks. The process includes data preprocessing (normalization and dataset splitting) and initializing neural networks for each metric with parameters such as layers (L), neurons ($N_{neurons}$), activation function (f), optimizer, learning rate (η), epochs (E), and batch size (B). Training utilizes backpropagation and gradient descent, with predictions evaluated via R^2, MSE, and MAE. By modeling nonlinear relationships, the algorithm ensures accurate predictions. The results include predictions and evaluation scores, demonstrating the neural network's effectiveness for IoT multi-objective tasks.

Algorithm 3 Neural Network for Multi-Objective Optimization

Input : Dataset with features: X;
Target variables: $Y_{ETX}, Y_{Latency}, Y_{Energy}$;
Neural network structure: Number of layers L, Neurons per layer $N_{neurons}$;
Activation function f;
Optimizer $Optimizer$ with learning rate η;
Number of epochs E, Batch size B;
Metrics: $ETX, Latency\ (ms), Consumed\ Energy\ (J)$;
Output : Predicted values for metrics: $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
Model performance scores (e.g., R^2, MSE).

Begin Neural Network Training

/* Data Preprocessing */
Normalize input features: $X \leftarrow NORMALIZE(X)$;
Split dataset into training and testing sets: $X_{train}, X_{test}, Y_{train}, Y_{test} \leftarrow TRAIN\_TEST\_SPLIT(X, Y)$;

foreach $metric \in \{ETX, Latency, Energy\}$ **do**
  /* Neural Network Initialization */
  Build model: $NN_{metric} \leftarrow INITIALIZE\_NN(L, N_{neurons}, f, Optimizer, \eta)$;
  Train model: $NN_{metric}.FIT(X_{train}, Y_{train}[metric], epochs = E, batch\_size = B)$;
  /* Evaluate the model */
  $\hat{Y}_{metric} \leftarrow NN_{metric}.PREDICT(X_{test})$;
  Compute performance metrics: R^2, MSE, MAE;

/* Return Results */
Return $\hat{Y}_{ETX}, \hat{Y}_{Latency}, \hat{Y}_{Energy}$;
End Neural Network Training

Algorithm 4 applies Q-Learning to optimize routing in IoT networks by minimizing ETX, latency, and energy consumption. The process begins with initializing the Q-table ($Q(s, a)$) to zero. Over $MaxEpisodes$, the algorithm explores the state space (S) using an ϵ-greedy policy to balance exploration and exploitation. Actions (a) are executed, resulting in state transitions (s') and rewards (r). Q-values are updated using the Bellman equation with learning rate (α), discount factor (γ), and maximum future rewards. After training, the optimal routing policy (π) is derived by selecting the action with the highest Q-value for each state. The algorithm outputs the optimized Q-table and routing policy, demonstrating Q-Learning's effectiveness in improving routing efficiency and reducing energy consumption and latency in IoT networks.

Algorithm 4 Q-Learning for Routing Optimization in IoT Networks

Input : State space S;
Action space A;
Learning rate α;
Discount factor γ;
Exploration probability ϵ;
Maximum episodes $MaxEpisodes$;
Metrics: $ETX, Latency\ (ms), Consumed\ Energy\ (J)$;
Output : Optimized Q-table Q;
Optimal routing policy π.

Begin Q-Learning Algorithm

/* Initialize Q-table */
$Q(s, a) \leftarrow 0, \forall s \in S, a \in A$;

for $episode \leftarrow 1$ **to** $MaxEpisodes$ **do**
  Initialize state $s \leftarrow INITIAL\_STATE()$;
  while ***not terminal state*** **do**
    /* Choose action using ε-greedy policy */
    $a \leftarrow$ **if** $random() < \epsilon$ **then** $RANDOM\_ACTION()$ **else** $\arg\max_a Q(s, a)$;
    Execute action a, observe reward r and next state s';
    /* Update Q-value */
    $Q(s, a) \leftarrow Q(s, a) + \alpha\big[r + \gamma \max_a Q(s', a) - Q(s, a)\big]$;
    $s \leftarrow s'$;

/* Extract optimal policy */
$\pi(s) \leftarrow \arg\max_a Q(s, a), \forall s \in S$;

/* Return Results */
Return Q, π;
End Q-Learning Algorithm

V. Results and Discussion

A. Experiment Environment

The tests were conducted on a device with an Intel(R) Core(TM) i5-7200U CPU @ 2.50GHz, 8 GB RAM, and a 64-bit Windows system. Python was used to implement categorization methods on Jupyter Notebook, with libraries such as pandas (1.5.3), Pulp (2.6.0), Deap (1.3.1), and seaborn. Dependencies and tools were managed using Anaconda, which facilitates the implementation and management of machine learning algorithms.

B. Performance of Algorithms Across All Simulations

This study simulated IoT networks with 50, 100, and 150 nodes to evaluate the impact of machine learning algorithms on network optimization. The algorithms effectively predicted ETX, latency, and energy consumption, allowing for performance comparisons. Tables II, III, and IV highlight the potential of machine learning in optimizing IoT networks and driving future advancements.

TABLE II. COMPARISON OF PERFORMANCE OF ALGORITHMS FOR SIMULATION 50

Algorithm	ETX	Latency (ms)	Energy Consumption (J)
Random Forest	5.63656	2.63308	2.62552
Decision Trees	5.34587	2.52793	2.63175
Gradient Boosting	5.56853	2.64258	2.61170
Neural Networks	5.29557	2.43862	2.72135
Q-Learning	5.53092	2.65587	2.70280

TABLE III. COMPARATIVE PERFORMANCE OF ALGORITHMS ON THE 100-NODE SIMULATION

Algorithm	ETX	Latency (ms)	Energy Consumption (J)
Random Forest	2.84176	64.19442	3.22043

Q-Learning	7.50000	0.68000	2.21000

C. Results of 50 Nodes

1) Random forest: The results in Fig. 1 reveal high accuracy for ETX and Latency, closely aligning with ideal predictions, but show challenges in predicting Consumed Energy, with greater deviations from actual values. This indicates a need for further tuning or advanced techniques, such as feature engineering or ensemble methods, to enhance energy prediction accuracy. The analysis highlights the model's strengths while identifying areas for improvement.

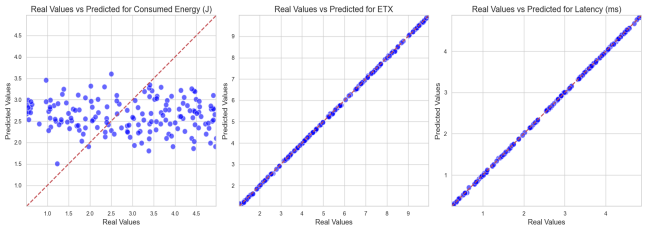

Fig. 1. Actual vs. Predicted values for Regression Analysis (RF).

2) Decision trees: Fig. 2 shows high accuracy for ETX and Latency but scattered deviations for Consumed Energy. Refinement through feature engineering, alternative algorithms, or more energy-focused data is needed for broader optimization.

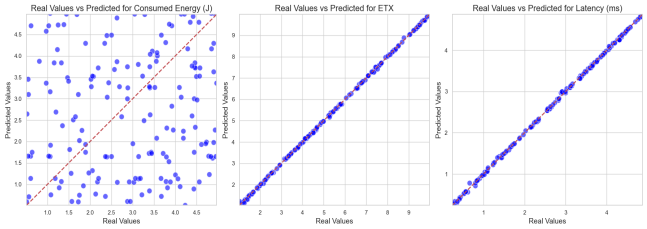

Fig. 2. Actual vs. Predicted values for Regression Analysis (DT).

3) Gradient boosting: The plots in Fig. 3 shows accurate ETX and Latency predictions, with tight clustering near the ideal line. Scattered Consumed Energy points suggest the need for refinement through feature engineering, non-linear models, or more data to improve energy prediction. Strengths and improvement areas are evident.

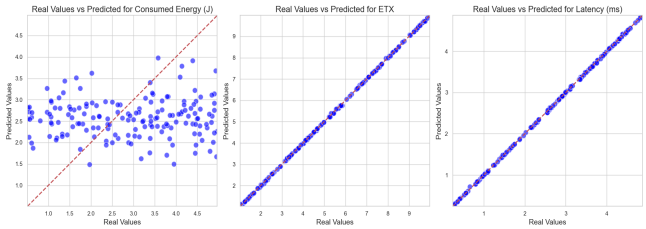

Fig. 3. Actual vs. Predicted values for Regression Analysis (GB).

Gradient Boosting curves in Fig. 4, 5 and 6 for a 50-node network show the trade-off between precision and recall as thresholds change. The F1 score peaks at the optimal threshold, balancing both. This flexibility allows optimization based on system priorities, enhancing detection or reliability.

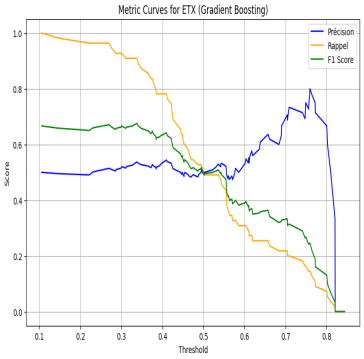

Fig. 4. Curves of ETX metric.

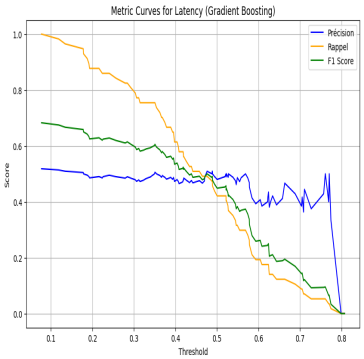

Fig. 5. Curves of the Latency metric.

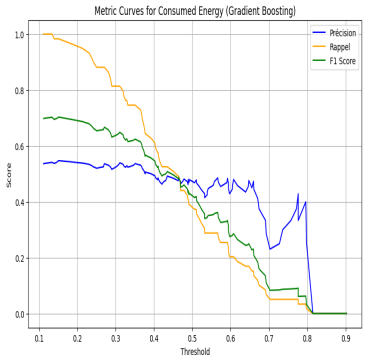

Fig. 6. Curves of the consumed energy metric.

4) Neural networks: The analysis in Fig. 7 shows strong ETX and Latency predictions but scattered Consumed Energy results. Minor ETX and Latency deviations suggest the need for better tuning, feature engineering, or more data to capture complex patterns. Strengths are evident, with areas for improvement noted.

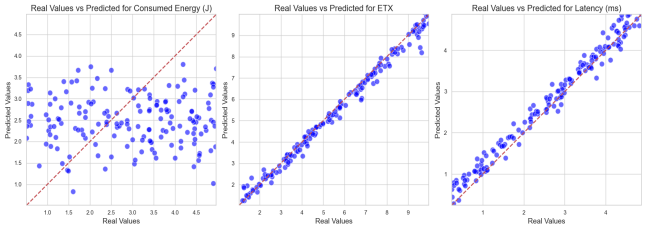

Fig. 7. Actual vs. Predicted values for Regression Analysis (Neural Networks).

5) Q-Learning: The confusion matrix in Fig. 8 and Fig. 9 shows that Q-learning effectively predicting low ETX and latency but struggling with consumed energy (Fig. 10) due to misclassifications. Refinement is needed to improve energy prediction accuracy.

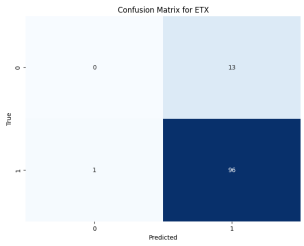

Fig. 8. Confusion Matrix of Etx.

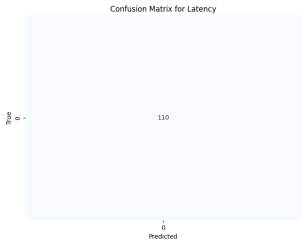

Fig. 9. Confusion Matrix of latency.

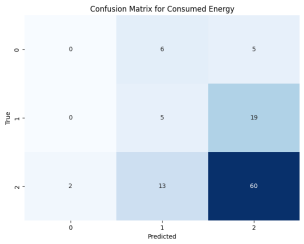

Fig. 10. Confusion Matrix of consumed energy.

6) Evolution of metrics: The graphs in Fig. 11 and Fig.12 shows ETX decreasing rapidly, Latency remaining stable, and Energy Consumption leveling off higher than ETX. This reflects a trade-off, with the system stabilizing at good connectivity, moderate latency, and low energy use.

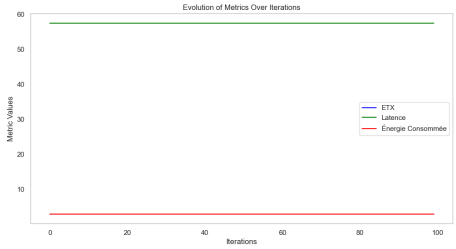

Fig. 11. Evolution of metrics over iterations.

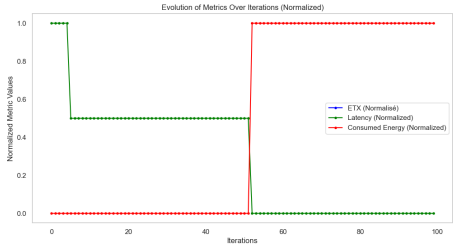

Fig. 12. (a) and (b) Evolution of Metrics over iterations (normalized).

D. Results of 100 Nodes

1) Random forest: The Random Forest model in Fig. 13 performs well for ETX and Latency with accurate clustering but struggles with Consumed Energy. Adding energy-specific features or advanced models could improve balance across metrics.

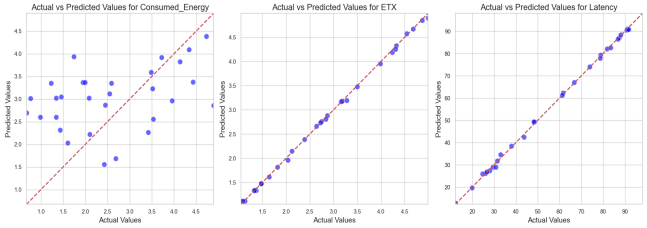

Fig. 13. Actual vs. Predicted values for Regression Analysis (RF).

2) Decision trees: The Decision Tree model n Fig. 14 performs well for ETX and Latency in a 100-node simulation but struggles with Consumed Energy due to non-linear limitations. Ensemble methods or energy-specific features could improve its balance across metrics.

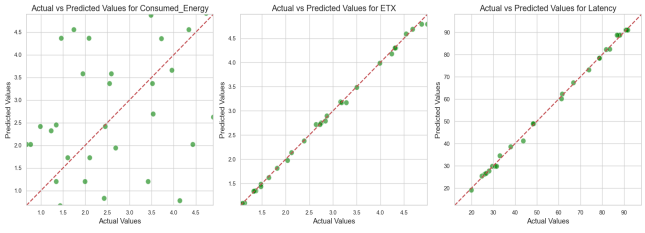

Fig. 14. Actual vs. Predicted values for Regression Analysis (DT)

3) Gradient boosting: Gradient Boosting excels in Fig. 15 with ETX and Latency but shows variance in Energy predictions, requiring refinements or energy-specific features for balanced performance.

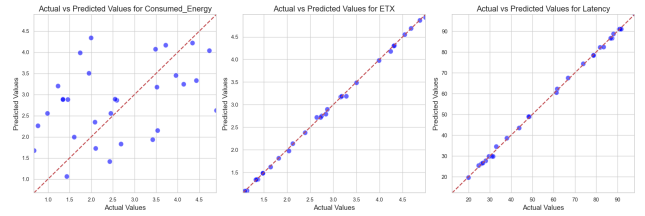

Fig. 15. Actual vs. Predicted values for Regression Analysis (GB).

4) Neural networks: The Neural Network performs in Fig. 16 well for Latency and moderately for ETX, but struggles with Consumed Energy, showing significant spread. Improvements may require tuning, targeted features, or hyperparameter optimization to achieve balanced accuracy across metrics.

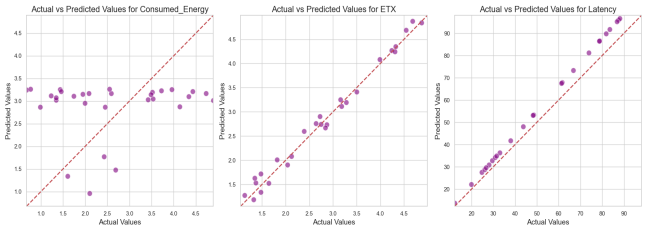

Fig. 16. Actual vs. Predicted values for Regression Analysis (Neural Networks).

The ROC curves and AUC in Fig. 17 values (0.87–0.92) show strong Neural Network performance in multiclass classification, with class 1 achieving the highest AUC (0.92). However, the lowest AUC (0.87) for class 0 indicates a performance gap. Model tuning or addressing class imbalances could improve discrimination for class 0.

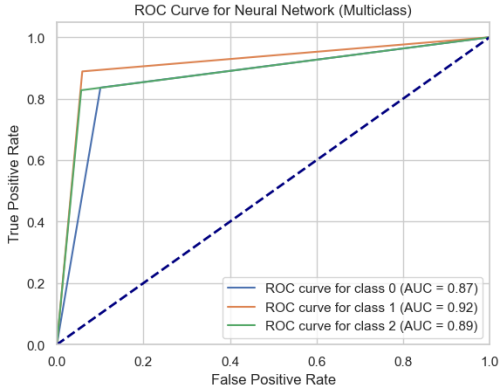

Fig. 17. ROC Curves of Neural Networks

5) Q-Learning: Fig. 18,19 and 20 shows that the model mainly classifies energy and ETX as "Medium," suggesting a learning bias. For latency, some distinction between "Medium" and "High" is observed, but no "Low" classifications appear, indicating possible limitations in detecting lower values.

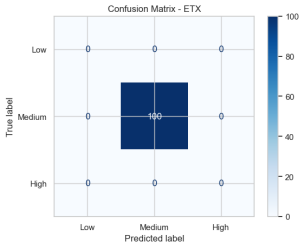

Fig. 18. Confusion Matrix of Q-learning(ETX).

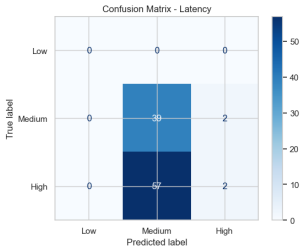

Fig. 19. Confusion Matrix of Q-learning(Latency).

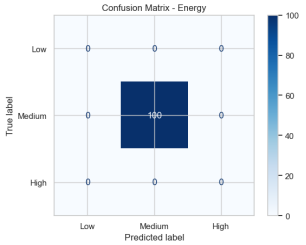

Fig. 20. Confusion Matrix of Q-learning(Consemd Energy).

E. 150 Nodes

1) Random forest: In the 150-node simulation, Fig. 21 show the Random Forest model excels in ETX and Latency, with predictions tightly clustered around the ideal line, reflecting effective feature representation. However, significant scatter in Consumed Energy predictions highlights challenges with complex patterns. Adding granular energy features or advanced ensemble methods could improve performance.

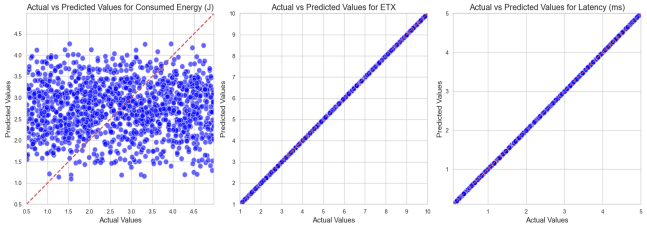

Fig. 21. Actual vs Predicted values for Regression Analysis (RF).

2) Gradient boosting: Fig. 22 shows that the Gradient Boosting model demonstrates high accuracy for ETX and Latency, with

predictions closely aligning with the ideal line in a 150-node network, reflecting well-represented features. However, broad scatter in Consumed Energy predictions highlights challenges in modeling complexities, suggesting the need for energy-focused features or ensemble techniques.

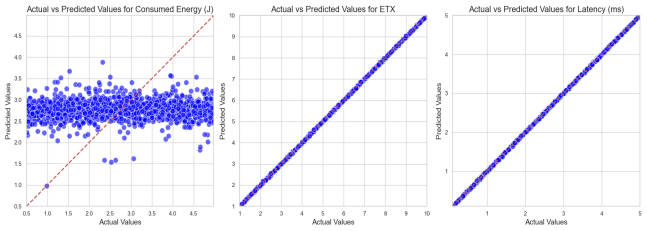

Fig. 22. Actual vs. Predicted values for Regression Analysis (GB).

3) Decision trees: Fig. 23 shows that the Decision Tree model performs well for ETX and Latency, with predictions aligning closely with the ideal line in a 150-node simulation, indicating ease of generalization. However, it struggles with Consumed Energy, showing broad scatter around the ideal line. Employing ensemble methods like Random Forest could enhance energy predictions.

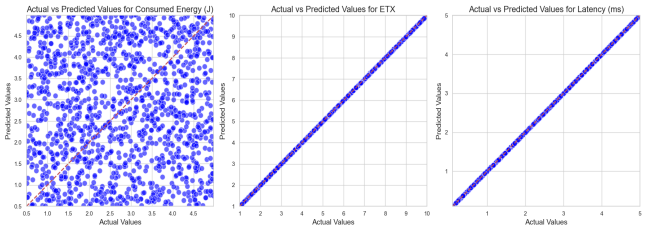

Fig. 23. Actual vs. Predicted values for Regression Analysis (DT).

4) Neural networks: Fig. 24 shows that the Neural Network model performs well for ETX and Latency, closely aligning with the ideal line in a 150-node network. However, its weak performance in Consumed Energy, marked by constant predictions, suggests oversimplification. Refining features, tuning the architecture, or applying regularization could improve sensitivity to energy variations.

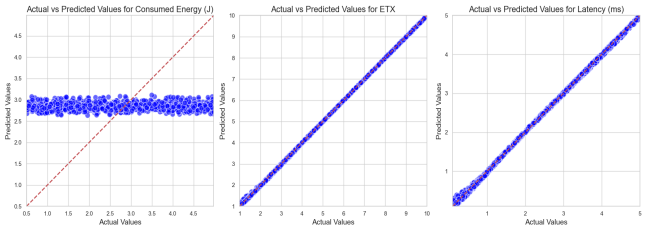

Fig. 24. Actual vs. Predicted values for Regression Analysis neural network.

5) Q-Learning: Fig. 25,26 and 27 shows that the confusion matrices indicate that the model excels at predicting the "No" class for ETX, Latency, and Consumed Energy, effectively identifying unaffected tasks. However, it struggles with the "Yes" class, potentially due to class imbalance or difficulty in capturing subtle differences. Further investigation is needed to identify the cause and enhance performance.

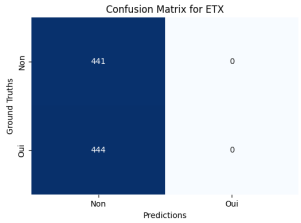

Fig. 25. Confusion Matrix of Q-learning(ETX).

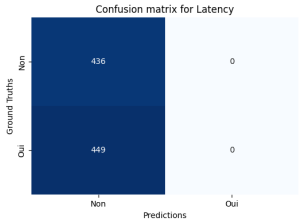

Fig. 26. Confusion Matrix of Q-learning(Latency).

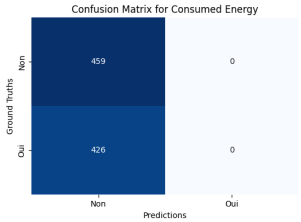

Fig. 27. Confusion Matrix of Q-learning(Consumed Energy).

Fig. 28, 29, and 30 compare ML algorithms in IoT based on ETX and latency, and energy consumption for 50, 100, and 150 nodes. Low ETX reflects better transmission efficiency. In 50-node networks, one algorithm shows high ETX, indicating challenges, while larger networks reveal variations, with some optimizing retransmissions. Latency is generally low in smaller networks, though inefficiencies appear for some algorithms. In larger networks, certain algorithms maintain low latency, while others increase due to overhead or longer paths. Energy consumption stabilizes in larger networks for most algorithms, though some struggle with scalability, highlighting differences in efficiency.

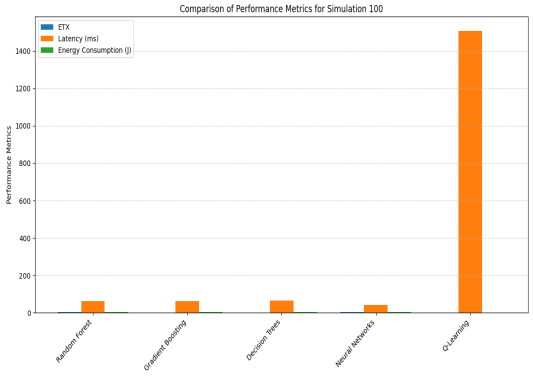

Fig. 29. Comparison for all metrics in 50 nodes with ML Algorithms.

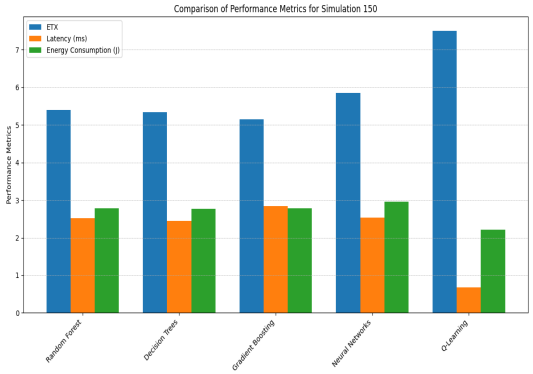

Fig. 30. Comparison for all metrics in 150 nodes with ML Algorithms.

VI. Discussion of the Results

This study provides a detailed evaluation of machine learning algorithms for optimizing IoT networks using the RPL protocol, focusing on ETX, latency, and energy consumption in simulations of 50, 100, and 150 nodes. Tree-based models like Random Forest and Gradient Boosting consistently demonstrated strong performance. For instance, Random Forest achieved an ETX of 5.63656, latency of 2.63308 ms, and energy consumption of 2.62552 J in the 50-node simulation, excelling in balancing accuracy and efficiency. Gradient Boosting performed well in 100-node simulations, with an ETX of 2.72260 and latency of 63.31554 ms, though energy predictions require further refinement.Energy consumption remains a challenging metric across all models. Neural Networks struggled significantly in the 150-node simulation, emphasizing the need for advanced architectures and tailored features. Q-Learning showed adaptability with low latency (0.68 ms) in the 150-node simulation but at the cost of higher ETX (7.50000), illustrating trade-offs between adaptability and transmission efficiency.These findings highlight the strengths of Random Forest and Gradient Boosting across multiple metrics, while Neural Networks and Q-Learning excel in specialized scenarios. The findings emphasize the need for algorithm selection based on network requirements and suggest exploring hybrid models to balance performance.While Q-Learning achieves low latency, it has a higher ETX, leading to potential inefficiencies in data transmission. Similarly, Neural Networks require significant computational resources, limiting their deployment in energy-constrained IoT environments.Incorporating real-world constraints into simulations could further enhance the practical applicability of these approaches, enabling more tailored optimization strategies for diverse IoT configurations.

VII. Conclusion

This study investigates how machine learning algorithms can optimize the RPL protocol in IoT networks. It focuses on three key performance metrics:ETX, latency, and energy consumption. By simulating networks of varying scales (50, 100, and 150 nodes), the research comprehensively evaluated the capabilities and limitations of several algorithms, including Random Forest, Gradient Boosting, Artificial Neural Networks (ANNs), and Q-Learning.The findings revealed that tree-based models, such as Random Forest and Gradient Boosting, excel in robustness and adaptability, showing exceptional predictive performance for ETX and latency in small and medium-sized networks. However, their energy consumption predictions require improvements, such as advanced feature engineering and enhanced ensemble techniques. Artificial Neural Networks, while capturing nonlinear dependencies effectively, struggled with energy consumption metrics in larger networks, underscoring the need for refined architectures and expanded datasets. Conversely, Q-Learning demonstrated remarkable adaptability, achieving significant latency reductions in larger networks, albeit at the cost of higher ETX, illustrating trade-offs between adaptability and transmission efficiency.A key insight from this research is the inherent trade-offs needed to address IoT network constraints. No single algorithm excels across all metrics, highlighting the necessity of hybrid approaches that combine the strengths of multiple models. For instance, integrating tree-based models for robustness with reinforcement learning techniques like Q-Learning for adaptability could lead to more efficient solutions in dynamic IoT environments. Beyond technical findings, this study establishes a foundation for future research, incorporating real-world constraints such as hardware limitations, dynamic network conditions, and application-specific requirements. Additionally, analyzing algorithm performance in real-time scenarios can refine their practical applicability and expand their utility.In conclusion, this work establishes a foundational methodology for IoT network optimization. By combining advanced simulations, machine learning models, and hybrid frameworks, this study paves the way for a new generation of intelligent, sustainable, and scalable IoT systems. The insights gained provide a robust foundation for future innovations in IoT networks, addressing challenges in performance optimization, energy efficiency, and resource management.
